18

19 **Abstract**

20 Stratospheric ozone recovery and increasing greenhouse gases are anticipated to have a large  
21 impact on the Southern Hemisphere extratropical circulation, shifting the jet stream and  
22 associated storm tracks. Models participating in the Coupled Model Intercomparison Project  
23 Phase 5 poorly simulate the austral jet, with a mean equatorward bias and 10° spread in their  
24 historical climatologies, and project a wide range of future trends in response to  
25 anthropogenic forcing in the Representative Concentration Pathways (RCP). Here, the  
26 question is addressed whether the unweighted multimodel mean (uMMM) austral jet  
27 projection of the RCP4.5 scenario can be improved by applying a process-oriented Multiple  
28 Diagnostic Ensemble Regression (MDER). MDER links future projections of the jet position  
29 to processes relevant to its simulation under present-day conditions. MDER is first targeted to  
30 constrain near-term (2015-2034) projections of the austral jet position, and selects the  
31 historical jet position as the most important of 20 diagnostics. The method essentially  
32 recognizes the equatorward bias in the past jet position, and provides a bias correction of  
33 about 1.5° southward to future projections. When the target horizon is extended to mid-  
34 century (2040-2059), the method also recognizes that lower stratospheric temperature trends  
35 over Antarctica, a proxy for the intensity of ozone depletion, provide additional information  
36 which can be used to reduce uncertainty in the ensemble mean projection. MDER does not  
37 substantially alter the uMMM long-term position in jet position, but reduces the uncertainty in  
38 the ensemble mean projection. This result suggests that accurate observational constraints on  
39 upper-tropospheric and lower stratospheric temperature trends are needed to constrain  
40 projections of the austral jet position.

## 41 **1. Introduction**

42 Uncertainty in the circulation response to anthropogenic forcing remains a pressing problem  
43 in climate projections (Shepherd 2014). The models participating in the Coupled Climate  
44 Model Intercomparison Project Phase 5 (CMIP5) simulate a wide spread in the austral jet  
45 position trends in both the historical and future scenarios, particularly in austral summer  
46 (Eyring et al. 2013; Gerber and Son 2014). Shifts in the jet and the associated storm track in  
47 this season have had significant impacts on regional temperatures and precipitation across the  
48 Southern Hemisphere (SH) in recent decades (e.g. Kang et al. 2011; Thompson et al. 2011),  
49 and have also impacted the meridional overturning of the ocean, with implications for carbon  
50 and heat uptake (e.g. Waugh et al. 2013). It is therefore important to provide reliable  
51 projections of future summer austral jet position trends.

52

53 Historical trends in the austral jet stream have been largest in austral summer (Marshall 2003),  
54 as the circulation has been impacted by two anthropogenic forcings in this season:  
55 stratospheric ozone loss and greenhouse gas (GHG) increase (Arblaster and Meehl 2006).  
56 Ozone depletion led to radiative cooling of the lower stratosphere over Antarctica in the late  
57 20<sup>th</sup> century and strongly impacted the SH extratropical circulation, shifting the jet stream  
58 poleward (Gillett and Thompson 2003; Son et al. 2010). The recovery of ozone is expected to  
59 have the opposite effect as ozone depletion, thus tending to shift the jet equatorward (Perlwitz  
60 et al. 2008; Son et al. 2008). Increasing GHGs appear to drive a poleward expansion of the jet  
61 streams in both hemispheres (Yin 2005), and controlled double CO<sub>2</sub> experiments suggest that  
62 the response of the jet in the SH is strongest in austral summer (Kushner et al. 2001).

63

64 The balance between ozone recovery and increasing GHGs will influence future austral jet  
65 position (Son et al. 2008; Arblaster et al. 2011). While ozone appears to have dominated the

66 response in the past (Polvani et al. 2011), the balance in the future depends in part on the  
67 speed of ozone recovery and the strength of future greenhouse gas emissions (Son et al. 2010;  
68 Simpkins and Karpechko 2012; Barnes and Polvani 2013; Eyring et al. 2013). Even for a  
69 given forcing scenario, however, there is still considerable spread. Amongst the CMIP5  
70 models, Gerber and Son (2014) found that in a moderate carbon future, as characterized by  
71 the Representative Concentration Pathway 4.5 (RCP4.5), differences in ozone changes  
72 contributed most significantly to the spread in future climate projections. There was also  
73 considerable spread associated with processes independent of the thermodynamic trends,  
74 however, suggesting that uncertainty in the dynamical response to temperature trends also  
75 plays a role in model spread.

76

77 CMIP5 models differ substantially in their ability to simulate the basic climatology and trends  
78 of the 20<sup>th</sup> century (Eyring et al. 2013). The austral circulation has long presented a particular  
79 challenge to climate models, with substantial biases in the basic position and variability of the  
80 jet stream (e.g. Kidston and Gerber 2010; Swart and Fyfe 2012). These biases have significant  
81 implications; for example, Bracegirdle et al. (2015) emphasize that a model's ability to  
82 represent the austral circulation is one of the most important factors influencing future  
83 projections of the Antarctic climate.

84

85 In this study, we diagnose relationships between models' ability to simulate the historical  
86 climate and their ability to simulate the future, with an ultimate goal of better discriminating  
87 amongst their projections of the future. This relates to the question whether the ordinary  
88 arithmetic ensemble mean, i.e. the "one-model-one-vote" approach (Knutti et al. 2010) gives  
89 the best estimate of future austral jet position. We use the Multiple Diagnostic Ensemble  
90 Regression (MDER) methodology of Karpechko et al. (2013) to relate future projections to

91 process-oriented diagnostics based on the 20<sup>th</sup> century in order to see if one can improve on  
92 the unweighted multimodel mean (or uMMM) projection of future climate..

93

94 We first explain the MDER method and detail the process-oriented diagnostics which are used  
95 to evaluate the models' ability to simulate the austral climate in Section 2. We include the  
96 main diagnostics that have been linked to the austral jet position in the recent literature.  
97 Section 3 then outlines the observational and reanalysis constraints on these diagnostics and  
98 lists the CMIP5 models used in this study. In Section 4, we use MDER to improve projections  
99 of the position of the jet stream in the near-term (2015-2034) and mid-term (2040-2059). We  
100 conclude our study in Section 5 with a discussion of the results.

101

## 102 **2. Method and Diagnostics**

### 103 **2.1. Multiple Diagnostic Ensemble Regression (MDER)**

104 Karpechko et al. (2013) developed the MDER method to show how Antarctic total column  
105 ozone projections in October are related to observable process-oriented present-day  
106 diagnostics in chemistry-climate models. The method identified key biases in model transport  
107 processes, and used them to establish future ozone projections with higher precision compared  
108 to the uMMM projection.

109

110 The method is based on statistical relationships between models' simulation of the historical  
111 climatology and their future projections, which are often referred to as "emergent constraints"  
112 (e.g. Bracegirdle and Stephenson 2012). If there is a robust linear relationship between future  
113 projections of a target variable (e.g. the position of the austral jet) and a diagnostic of the past  
114 climate, one can use observations to make an improved forecast, as illustrated schematically  
115 in Figure 1. The key idea is to use the models to establish a relationship between the historical

116 climatology and future projections – i.e. the linear regression illustrated by the red line – and  
 117 use this relationship to estimate the future projection based on historical observations. The  
 118 method thus depends (1) on the existence of robust correlations between key processes and  
 119 the future variable to be projected and (2) the ability to constrain the relationships with  
 120 available observations.

121

122 As emphasized by Bracegirdle and Stephenson (2012), one must be wary of spurious  
 123 relationships between the past climatology and future projections. This danger of over-fitting  
 124 grows larger when considering multiple diagnostics at once, and the main difficulty of the  
 125 MDER method stems from the need to systematically reject spurious relationships and avoid  
 126 using redundant information, i.e. cases where the same effective emergent constraint is  
 127 captured by two different diagnostics. Cross validation is used to help filter out spurious  
 128 relationships and redundancy is avoided by a step-wise regression procedure, as detailed  
 129 below.

