# Introduction

- Along Antarctica's coastline outlet **glacier** terminus positions and ice shelf extents are very dynamic and constantly changing.
- The extent of ice shelves and glaciers is important as their **floating ice buttresses ice** sheet flow.
- Less buttressing **increases ice sheet** discharge. The consequence is a higher contribution to sea level rise.

But where are changes in frontal position most frequent?

– Many glacial extent studies on single glaciers or coastal sections exist but no **circum-Antarctic record** because manual delineation of frontal positons from aerial and satellite imagery is **very time-consuming**.

- To analyze where changes took place, over 100 existing studies were reviewed and compiled to one single data set

# Advancing & Retreating Fronts

#### HeatMap of Antarctic Glacial Extent Studies **Study Duration of Antarctic Glacial Extent Studies** Number of studied features in a radius of 200 km Duration in Years since first Documentation of Frontal Position in Literature **Study Duration** in years > 100 80 - 100 60 - 80 **40 - 60 20 - 40** 500 1000 km

### Study Duration

The study of glacial extents started with first expeditions to Antarctica in the early1900s.

In the last years, data availability dramatically increased thanks to numerous earth observation missions such as Landsat and Sentinel.

Longest studies exist for Ross Ice Shelf and Mertz Glacier. In the 1970s, the launch of Landsat also allowed studies on a larger scale even for smaller and unnamed glaciers.

#### Research Hotspots

The number of glacial extent studies is distributed unevenly along Antarctica's coastline.

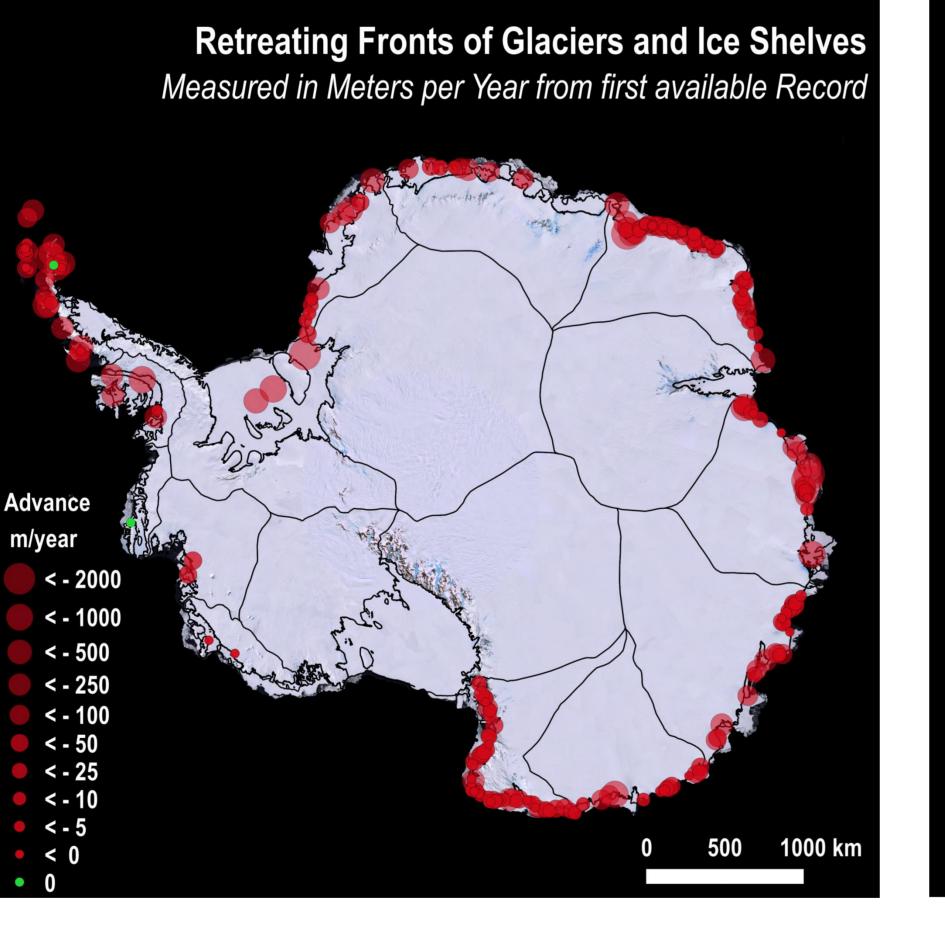

Information on front fluctuations is agglomerated in coastal sections with small glacier catchments.

The Antarctic Peninsula is by far the most studied area. Furthermore, the coast along Victoria Land, Enderby Land and specific ice shelves such as Amery, Ronne-Filchner and Ross are hotspots of research.

