Received 4 March 2011; revised 30 June 2011; accepted 7 July 2011; published 29 September 2011.

[1] The final warming of the stratospheric polar vortex at the end of northern hemisphere winter is examined in ECMWF ERA-Interim reanalysis data and an ensemble of chemistry climate models, using 20 years of data from each. In some years the final warming is found to occur first in the mid-stratosphere, and in others to occur first in the upper stratosphere. The strength of the winter stratospheric polar vortex, refraction of planetary waves, and the altitudes at which the planetary waves break in the northern extratropics lead to this difference in the vertical profile of the final warming. Years in which the final warming occurs first in the mid-stratosphere show, on average, a more negative NAO pattern in April mean sea level pressure than years in which the warming occurs first in the upper stratosphere. Thus, in the northern hemisphere, additional predictive skill of tropospheric climate in April can be gained from a knowledge of the vertical profile of the stratospheric final warming.

1. Introduction

[2] The final warming of the winter stratosphere is associated with the breakdown of the polar vortex. During the

final warming, the zonal mean zonal wind in the extratropics undergoes a reversal from a westerly to an easterly direction. The final warming occurs in November/December in the southern hemisphere (SH), and from as early as March to as late as May in the northern hemisphere (NH) [Waugh and Rong, 2002]. As explained below, the timing of the final warming is of considerable interest, both due to its sensitivity to stratospheric ozone concentrations and its potential role in tropospheric predictability.

[3] The final warming is driven partly by the radiative cycle in the stratosphere. The equator-pole temperature gradient caused by shortwave heating and longwave cooling means that the zonal mean flow is westerly in the winter stratosphere and easterly in the summer stratosphere. However, the dynamics of planetary wave propagation and breaking erodes the polar vortex, drives a poleward eddy heat flux, and drives a meridional circulation which leads to downwelling in the extratropics and associated adiabatic warming. These processes cause the final warming to occur earlier in the year than if the warming were solely radiatively driven [Forster *et al.*, 1997]. Indeed, evidence from analysis and reanalysis data suggests the observed final warming is substantially wave driven in both hemispheres [Yamazaki, 1987; Black and McDaniel, 2007b].

[4] In chemistry-climate models, the timing of the simulated final warming is important since a bias in this time is suggestive of a polar temperature/ozone bias (SH only) [Hurwitz *et al.*, 2010]. Further, once the vortex breakdown

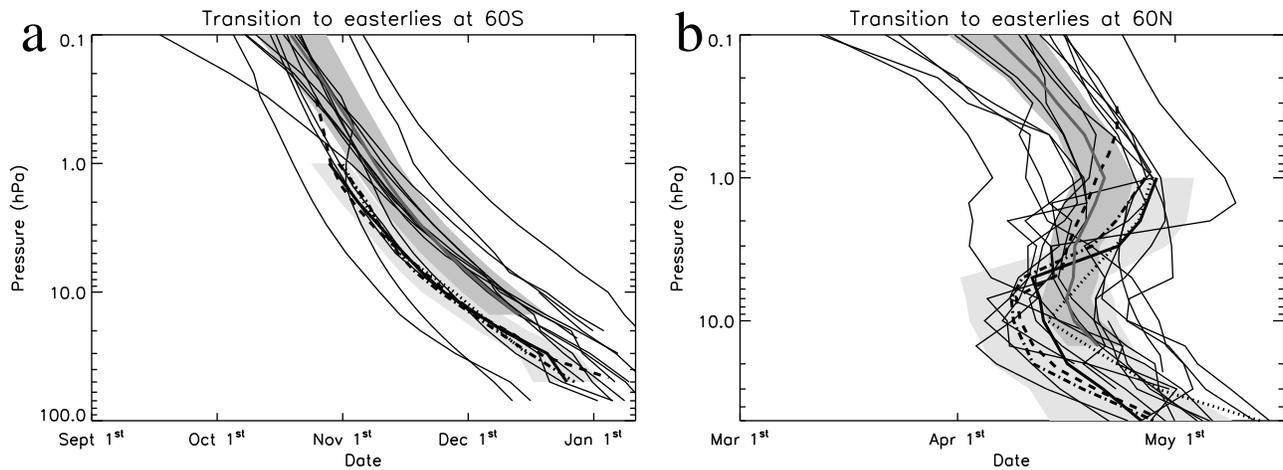

Figure 1. Final transition of zonal mean zonal wind from westerly to easterly at (a) 60°S and (b) 60°N. CCMVal-2 monthly mean model data is used (from 1980–1999), with each model represented by a thin black line and the multimodel mean shown as a thick gray line. The dark gray shading indicates the inter-model standard error, scaled to represent a 95% confidence interval. ERA-Interim (1989–2009), ERA-40 (1980–2002), and NCEP (1980–1999) reanalysis and UKMO analysis data (1992–2001) are shown as thick black solid, dot-dashed, dotted and dashed lines respectively, with light gray shading indicating the interannual standard deviation in the ERA-Interim data, again scaled to represent a 95% confidence interval.

has occurred, transport of ozone rich air to polar latitudes can once more occur [Eyring *et al.*, 2006; Yamazaki, 1987].

[5] There are also implications for the high latitude troposphere. During a final warming there is evidence of more consistent stratosphere-troposphere coupling than that due to mid-winter sudden warmings with, for example, influence on the North Atlantic Oscillation (NAO) [Black *et al.*, 2006]. Ayarzagüena and Serrano [2009] note the effect of the NH final warming time on the Euro-Atlantic area in April, referring to “early” and “late” final warmings [Waugh and Rong, 2002].

[6] In the present study, the final warming time is defined, at each height, as the time when the zonal mean zonal wind, U , at 60° becomes easterly for the final time that spring. Data is used from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim [Simmons *et al.*, 2007; Dee *et al.*, 2011] and ERA-40 [Uppala *et al.*, 2005] reanalysis for years 1989–2009 and 1980–2002 respectively, the National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP) reanalysis [Kalnay *et al.*, 1996] for years 1980–1999, and the UK Met Office (UKMO) stratospheric analysis [Swinbank and O’Neill, 1994] for years 1992–2001. Data is also used from models included in phase 2 of the Chemistry-Climate Model Validation Activity for SPARC (CCMVal-2) taken from years 1980–1999 of the historical simulations [Eyring *et al.*, 2008]. See *SPARC CCMVal* [2010, chapters 2 and 4] for details of the models and dynamics respectively. The majority of this work uses ERA-Interim data only (six-hourly data was obtained for more accurate calculation of non-linear diagnostics which were then averaged to form daily fields).