130

131 More formally, the method exploits relationships between a climate response variable  $y$  and a  
 132 set of  $m$  diagnostics of the present climate  $x_j$ , where  $j = 1, 2 \dots m$ . For a set of  $n$  climate  
 133 models, the multiple linear regression of the relation can be written in matrix form:

$$134 \quad \mathbf{Y} = \mathbf{1}\beta_0 + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad (1)$$

135 where  $\mathbf{Y} = \{y_1, y_2, \dots, y_n\}^T$  is the vector of the climate response variables in the model  
 136 projection (a superscript  $T$  denotes the transpose);  $\mathbf{1} = \{1, 1, \dots, 1\}^T$  is a column-vector of size

$$137 \quad n; \quad \mathbf{X} = \begin{pmatrix} x_{1,1} & x_{1,2} & \dots & x_{1,m} \\ x_{2,1} & x_{2,2} & \dots & x_{2,m} \\ \dots & \dots & \dots & \dots \\ x_{n,1} & x_{n,1} & \dots & x_{n,m} \end{pmatrix} \text{ is the matrix of diagnostics and } \boldsymbol{\varepsilon} \text{ is the vector of}$$

138 independent random variables of size  $n$  representing the uncertainty in the projections. The  
 139 parameters  $\beta_0$  and  $\boldsymbol{\beta}$  of the multiple regression represented in Eq. (1), where  $\boldsymbol{\beta}$  is a column-

140 vector of size  $m$ , are estimated by a least square fit. A key additional assumption for MDER is  
141 that the relationship defined by Eq. (1) and parameters estimated from the model ensemble  
142 simulations holds also for the true climate – and not just for the climate models. Under this  
143 assumption Eq. (1) can be used to estimate the climate response  $y_0$ , given the vector of  
144 observed diagnostics  $\mathbf{X}_0$ :

$$145 \quad \hat{y}_0 = \hat{\beta}_0 + \mathbf{X}_0^T \hat{\boldsymbol{\beta}}, \quad (2)$$

146 where the hatted quantities indicate that a variable is the best fit determined from the  
147 regression analysis.

148

149 The selection of the diagnostics  $x_j$  in MDER is done in a two-step process. First, physical  
150 processes which are expected to influence the climate response  $y$  must be identified. A set of  
151 diagnostics representing these processes are selected based on expert judgement, as discussed  
152 in Section 2.2. This step is necessarily subjective, and Eyring et al. (2005) and Bracegirdle et  
153 al. (2015) provide practical examples of diagnostic selections. Second, a stepwise regression  
154 procedure (von Storch and Zwiers 1999) is applied in order to only choose a subset of  
155 diagnostics for the multiple linear regression which contribute significantly to intermodel  
156 variation in the climate response  $y$ . In the stepwise regression diagnostics are iteratively added  
157 to and removed from the regression model depict by Eq. (1). This will continue until the  
158 regression sum of squares is not further increased by adding more diagnostics according to an  
159 F-test, with the level of significance chosen in this study being  $p = 0.05$ . A more detailed  
160 description of the stepwise regression can be found in von Storch and Zwiers (1999).

161

162 An example of a model weighting strategy which uses only the first (subjective) step for  
163 diagnostic selection is giving by Waugh and Eyring (2008). However, as discussed in

164 Räisänen et al. (2010), Bracegirdle and Stephenson (2012) and Karpechko et al. (2013), it is  
165 not necessary that all the subjectively selected diagnostics play a discernible role in climate  
166 response, or contribute significantly to intermodel spread in the response. As a result, the  
167 statistical model in Eq. (1) may become overfitted and not necessarily provide the best  
168 estimate of the climate response.

169

170 For example Karpechko et al. (2013) initially selected 19 diagnostics known to be relevant to  
171 stratospheric ozone under present day conditions; but only 1 to 4 diagnostics, depending on  
172 the forecast period, were selected by the stepwise algorithm during the second step (i.e.  $m$  was  
173  $\leq 4$  in their study). Similarly Räisänen et al. (2010) found that up to 4 diagnostics could be  
174 added to the regression model before overfitting problems started to emerge. Räisänen et al.  
175 (2010) applied a multiple regression model, as in Eq. (1), to diagnose the climate response in  
176 surface air temperature, but used ad-hoc diagnostics which were not necessarily directly  
177 related to physically relevant processes.

178

179 In order to assess whether projections following from the MDER algorithm may be  
180 susceptible to overfitting, we perform a cross-validation strategy (Michaelsen 1987). In the  
181 field of weather forecasting, one can test a predictive model against subsequent observations,  
182 but clearly we cannot wait to verify climate model projections. Thus we perform cross-  
183 validation in a “pseudo reality,” where, one model at a time is chosen to represent reality  
184 (hence the term pseudo reality) and withdrawn from the model ensemble. As a measure of  
185 prediction error, a squared difference between the projected future jet position and the jet  
186 change in this pseudo reality is calculated for both MDER and uMMM approaches. The  
187 process is repeated  $n$  times, once using each model as the pseudo reality, and the resulting  
188 root mean squared errors (RMSE) quantifies the accuracy of the prediction.

189

190 Diagnostics which have been known to impact on the austral jet stream are discussed in the  
191 following subsection and listed in Table 1. The MDER method and the calculation of the key  
192 process-oriented diagnostics for austral jet position were implemented in the Earth System  
193 Model Evaluation Tool (ESMValTool, Eyring et al. (2015)), and individual results of the  
194 diagnostics calculated from models and observations or reanalyses are shown in the  
195 supporting information. The austral jet position is calculated as the December-January-  
196 February (DJF) latitude of maximum zonal mean zonal wind at 850 hPa between 30°S and  
197 80°S, following Son et al. (2009). To diagnose the exact latitude of the maximum zonal mean  
198 zonal wind, a parabolic fit around the three points of maximum wind speed was calculated for  
199 each time step.

200

## 201 **2.2. Key process-oriented diagnostics for austral jet position**

202 Several processes have been linked to the austral jet position in the literature. For most  
203 diagnostics, we include both the climatological value (denoted by  $\_c$ ) and the linear trend  
204 (denoted by  $\_t$ ) over the observation period, which we defined to be 1979-2005. An exception  
205 is the meridional gradient of Absorbed Shortwave Radiation (ASR) diagnostic (ASR-SH),  
206 which was defined only for a shorter period (2000 – 2005) due to the lack of observations  
207 before 2000. The choice of 1979-2005 restricts us to the satellite era, where we have some  
208 confidence in the reanalyses, and ends with the historical scenario in the CMIP5. The precise  
209 definition of each diagnostic, its value in the reanalysis/observational data set, and its  
210 multimodel mean value from the CMIP5 ensemble are listed in Table 1. The values from each  
211 individual model and the observational or reanalysis datasets are presented in the supporting  
212 information (Figures S1 to S11).

213

214 In the list below we briefly justify the inclusion of each diagnostic in our analysis. Note,  
215 however, that the vast majority of the diagnostics will not ultimately be utilized by MDER to  
216 predict future jet position. This is largely due to the fact that many diagnostics are correlated  
217 with each other (e.g. biases in the climatological position of the jet stream are highly  
218 correlated with biases in the natural variability; Kidston and Gerber 2010). The abbreviated  
219 short names in the list below are used in the figures and are specified again in Table 1.

220

- 221 • **O3-SP:** *Stratospheric ozone at 50 hPa, averaged over the south pole*, directly captures  
222 differences in the strength of the ozone hole and recovery (Eyring et al. 2013). Many  
223 models used the Cionni et al. (2011) dataset generated by SPARC, a few models  
224 interactively simulated ozone, and others used datasets generated by related Chemistry  
225 Climate Models.
- 226 • **O3-NGlob:** The *near global mean ozone at 50 hPa* diagnostic provides a complementary  
227 measure of ozone loss and recovery, and impacts near-global lower stratospheric  
228 temperatures trends in particular (Eyring et al. 2013).
- 229 • **T-SP:** *South Polar stratospheric temperature at 100 hPa* is another indicator of ozone  
230 change (depletion/recovery). Due to differences in models radiation schemes and  
231 dynamical feedbacks, models with the same ozone can simulate different thermal trends  
232 despite having the same underlying ozone. The radiative cooling in the lower stratosphere  
233 due to ozone depletion results in an enhanced temperature gradient in the upper  
234 troposphere/lower stratosphere (UTLS), and therefore accelerates the austral jet (Wilcox  
235 et al. 2012). Gerber and Son (2014) found variance in T-SP to be a significant source of  
236 spread in CMIP5 models in both the historical and future scenario integrations.

