Abstract. Aviation contributes to climate change, and the climate impact of aviation is expected to increase further. Adaptations of aircraft routings in order to reduce the climate impact are an important climate change mitigation measure. The air traffic simulator AirTraf, as a submodel of the European Center Hamburg general circulation model (ECHAM) and Modular Earth Submodel System (MESSy) Atmospheric Chemistry (EMAC) model, enables the evaluation of such measures. For the first version of the submodel AirTraf, we concentrated on the general setup of the model, including departure and arrival, performance and emissions, and technical aspects such as the parallelization of the aircraft trajectory calculation with only a limited set of optimization possibilities (time and distance). Here, in the second version of AirTraf, we focus on enlarging the objective functions by seven new options to enable assessing operational improvements in many more aspects including economic costs, contrail occurrence, and climate impact. We verify that the AirTraf setup, e.g., in terms of number and choice of design variables for the genetic algorithm, allows us to find solutions even with highly structured fields such as contrail occurrence. This is shown by example simulations of the new routing options, including around 100 North Atlantic flights of an Airbus A330 aircraft for a typical winter day. The results clearly show that AirTraf 2.0 can find the different families of optimum flight trajectories (three-dimensional) for specific routing options; those trajectories minimize the corresponding objective functions successfully. The minimum cost option lies between the minimum time and the minimum fuel options. Thus, aircraft operating costs are minimized by taking the best compromise between flight time and fuel use. The aircraft routings for

contrail avoidance and minimum climate impact reduce the potential climate impact which is estimated by using algorithmic climate change functions, whereas these two routings increase the aircraft operating costs. A trade-off between the aircraft operating costs and the climate impact is confirmed. The simulation results are compared with literature data, and the consistency of the submodel AirTraf 2.0 is verified.

1 Introduction

Climate impact due to aviation emissions is an important issue. Nowadays global aviation contributes only about 5 % to the anthropogenic climate impact (Skeie et al., 2009; Lee et al., 2009, 2010). However, the aviation's contribution to the climate impact is expected to increase further because global air traffic strongly grew in terms of revenue passenger kilometers (RPKs) by 7.4 % in 2016 compared to 2015 (ICAO, 2017). The aviation climate impact consists of carbon dioxide (CO₂) emissions and of non-CO₂ effects. The non-CO₂ effects comprise nitrogen oxides (NO_x) which lead to concentration changes of ozone and methane, water vapor (H₂O), hydrocarbons (HC), carbon monoxide (CO), sulfur oxides (SO_x), non-volatile particulate matter such as black carbon (BC), persistent linear contrails, and contrail-induced cirrus clouds (Wuebbles et al., 2007; Lee et al., 2009; Brasseur et al., 2016). These effects change the radiative balance of the Earth's climate system and cause radiative impact. The radiative impact potentially drives the climate system into a new state of equilibrium through temperature changes. Lee et al. (2009)

stated that the CO₂ emissions have the main impact and that the estimated radiative forcing (RF) of aviation CO₂ in 2005 was 28.0 mW m⁻² (15.2–40.8 mW m⁻², 90 % likelihood range). The non-CO₂ emissions and the induced clouds also have a large effect on RFs; for example, the estimated RFs in 2005 for total NO_x and for persistent linear contrails were 12.6 mW m⁻² (3.8–15.7 mW m⁻², 90 % likelihood range) and 11.8 mW m⁻² (5.4–25.6 mW m⁻², 90 % likelihood range), respectively (Lee et al., 2009). In particular, the radiative impact of contrails remains uncertain, and recent studies report higher RF. Burkhardt and Kärcher (2011) estimated the contrail cirrus RF of 37.5 mW m⁻² for the year 2002; Schumann et al. (2015) reported the RF of 63 mW m⁻² for the year 2006; and Bock and Burkhardt (2016) estimated the RF of 56 mW m⁻² for the year 2006. As for timescales of their impacts, the emitted CO₂ becomes uniformly mixed in the whole atmosphere, and its perturbation remains for millennia. In contrast, the non-CO₂ effects occur on short timescales, e.g., the emitted NO_x remains for a few days to months; the contrails last several hours. Thus, the non-CO₂ effects depend strongly on the ambient (local) atmospheric conditions (Fichter et al., 2005; Mannstein et al., 2005; Gauss et al., 2006; Grewe and Stenke, 2008; Frömming et al., 2012; Brasseur et al., 2016; Lund et al., 2017). To investigate measures for reducing the aviation climate impact, the impact of both CO₂ and non-CO₂ effects must be considered; therefore, geographic location, altitude, the time of released non-CO₂ emissions and induced clouds, and corresponding local atmospheric conditions need to be considered.