[7] In the following sections, the dynamics behind the vertical profile of the final warming in the northern hemisphere shed new light on the interannual variability of the final warming time and its implications for adding skill to

the seasonal forecasts of dynamical tropospheric fields in April.

2. Vertical Profiles of the Final Warming Time

[8] Figure 1 shows the climatological final warming time at 60°S [Butchart *et al.*, 2011; Eyring *et al.*, 2006; Scaife *et al.*, 2002] and 60°N [Hardiman *et al.*, 2010] for the CCMVal-2 models, ERA-Interim, ERA-40, and NCEP reanalysis data, and UKMO analysis data (see figure caption for details). In the southern hemisphere (Figure 1a) this final warming time occurs first in the upper stratosphere and then propagates downwards in time. There is good agreement between all reanalyses and the slope of the downward propagation is captured well by the multi-model mean. However, most models show a final warming time which is too late, consistent with there being a cold bias in the winter stratosphere in most models. In the northern hemisphere (Figure 1b) the final warming occurs first in the mid-stratosphere, at around 10 hPa. Here the reanalyses show slightly different climatological final warming times, and the interannual variability in the final warming time is somewhat greater than in the southern hemisphere [see Graverson and Christiansen, 2003]. The models also show a greater range of final warming times. Nevertheless the vertical profile of final warming time, occurring first in the mid-stratosphere, is captured well by most models. These profiles are suggestive of a warming in the northern hemisphere which is further from radiative equilibrium, or more dynamically driven, than is the southern hemisphere warming. Consistent with this, the northern hemisphere final warming occurs earlier in the annual cycle than the southern hemisphere warming, even at 1 hPa. A warming first in the mid-stratosphere implies that the upper stratosphere is then somewhat decoupled from the middle and lower stratosphere since waves are unable to propagate through the mean easterly flow at 10 hPa. Thus the upper

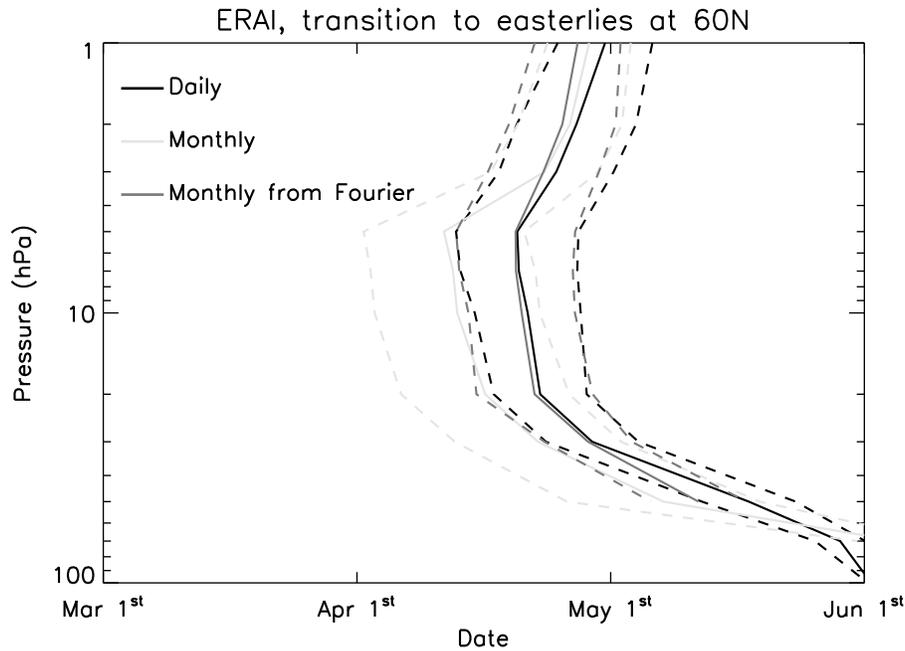

Figure 2. Final transition of zonal mean zonal wind, U , from westerly to easterly at 60°N in ERA-Interim calculated from: daily data (black lines), linear regression of monthly mean data (light gray lines), and a Fourier fit to the annual cycle in monthly mean data (using the first 6 Fourier components, i.e. up to 5 cycles per year; dark gray lines). Solid lines give final warming date, and dashed lines show interannual standard deviation scaled to represent a 95% confidence interval.

stratospheric final warming would be expected to proceed on radiative timescales.

[9] In Figure 1, monthly mean data is used, and the final warming date (when U becomes easterly) is calculated using linear interpolation by assuming the monthly mean value represents the value on day 15 of the month. Monthly mean data was shown as sufficient to accurately calculate the southern hemisphere final warming time in the work of *Hardiman et al.* [2010]. To demonstrate that monthly mean data is also sufficient in the northern hemisphere, Figure 2 shows the northern hemisphere final warming time calculated for ERA-Interim using daily data, linear interpolation of monthly mean data (as in Figure 1), and a Fourier fit to the annual cycle in monthly mean data. Both methods of extracting the final warming date from monthly mean data qualitatively reproduce the vertical profile obtained from the daily data (namely that the warming occurs first in the mid-stratosphere). Further, the Fourier fit quantitatively agrees with the daily data to well within the 95% confidence interval, showing that the information required to extract the final warming date is contained within the monthly mean data. Indeed, only up to the semi-annual Fourier component (the second harmonic) needs to be included to accurately obtain the final warming date (not shown). Linear interpolation produces a final warming date that is too early in April in the mid-stratosphere and finds 81% of winters to be 10 hPa-first as opposed to 72% of winters being 10 hPa-first when calculated from daily data. However, using daily data to calculate the final warming date has problems of its own in the northern hemisphere, with eastward winds remaining close to zero for several days before becoming westward or undergoing a short transition back to an eastward direction after the

main final warming has occurred (both of these events leading to an earlier final warming date being given by linear interpolation). In the present study the ability to qualitatively reproduce the vertical profile of final warming times is sufficient. For simplicity linear interpolation of monthly mean data is used to obtain the final warming date for CCMVal-2 models, since this only requires data for the late winter and spring months.