- 237 • **T-NGlob:** The *near global mean temperature at 100 hPa* is again a complementary  
238 measure of stratospheric trends, seeking to identify differences between the models that  
239 are not confined to the polar cap.
- 240 • **T-Trop:** Changes in *upper troposphere temperatures in the tropics at 250 hPa* influence  
241 temperature gradients in the UTLS (Wilcox et al. 2012), and were also a key driver of  
242 model spread in the analysis of Gerber and Son (2014). Upper-tropospheric temperatures  
243 in the tropics are influenced by both changes in surface temperatures and changes in the  
244 atmospheric stability.
- 245 • **U-Jet:** The historical *DJF SH jet position at 850 hPa* has been found to correlate with a  
246 models response (Kidston and Gerber 2010). This could reflect geometric constraints on  
247 the circulation (Barnes and Polvani 2013) and/or differences in the dynamics of the jet  
248 with latitude (Garfinkel et al. 2013). Recent trends in the jet also provide a measure of  
249 how sensitive the jets are to forcings, and may also reflect natural variability, as discussed  
250 in Section 5.
- 251 • **H-SH:** Along with U\_jet, the *latitude of the SH Hadley cell boundary defined by zero  $\Psi$  at*  
252 *500 hPa* gives us information about circulation biases and trends associated with ozone  
253 depletion over the past period (Son et al. 2010), where  $\Psi$  denotes the meridional stream  
254 function.
- 255 • **P-SH:** A decrease in *extratropical zonal mean tropopause pressure integrated south of*  
256 *50°S* is associated with warming of the troposphere and cooling of the lower stratosphere  
257 (two signatures of global warming) and has been strongly linked to the position of the  
258 extratropical jet streams (Lorenz and DeWeaver 2007).
- 259 • **SAM-efold:** The *e-folding time scale of a models' Southern Annular Mode (SAM) in the*  
260 *troposphere* characterizes the strength of interactions between baroclinic eddies and the  
261 extratropical jet stream (Lorenz and Hartmann 2001; Gerber et al. 2008a). Fluctuation

262 dissipation theory suggests that the time scales of natural variability may be related to the  
263 response to external forcing (Gerber et al. 2008b; Ring and Plumb 2008), and there is  
264 evidence for this in comprehensive climate models (Kidston and Gerber 2010; Son et al.  
265 2010; Barnes and Polvani 2013).

266 • **ASR-SH:** Ceppi et al. (2014) link changes in the jet stream to changes in the *meridional*  
267 *gradient of SH Absorbed Shortwave Radiation (ASR)*. Changes in the ASR gradient can  
268 force changes in the equator-to-pole temperature gradient, directly impacting the  
269 baroclinicity of the atmosphere.

270 • **SIE-SP:** Changes and biases in the climatological mean *sea-ice extent in the Southern*  
271 *Ocean* impact the local energy budget, and could influence the equator-to-pole  
272 temperature gradient (Stroeve et al. 2012; Ceppi et al. 2014; Bracegirdle et al. 2015).

273

### 274 **3. Models, observational and reanalysis constraints**

275 The MDER method was applied to 28 models of the CMIP5 ensemble, as listed in Table 2,  
276 created and run by 18 different modeling centers. Many centers provided multiple ensemble  
277 member integrations of the same model and scenario. We use all the available ensemble  
278 members, which helps reducing the impact of natural variability. In order not to bias the  
279 MDER method towards models which ran more ensemble integrations, we first average all  
280 ensemble members for each individual model together prior to the calculations. Hence MDER  
281 only sees one historical and future (RCP4.5) time series for each model. Only models that  
282 provided output for all process-oriented present-day diagnostics are included into the analysis,  
283 because the method does not allow for missing values (Karpechko et al. 2013).

284

285 The future trends in the austral jet position were calculated from monthly means from the  
286 RCP4.5 scenario integrations, which are forced by changing GHGs concentrations, but also

287 include aerosol, ozone, and land use changes, and natural forcings (Taylor et al. 2012). The  
288 present-day diagnostics were calculated from the monthly mean CMIP5 historical  
289 simulations, in general for the period 1979 – 2005 (see details in Table 1) and results are  
290 shown in the supplementary material. Each of the present-day diagnostics is compared with  
291 monthly mean reanalysis data or observations as listed in Table 1.

292

293 Direct measurements are used in the diagnostics where available, but for many diagnostics we  
294 had to rely on meteorological reanalysis. For the evaluation, monthly means for the period  
295 1979–2005 are used except for the zonal means of net balanced climatology Top-of-  
296 Atmosphere (TOA) fluxes which are only available for the period 2000 – 2014. A list of the  
297 reanalysis and observations used in this study is given in Table 1.

298

#### 299 **4. Application of MDER to projections of the summertime austral jet position**

300 To highlight how the most important factors constraining the jet stream evolve in time, we  
301 apply MDER to two time horizons. We first focus on the jet position in the near-term from  
302 2015-2034. A twenty-year period was selected to reduce the influence of natural variability in  
303 the jet stream. Over this short time horizon, no significant changes in anthropogenic forcings  
304 occur in the RCP4.5 scenario, so we expect the method to focus on correcting biases in the  
305 historical climatologies. We then focus the method on a mid-century projection, 2040-2059, a  
306 time when the stratospheric ozone and greenhouse gas concentrations have changed.

307

##### 308 **4.1. Near-term projections of the austral jet position**

309 Figure 2a shows the absolute value of the correlation coefficients between the short-term  
310 projection of the austral jet position and our 20 process-oriented present-day diagnostics. The  
311 coefficients reveal a strong correlation between the climatological mean of the historical

312 austral jet position (U-Jet\_c) and the near-term projection of the austral jet position. The  
313 correlation coefficient is near unity with a tight uncertainty envelope, as quantified by the  
314 95% confidence interval. Models simulating the jet too far equatorward in the historical  
315 simulations (which can be seen in Figure S6) also do so for the near-term future, and vice  
316 versa. The high correlation between the historical and the projected austral jet position will  
317 cause the MDER algorithm to recognize and correct for this well-known equatorial bias in the  
318 CMIP5 model ensemble.

319

320 The climatological mean of the Hadley cell boundary (H-SH\_c, Figure S7) position ( $r = 0.90$ )  
321 and trend ( $r = 0.58$ ) are also highly correlated with the jet position from 2015-2034, although  
322 the relationship is of opposite sign for the trend. Biases in the position of the SH Hadley cell  
323 mirror biases in the extratropical jet stream (Son et al. 2010; Arblaster and Meehl 2006), such  
324 that the first relationship is strongly linked to the connection with the historical jet position U-  
325 Jet\_c discussed above. At face value, the negative correlation between the near-term jet  
326 position and the trend in the SH Hadley cell position (H-SH\_t) suggests that models which  
327 saw more expansion of the tropics in the late 20<sup>th</sup> century tend to have a more equatorward jet  
328 in coming decades. Given that the near-term jet is so highly correlated with the jet in the past,  
329 this could reflect the fact that models with an equatorward bias in their climatology are more  
330 sensitive to external forcing (and so exhibited larger trends in the 20<sup>th</sup> century), as found by  
331 Kidston and Gerber (2010) for future jet shifts. The late 20<sup>th</sup> century trend in the jet stream  
332 itself, U-Jet\_t is also negatively correlated with the 2015-2034 jet position, albeit more  
333 weakly. It is unclear to us why the trend in the Hadley cell is more strongly associated with jet  
334 position than the trend in the jet itself.

335

336 The e-folding time scale of SAM (SAM-efold, Figure S10) also exhibits a statistically  
337 significant positive correlation ( $r = 0.59$ ) with the near-term projection of the austral jet. As in  
338 the case of the Hadley cell, the SAM e-folding time scale is linked to the historical jet  
339 position U-Jet\_c (e.g. Kidston and Gerber 2010), and so again may be a manifestation of the  
340 same relationship. Since the H-SH and SAM-efold diagnostics ultimately provide somewhat  
341 redundant information compared to the diagnostic U-Jet\_c, the MDER algorithm rejects them  
342 from the regression model.

343

344 The diagnostic of near global climatological mean ozone (O3-NGlob\_c, Figure S1) shows the  
345 fifth highest correlation, and the link is statistically significant ( $r = 0.50$ ) at the 95%  
346 confidence level. The correlation could reflect that fact that models which experienced larger  
347 ozone loss over the historical period (and so exhibit a climatology with less ozone) also  
348 experienced a stronger ozone hole, and so a poleward shift in the jet stream (Eyring et al.  
349 2013).

350

351 The remaining correlations in Figure 2a are not statistically significant at the 95% level of the  
352 linear regression. In general, however, diagnostics indicating biases in the SH circulation  
353 climatology show a stronger correlation to the near-term austral jet stream position than  
354 diagnostics which characterize trends over the historical period.

