Abstract—Ultra-wideband (UWB) is a promising positioning system that has undergone massive research development in recent years. Most UWB systems assume prior knowledge on the positions of the UWB anchors. Without knowing the anchor positions, an accurate position estimate of a user is difficult. Hence, this paper presents a novel simultaneous localization and mapping (SLAM) approach for pedestrian localization using a UWB system, where the locations of the anchors are unknown. We fuse the distance estimates of the UWB system with heading information obtained from an inertial measurement unit (IMU). We evaluate the proposed algorithm based on measurements with a moving pedestrian and fixed anchors with unknown positions. The evaluations show that an accurate position estimation of both the pedestrian and the anchors is possible without any prior knowledge on the anchor positions.

I. INTRODUCTION

The proliferation of smartphones has made positioning technologies available to a wide range of users [1]. For outdoor localization, global navigation satellite systems (GNSSs) are the most well-known and mostly used technologies for positioning. In open sky conditions, GNSSs provide a sufficient position accuracy for most mass market applications. However, indoors or in urban canyons the GNSS positioning accuracy might be drastically reduced. In these situations, the received GNSS signals might be blocked, affected by multipath effects or received with low power. To enhance the positioning performance, different methods and sensor systems can provide position information to support or replace GNSSs [2], [3]. Most of the indoor positioning systems use local infrastructure like positioning with radio frequency identification (RFID) [4], mobile communication base-stations [5], [6], wireless local area network (WLAN) [7] or ultra-wideband (UWB) systems [8]–[11]. Using WLAN for indoor positioning is a common approach because WLAN infrastructure is widely deployed [12], [13]. On the other hand, UWB is a promising positioning system that has undergone massive research development in recent years [14], [15]. The localization with UWB signals is based on the parameters extracted from the signals that travel among different nodes. UWB systems use a large bandwidth which enables positioning precision in the order of 10 cm. However, also UWB systems experience multipath and non-line-of-sight (NLoS) propagation which degrade the accuracy significantly. In order to improve the position performance, e.g. [16], [17] use additionally information from an inertial measurement unit (IMU). However, all of the UWB systems assume the prior knowledge on the positions of the UWB base stations, called anchors. Without knowing the anchor positions, an accurate position estimate of the pedestrian is difficult [18]. Contrarily to predetermined the position of the anchors, simultaneous estimation of the receiver and the anchor positions, called simultaneous localization and mapping (SLAM), is attracting a lot of research interest. Generally, SLAM addresses the problem of estimating the location of a moving object and simultaneously building the map of the unknown environment [19]–[23]. In SLAM, the map and the user trajectory are estimated without prior knowledge on the anchor locations. SLAM was originally presented within the robotics community as a technique to jointly estimate the position of a robot and the map of detected landmarks. The most well-known algorithmic implementations are based on the extended Kalman filter (EKF) [19]–[21], [24], GraphSLAM [25] and FastSLAM [26]. State-of-the-art techniques of SLAM within the robotics community use cameras [27] and range measurements [28], [29] to obtain observations of the landmarks. In recent years, pedestrian SLAM became a famous research area [18], [30], [31]. Especially, [18] proposes an indoor pedestrian localization scheme applying SLAM, where ranges from IEEE802.15.4a anchors are measured, and the pedestrian is equipped with an IMU.

In this paper, we present a novel approach which estimates the location of the tag and the receiver simultaneously. We use DecaWave’s DW1000 UWB transceiver which enables cost effective real-time positioning with high accuracy in the order of 10 cm in indoor and outdoor scenarios. In order to estimate the distance between the anchors and receiver (tag), we use a two way ranging method. The proposed SLAM algorithm allows to set up the anchors at arbitrary positions, which are estimated during run-time. To resolve ambiguities, we fuse the distance estimates of the UWB systems with heading information obtained from an IMU. Theoretically, the measurements of the IMU can be directly used in an inertial
navigation system. However, the position calculation involves double integrations, and hence, even small measurement errors quickly cause a drift in the position solution [32]. To avoid that, we only use heading measurements from the IMU which solely requires an alignment of the coordinate systems. As we are dealing with a relative positioning system, the derived algorithm requires prior knowledge of the initial receiver position and moving direction only to define a local coordinate system. The positioning algorithm derived in this paper is implemented as a Rao-Blackwellized particle filter (RBPF), where a movement model for pedestrians incorporates the heading information from the IMU.

Fig. 1: System model consisting of a UWB receiver and an IMU.