[10] Although the climatological final warming dates shown in Figure 1 show a warming occurring first in the mid-stratosphere, when individual years are considered it is found that the warming may either occur first in the mid-stratosphere (hereafter referred to as a “10 hPa-first year”) or it may occur first in the mesosphere and descend in a fashion similar to a southern hemisphere final warming (hereafter referred to as a “1 hPa-first year”). Figure 3 shows the NH final warming times composited over 10 hPa-first years (years in which U (60°N) becomes easterly at 10 hPa before it becomes easterly at 1 hPa; Figure 3a) and 1 hPa-first years (years in which U (60°N) becomes easterly at 1 hPa before it becomes easterly at 10 hPa; Figure 3b), for ERA-Interim and the CCMVal-2 models. At 0.1 hPa the warming times are similar in both cases – the key difference is whether or not a warming takes place first in the mid-stratosphere. At 10 hPa, slightly more than half the models show a final warming time earlier than ERA-Interim in both cases, but in Figure 1b the models generally show a later final warming time than ERA-Interim at 10 hPa. The likely reason for this is that, in ERA-Interim 81% of years are 10 hPa-first years, whereas only 36% of all modeled years are 10 hPa-first years.

[11] While the distribution of the difference in the final warming time at 10 hPa compared to 1 hPa is not strictly

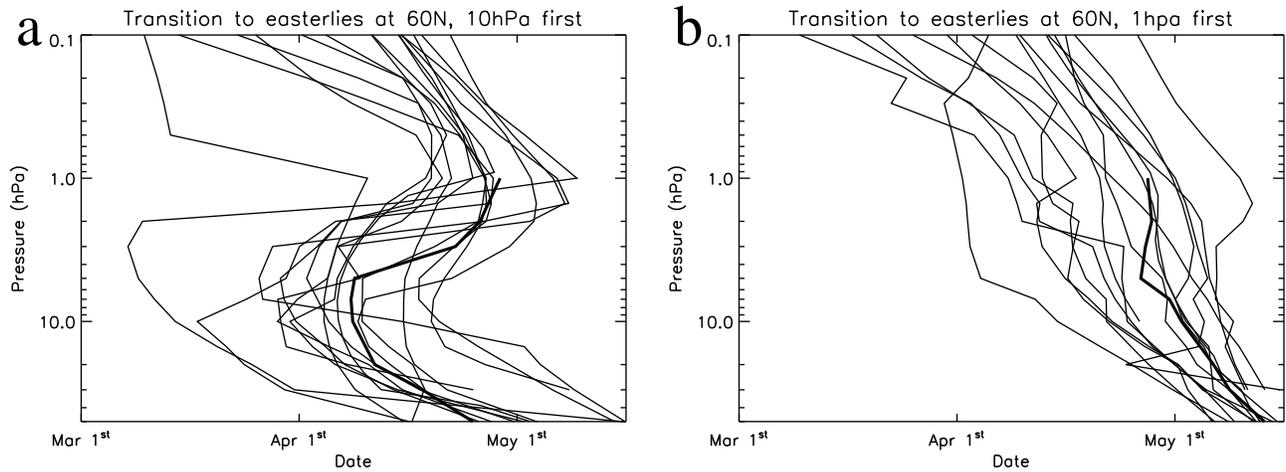

Figure 3. Mean final warming date at 60°N composited over (a) 10 hPa-first years and (b) 1 hPa-first years (defined in text), calculated from CCMVal-2 model data (thin lines) and ERA-Interim (thick line).

bimodal, the behavior of the 10 hPa-first and 1 hPa-first cases is quite distinct, resulting from qualitatively different behavior in the period prior to the warming. (It is interesting to note that, in ERA-Interim, the final warming in the southern hemisphere is of “1 hPa-first” type in every year except 2002 when the final warming occurs first at around 3 hPa. This is the year in which a mid-winter sudden warming was seen in the southern hemisphere. No “10 hPa-first” type final warmings are found in the southern hemisphere in the models.)

3. Causes of the Different Vertical Profiles

[12] It might be expected that more dynamically active winters lead to 10 hPa-first final warmings, and less dynam-

ically active winters to 1 hPa-first final warmings. (Here less dynamically active means less wave-mean flow interaction. Dynamical wave coupling will still occur [Perlwitz and Harnik, 2004].) Figure 4 shows that, for ERA-Interim, February mean zonal mean zonal wind, composited over all winters showing a 10 hPa-first final warming, is indeed anomalously weak. The anomaly is small since the majority of winters in ERA-Interim show a 10 hPa-first final warming (an anomalously strong polar vortex with anomalies of up to 5 m s^{-1} is seen in the 1 hPa-first case, not shown). The signal in the tropics, changing sign around 30 hPa, suggests possible links to the phase of the Quasi-Biennial Oscillation (QBO) [Baldwin *et al.*, 2001]. However there are many more 10 hPa-first years than 1 hPa-first years, so any link to the QBO is likely to be weak and may be the result of randomly selecting

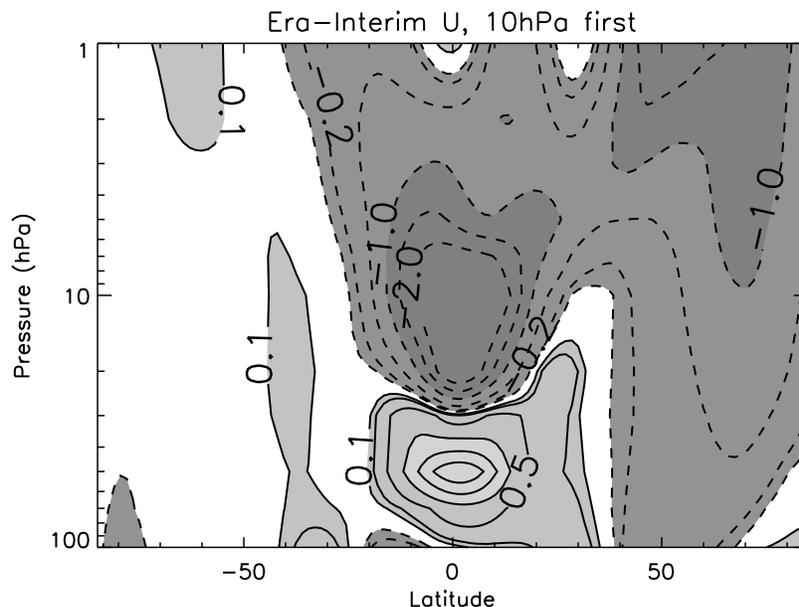

Figure 4. Composite of February mean zonal mean zonal wind anomalies (February mean climatology removed) (m s^{-1}) over winters that go on to show a 10 hPa-first final warming, ERA-Interim. Solid contours and light gray shading indicate positive values, dashed contours and dark gray shading indicate negative values. Contour interval is logarithmic.