355

356 From all the diagnostics included, the MDER algorithm creates a parsimonious regression  
357 model to predict the near-term austral jet position, focusing exclusively on the diagnostic U-  
358 Jet\_c, as shown in Figure 3a. The model is simply  $-1.36 + 0.98 \times \text{U-Jet}_c$ . In essence, the  
359 algorithm detects the equatorward bias of the CMIP5 models in the jet stream in the past and  
360 provides a correction to the future projection. As the result depends on a single parameter,

361 Figure 3a can be compared quite easily with our schematic diagram in Figure 1. MDER  
362 focuses on the nearly perfect correlation between the historical jet position (U-Jet\_c) and jet  
363 location in 2015-2034. The uMMM projection puts the jet at 48.9°S (red horizontal line), but  
364 knowing that the historic jet was biased in the CMIP5 models (located on average at 48.5  
365 instead of 50.0°S), MDER suggests that it should also be 1.5° poleward of the uMMM in  
366 2015-2034, at 50.4°S, as indicated by the blue dashed lines.

367

368 While the result is almost trivial, this is the first time, to our knowledge, that projections of  
369 the future multi-model jet position have been bias corrected. Taking the uMMM would place  
370 the jet at 48.9°S over the period 2015-2034, substantially equatorward of its current position  
371 in reanalysis. MDER suggests that it should be at 50.4°S, just a bit poleward of its current  
372 location.

373

374 Cross validation of the results indicates that MDER can reduce uncertainty in the jet  
375 projection. This is realized by comparing the results of future austral jet position estimates  
376 with the MDER method against the uMMM in pseudo reality, following Karpechko et al.  
377 (2013). The root mean squared projection error (RMSE) of the near-term austral jet positions  
378 is nearly an order of magnitude lower using the MDER method compared to uMMM (Figure  
379 4;  $RMSE_{MDER} = 0.42$  deg;  $RMSE_{uMMM} = 2.37$  deg). This dramatic drop in uncertainty in the  
380 cross-validation can be understood more easily by viewing time series of the jet position,  
381 shown in Figure 5. In the cross validation test with an uMMM methodology, one is effectively  
382 seeking to predict one model's jet position (i.e., the pseudo reality) using the positions  
383 projected by all the other models. The  $RMSE_{uMMM}$  thus reflects the spread in the *mean jet*  
384 *position* from 2015-2034, a spread on the order of degrees. The errors are large because the  
385 uMMM cannot successfully predict cases when the pseudo reality is an outlier model. With

386 MDER, however, we explicitly take into account information on the historical jet position in  
387 the model chosen as the pseudo reality, and only use the other models to estimate the *jet shift*  
388 between 1979-2005 and 2015-2034. For this short time horizon, the forced signal is small, on  
389 the order  $1/10^{\text{ths}}$  of a degree.

390  
391 We should emphasize that the RMSE error bounds obtained in the cross-validation exercise  
392 provide nice illustration of the actual prediction errors associated with uMMM and MDER.  
393 Formal estimates of the prediction errors from the full model ensemble further demonstrate  
394 how the prediction uncertainty is reduced by MDER in comparison to uMMM. Based on 28  
395 realizations of climate change under the RCP 4.5 scenario, the 95% confidence intervals for  
396 MDER and uMMM methods are 0.8 or 4.8 deg correspondingly. Here, the MDER error is  
397 calculated in a standard way as confidence interval for the response variable of regression  
398 (e.g. Karpechko et al. 2013, Eq. 6). For uMMM the corresponding confidence interval is  
399 given by  $t_{(1+\tilde{p})/2} \times s$  where  $s$  is the standard deviation across individual model projections,  
400  $t_{(1+\tilde{p})/2}$  is the  $(1 + \tilde{p})/2$  quantile of  $t$  distribution and  $\tilde{p}=0.95$ . The MDER uncertainty is  
401 calculated assuming perfect knowledge of the observed diagnostics.

402  
403 A more realistic uncertainty bound should reflect both uncertainty in the multi-model estimate  
404 of the climate signal (in case of MDER, uncertainty in the change between 1979-2005 and  
405 2015-2034), and uncertainty associated with calculation of the diagnostics. The latter is  
406 affected by reanalysis errors and internal variability. While reanalysis errors can only be  
407 estimated qualitatively (see discussion in Section 5), the influence of the internal variability  
408 can be directly incorporated into the prediction uncertainty. In 27 years of reanalysis, the  
409 mean jet can only be bounded to the range  $50.0 \pm 0.5$  deg with 95% confidence. When  
410 uncertainty associated with internal variability is taken into account (by the law of error

411 propagation) the uncertainty of MDER prediction becomes 1 deg., still considerably less than  
412 the uncertainty of uMMM method.

413

#### 414 **4.2. Mid-term projections of the austral jet position**

415 A key finding from our application of MDER to the near-term jet position is that the  
416 climatological biases in CMIP5 historical integrations are larger than any of the shifts  
417 predicted in the next two decades. We next apply the MDER to mid-term (2040 - 2059) jet  
418 position where the forcing signal is larger. As we will show, however, the mean trends in the  
419 jet remain small, likely due to the fact that stratospheric ozone loss and greenhouse gas  
420 increases tend to oppose each other in coming decades (e.g. Perlwitz et al. 2008, Son et al.  
421 2008). Nonetheless, MDER suggest that we can glean more information than a simple bias  
422 correction when focusing on longer-term projections.

423

424 Figure 2b illustrates correlations between the process-oriented diagnostics and the mid-term  
425 austral jet projections. Even at mid-century, SH circulation biases in the historical integrations  
426 are still the most important. The top five diagnostics with the strongest correlations to mid-  
427 term austral jet positions are the same as for near-term. The importance of the remaining 15  
428 process-oriented diagnostics has changed, although those correlation coefficients are  
429 generally not statistically significant.

430

431 Despite the similarities in the correlation structure, MDER obtains a more complex result for  
432 the mid-term projection. The method initially constructs the regression model,  $-1.66 + 1.02 \times$   
433  $U\text{-Jet}_c - 0.40 \times T\text{-SP}_t - 0.10 \times T\text{-SP}_c$ , involving three diagnostics: the historical austral jet  
434 positions ( $U\text{-Jet}_c$ ), stratospheric south polar cap temperature trends at 100 hPa ( $T\text{-SP}_t$ ) and  
435 the 100 hPa polar cap temperature climatology,  $T\text{-SP}_c$ . While the  $U\text{-Jet}_c$  term can again be

436 interpreted as a bias correction of the austral position in the CMIP5 models, the T-SP terms  
437 indicate the diagnostics associated with the formation of the ozone in the historical period can  
438 be used to improve future projections of the jet position.

439

440 The negative sign of the T-SP<sub>t</sub> term reflects the fact that models which experienced larger  
441 stratospheric cooling over the historical period tend to exhibit a more equatorward shift of the  
442 jet in the future. Wilcox et al. (2012) and Gerber and Son (2014) found that models with more  
443 cooling over the polar cap tend to experience a more poleward shift in the jet, suggesting that  
444 the jet is responding to the equator-to-pole temperature gradient in the upper  
445 troposphere/lower stratosphere. Here, the relationship has changed sign because we are  
446 comparing cooling over the historical period to an equatorward shift in the future. Models  
447 which experienced a strong thermodynamic response to ozone loss in the past are likely to  
448 have an equal and opposite response to ozone recovery in the future, i.e. more warming, and  
449 so a more equatorward jet shift. T-SP<sub>t</sub> can thus be acting as a proxy for the strength of ozone  
450 loss and recovery, a key driver of austral jet shifts. We emphasize, however, that it is the  
451 temperature response to ozone loss which appears to be crucial. The regression model picks  
452 T-SP<sub>t</sub> over the actual historic trend in ozone, O3-SP<sub>t</sub>, even though both statistics are nearly  
453 equally correlated with future jet position. Many models used a similar ozone data (Cionni et  
454 al. 2012), but do not exhibit a uniform thermal response due to differences in their radiation  
455 schemes.

456

457 We were concerned that the negative sign of the correlation with T-SP<sub>c</sub> could reflect a  
458 similar connection to the ozone hole, as ozone depletion already occurred over the entire  
459 historical period (1979-2005): a colder historical climatology is indicative of a larger ozone  
460 hole. It is thus unclear how the climatology would contain information independent from the

461 polar cap temperature trend, which raises the danger that MDER could be overfitting the  
462 diagnostics. In order to avoid inclusion of redundant information with unclear physical  
463 interpretation, we recalculated the regression model, intentionally removing the T-SP\_c  
464 diagnostic, and obtained the result:  $-1.41 + 0.99 \times \text{U-Jet}_c - 0.36 \times \text{T-SP}_t$ . The difference  
465 between the projections made by these two models is  $0.2^\circ$ , much smaller than the uncertainty  
466 of either statistical model (see below). Based on further cross-validation tests (not shown), we  
467 believe the simple model is more robust and apply it in Figure 3b. It incorporates two  
468 physically justified constraints: a correction for biases in the climatological jet position and a  
469 correction based on the intensity of thermodynamic response to stratospheric ozone loss.