The paper is structured as follows. In Section II, we derive the proposed algorithm. Section III describes the measurement equipment and the indoor measurement scenario. Our algorithm is evaluated based on measurements in Section IV. Finally, Section V concludes the paper.

Throughout the paper, we will use the following notation:

- \((\cdot)^T\) stands for matrix (or vector) transpose.
- All vectors are interpreted as column vectors.
- Matrices are denoted by bold capital letters and vectors by bold small letters.
- \(\|A\|^2 = \sum_i \sum_m |A_{i,m}|^2\) represents the square of the Frobenius norm of \(A\) with elements \(A_{i,m}\).
- \(a \sim \mathcal{N}(x; \mu_a, \sigma_a^2)\) denotes a Gaussian distributed random variable \(a\) with mean \(\mu_a\) and variance \(\sigma_a^2\).
- \(1 : k\) stands for all integer numbers starting from 1 to \(k\), thus 1, 2, \ldots, \(k\).
- \(p(x)\) denotes the probability density function of \(x\).
- \(c\) is the speed of light.

II. Position Estimation

Fig. 1 presents the available sensors together with the corresponding measurements. As shown on the left, we use an UWB system which estimates the propagation distances

\[
d_i(t_k) = \|r_u(t_k) - r_{A,i}(t_k)\| \quad (1)
\]

between the tag located at \(r_u(t_k)\) and \(N(t_k)\) anchors located at \(r_{A,i}(t_k)\) with \(i = 1, \ldots, N(t_k)\). We consider a static environment with a fixed number of anchors and a receiver moving along an arbitrary trajectory. However, for notational convenience, a time dependence on \(t_k\) is introduced here for the anchor positions \(r_{A,i}(t_k)\). The estimated distances \(\hat{d}_i(t_k)\) of all \(N(t_k)\) anchors are used as measurements

\[
z(t_k) = [\hat{d}_1(t_k), \ldots, \hat{d}_{N(t_k)}(t_k)]^T \quad (2)
\]

in the localization algorithm with the corresponding variances \(\sigma_z(t_k)\).

As mentioned in the introduction, the anchor positions are assumed to be unknown. In order to use the distances estimated by the UWB system, the tag and anchor positions have to be estimated simultaneously. Thus, the state vector \(x(t_k)\) describing the complete system at time instant \(t_k\) is

\[
x(t_k) = [x_u(t_k)^T, x_A(t_k)^T]^T \quad (3)
\]

with the tag states \(x_u(t_k)\) and the anchor states \(x_A(t_k)\). The tag state \(x_u(t_k)\) includes the tag position \(r_u(t_k)\) and the tag velocity \(v_u(t_k)\) with

\[
x_u(t_k) = [r_u(t_k)^T, v_u(t_k)^T]^T \quad (4)
\]

and the anchor states

\[
x_A(t_k) = [r_{A,1}(t_k)^T, \ldots, r_{A,N(t_k)}(t_k)^T]^T \quad (5)
\]

for the \(N(t_k)\) anchor positions \(r_{A,i}(t_k)\).

Additionally, as illustrated in Fig. 1, an IMU is used. The IMU provides measurements of the accelerations \(\omega_b^i(t_k)\) and turn rates \(\omega_b^i(t_k)\) in three dimensions. After calibration, the heading change \(\hat{\Psi}(t_k)\) is used as a control input and is therefore directly integrated into the transition model of the pedestrian carrying the tag.

As we consider a dynamic system, the state estimation can be described based on a discrete time formulation by a transition model and a measurement model, with

\[
x(t_k) = f(x(t_k-1), u(t_k), w(t_k)) \quad (6)
\]

\[
z(t_k) = h(x(t_k), n(t_k)) \quad (7)
\]

The transition model in (6) describes the state evolution from time instant \(t_{k-1}\) to time instant \(t_k\) employing a possible nonlinear function \(f(\cdot, \cdot, \cdot)\) using the control input \(u(t_k)\) and process noise \(w(t_k)\). The measurement model (7) relates the state vector to the measurements at time instant \(t_k\) with a possible nonlinear function \(h(\cdot, \cdot)\) and measurement noise \(n(t_k)\). Fig. 2 shows the considered Dynamic Bayesian Network where we assume a first-order hidden Markov model.
Equations (6) and (7) can also be seen from a Bayesian perspective: based on measurements, we want to recursively estimate the unknown probability density function (PDF) of the state \( x(t_k) \). In a recursive Bayesian formulation, this problem can be described as finding the probability distribution