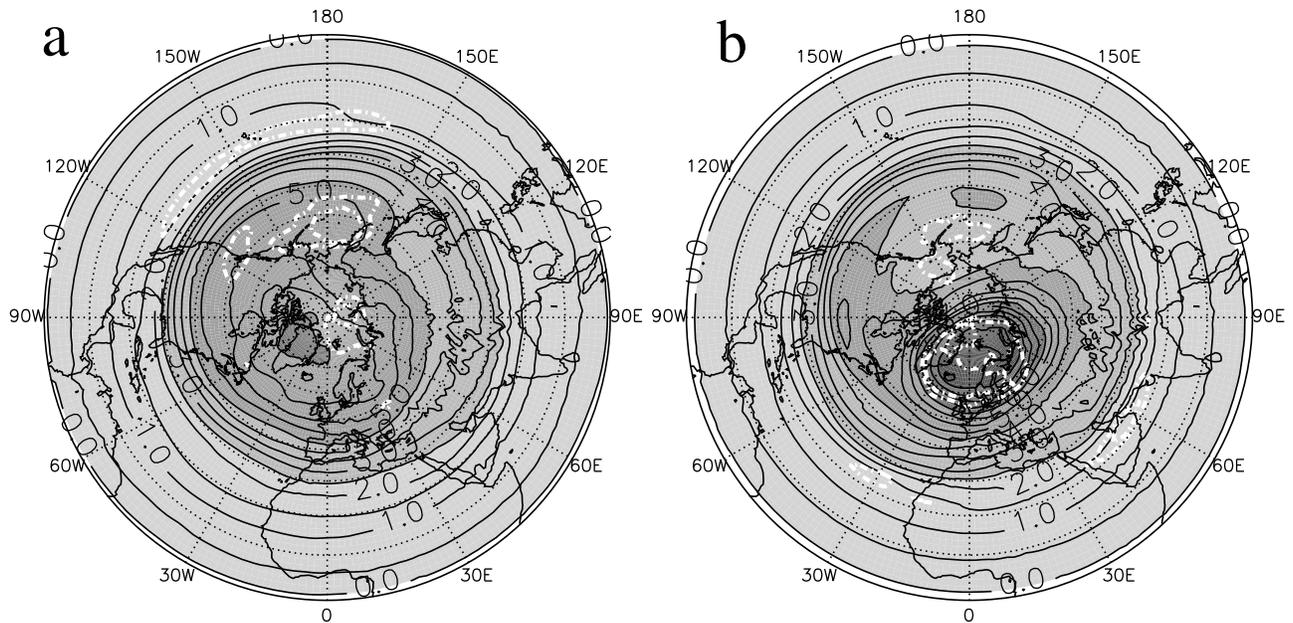

Figure 5. Potential vorticity on 840K surface (~ 10 hPa) averaged in each year over the 20 days before the final warming date and composited over (a) 10 hPa-first years and (b) 1 hPa-first years, ERA-Interim. Units are $(\text{gH}/p) 10^{-4} \text{K m}^{-1} \text{s}^{-1}$, where $g = 9.80665 \text{m s}^{-2}$, $H = 7000 \text{m}$, and $p = 1000 \text{hPa}$. White dot-dashed lines show statistical significance, calculated using a T-test, at 90% and 95% levels.

winters in a particular phase of the QBO and indeed the signal here would be inconsistent with the Holton-Tan effect [Holton and Tan, 1980].

[13] Further evidence of a weaker polar vortex in 10 hPa-first years is shown in Figure 5. Potential vorticity on the 840K isentropic surface (~ 10 hPa) is averaged in each year over the 20 days before the final warming date at 5 hPa and composited over 10 hPa-first years (Figure 5a) and 1 hPa-first years (Figure 5b), using daily ERA-Interim data. It can be seen that the averaged polar vortex in 10 hPa-first years is weaker with a weaker PV gradient at the vortex edge, char-

acteristic of more dynamically active regimes. This difference, calculated here in both composites using the final warming date at 5 hPa, is independent of the exact choice of final warming dates (and therefore of the exact height at which the final warming date is defined). In both composites the polar vortex is, characteristically, centered off the pole, toward 45°W in the 10 hPa-first case and 30°E in the 1 hPa-first case.

[14] These differences in polar vortex strength and structure lead to differences in planetary wave propagation and breaking over the 20 days before the final warming date

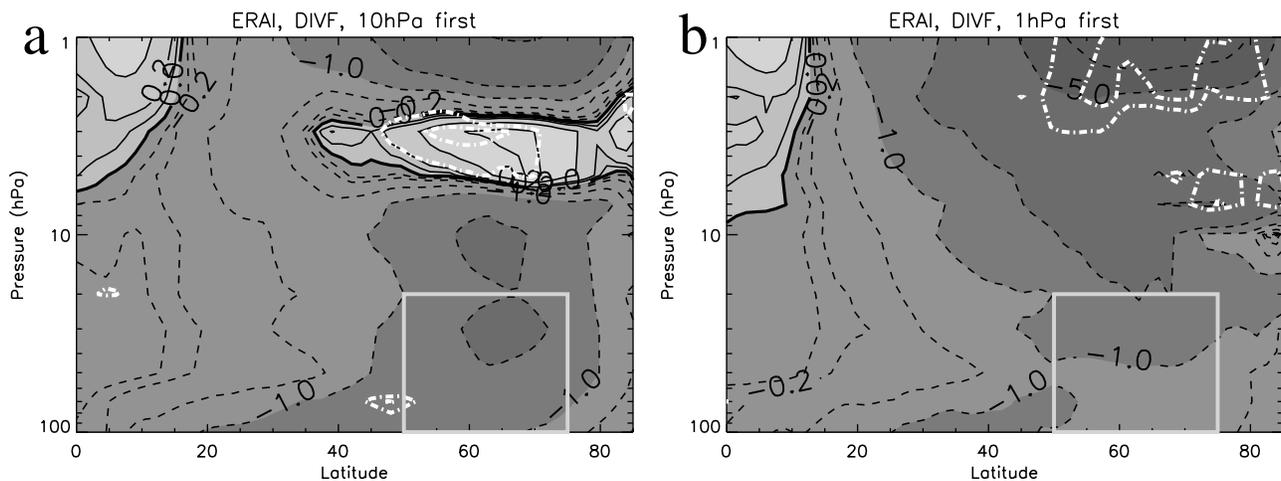

Figure 6. Scaled EP-flux divergence (DIVF) averaged in each year over the 20 days before the final warming date and composited over (a) 10 hPa-first years and (b) 1 hPa-first years, ERA-Interim. Solid contours and light gray shading indicate positive values, dashed contours and dark gray shading indicate negative values. Contour interval is logarithmic. White dot-dashed lines show statistical significance at 90% and 95% levels.