470

471 Figure 4 shows also the cross validation tests for the mid-range jet projection. As one might  
472 expect the  $\text{RMSE}_{\text{MDER}}$  prediction error ( $0.59 \text{ deg}$ ) is larger for the mid-21st century case than  
473 for the near-term analysis (where it was  $0.42 \text{ deg}$ ), but still more than four times less than the  
474 uMMM prediction error ( $\text{RMSE}_{\text{uMMM}} = 2.47 \text{ deg}$ ). Again, the key is that the shifts in the jet  
475 stream, even 50 years away, are small relative to the biases in the models historical  
476 climatology. As noted in the discussion of section 4.1, the RMSE errors reflect our  
477 uncertainty in light of 28 realizations of the future, and do not account for uncertainty in jet  
478 associated with a single realization, as will be the case with our one Earth.

479

480 From the regression model in Figure 3b, the MDER analysis predicts an austral jet stream  
481 position for the mid-term climatological mean of  $50.6^\circ\text{S}$ , implying a mean shift of  $0.2^\circ$   
482 southward compared to the 2015-2034 position of the austral jet (or  $0.6^\circ$  southward from its  
483 historical climatology). The uMMM projection,  $50.0^\circ\text{S}$ , suggests a small southward shift from  
484 the 2015-2034 mean as well, but only by  $0.1^\circ$ . Note that this is still northward of the jet

485 location in historical reanalysis: naïvely comparing the future projection with historical  
486 reanalysis would give one the opposite trend.

487

488 In our near-term application, MDER took the shift in the uMMM projection and bias  
489 corrected for the mean jet location. With inclusion of information on stratospheric polar cap  
490 temperature trends, MDER modifies the jet trend as well. We emphasize, however, that this  
491 modification (and the total trends themselves) is very small relative to the 1.5° bias in the  
492 models historical jet position climatology. The trends are also small relative to uncertainty in  
493 the jet position associated with natural variability; given 1979-2005 reanalysis data, we can  
494 only say that the mean jet position was between  $50.0 \pm 0.5^\circ\text{S}$  with 95% confidence.

495

## 496 **5. Summary and Discussion**

497 We have used a multiple diagnostic ensemble regression (MDER) algorithm to analyze the  
498 austral jet position in projections of the 21<sup>st</sup> century under the RCP 4.5 scenario, a moderate  
499 carbon future. MDER allowed us to us to incorporate 20 process-oriented constraints from  
500 observations and reanalysis to improve upon the unweighted multimodel mean (uMMM)  
501 projection. The method can be interpreted as a re-weighting of models based on biases in their  
502 historical climatologies (Karpechko et al. 2013).

503

504 We first applied the MDER method to the near-term climatological mean (2015-2034) of the  
505 austral jet position. The method removed the equatorward bias in the jet stream, suggesting  
506 that the best estimate of its future position should be 1.5° southward of that found in the  
507 uMMM projection (48.9°S). We next focused on a mid-century austral jet stream projection, a  
508 target period of 2040-2059. In addition to the same need to correct for the climatological jet  
509 position bias, MDER found that lower stratospheric polar cap temperature trends over the

510 historical period could be used to effectively discriminate future trends. From a physical  
511 standpoint, historical temperature trends are an indicator of the intensity of the ozone hole. It  
512 is likely that models with more intense cooling over the historical period of ozone loss will  
513 experience more intense warming as ozone recovery, and hence a more equatorward shift in  
514 the jet stream as it responds to changes in the upper troposphere/lower stratosphere  
515 temperature gradient.

516

517 Expected shifts in the jet stream in coming decades are generally small, on the order of  $1/10^{\text{th}}$   
518 of a degree, in part due to cancellation between the impacts of stratospheric ozone recovery  
519 and increased greenhouse gas loading (e.g. Perlwitz et al. 2008). Biases in some models  
520 climatological jet position, on the other hand, are on the order of degrees, and the multimodel  
521 mean position is 1.5 degrees poleward of that found in ERA-Interim reanalysis. Thus, a naïve  
522 use of the uMMM to project the mean jet position in the near or mid-term places the future jet  
523 *equatorward* of its current position, even though most models project that it should shift  
524 slightly *poleward* over this period. While this bias correction is a fairly straightforward result,  
525 it is, to our knowledge, the first effort to account for this bias in future projections.

526

527 Getting the jet in the right place has significant implications. First, it is co-located with the  
528 storm track, and so tightly linked with the boundary between the subtropical dry zone and  
529 extratropical precipitation maximum. Shifts in the jet have significant impacts on regional  
530 precipitation (e.g. Kang et al. 2011; Thompson et al. 2011) and it is critical that regional  
531 modeling efforts to downscale climate information from global models account for this bias.  
532 Second, the surface wind stress associated with the jet stream plays a key role in the  
533 overturning circulation of the ocean (Vaugh et al. 2013). Biases in the austral jet position

534 limit our ability to accurately model the heat and carbon uptake of the deep ocean (Swart and  
535 Fyfe 2012).

536

537 Given these large model biases, an alternative approach would be to first compute the jet shift  
538 from the historical period to the future using the models, and then to simply add this to the  
539 historical climatology based on reanalyses (e.g. Räisänen 2007). MDER effectively led to this  
540 result for the near-term projection. This change based approach, however, relies on the  
541 explicit assumption that biases in simulated present-day and future climates remain constant  
542 (i.e. that the jet shift only depends on the applied forcing and is independent on present jet  
543 positions). MDER does not make this assumption, and it did make a difference (albeit a small  
544 one) for the mid-term projection.

545

546 Our regression model for the mid-range jet projection suggests that we can use a historical  
547 *trend* in polar stratospheric temperatures to better estimate the future jet position.  
548 Constraining this trend with reanalysis, however, is problematic, as changes in the  
549 observational network can lead to spurious trends. Calvo et al. (2012) suggest that Antarctic  
550 lower stratospheric cooling due to ozone depletion (T\_SP\_t) may be underestimated by ERA-  
551 Interim by as much as a factor of 2 compared to radiosonde observations. On the other hand,  
552 the interannual variability of the temperatures is so large that the discrepancy between trend  
553 estimates based on ERA-Interim and radiosondes is within statistical uncertainty (Calvo et al.  
554 2012).

555

556 To test this for our study, Figure 6 of the supporting information compares the T-SP  
557 diagnostics derived from the CMIP5 models with ERA-Interim data and the radiosonde  
558 observations that were analyzed by Young et al. (2013): HadAT2 (Hadley Centre

559 Atmospheric Temperatures, ver. 2, Thorne et al. (2005)); IUK (Iterative Universal Kriging,  
560 Sherwood et al. (2008)); RAOBCORE (Radiosonde Observation Correction using Reanalysis,  
561 ver. 1.5, Haimberger et al. (2008)); RICH-obs (Radiosonde Innovation Composite  
562 Homogenization (obs), ver. 1.5, Haimberger et al. (2012)). For the season (DJF) and period  
563 (1979-2005) considered in our study, the mean trend in ERA-Interim is approximately -1.4  
564 K/dec, and so slightly smaller than that in the radiosonde datasets, where the trends vary  
565 between -1.6 and -2.2 K/dec, The ERA-Interim trend, however, is still mostly within the given  
566 observational uncertainty. We also found that the ERA-Interim climatology (lower panel in  
567 Figure 6) is very similar to the radiosonde climatology.

568

569 The focus of MDER on different time periods provides additional insight into which physical  
570 processes are important for projections at the mid-term horizon. In the near term, diagnostics  
571 focused on biases in the climatology are most important. At midcentury, uncertainty  
572 associated with stratospheric ozone trends also becomes important. Towards the end of the  
573 century, when the ozone hole is mostly recovered, uncertainty in tropical warming trends  
574 begin to appear in the MDER results (not shown). The tropical warming trends over the  
575 historic period give an indication of how sensitive a model is to greenhouse gas warming:  
576 models that warm more over the historic period tend to warm more in the future, and so  
577 project greater circulation trends. We did not present these results here, however, due to the  
578 lack of reliable direct measurements of upper troposphere temperature trends. Our study thus  
579 emphasizes the need for reliable long term climate records, which may prove critical for  
580 constraining future model projections.