\[
p(x(t_k)|z(t_{1:k}), u(t_{1:k}), x(t_0)) = p(x_A(t_k), x(t_k)|z(t_{1:k}), u(t_{1:k}), x(t_0)),
\]

with the measurements \( z(t_{1:k}) = [z(t_1)^T, \ldots, z(t_k)^T]^T \), which are the sets of propagation delays for the time instants \( t_1, \ldots, t_k \), and the control inputs \( u(t_{1:k}) = [\tilde{\psi}(t_1), \ldots, \tilde{\psi}(t_k)]^T \), respectively. Finding the probability distribution in (8) can be regarded as a SLAM problem [22, 23]. It is the joint posterior density of the anchor states and tag state given the measurements, the control inputs and the initial state of the tag. Fig. 3 visualizes the SLAM process of this work: the tag moves through an environment and takes relative delay measurements between a number of anchors with unknown positions and the tag. In order to use the delay measurements, the localization algorithm estimates the tag and anchor positions simultaneously. The true locations are not known or can not be measured directly.

Based on recursive Bayesian filtering, the posterior distribution \( p(x_A(t_k), x(t_k)|z(t_{1:k}), u(t_{1:k}), x(t_0)) \) can be obtained recursively by a prediction and an update step. In the prediction step, the PDF

\[
p(x_A(t_k), x(t_k)|z(t_{1:k-1}), u(t_{1:k-1}), x(t_0))
\]

\[
\times p(x_A(t_k)|x(t_{k-1}), u(t_k))
\]

is calculated, where we assume a first-order Markov model with the transition prior

\[
p(x(t_k)|x(t_{k-1}), u(t_k)).
\]

The transition prior depends on the state \( x(t_{k-1}) \) and the applied control input \( u(t_k) \) and is independent of both the observations and the anchor positions. During the update step with

\[
p(x_u(t_k), x_A(t_k)|z(t_{1:k}), u(t_{1:k}), x_u(t_0))
\]

\[
= p(x_u(t_k), x_A(t_k)|z(t_{1:k-1}), u(t_{1:k}), x_u(t_{k-1}))
\]

\[
\times p(z(t_k)|x_u(t_k), x_A(t_k))
\]

the measurement \( z(t_k) \) is used to correct the prediction based on the measurement likelihood

\[
p(z(t_k)|x_u(t_k), x_A(t_k)).
\]

Equations (9) and (11) provide a recursive procedure for calculating the joint posterior \( p(x_u(t_k), x_A(t_k)|z(t_{1:k}), u(t_{1:k}), x_u(t_0)) \) for the tag state \( x_u(t_k) \) and anchors \( x_A(t_k) \) at time instant \( t_k \) based on all measurements \( z(t_{1:k}) \) and all control inputs \( u(t_{1:k}) \). In the following we describe the transition and the measurement model.

\[\text{Fig. 2: First-order hidden Markov model representing the dynamic system.}\]

\[\text{Fig. 3: Overview of the SLAM problem: the moving tag simultaneously estimates its location and the location of the anchors.}\]
The anchor states $x_{A,i}(t_k)$ are time-invariant, hence, we obtain for the transition prior $p(x_{A,i}(t_k)|x_{A,i}(t_{k-1}))$ of the $i$-th anchor
\begin{equation}
p(x_{A,i}(t_k)|x_{A,i}(t_{k-1})) = \delta(x_{A,i}(t_k) - x_{A,i}(t_{k-1})).
\end{equation}

To describe the transition prior $p(x_u(t_k)|x_u(t_{k-1}), u(t_k))$ of the tag state vector we consider a pedestrian holding a hand-held device as shown in Fig. 4. The hand-held device is equipped with the UWB tag and an IMU. For the movement model, we follow a strapdown approach [32]. IMUs include in general accelerometers measuring accelerations $\mathbf{a}^j(t_k)$ and gyroscopes measuring turn rates $\omega^j(t_k)$, as indicated in Fig. 1. These measurements are provided with respect to the sensor alignment [32], i.e., the body frame. In order to obtain the measurements in a two-dimensional Cartesian coordinate system as shown in Fig. 4, a transformation between the coordinate systems is necessary, see e.g. [33]. In our considered measurement scenario, the position of the IMU is assumed as constant with respect to the pedestrian. Therefore, we are able to calculate the coordinate transformation matrices during the calibration phase when the pedestrian is standing at the beginning of the measurements. For practical systems, where the sensor is decoupled, the sensor orientation has to be estimated continuously by applying strapdown navigation together with in-field calibration [34].

