Abstract

The Next Generation Transit Survey (NGTS) is a photometric survey for transiting exoplanets, consisting of 12 identical 0.2-m telescopes. We report a measurement of the transit of HD 106315 c using a novel observing mode in which multiple NGTS telescopes observed the same target, with the aim of increasing the signal-to-noise ratio. Combining the data allows the robust detection of the transit, which has a depth less than 0.1%, rivaling the performance of much larger telescopes. We demonstrate the capability of NGTS to contribute to the follow-up of *K2* and Transiting Exoplanet Survey Satellite discoveries using this observing mode. In particular, NGTS is well-suited to the measurement of shallow transits of bright targets. This is particularly important to improve orbital ephemerides of relatively long-period planets, where only a small number of transits are observed from space.

KEYWORDS

planetary systems, planets and satellites: HD 106315 c, techniques: photometric

1 | INTRODUCTION

The Next Generation Transit Survey (NGTS; Wheatley et al. 2018) is the highest precision wide-field, ground-based transit survey in operation, allowing it to detect much shallower transits than the previous generation of such surveys, such as Wide Angle Search for Planets (Pollacco et al. 2006) and Hungarian-made Automated Telescope Network (Bakos et al. 2002). To date, NGTS has discovered a number of transiting exoplanets (Bayliss et al. 2018; Costes et al. 2020; Eigmüller et al. 2019; Günther et al. 2018; Jackman et al. 2019b; McCormac et al. 2019; Raynard et al. 2018; Vines et al. 2019), as well as probing other astrophysical phenomena, such as stellar flares (Jackman et al. 2019a) and low-mass eclipsing binary systems (Casewell et al. 2018).

The performance of NGTS was recently demonstrated in the detection of NGTS-4b, whose $0.13 \pm 0.02\%$ deep transit makes it the system with the shallowest transit ever discovered from the ground (West et al. 2019). The detection of even shallower transits, and thus smaller planets, from space has now become routine. *K2*, the second incarnation of NASA's *Kepler* spacecraft (Howell et al. 2014) has discovered many such systems. In 2018, Transiting Exoplanet Survey Satellite (TESS; Ricker et al. 2015) began its 2-year survey of 85% of the sky.

One limitation of *K2* and TESS, however, is their observing baseline, which is typically around 80 days in the case of *K2*, and as short as 27 days for TESS. This places strong upper limits on the orbital periods of the systems discovered by these instruments. Less than 10% of the 389 planets discovered to date by *K2* orbit with periods longer than 25 days.¹

HD 106315, also known as K2-109 ($\alpha_{J2000} = 12h13m53.40s$, $\delta_{J2000} = -00^\circ 23' 36''.55$) is a system of two planets detected in Campaign 10 of *K2* orbiting a bright ($V = 8.9$) F5V star (Crossfield et al. 2017; Rodriguez et al. 2017). During observations of Campaign 10, only two transits of the outer planet “c” were observed. This not only limited the precision to which key system parameters could be determined, but resulted in a rather poorly constrained orbital ephemeris. According to the ephemeris of Rodriguez et al. (2017), the 1σ uncertainty in the transit time would reach 5 hr just 5.5 years after the discovery epoch. Photometric transit observations from the ground were required in order to prevent the ephemeris from being “lost” altogether, and thus impede future follow-up efforts. With this in mind, we scheduled NGTS observations of the system (section 2).

In addition to our NGTS observations, Lendl et al. (2017) observed two transits of HD 106315 c from the

ground with the 1.2-m Euler telescope, allowing the ephemeris to be refined and reducing the uncertainty on the orbital period by a factor of four. Similarly, Barros et al. (2017) observed one transit with one of the 1-m telescopes of the Las Cumbres Observatory. They also measured the masses of both planets orbiting HD 106315 with 93 radial velocities from High Accuracy Radial velocity Planet Searcher.

Observations of such a shallow transit would also prove a good test of the capabilities of NGTS in nonsurvey mode. In the normal mode of operation, each of the 12 NGTS telescopes observes a separate field, in order to cover the largest possible area of sky, and maximize the number of new planetary systems detected. For these observations, however, we decided to test observing the same target with all the telescopes. This is a mode of operation that we expect to prove invaluable in confirming and better characterizing shallow transits detected by NGTS itself, and in following up shallow transits detected by TESS.