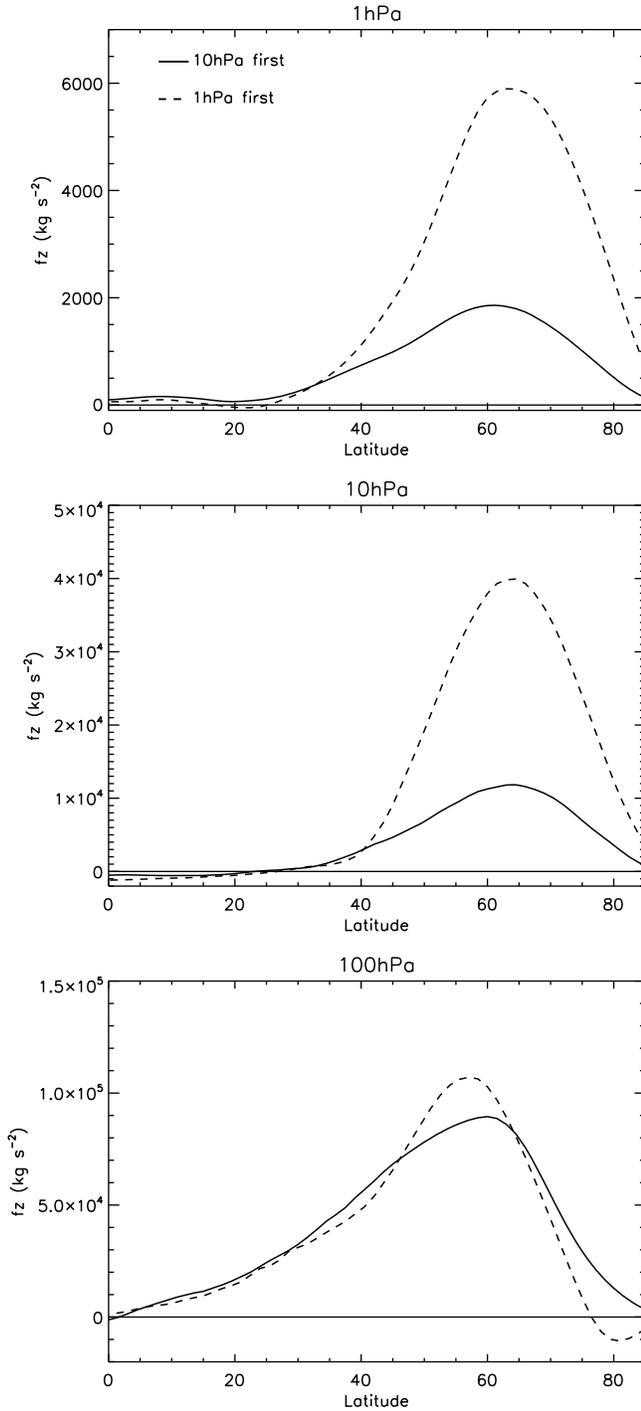

Figure 7. Vertical component of EP-flux ($F^{(z)}$) averaged in each year over the 20 days before the final warming date and composited over 10 hPa-first years (solid lines) and 1 hPa-first years (dashed lines) at 1 hPa, 10 hPa and 100 hPa, ERA-Interim. Zero line is plotted.

which, as shown below, contribute to the different vertical profiles of final warming.

[15] The forcing on the zonal mean flow by the breaking of planetary waves is given by the Eliassen-Palm flux (hereafter

EP-flux) divergence [Andrews *et al.*, 1987], here scaled to units of zonal acceleration:

$$\text{DIVF} = \frac{\nabla \cdot \mathbf{F}}{\rho_0 a \cos \phi}. \quad (1)$$

where \mathbf{F} is the EP flux vector

$$\mathbf{F}^{(\phi)} = \rho_0 a \cos \phi \left(\bar{u}_z \frac{\overline{v'\theta'}}{\bar{\theta}_z} - \overline{v'u'} \right) \quad (2a)$$

$$F^{(z)} = \rho_0 a \cos \phi \left\{ \left[f - \frac{(\bar{u} \cos \phi)_\phi}{a \cos \phi} \right] \frac{\overline{v'\theta'}}{\bar{\theta}_z} - \overline{w'u'} \right\}. \quad (2b)$$

f is the Coriolis parameter, (u, v, w) is three-dimensional velocity in spherical co-ordinates (λ, ϕ, z) , z is $\log(\text{pressure})$ height, a the Earth's radius, and $\rho_0(z)$ the density profile of the atmosphere.

[16] Figure 6 shows the scaled EP-flux divergence (DIVF) averaged in each year over the 20 days before the final warming date at 5 hPa and composited over 10 hPa-first years and 1 hPa-first years as in Figure 5. Below 20 hPa at around 60°N (region denoted by gray box in Figure 6) there is greater EP-flux convergence in the 10 hPa-first composite, acting to decelerate the zonal mean flow in the lower stratosphere. There is also a region of EP-flux divergence (positive acceleration of the mean flow) around 5 hPa and poleward of 40°N in the 10 hPa-first composite. This divergence comes from the horizontal component of the EP-flux, and is due to a greater equatorward propagation of planetary waves in the 10 hPa-first composite, increasing with decreasing latitude in this region. This structure of EP-flux divergence above EP-flux convergence before a final warming is seen also in the work of Black and McDaniel [2007a]. Planetary waves in the 1 hPa-first composite, however, decelerate the mean flow at all heights (poleward of 15°N), more strongly in the upper stratosphere than the lower stratosphere (Figure 6b). The differences between the composites are most apparent poleward of 35°N. The vertical component of the EP-flux ($F^{(z)}$) through 100 hPa, 10 hPa, and 1 hPa surfaces (shown in Figure 7) further demonstrates that, although there is the same planetary wave flux into the stratosphere in both composites, there is less wave flux across the 10 hPa and 1 hPa surfaces in 10 hPa-first years than there is in 1 hPa-first years. This demonstrates more wave breaking below 10 hPa in the 10 hPa-first years (even though the difference below 10 hPa is not as statistically significant as the difference above).