780

781 **Table 1:** Description of the diagnostics, reanalysis or observational data used to constrain the  
782 models , their mean value and uncertainty for the diagnostic, the corresponding value in the  
783 CMIP5 ensemble, and a reference. The substring “t” denotes the trend of this diagnostic and the  
784 substring “c” the climatological mean calculated for the period 1979 – 2005, except for the ASR-  
785 SH diagnostic, which was calculated for the period 2000 - 2005.

Short Name	Diagnostic	Reanalysis / Observations	Reanalysis / Observational Value	CMIP5 Mean $\pm$ Stddev	References
<b>Impact of Antarctic Ozone Depletion on the position of the jet stream</b>					
T-SP_t	Trends and climatological means in ONDJ polar stratospheric temperatures at 100 hPa over Antarctica (60-90°S)	ERA-Interim ( <i>Dee et al. 2011</i> )	-1.17 $\pm$ 0.63 K/dec	-1.40 $\pm$ 0.72 K/dec	<i>Figure 10d of Eyring et al. (2013)</i> Figure 10 of Gerber and Son (2014)

789 **FIGURES CAPTIONS**

790 **Figure 1:** A schematic diagram illustrating the linear regression model for constraining future  
791 projections of the jet position. Each blue dot represents (hypothetical) output from different  
792 climate models, comparing a model's performance on a diagnostic based on the historical  
793 scenario integration (x-axis) with its projection of the jet position in the future (y-axis). The  
794 unweighted Multi-Model Mean (uMMM) projection is the average of all blue dots in y, and  
795 marked by the horizontal blue arrow. The linear relationship between the past diagnostic and  
796 future projection illustrates an emergent constraint, which is quantified by linear regression  
797 (red line). The linear relationship can be used to estimate the future projection based on the  
798 observations of the past diagnostic, as marked by the black arrows. Uncertainty in the new  
799 projection (gray shading) arises from two sources: uncertainty in the observational constraint  
800 (green shading) and uncertainty in the linear regression (red shading).

801 **Figure 2:** Absolute values of the correlation coefficient between future austral jet position and  
802 present-day diagnostics as listed in Table 1 across the CMIP5 model ensemble (see Table 2),  
803 for (a) the near-term austral jet position climatological mean (2015-35) and (b) the mid-term  
804 austral jet position climatological mean (2040-59). Error bars show the 95% confidence  
805 intervals for the correlation coefficients. Colored markers indicate positive (red) and negative  
806 (blue) correlations.

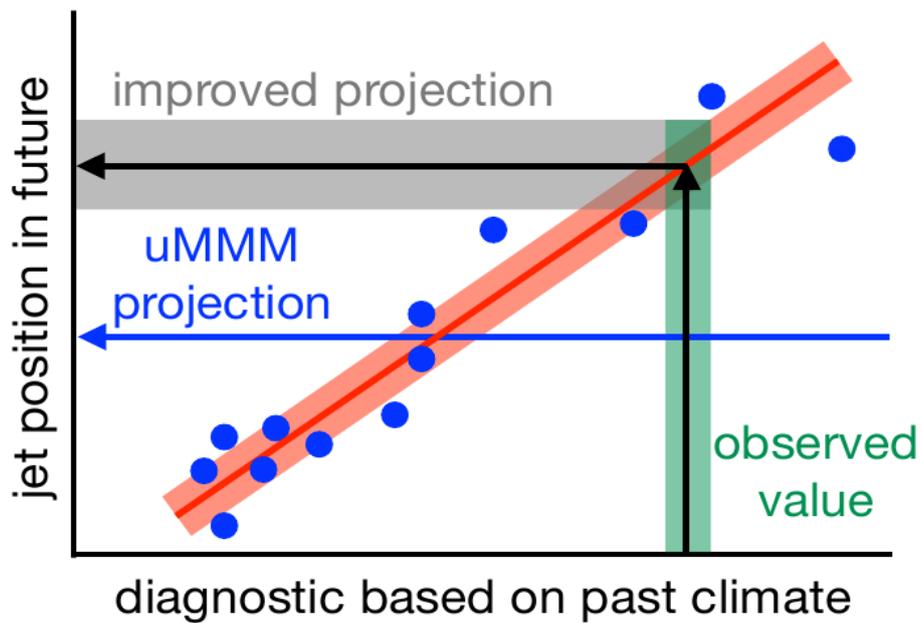

807 **Figure 3:** Scatter plot showing the correlation between the future austral jet position and (a)  
808 the quantity  $(-1.36 + 0.98 \times \text{U-Jet}_c)$  for the near term climatological mean (2015-34) and (b)  
809 the quantity  $(-1.41 + 0.99 \times \text{U-Jet}_c - 0.36 \times \text{T-SP}_t)$  for the mid-term climatological mean  
810 (2040-59). Numbers indicate estimates of simulated climatological mean values of each  
811 CMIP5 model and the error bars show one standard deviation of the means, calculated from  
812 seasonal means. The solid blue line shows the least squares linear fit to the CMIP5 model

813 ensemble and the gray shading marks the 95% confidence interval for the least squares linear  
814 regression. The orange shading indicates one standard deviation of the observed  
815 climatological mean values calculated using historical values. The red dotted line shows the  
816 unweighted ensemble mean (uMMM) and the blue dashed line the MDER prediction.

817 **Figure 4:** Root mean squared error (RMSE) differences between the ensemble-mean future  
818 climatological mean (2015-34 and 2040 - 2059) austral jet position and the future  
819 climatological mean austral jet position in pseudo reality for each pseudo reality considered  
820 (grey circles) under the RCP4.5. The ensemble mean is calculated for each scenario from the  
821 unweighted model mean (uMMM, red boxes) and the MDER method (blue boxes). The cross  
822 indicates the RMSE for each case and the boxes show the 25th-75th percentiles across the  
823 error ensemble. The bars inside the box indicate the median of the ensemble.