The observations of HD 106315 offered a good opportunity to test this observing mode, and to quantify the advantages of combining data from multiple identical telescopes. This has particular relevance for the upcoming PLATO (PLANets, Transits and Oscillations; Rauer et al. 2014) mission, which will use a total of 26 0.12-m space-based telescopes with overlapping fields-of-view to monitor a large area of sky for nearby transiting exoplanets.

The remainder of this paper is laid out as follows: in section 2 we present our NGTS observations of HD 106315. In section 3 we describe our data analysis and custom-built pipeline to produce light curves of HD 106315. In section 4.2 we investigate the combining of data from multiple telescopes to produce a single light curve. Our discussion and conclusions can be found in section 6.

2 | OBSERVATIONS

We observed a field centered on HD 106315 with 11 of the 12 NGTS telescopes on the night of March 8/9, 2017/09. Each telescope has an aperture diameter of 0.2 m. The cameras associated with these telescopes are identified within the NGTS project, and in the rest of this paper as 01, 02, 03, 06, 07, 08, 09, 10, 11, 12, and 13. In contrast to the usual NGTS survey mode, we defocussed each of the telescopes slightly in order to avoid saturation or nonlinearity of the charge-coupled device (CCD) response, since HD 106315 is slightly brighter than the usual NGTS bright limit.

We note that our observations were taken on the same night as the first transit observed by Lendl et al. (2017), which was also observed by Barros et al. (2017). These observations were conducted at La Silla and Cerro Tololo,

¹Statistics from NASA Exoplanet Archive (Akeson et al. 2013), retrieved September 19, 2019

which lie to the south of the NGTS site at Paranal, by around 500 and 600 km, respectively.

Our observations of HD 106315 comprise around 2730 images per telescope—more than 27,000 in total, spanning 7.56 hr. The normal survey mode for NGTS uses 10 s exposures, but for these observations of HD 106315 we used 7 s exposures to further reduce the likelihood of saturation. With the fast readout time of the NGTS CCDs, this results in an observing cadence of 10 s.

3 | LIGHT CURVE GENERATION

Since our photometry is defocused, the observations could not be reduced using the standard NGTS photometry pipeline (Wheatley et al. 2018), used for the processing of survey observations. Instead, we developed a standalone pipeline for the processing of such datasets, based on standard aperture photometry with PHOTUTILS (Bradley et al. 2016), part of the ASTROPY python package (Astropy Collaboration et al. 2013).

The major processing steps are described briefly below, and are performed on a per-camera basis. Image calibration is performed via standard bias and flat corrections as per the usual NGTS data reduction pipeline (Wheatley et al. 2018). A master frame is generated, and SEXTRACTOR used to perform astrometry, enabling a source catalogue to be generated, and cross-matched with UCAC4 (Zacharias et al. 2013). Aperture photometry is then performed on each source (with an aperture radius of 3.0 pixels = 15", optimized to minimize the out-of-transit root-mean-squared scatter (rms)), along with background estimation via sky annuli (with inner and outer radii of 9.0 and 14.0 pixels, respectively).

The raw light curves are detrended by fitting polynomials to the airmass, and to the CCD x and y positions. The HD 106315 light curve is further corrected by means of a combined reference star, consisting of the flux from five nearby stars of similar magnitude (Table 1). We found the light curves of HD 106315 generated in this way to contain little correlated noise (see Appendix A).

4 | MEASURING THE PLANETARY RADIUS

4.1 | Single-telescope light curves

We started our analysis with the 11 light curves, each the output of a different telescope/camera, the generation of which is described in section 3. We first fit a transit model to each light curve individually. The fits were performed with the Transit Light Curve Modeler (TLCM²; Csizmadia