[17] For given values of zonal mean zonal wind, U , and zonal mean temperature, T , the regions to which planetary waves tend to propagate is given by the wave refractive index n^2 [Matsumo, 1970] where, following the notation of Simpson *et al.* [2009]:

$$n^2 = \left[\frac{\bar{q}_\phi}{a(\bar{u} - c)} - \left(\frac{k}{a \cos \phi} \right)^2 - \left(\frac{f}{2NH} \right)^2 \right] a^2 \quad (3)$$

c is zonal phase speed (assumed to be 0 here), k is zonal wavenumber ($k = 1$ here), N the buoyancy frequency, H a

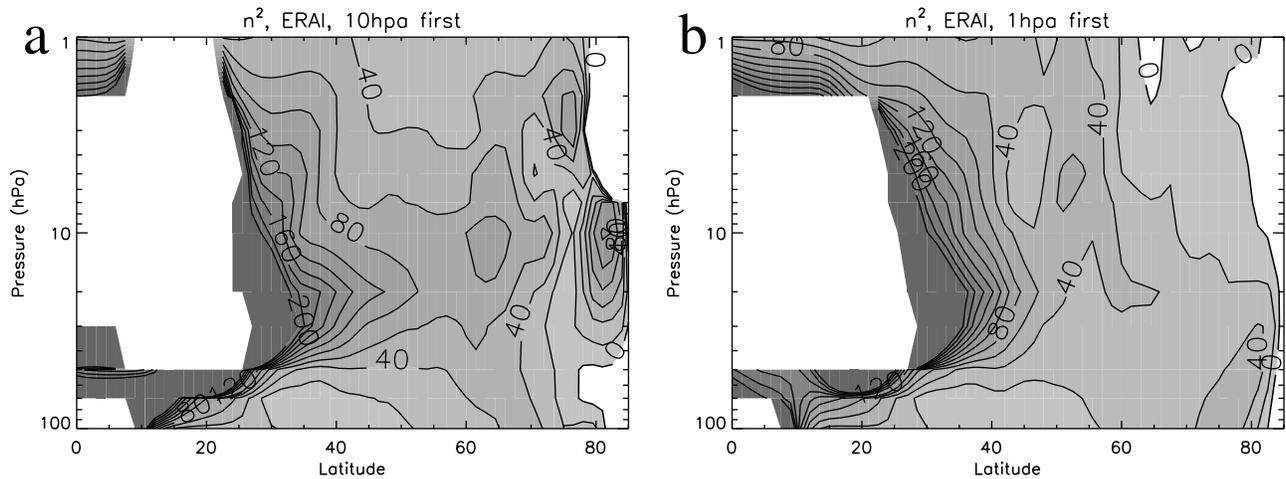

Figure 8. Wave refractive index, n^2 (m^{-2}), calculated from U and T averaged in each year over the 20 days before the final warming date and composited over (a) 10 hPa-first years and (b) 1 hPa-first years, ERA-Interim. Not plotted for regions where $\bar{u} - c < 0$ or $n^2 < 0$.

scale height, and \bar{q}_ϕ the meridional gradient of the quasi-geostrophic potential vorticity [Andrews *et al.*, 1987, equation (3.4.8)].

[18] Planetary waves tend to propagate away from regions of low refractive index, and toward regions of high refractive index. Figure 8 shows the wave refractive index calculated from U and T averaged over the 20 days before the final warming date in each year, and composited as before. The two composites are very similar, except in the region of 10 hPa from around 50°N to 70°N where the refractive index

is twice as large in the 10 hPa-first case than in the 1 hPa-first case. This local maxima in the 10 hPa-first composite suggests a focusing of waves into this region which causes the final warming to occur first in the mid-stratosphere in these years.

[19] To understand further the meridional wave guide which leads to the focusing of planetary waves in the extratropics, Figure 9 shows regions of meridional and vertical wave evanescence following the method of Harnik and Lindzen [2001]. Between 100 hPa and 10 hPa around 70°N ,

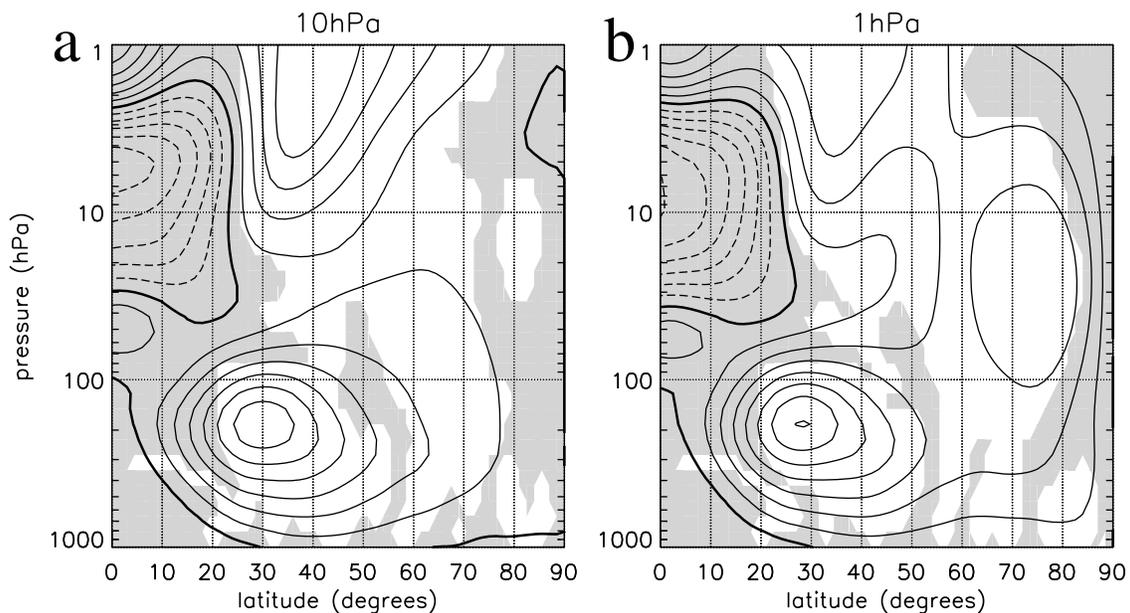

Figure 9. Regions of meridional and vertical wave evanescence (shaded), calculated from U and T averaged in each year over the 20 days before the final warming date and composited over (a) 10 hPa-first years and (b) 1 hPa-first years, ERA-Interim. Most shading comes from meridional wave evanescence, with shading in the extratropics above 3 hPa in the 1 hPa-first case coming from vertical wave evanescence. Contours show positive (solid) and negative (dashed) U , with zero contour plotted as thick solid line. Contour interval is 5 m s^{-1} .