As indicated in Fig. 4, we follow a two-dimensional positioning approach in the Cartesian coordinate system with the receiver position
\begin{equation}
r_u(t_k) = [r_{u,x}(t_k), r_{u,y}(t_k)]^T,
\end{equation}
where $r_{u,x}(t_k)$ and $r_{u,y}(t_k)$ denote the x-y positions. The receiver velocity state is
\begin{equation}
v_u(t_k) = R(\tilde{\Psi}(t_k)) \cdot v_u(t_{k-1}) + n_u(t_k),
\end{equation}
with the rotation matrix
\begin{equation}
R(\tilde{\Psi}(t_k)) = \begin{pmatrix}
\cos(\tilde{\Psi}(t_k)) & -\sin(\tilde{\Psi}(t_k)) \\
\sin(\tilde{\Psi}(t_k)) & \cos(\tilde{\Psi}(t_k))
\end{pmatrix},
\end{equation}
and
\begin{equation}
\tilde{\Psi}(t_k) = \hat{\Psi}(t_k) + w_\psi(t_k),
\end{equation}
which includes the heading rate $\hat{\Psi}(t_k)$ measurements from the IMU after calibration, and the heading noise $w_\psi(t_k)$.

B. Measurement Model

For the measurement likelihood $p(z(t_k)|x(t_k))$, we assume that the elements of $z(t_k)$ are independent Gaussian distributed conditioned on the current state $x(t_k)$,
\begin{equation}
p(z(t_k)|x(t_k)) = \prod_{i=1}^{N(t_k)} \frac{1}{\sqrt{2\pi}\sigma_{d,i}(t_k)} e^{-\frac{(d_{i,t_k} - d_{i}(t_k))^2}{2\sigma_{d,i}(t_k)^2}},
\end{equation}
with the distance estimate $d_{i,t_k}$, the propagation length $d_i(t_k)$ and the corresponding variance $\sigma_{d,i}^2(t_k)$ for the $i$-th anchor. The propagation length $d_i(t_k)$ is
\begin{equation}
d_i(t_k) = \|r_u(t_k) - r_{A,i}(t_k)\| + d_b(t_k)
\end{equation}
which is similar to $d_i(t_k)$ of (1) with an additional measurement error $d_b(t_k)$ to include NLoS, multipath and general estimation errors.

C. Particle Filter Implementation

In this section, we summarize the particle filter (PF) implementation of the algorithm derived in Section II. PFs provide numerical approximations to the nonlinear Bayesian filtering problem. They approximate the posterior density of the state vector $x(t_k)$ at time step $t_k$ by $N_p$ particles with the particle states $x^{(j)}(t_k)$ and associated weights $w^{(j)}(t_k)$ with $j = 1, \ldots, N_p$ [35]-[37]. The implementation is similar to the Channel-SLAM algorithm presented in [38]. We implemented the algorithm based on Rao-Blackwellization [39]. The posterior density $p(x_u(t_k), x_A(t_k)|z(t_{1:k}), u(t_{1:k}), x_u(t_0))$ of (8) can be written as
\begin{equation}
p(x_u(t_k), x_A(t_k)|z(t_{1:k}), u(t_{1:k}), x_u(t_0))
= \prod_{i=1}^{N(t_k)} p(x_{A,i}(t_k)|x_u(t_k), z_{i}(t_{0:k}))
\end{equation}
\begin{equation}
\times \prod_{i=1}^{N(t_k)} p(x_u(t_k)|x_u(t_k), z_{i}(t_{0:k})).
\end{equation}

Hence, the RBPF contains additionally to the samples $x^{(j)}(t_k)$ from $p(x_u(t_k)|z(t_{0:k}), u(t_{1:k}), x_u(t_0))$ a representation of anchor states $p(x_{A,i}(t_k)|x^{(j)}(t_k), z_{i}(t_{0:k}))$ for each particle $j$. We use PFs to estimate the subspaces representing the anchor
states inside a PF. The reason to use a PF instead of a low complexity EKF is the non-linearity of the measurements in (1). As shown in Fig. 5, the algorithm is based on a superordinate particle filter (superPF) and subordinate particle filters (subPFS): Each particle \( j = 1, \ldots, N_p \) of the superPF with the state vector \( \mathbf{x}_i^{(j)}(t_k) = \left[ \mathbf{x}_u^{(j)}(t_k)^T, \mathbf{u}^{(j)}(t_k)^T \right]^T \) holds \( N(t_k) \) subPFS. Each subPF is represented by the particles \( \mathbf{x}_{A,i}^{(j,a)}(t_k) \) with \( a = 1, \ldots, N_{P,j,i}(t_k) \) where \( N_{P,j,i}(t_k) \) stands for the number of particles in the \( i \)-th subPF with \( i = 1, \ldots, N(t_k) \), estimating \( \mathbf{x}_{A,i}^{(j,a)}(t_k) \).