TABLE 1 List of comparison stars used

ID	UCAC4 ID	r mag	$J - K$
Target	449-052646	9.396	0.263
Ref1	447-053330	8.707	0.675
Ref2	449-052685	9.377	0.879
Ref3	444-054438	8.663	0.209
Ref4	446-054654	9.438	0.659
Ref5	444-054448	10.585	1.03

in press), which uses MCMC for error estimation. In our first set of fits, the following parameters were freely fit: the planet-to-star radius ratio, R_p/R_* , the impact parameter, b , the limb-darkening coefficients, $u_+ = u_1 + u_2$ and $u_- = u_1 - u_2$, and an offset to account for possible imperfect light curve normalization. The scaled orbital major semi-axis, a/R_* , was allowed to vary within the 1σ uncertainties determined by Rodriguez et al. (2017) ($a/R_* = 25.69 \pm 1.2$). The ephemeris was fixed to that of Barros et al. (2017) ($P = 21.05704$ days, $t_0 = 2457569.0173$ [BJD_{TDB}]), and the orbital eccentricity, e was fixed at zero. Each MCMC run used 20 independent chains, and we used the Gelman-Rubin statistic (Gelman & Rubin 1992) to check for convergence. As a final check, the fits were repeated to check the consistency of the results, which were near identical (variations in the best-fitting parameter values were much smaller than the associated 1σ errors). The light curves are shown along with the fits (blue lines) in Figure 1.

Looking at the resulting R_p/R_* values (blue points, Figure 2), we see that in three cases (cameras 06, 09, 13) the best-fitting model is a straight line that does not include a transit. In these cases, the best-fitting impact parameter is larger than $R_* + R_p$, hence there is no transit. In these three cases, and for camera 10, the radius ratio is poorly constrained. In the six remaining cases, the radius ratio is reasonably well determined, and in good agreement with the value determined by Rodriguez et al. (2017) (the discrepancies are $<1\sigma$ in all cases, except camera 03, where the discrepancy is $<2\sigma$).

To simply things further, and to “force” the fitted model to include a transit, we decided to constrain the impact parameter to lie between 0.6 and 0.8, encompassing the best-fitting $0.688^{+0.044}_{-0.094}$ of Rodriguez et al. (2017). We also opted to fix the limb-darkening coefficients, using values from Sing (2010) for a star with $T_{*,\text{eff}} = 6250$ K, $[\text{Fe}/\text{H}] = -0.3$, and $\log g_* [\text{cgs}] = 4.5$. The mean rms of the residuals to a single telescope fit is 2700 ppm per minute or 500 ppm per half hour.

FIGURE 1 Light curves from individual Next-Generation Transit Survey (NGTS) telescopes, binned to 1 min (small gray circles) and 10 min (large black circles). The best-fitting models from a fit where b , u_+ , and u_- were free parameters is shown with a blue line, and from a fit where u_+ and u_- were fixed, and b was constrained is shown with a green line

4.2 | Combining data from multiple NGTS telescopes

After fitting the individual light curves, we resolved to fit the light curves from multiple NGTS telescopes together,

to see how our determination of R_p/R_* changes as the number of light curves used in the fit increases. We decided to perform two experiments, one where the light curves are added from “best-to-worst,” and one in which the light curves are added from “worst-to-best.” Our ranking

FIGURE 2 Fitted radius ratio for single-telescope light curves. The value and uncertainty of R_p/R_* determined by Rodriguez et al. (2017) is indicated with a red line. Results from the fits where b , u_+ , and u_- were free parameters are displayed with blue circles. Results from fits where u_+ and u_- were fixed, and b was constrained, are displayed with green squares

of the individual light curves is carried out on the basis of the magnitude of the uncertainty on R_p/R_* from the individual fits with limb-darkening and impact parameter freely fitted (the blue circles in Figure 2). Thus, camera 03 is regarded as the “best,” and camera 13 as the “worst” individual light curve.

To allow for imperfect flux normalization, we fit for a constant offset in flux between each additional light curve. Figure 3 shows the fitted value of R_p/R_* and its uncertainty, σ_{R_p/R_*} as a function of the number of NGTS light curves included in the fit. This figure shows a gradual convergence to $R_p/R_* = 0.0264 \pm 0.0022$ when light curves from all 11 telescopes are included in the analysis.

Furthermore, the uncertainty in the radius ratio decreases as a function of the number of telescopes, n_{tel} , for both the “best-to-worst” and “worst-to-best” cases. By taking σ_{R_p/R_*} for a single light curve, and scaling this value by $1/\sqrt{n_{\text{tel}}}$, a comparison to the expected white noise behavior may be made. The theoretical curves in the lower panel of Figure 3 show such a relation for three different values of σ_{R_p/R_*} , corresponding to the smallest, largest and mean values of σ_{R_p/R_*} from the fits to individual light curves (with limb-darkening and the impact parameter constrained; green squares in Figure 2). When the “best” light curve is fitted first, the data follow the white noise curve very closely, with only a slight deviation as n_{tel} approaches 11, and the newly-included data is increasingly poor. In contrast, when we begin fitting the “worst” light curve first, the improvement in σ_{R_p/R_*} is slow initially, but then undergoes a more rapid reduction as better data is added.