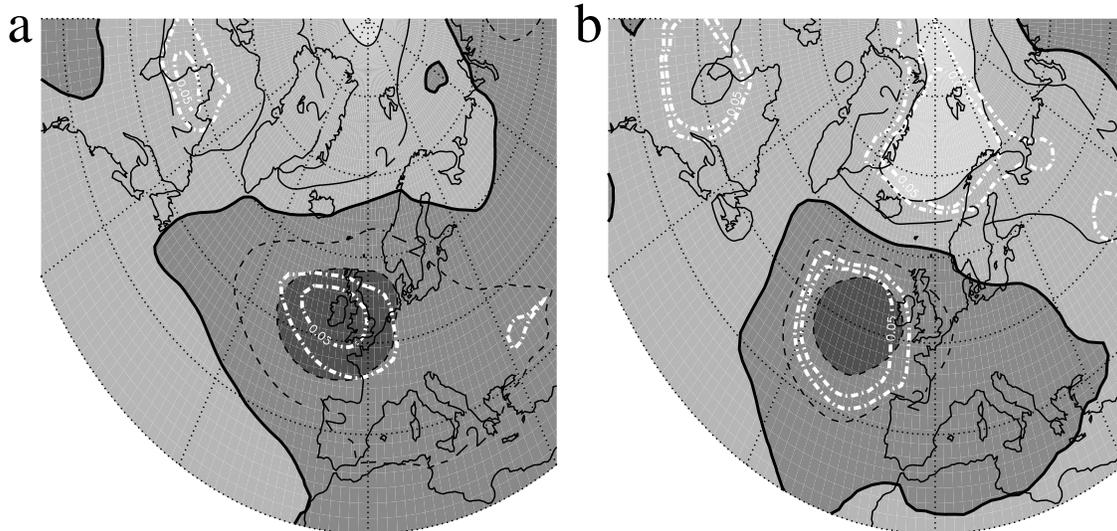

Figure 10. (a) March MSLP (60°W – 30°E , 30°N – 90°N), ERA-Interim, difference in composite over years in which the polar vortex is anomalously weak in February and years in which the polar vortex is anomalously strong in February. (b) April MSLP (60°W – 30°E , 30°N – 90°N), ERA-Interim, difference in composite over years in which the polar vortex is anomalously weak in March and years in which the polar vortex is anomalously strong in March. White dot-dashed lines show statistical significance at 90% and 95% levels (i.e. T-test p-values of 0.1 and 0.05). Shading and contour style as before, with zero contour plotted as thick solid line. Contour interval is 2 hPa.

U is much weaker in the 10 hPa-first composite, with values $<5 \text{ m s}^{-1}$, than in the 1 hPa-first composite, with values $>15 \text{ m s}^{-1}$. Also waves are confined to a region 40°N – 70°N in the 10 hPa-first composite as opposed to being confined to 40°N – 80°N in the 1 hPa-first composite. The result is that, in 10 hPa-first years, waves are forced to propagate through a region of very weak zonal wind just below 10 hPa where, for stationary waves, non-linear effects will dominate and wave breaking will likely occur [Andrews *et al.*, 1987, pp. 253–258], leading to a decrease in zonal wind and potential for a positive feedback. Thus planetary waves will likely break lower in 10 hPa-first years than in 1 hPa-first years, leading to the differences in planetary wave propagation and breaking already seen (Figures 6 and 7), and the different vertical profiles of final warming.

4. Impact on the Troposphere

[20] Knowledge of the strength of the stratospheric polar vortex aids prediction of tropospheric fields in the following month [Black *et al.*, 2006]. Defining the strength of the polar vortex in any given month as the value of the monthly mean zonal mean zonal wind at 60°N and 10 hPa, Figure 10a shows the difference in composites of ERA-Interim March MSLP (Mean Sea Level Pressure) over years in which the polar vortex is anomalously weak (weaker than climatology) in February and years in which the polar vortex is anomalously strong (stronger than climatology) in February (60°W – 30°E , poleward of 30°N), and Figure 10b shows the same using April MSLP and March polar vortex strength. Following weak vortex months, MSLP is anomalously high over the pole and anomalously low over much of Europe. (See also the response to weak and strong vortex events shown by Baldwin and Dunkerton [2001] and Baldwin and Thompson

[2009]. These papers emphasize the annular nature of this response, but focus here is on the Atlantic sector where the magnitude of the response is far greater than elsewhere.)

[21] Stratospheric warmings give the potential for more skillful prediction of tropospheric fields since the signals of these stratospheric warmings propagate downwards to the troposphere, influencing tropospheric fields up to a few weeks after the initial warming took place [Baldwin and Dunkerton, 2001]. During a stratospheric warming, the stratosphere and troposphere are coupled more strongly than normal [Black *et al.*, 2006].

[22] One advantage of final warmings over sudden stratospheric warmings (SSWs) is that final warmings are guaranteed to occur at the end of every winter whereas the timing of SSWs is much more difficult to predict, and even whether they occur or not during a given winter is subject to enormous decadal variability [Charlton-Perez *et al.*, 2008]. The average final warming date in the mid-stratosphere is April 15th for 10 hPa-first years (calculated using daily data – not shown), and Figures 5 and 6 show a significant difference (at the 95% confidence level) in dynamical fields over the 20 days leading up to this final warming. To demonstrate the difference in signal of 10 hPa-first final warmings and 1 hPa-first final warmings on tropospheric fields, Figure 11a shows the difference between April mean MSLP composited over 10 hPa-first years and April mean MSLP composited over 1 hPa-first years. The pattern obtained is very similar to that in Figure 10, but the signal is much stronger and is statistically significant at the 95% level over larger regions (this is in part expected as information from early April is included in Figure 11a). The pattern is similar to a negative NAO pattern [Black *et al.*, 2006], and although it is centered further north ($\sim 65^{\circ}\text{N}$) than is the NAO pattern (50 – 55°N), the correlation coeffi-