Consequently, similar to [38], the posterior density \( p(\mathbf{x}_u(t_k), \mathbf{x}_A(t_k)|\mathbf{z}(t_{1:k}), \mathbf{u}(t_{1:k}), \mathbf{x}_u(t_0)) \) can be approximated by importance samples, see [36], as

\[
p(\mathbf{x}_u(t_k), \mathbf{x}_A(t_k)|\mathbf{z}(t_{1:k}), \mathbf{u}(t_{1:k}), \mathbf{x}_u(t_0)) \approx \sum_{j=1}^{N_u} w^{(j)}(t_k) \delta \left( \mathbf{x}_u(t_k) - \mathbf{x}_u^{(j)}(t_k) \right),
\]

where \( w^{(j)}(t_k) \) defines the weight for the \( j \)-th particle at time instant \( t_k \) with

\[
w^{(j)}(t_k) \propto p(\mathbf{z}(t_k)|\mathbf{x}_u^{(j)}(t_k), \mathbf{z}(t_{k-1})) \propto \prod_{i=1}^{N(t)} \sum_{a=1}^{N_{P,j,i}(t_k)} w^{(j,a)}(t_k)
\]

and the weight \( w^{(j,a)}(t_k) \) of the subPFS at time instant \( t_k \) with

\[
w^{(j,a)}(t_k) = p(\mathbf{d}_{i}(t_k)|\mathbf{z}^{(j)}(t_k), \mathbf{x}_{A,i}^{(j,a)}(t_k)).
\]

Resampling is performed at each time instant to prevent degeneration, hence, (24) and (25) do not depend on the weights \( w^{(j)}(t_{k-1}) \) and \( w^{(j,a)}(t_{k-1}) \), respectively.

### III. Measurement Equipment and Scenario

#### A. Measurement Equipment

The pedestrian is equipped with a hand-held device including an UWB tag, a Xsense IMU (MTI-G-700) and a laptop which stores the IMU and UWB measurement data. We use the so called Loco Positioning system produced by Bitcraze AB, see https://www.bitcraze.io/ for our measurements. The Loco Positioning system is based on the Decawave DWM1000 chip and has an accuracy in the 10 cm range. For the measurements, the UWB system is configured to a bandwidth of 500 MHz and a carrier frequency of 3.5 GHz. Fig. 6 shows the Loco Positioning Node which can act either as an anchor or as a tag. As an anchor, it is part of the reference base for the system. In tag mode, it can be connected to a computer for recording the distance estimates.

The UWB system uses a two way ranging method as depicted in Fig. 7 which allows the tag to measure its distance to an anchor \( i \). The protocol contains four messages, two are sent by the tag, and two by the anchor. Afterwards, the propagation delay is estimated by

\[
\hat{d}_i(t_k) = c \cdot \frac{\Delta \tau,1,i(t_k) \cdot \Delta \tau,4,i(t_k) - \Delta \tau,2,i(t_k) \cdot \Delta \tau,3,i(t_k)}{\Delta \tau,1,i(t_k) \cdot \Delta \tau,4,i(t_k) + \Delta \tau,2,i(t_k) \cdot \Delta \tau,3,i(t_k)},
\]

based on the transmitting and receiving time stamps illustrated in Fig. 7.

#### B. Measurement Scenario

Fig. 8 shows the indoor measurement scenario in top view with the five anchor positions indicated by \( A_i \) for \( i = 1, \ldots, 5 \) and the pedestrian track in blue. The measurements were conducted in the kitchen area of an office building. The pedestrian is moving on the indicated blue track starting at \( M_1 \) and ending at \( M_7 \) for 87 s in the order: \( M_1 \Rightarrow M_2 \Rightarrow M_3 \Rightarrow M_4 \Rightarrow M_5 \Rightarrow M_2 \Rightarrow M_3 \Rightarrow M_4 \Rightarrow M_5 \Rightarrow M_7 \). During the pedestrian movement, the line-of-sight (LoS) path between the anchors and the tag is most of the time present, however sometimes shaded by the body of the pedestrian or by furniture. Fig. 9 shows the estimated propagation distances \( \hat{d}_i(t_k) \) in meter versus the pedestrian moving time in seconds. Additionally, the figure shows by the black lines the corresponding calculated propagation distances, which match to the UWB measurements.