FIGURE 3 Upper panel: Fitted radius ratio as a function of number of telescopes combined. The blue circles represent the combinations starting with the two “best” (see text) light curves and adding successively worse light curves. The red squares represent the combinations starting with the two “worst” light curves, and adding successively better light curves. The red line and shaded region indicate the best-fitting solution and 1σ uncertainties of Rodriguez et al. (2017). Lower panel: uncertainty on fitted radius ratio. The red squares and blue circles correspond to the same fits as the upper panel. The blue dashed line represents the expected white noise case based on the best individual light curve, the red dotted line the same, but based on the worst individual light curve, and the green dash-dotted line is based on the mean uncertainty on the radius ratio from the individual light curves

We note that the value of R_p/R_* that our fits converge upon is somewhat smaller than that of Rodriguez et al. (2017) (indicated with a red line in Figure 2), at a significance of 2.1σ . One possible reason for this apparent discrepancy is the limb-darkening coefficients chosen for our fit to the NGTS data. Although the NGTS and *Kepler* passbands are similar (Figure 4), the blue cut-offs do differ markedly, and limb-darkening is stronger at these shorter wavelengths. To test this hypothesis, we tried several different approaches to choosing the limb-darkening

FIGURE 4 Comparison of *Kepler/K2* and Next-Generation Transit Survey (NGTS) instrument response as a function of wavelength. The Kepler data are taken from the Kepler Science Center, and the NGTS data from Wheatley et al. (2018)

coefficients, including a fit that allowed them to vary significantly. We observed no discernible dependence of the fitted R_p/R_* on the chosen limb-darkening coefficients.

A second potential explanation for the lower-than-expected value of R_p/R_* , is the difficulty in determining the out-of-transit baseline flux. In the uppermost panel of Figure 5 we plot the combined light curve from all 11 NGTS cameras, while the bottom panel shows the airmass of HD 106315 during the course of the night. The observations begin and end at airmass 2, meaning that all of the out-of-transit data is taken at relatively high airmass. There is almost no pre-transit data, and only a limited amount of posttransit data, significantly less than in-transit data. The light curve shows an apparent decrease in flux at the end of the night, as well as significantly increased scatter evident in the unbinned light curve, corresponding to data taken when the target was at an airmass greater than about 1.5. To test this theory, we tried fitting the light curves from all 11 telescopes, but excluding data taken at the end of the night at airmass values greater than 1.5. We also did the same, but excluding the high-airmass data from both the beginning and end of the night. The resulting light curves and best-fitting models are shown in Figure 5.

By excluding the high-airmass data from the end of the night, we recover a transit depth and hence R_p/R_* in better agreement with the previously-published values, based on the higher-precision *K2* light curve. The removal of additional high-airmass data, from the beginning of the night results in a virtually identical determination of R_p/R_* , but a slightly shorter duration transit. This results from the complete lack of data covering transit ingress in this case (Figure 5).

FIGURE 5 Combined (11 telescope) light curve of HD 106315. From top to bottom: (a) full light curve binned to 1 min (small gray points) and 10 min (large blue points), with best-fitting model (described in section 4.2). (b) As top panel, but with observations made at airmass > 1.5 excluded from the fit, which is shown with a solid green curve. The red dashed curve shows the fit from the top panel. (c) As (b), but with high-airmass data at the start of the night excluded as well. (d) Target airmass during the observations

In Table 2 and Figure 6 we compare the R_p/R_* resulting from our fits to those previously published by others. Even without removing the high-airmass data, our result is in reasonable agreement with others (less than 2σ , except for Rodriguez et al. (2017), with whose value ours is slightly more than 2σ discrepant). Excluding the high-airmass data at the end of the night from our fit results in an approximately 1σ change in the value of R_p/R_* . This new value is within about 1σ of all previously-published values.

The rms of the residuals to our 11 telescope fit is 850 ppm per minute or 240 ppm per half hour. These values fall to 777 and 204 ppm, respectively, when removing the high-airmass data at the start of the night, and 657 and 145 ppm when high-airmass data from both the beginning and the end are excluded.