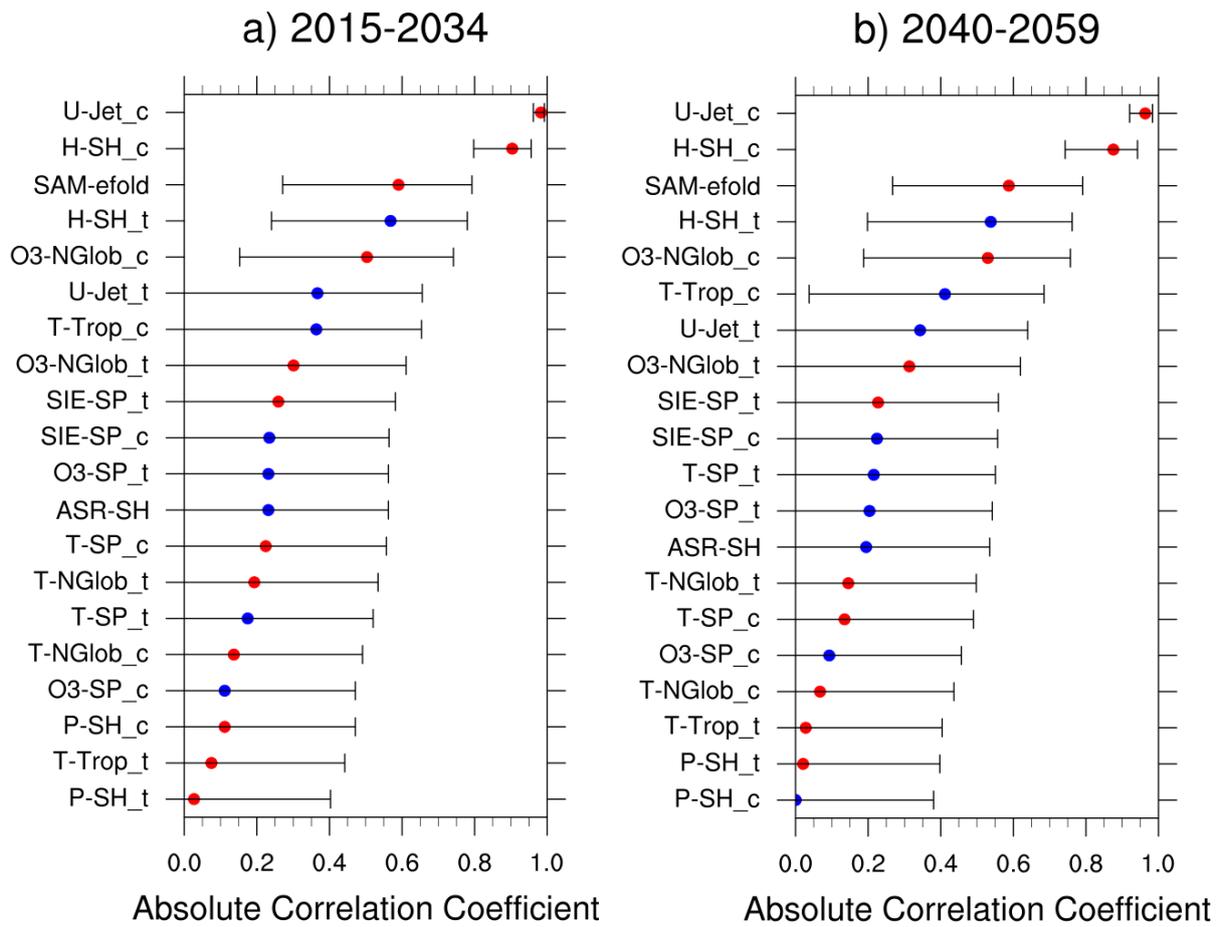

824 **Figure 5:** Time series of the austral jet position for RCP4.5 scenario between 1980 and 2100.  
825 Grey lines show the individual models (iteratively smoothed with a 1-2-1 filter, repeated 30  
826 times, to reduce the noise) and the red dotted line the unweighted model mean across all  
827 CMIP5 models in Table 2. Diamonds show the predicted mean estimate resulting from the  
828 MDER analysis, for the near-term (2015 - 34) and mid-term (2040 - 59) climatological means  
829 austral jet position. Error bars indicate the 95% confidence interval of the regression analysis.  
830 The orange line shows the reanalysis data from ERA-Interim.

831 **Figure 1:** Trends in October-November-December-January (ONDJ) temperature anomalies  
832 (ta) at 100 hPa over Antarctica for radiosondes data (HadAT2; RAOBCORE; RICH-obs), the  
833 ERA-Interim reanalysis and the individual models of the CMIP5 ensemble. Vertical lines  
834 indicate the sample standard deviation of the mean value.

836

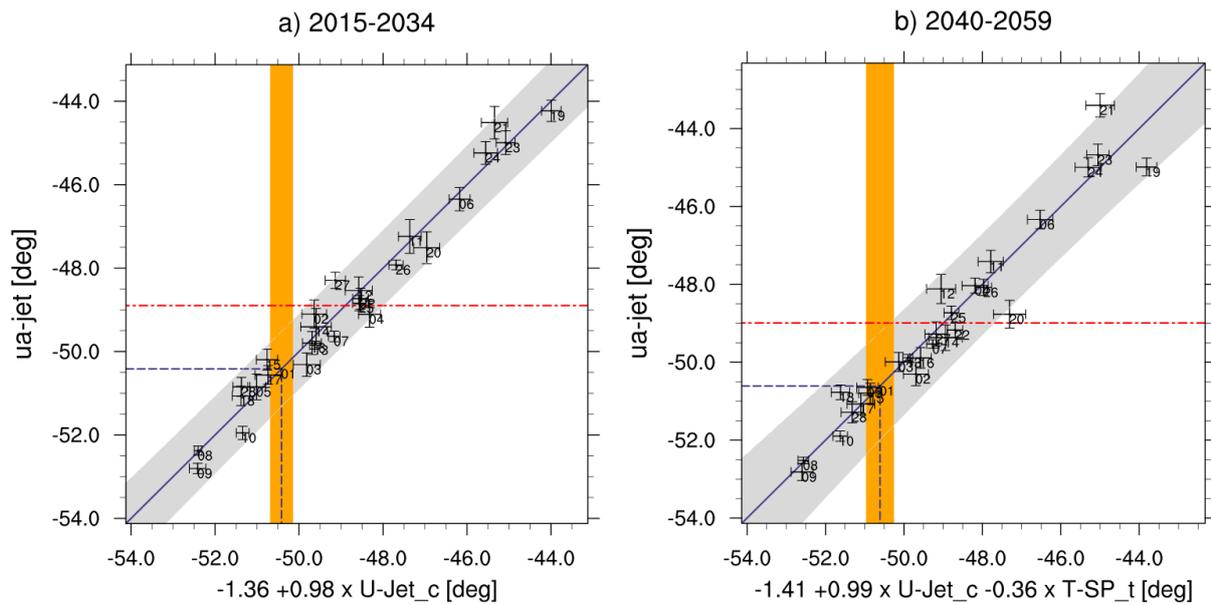

837 **Figure 2:** A schematic diagram illustrating the linear regression model for constraining future  
 838 projections of the jet position. Each blue dot represents (hypothetical) output from different  
 839 climate models, comparing a model's performance on a diagnostic based on the historical  
 840 scenario integration (x-axis) with its projection of the jet position in the future (y-axis). The  
 841 unweighted Multi-Model Mean (uMMM) projection is the average of all blue dots in y, and  
 842 marked by the horizontal blue arrow. The linear relationship between the past diagnostic and  
 843 future projection illustrates an emergent constraint, which is quantified by linear regression  
 844 (red line). The linear relationship can be used to estimate the future projection based on the  
 845 observations of the past diagnostic, as marked by the black arrows. Uncertainty in the new  
 846 projection (gray shading) arises from two sources: uncertainty in the observational constraint  
 847 (green shading) and uncertainty in the linear regression (red shading).

848

849 **Figure 3:** Absolute values of the correlation coefficient between future austral jet position and  
 850 present-day diagnostics as listed in Table 1 across the CMIP5 model ensemble (see Table 2),  
 851 for (a) the near-term austral jet position climatological mean (2015-35) and (b) the mid-term  
 852 austral jet position climatological mean (2040-59). Error bars show the 95% confidence  
 853 intervals for the correlation coefficients. Colored markers indicate positive (red) and negative  
 854 (blue) correlations.

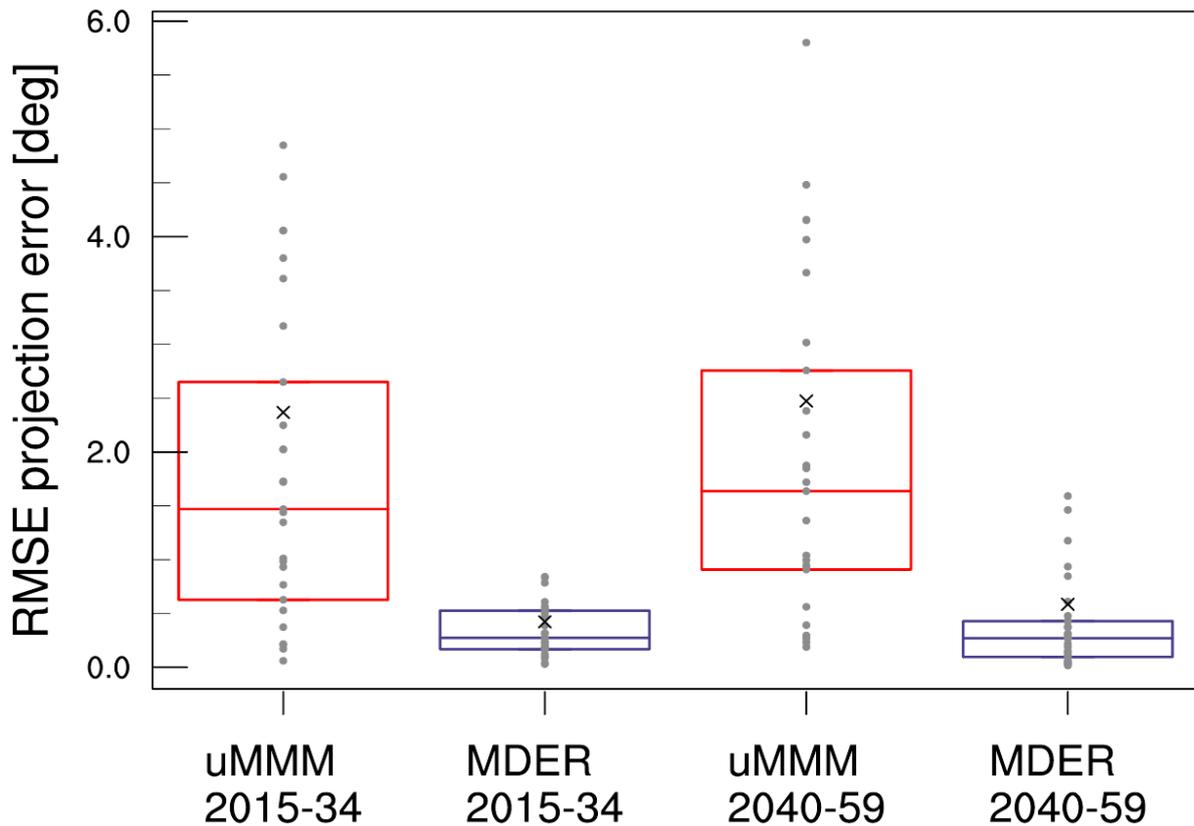

855

856

857 **Figure 4:** Scatter plot showing the correlation between the future austral jet position and (a)  
 858 the quantity  $(-1.36 + 0.98 \times \text{U-Jet}_c)$  for the near term climatological mean (2015-34) and (b)  
 859 the quantity  $(-1.41 + 0.99 \times \text{U-Jet}_c - 0.36 \times \text{T-SP}_t)$  for the mid-term climatological mean  
 860 (2040-59). Numbers indicate estimates of simulated climatological mean values of each  
 861 CMIP5 model and the error bars show one standard deviation of the means, calculated from  
 862 seasonal means. The solid blue line shows the least squares linear fit to the CMIP5 model  
 863 ensemble and the gray shading marks the 95% confidence interval for the least squares linear  
 864 regression. The orange shading indicates one standard deviation of the observed  
 865 climatological mean values calculated using historical values. The red dotted line shows the  
 866 unweighted ensemble mean (uMMM) and the blue dashed line the MDER prediction.