### IV. Evaluations Based on Measurements

The evaluations are performed using \( N_t = 2000 \) particles in the superPF, whereas the number of particles for the subPFS for each node is different depending on the estimated delay. The developed algorithm obtains the measurements \( \mathbf{z}(t_k) \) and the heading rate \( \hat{\Psi}(t_k) \) every \( T = t_k - t_{k-1} = 0.1 \) s. The error in the heading noise of (19) is modeled by a Gaussian density \( w_\Psi(t_k) \sim \mathcal{N}(\hat{\psi}, \sigma_\psi^2(t_k)) \) with standard deviation \( \sigma_\psi(t_k) = 1^\circ \). For the initialization, we use prior information \( p(\mathbf{x}_u(t_0)) \) including the starting position and velocity. Being a relative positioning system, the algorithm requires prior knowledge of the initial receiver position and moving direction only to define a local coordinate system. Hence, an unknown starting position and direction or larger initial uncertainties may result in a biased and rotated coordinate system in the estimation.

To evaluate the positioning performance of the proposed algorithm, we compare it to a positioning algorithm with perfect knowledge of all anchor positions. In the following we refer to this algorithm as UWB Pos., which can be seen as

Fig. 7: The two way ranging protocol allows a tag to measure its distance to an anchor.

a lower bound for the proposed algorithm referred to as UWB SLAM. We assume the starting position and direction of the pedestrian to be known. Fig. 10 shows the root mean square errors (RMSEs) RMSE$_u(t_k)$ = $\sqrt{E[\|\hat{r}_u(t_k) - \tilde{r}_u(t_k)\|^2]}$ of the estimated pedestrian position versus the pedestrian moving time for UWB SLAM in blue and UWB Pos. in green. Because the PF includes randomness, the position estimates differ for each evaluation due to a finite number of particles even if the same measurement data are used. Therefore, we perform 200 independent evaluations based on the same measurement data. Because of the initialization of the receiver position using prior knowledge, both algorithms perform similarly at the beginning of the track, where the position error is rather low. Afterwards, the RMSE$_u(t_k)$ for both algorithms varies between 0.1 m and 1 m. UWB Pos. can be interpreted as a lower bound and estimates the receiver position with the lowest RMSE. However, at some time steps UWB Pos. has a slightly higher RMSE than UWB SLAM which might be due to the small inaccuracies in the calculation of the VT positions. Fig. 11 shows the cumulative distribution functions (CDFs) of the error of the estimated receiver position for the mentioned algorithms. In order to reduce the effect of the initialization, the CDFs do not consider the first 4 s of the pedestrian movement.
Fig. 9: Recorded delays versus the pedestrian moving time in seconds.

Fig. 10: RMSE \( t_k \) versus the pedestrian moving time in seconds for the described SLAM algorithm and a positioning algorithm with knowledge of the anchor positions.

Fig. 11: CDF of the receiver position error for UWB Pos. and UWB SLAM. In order to reduce the effect of the initialization around the starting position, the evaluations do not consider the first 5 s of the pedestrian movement.

Fig. 12: RMSE \( A_i(t_k) \) versus the pedestrian moving time in seconds for the anchors \( A_1, A_2, A_3, A_4 \) and \( A_5 \).

V. CONCLUSIONS

In this paper, we presented a SLAM algorithm for localization of a pedestrian using a UWB system with unknown anchor positions. The tag and anchor positions are estimated simultaneously based on range measurements between the anchors and the tag. Our evaluations show that an accurate positioning performance can be achieved even if the anchor positions are unknown. The pedestrian RMSE was almost always below one meter, and in 90 % of the time below 0.77 m. In addition, the locations of the five anchors could be estimated with final RMSEs between 0.05 and 0.5 m.

VI. ACKNOWLEDGEMENT

This work has been performed in the framework of the DLR project Navigation 4.0 and the European Unions Horizon
2020 research and innovation programme under grant agreement No. 636537 HIGHTS (High precision positioning for Cooperative-ITS applications).