FIGURE 6 Comparison of our measured R_p/R_* values with values in the published literature. The numbers on the y-axis correspond to those in Table 2

5 | IMPROVING THE EPHEMERIS

Since one of the motivations for these observations was to improve our knowledge of the planet’s orbital ephemeris (section 1), we performed a series of fits designed to measure only the time of mid-transit. Our fitting procedure was similar to that described in section 4.2, but here we fixed the values of a/R_* , b , and R_p/R_* to those determined from the *K2* light curve (Rodriguez et al. 2017). The epoch of mid-transit and a vertical offset (to account for imperfect flux normalization) were the only parameters for which we fitted.

We performed a fit to each individual light curve, the results of which are shown in Figure 7. We also performed a series of fits, in which we incrementally added additional light curves. We used the same ranking of light curves as in section 4, and again performed two sets of fits, starting with both the “best” and the “worst” light curves. The results of these fits are shown in Figure 8.

Similarly to the radius-ratio case, we see that adding an increasing number of telescopes results in a better-determined transit time. The results show a greater departure from the simple white noise ($1/\sqrt{n_{\text{tel}}}$) case than did the radius ratio. As the number of telescopes

FIGURE 7 Fitted time of mid-transit for single-telescope light curves. The value and uncertainty of t_{mid} from the *K2* ephemeris (Rodriguez et al. 2017) is indicated with a red solid line, and pink shaded region. The dashed green line, and region indicates the t_{mid} from the Eulercam observations (Lendl et al. 2017)

used increases, there is a relatively rapid improvement in our epoch determination until five telescopes, but then only modest improvement beyond that. Our value of the epoch from combining all 11 light curves is very close to that obtained with a 1-m telescope, both in the value and its precision (Lendl et al. 2017). Our observations result in an epoch value that is significantly better determined than that from the *K2* observations alone, reducing the 1σ uncertainty from more than half an hour, to just 5.6 min. This demonstrates the power of such observations to improve the ephemeris, and hence the future observability, of transiting systems like HD 106315.

6 | DISCUSSION AND CONCLUSIONS

6.1 | Summary and outlook for NGTS follow-up of TESS targets

By observing the same target with multiple NGTS telescopes, and combining the resulting data, we are able to measure an exoplanet transit with a depth of just

TABLE 2 Comparison of fitted planet-to-star radius ratio with previously published values

No.	Source	R_p/R_*	Significance of difference w.r.t.

FIGURE 8 Upper panel: Fitted epoch of mid-transit as a function of number of telescopes combined. The blue circles represent the combinations starting with the two “best” (see text) light curves and adding successively worse light curves. The red squares represent the combinations starting with the two “worst” light curves, and adding successively better light curves. Note that the two-telescope point is a significant outlier, and is therefore not shown. The dashed green line and red shaded region indicate the best-fitting solution and 1σ uncertainties from observations with a 1-m telescope (Lendl et al. 2017). The green triangle indicates the transit time and uncertainty predicted by the ephemeris based on *K2* photometry alone (Rodriguez et al. 2017). Lower panel: Uncertainty on transit epoch. The red squares and blue circles correspond to the same fits as the upper panel. As in Figure 3, the solid red line represents the individual light curve with the smallest uncertainty, scaled by $1/\sqrt{n_{\text{tel}}}$. The dotted green line is the same, but based on the mean uncertainty from an individual light curve. The dashed black line is the uncertainty obtained by observing the same transit using a 1-m telescope (Lendl et al. 2017)

1 mmag. The precision of this measurement rivals 1-m class telescopes such as Euler (Lendl et al. 2017), even though the diameter of a single NGTS telescope is just 0.2 m. We are able to reduce the noise by binning data from multiple telescopes, as expected given that for bright stars the NGTS noise budget is dominated by scintillation (Wheatley et al. 2018).

Our observations of HD 106315 demonstrate the sensitivity of NGTS to shallow transits, particularly in “follow-up” rather than “survey” mode. TESS discovers a

large number of transiting planets for which only one or two transits are observed with TESS (Cooke et al. 2018; Villanueva Jr. et al. 2019). Observing additional transits with ground-based observations is crucial to refine system parameters, particularly the orbital ephemeris, and we have demonstrated here that NGTS is extremely well suited to this task.