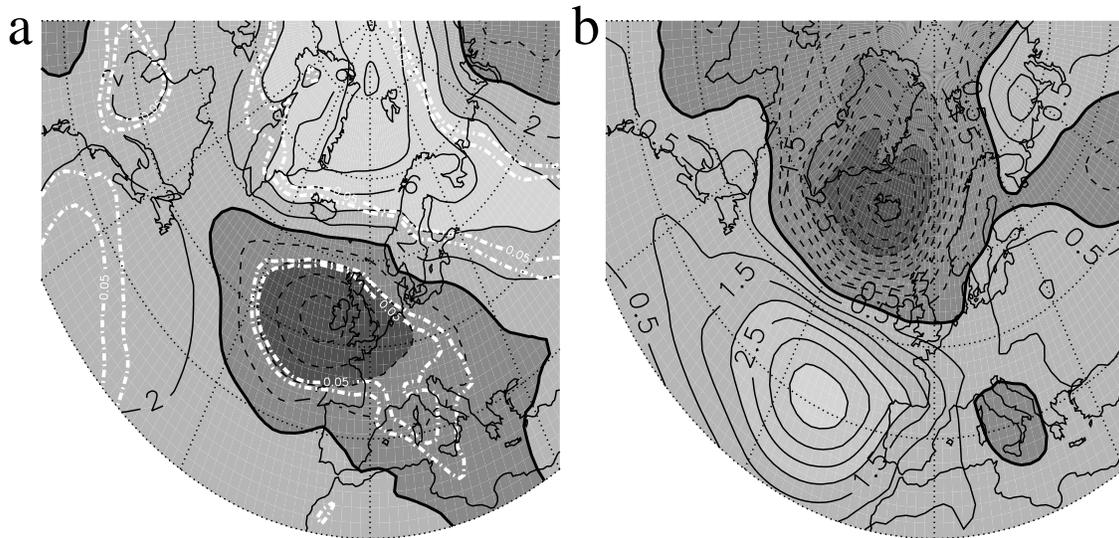

Figure 11. (a) April MSLP (60°W – 30°E , 30°N – 90°N), ERA-Interim, difference in composite over 10 hPa–first years and composite over 1 hPa–first years. Pattern similar to negative NAO pattern. White dot-dashed lines show statistical significance at 90% and 95% levels. Contour interval is 2 hPa. (b) NAO pattern calculated by regressing ERA-Interim April mean MSLP anomalies on to the April monthly NAO index. Contour interval is 0.5 hPa.

cient with the NAO pattern (Figure 11b) over 60°W – 30°E and 30°N – 90°N is -0.52 . The signal in Figure 11a, up to 8 hPa in magnitude over Ireland and Greenland, is about twice the interannual standard deviation in April mean MSLP in these regions (not shown), and so can be considered a significant impact on surface climate. Here the NAO pattern, shown in Figure 11b, is calculated by regressing ERA-Interim April mean sea level pressure anomalies on to the April monthly NAO index (obtained from <http://www.cru.uea.ac.uk/~timo/datapages/naoi.htm>).

[23] *Christiansen* [2005] shows the decorrelation time of the NAO to be around 20 days. Indeed, for ERA-Interim the type of final warming profile (evident from about April 1st, say) correlates no better with the NAO index calculated from a difference in April mean MSLP over Gibraltar and over Reykjavik than does the NAO index calculated from April 1st MSLP (not shown). However, Figure 11b shows the NAO pattern to be localized over the Atlantic, and the signal over Europe seen in Figure 11a is *not* well predicted using April 1st MSLP (not shown). Figure 10 is suggestive of the fact that this signal of same signed MSLP anomalies over the Atlantic and over Europe may instead descend from the polar vortex [see also *Ineson and Scaife*, 2009, Figure 5]. That the state of the stratosphere on a given date offers more predictive skill than the surface pressure on that date is consistent with the analysis of *Baldwin et al.* [2003].

5. Summary and Discussion

[24] The climatological mean final warming in the northern hemisphere occurs first in the mid-stratosphere at around 10 hPa, as seen in both reanalysis data and chemistry-climate model simulations. The final warming occurs around April, earlier in the seasonal cycle than in the southern hemisphere, consistent with the northern hemisphere final warming being

more dynamically, rather than radiatively, driven. The information necessary to diagnose the vertical profile of final warming times to well within the 95% confidence interval is contained in monthly mean data.

[25] On considering individual years it becomes apparent that the climatological final warming profile in the northern hemisphere consists of years in which the final warming occurs first in the mid-stratosphere (termed “10 hPa–first years”) and years in which the final warming occurs first in the mesosphere and propagates downwards through the stratosphere as in the southern hemisphere (“1 hPa–first years”). The late bias seen for climatological mean final warming time in models is likely due to the fact that only 36% of all modeled years are 10 hPa–first years, whereas 81% of years are 10 hPa–first years in ERA-Interim. The small fraction of 10 hPa–first years in the models is consistent with the finding that models’ internal variability is too weak [*Butchart et al.*, 2011]. Indeed, the models’ ability to capture the correct final warming date is now arguably worse than their ability to correctly simulate the frequency of sudden stratospheric warmings in the Northern Hemisphere [*Butchart et al.*, 2011].

[26] Years in which the final warming occurs first in the mid-stratosphere show, on average, a weaker polar vortex with more planetary wave breaking below 10 hPa in the days leading up to the final warming than is seen in 1 hPa–first years. This wave breaking is caused by the meridional wave guide confining waves to a narrower region and the zonal mean zonal wind being very much weaker in this region than it is in 1 hPa–first years. It is unclear what causes these differences in the wave guide and zonal mean zonal wind in the first place.

[27] These different final warming profiles allow potential predictive skill of the surface climate in April. The mean final warming time in the mid-stratosphere in 10 hPa–first years

is April 15th, and significant differences in the dynamical fields are seen between 10 hPa–first years and 1 hPa–first years in the 20 days leading up to the final warming. On average, 10 hPa–first years lead to a more negative NAO pattern in Mean Sea Level Pressure (MSLP) in April than do 1 hPa–first years and to anomalously low MSLP over Europe. The difference in MSLP between 10 hPa–first and 1 hPa–first years is around twice the interannual standard deviation in April mean MSLP in some regions.

[28] Improving the predictability of the NAO may have important implications for seasonal forecasting, as it is known to influence temperature, precipitation and cloudiness over northern Europe through changing the position of the North Atlantic storm track [Folland et al., 2009].

[29] **Acknowledgments.** The work of SCH and NB was supported by the Joint DECC/Defra Met Office Hadley Centre Climate Programme (GA01101). The authors would like to thank Steven Rumbold for several useful discussions during the course of this work, and William Seviour for producing the planetary wave flux diagnostics from ERA-Interim data. ECMWF ERA-Interim data used in this study have been provided by ECMWF, ERA-40 data used in this study have been obtained from the ECMWF data server, and NCEP Reanalysis data was provided by the NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their Web site at <http://www.esrl.noaa.gov/psd/>. The authors also acknowledge John Austin for providing the GFDL AMTRAC3 model data, the CCMVal Activity for WCRP's SPARC (Stratospheric Processes and their Role in Climate) project for organizing and coordinating the CCM data analysis activity, and the British Atmospheric Data Center (BADC) for collecting and archiving the CCMVal model output. The CCSRNIES simulations in the CCMVal were completed with the super computer at CGER, NIES and supported by the Global Environment Research Fund of the Ministry of the Environment of Japan (A-071).