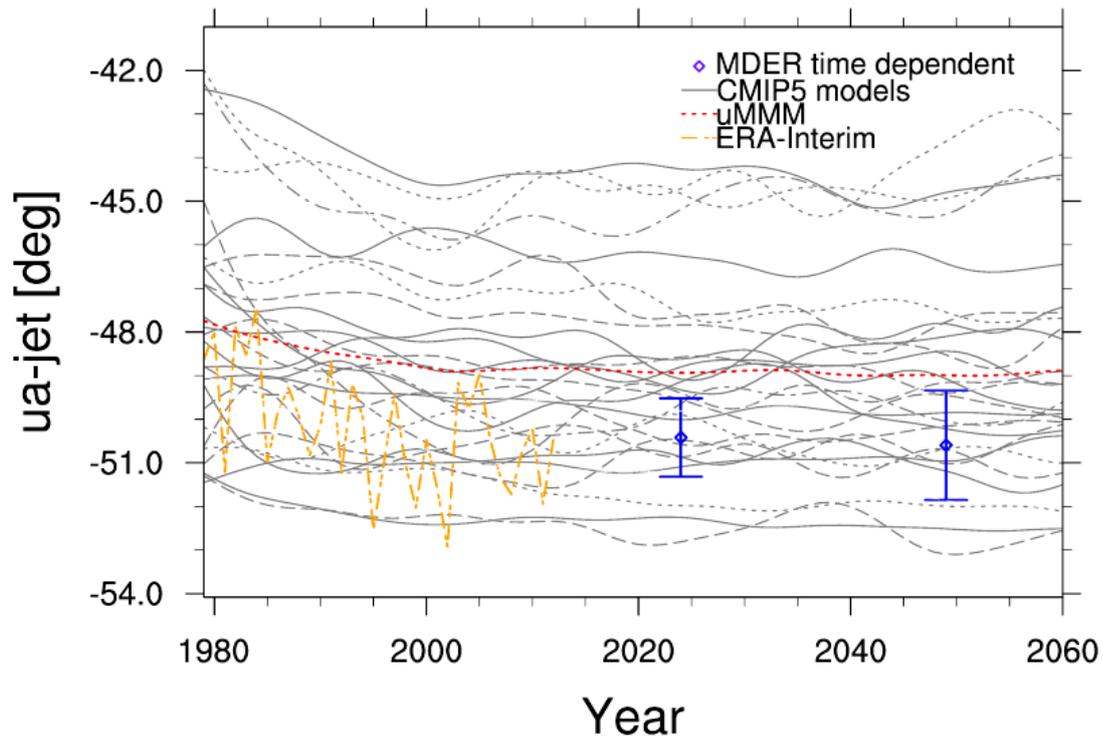

867

868

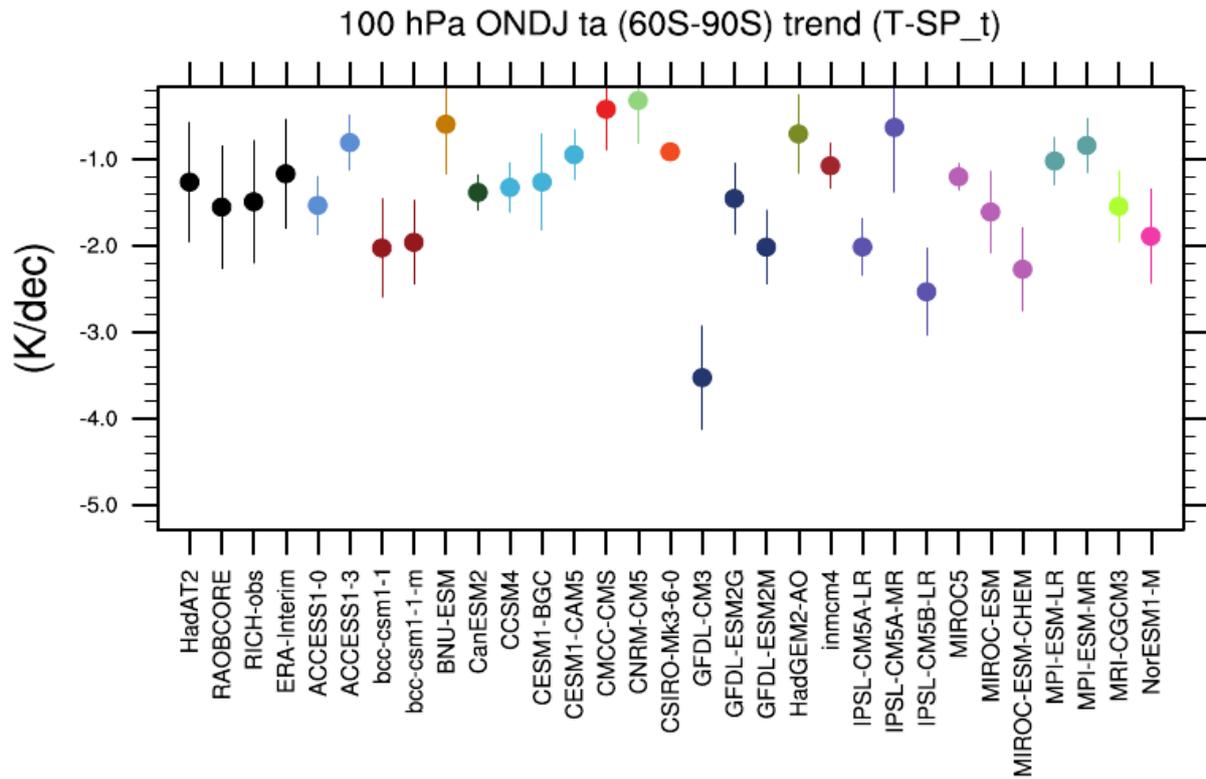

869 **Figure 5:** Root mean squared error (RMSE) differences between the ensemble-mean future  
 870 climatological mean (2015-34 and 2040 - 2059) austral jet position and the future  
 871 climatological mean austral jet position in pseudo reality for each pseudo reality considered  
 872 (grey circles) under the RCP4.5. The ensemble mean is calculated for each scenario from the  
 873 unweighted model mean (uMMM, red boxes) and the MDER method (blue boxes). The cross  
 874 indicates the RMSE for each case and the boxes show the 25th-75th percentiles across the  
 875 error ensemble. The bars inside the box indicate the median of the ensemble.

876

877

878 **Figure 6:** Time series of the austral jet position for the RCP4.5 scenario between 1980 and  
 879 2100. Grey lines show the individual models (iteratively smoothed with a 1-2-1 filter,  
 880 repeated 30 times, to reduce the noise) and the red dotted line the unweighted model mean  
 881 across all CMIP5 models in Table 2. Diamonds show the predicted mean estimate resulting  
 882 from the MDER analysis, for the near-term (2015 - 34) and mid-term (2040 - 59)  
 883 climatological means austral jet position. Error bars indicate the 95% confidence interval of  
 884 the regression analysis. The orange line shows the reanalysis data from ERA-Interim.

885

886 **Figure 7:** Trends in October-November-December-January (ONDJ) temperature anomalies  
 887 (ta) at 100 hPa over Antarctica for radiosondes data (HadAT2; RAOBCORE; RICH-obs), the  
 888 ERA-Interim reanalysis and the individual models of the CMIP5 ensemble. Vertical lines  
 889 indicate the sample standard deviation of the mean value.