#### Retreating Fronts

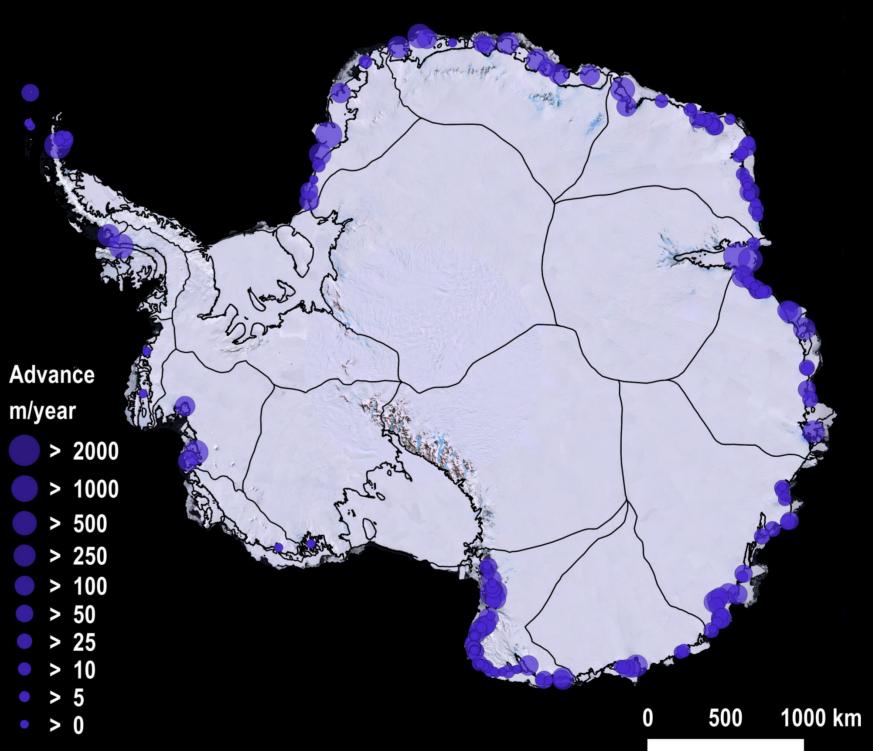

In the very North of the Antarctic Peninsula in the Region of Trinity Peninsula and James Ross Island strong retreat rates can be observed.

An accumulation of glacier retreat at East Antarctica can be seen at Victoria Land and Enderby Land.

Advancing Fronts of Glaciers and Ice Shelves Measured in Meters per Year from first available Record

#### Advancing Fronts

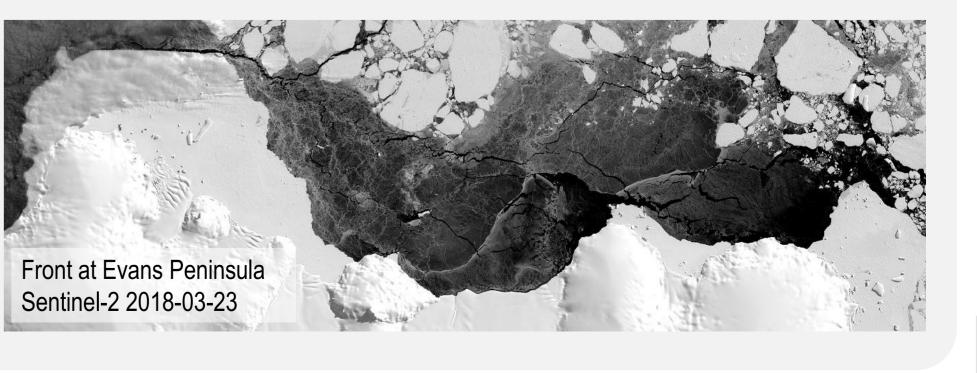

Most advancing tendencies can be observed along the east Antarctic coast.

Only isolated glaciers along the Antarctic Peninsula advance slightly.

A very strong advancing front of the Amery ice shelf is obvious.

# Conclusion

- Hotspots of Antarctic glacial extent studies exist. Especially **sensitive regions** with very dynamic front fluctuations are studied more frequently. Besides, **data availability** influences the choice of study regions.
- The duration of studies is still very short as good data coverage only exists since the launch of Landsat. Short time-series make it **difficult to link retreating** fronts to climate change.
- **Strong retreat rates** are observed along the Antarctic Peninsula with almost no advancing glaciers.
- **East Antarctica** was always thought to be **more stable** but besides many advancing fronts glacier retreat can be observed. As measurements are short and inhomogeneous in duration the results only reflect short-term tendencies.
- To better assess the influence of a warming climate on the calving cycle of glaciers and ice shelves, **longer** and more homogeneous data sets are necessary.