For many bright targets, NGTS’ wide field-of-view combined with its high photometric precision places it among the very best ground-based facilities for follow-up transit observations. This is because 1-m class telescopes, while perhaps offering similar photometric precision, typically have rather limited fields-of-view, resulting in few or no available reference stars of similar brightness to the target. Each NGTS telescope has a field-of-view of $2.8^\circ \times 2.8^\circ$, and thus plenty of reference stars for even bright targets.

Further observations in the multi-telescope mode employed here will allow us to build up experience of how photometric precision varies both with the number of telescopes used in the observations, and with target brightness. This will allow the selection of the optimal number of telescopes for a given target, improving the efficiency of telescope operations.

Since our observations of HD 106315, transits of several other targets have been successfully observed in multi-camera mode, with various numbers of cameras employed (Lendl et al. 2019; Jenkins et al. under review).

6.2 | Looking forward to PLATO

Although seemingly very different types of transit survey, PLATO (Rauer et al. 2014) and NGTS have several common characteristics which makes the analysis performed in this work relevant in the context of PLATO. PLATO is designed to detect the transits of Earth-sized planets in Earth-like orbits around Sun-like stars. However, such transits can only be detected by combining data from multiple PLATO telescopes. Datasets like the one analyzed in this work, where the transit is shallow with respect to the noise level, therefore offer a platform to explore possible strategies for combining data from multiple telescopes in PLATO.

Both NGTS and PLATO consist of a number of identical individual telescopes, which are subject to sources of noise, some of which are common between multiple telescopes, and some of which act at the level of the individual telescopes (Table 3). For instance, the PLATO telescopes share a common spacecraft platform and so jitter arising from the spacecraft pointing will affect all telescopes in a similar way. While the NGTS telescopes are mounted independently, they are all located in the same enclosure, and thus experience environmental and atmospheric effects in common.

	NGTS	PLATO
Individual telescope	Pointing	Telescope optical unit temperature
	Focus	Focus
		Position of target on CCD
Common across all telescopes	Airmass, temperature	Spacecraft pointing
	Seeing	Solar activity
	Temperature	

TABLE 3 Comparison of noise sources in NGTS and PLATO photometry

PLATO will combine data from multiple telescopes taking nonsimultaneous exposures (timing offsets are up to 18.75 s). Similarly, the NGTS exposures were not synchronized. The multi-telescope mode of NGTS offers the possibility of testing different approaches to combining/binning data from multiple cameras, with a view to optimizing the performance of PLATO.

ACKNOWLEDGMENTS

This work is based on data collected under the NGTS project at the ESO La Silla Paranal Observatory. The NGTS facility is operated by the consortium institutes with the support from the UK Science and Technology Facilities Council (STFC) project ST/M001962/1. We thank our anonymous referee for their helpful comments, which helped to improve the manuscript.

AUTHOR BIOGRAPHY

Alexis M S Smith is a postdoctoral researcher at the DLR's Institute of Planetary Research in Berlin-Adlershof. He was awarded his PhD by the University of St Andrews (UK) in 2009 for work on the Wide Angle Search for Planets (WASP), and worked in the UK and in Poland before moving to Germany in 2015. Alexis has specialised in the detection and characterisation of transiting exoplanets, and is an active member of the NGTS and KESPRINT consortia. He also serves on the Science Team of ESA's CHEOPS mission, a telescope in low-Earth orbit that will characterise known transiting exoplanets.

residuals to these fits were analyzed by binning them with a range of bin sizes, and determining the rms in each case. Figure A1 shows the results of this analysis, and indicates that little-to-no residual systematic noise is present in the photometry, with the exception of camera 03.

APPENDIX A. FITS AND NOISE PROPERTIES OF INDIVIDUAL NEXT-GENERATION TRANSIT SURVEY LIGHT CURVES

As discussed in section 4.1, we fitted each individual Next-Generation Transit Survey light curve separately. The

FIGURE A1 The rms of the binned residuals for each individual light curve (green curves). The plots here result from fits with fixed limb-darkening, and constrained impact parameter, but are virtually indistinguishable from those resulting from fits with the aforementioned parameters freely fitted. The white noise expectation, where the rms decreases in proportion to the square root of the bin size, is shown with a gray line in each panel