In recent years, Grewe et al. (2017a, b) and Matthes et al. (2012, 2017) have proposed a climate-optimized routing as an important operational measure for reducing the aviation climate impact. This routing allows a significant reduction of the climate impact by optimizing flight routes to avoid regions where released emissions (including contrails) have a large climate impact. The climate-optimized routing is immediately applicable to present airline fleets, whereas other, more technological measures (e.g., efficient engines, blended wing–body configurations, and laminar flow controls; Green, 2005) require several years before implementation. Moreover, the routing can be used in addition to the technological measures for reducing the aviation climate impact.

Benefits of the climate-optimized routing have been examined before (Gierens et al., 2008; Schumann et al., 2011; Sridhar et al., 2013; Søvde et al., 2014; Lührs et al., 2016); for example, Frömming et al. (2013) and Grewe et al. (2014b) developed climate cost functions (CCFs) for the climate-optimized routing. They calculated global-average RFs resulting from local unit emissions (CO₂, NO_x, H₂O, and contrails) over the North Atlantic for typical weather patterns by using the European Center Hamburg general circulation model (ECHAM) and Modular Earth Submodel System (MESSy) Atmospheric Chemistry (EMAC) model

(Jöckel et al., 2010, 2016). Those RFs were used to calculate the global and temporal average near-surface temperature response over 20 years, which describes the climate impacts (i.e., future temperature changes) caused by those emissions on a per unit basis. The resulting data set is called the CCFs. The CCFs describe the climate impact which is induced by aviation's CO₂ and non-CO₂ effects (H₂O, ozone, methane, ozone originating from methane changes, and contrails including the spread into contrail-cirrus), and the CCFs of those effects except CO₂ are a function of geographic location, altitude, and time. Because of the long residence time of CO₂, its impact is the same regardless of location, altitude, and time of emission. The obtained CCFs can be used as a measure of the climate impact of aviation and form the basis for the climate-optimized routing. Grewe et al. (2014a) calculated the CCFs for a winter day and optimized 1 d transatlantic air traffic (391 eastbound and 394 westbound flights) using the CCFs in the system for traffic assignment and analysis at macroscopic level (SAAM; Eurocontrol, 2012). They reported that the climate impact decreased by up to 25 % with a small increase in economic costs of less than 0.5 %. This revealed a great potential for the climate-optimized routing. On the other hand, a trade-off between climate impact and economic cost existed; i.e., the climate-optimized and the cost-optimized routings were conflicting strategies. Grewe et al. (2017b) extended this study and investigated the feasibility of the climate-optimized routing for realistic conditions. Similar transatlantic air traffic simulations (about 800 flights) were performed for five representative winter and three representative summer days, which took safety aspects into account. They found that a decrease in potential climate impact of 10 % was achieved at a cost increase of only 1 %.

The benefits of the climate-optimized routing were investigated by using different climate metrics. Ng et al. (2014) optimized flight trajectories for a total climate cost which was calculated by the absolute global temperature change potential (AGTP) (pulse AGTP values for three time horizons; Shine et al., 2005) due to CO₂ emissions and contrails. A total of 960 transatlantic flights (482 eastbound and 478 westbound flights) were analyzed for a specific summer day. They reported that the climate-optimized routing reduced the total AGTP (for the medium-term climate goal of 50 years) by 38 % with an additional flight time of 3.1 % and with extra fuel use of 3.1 % for the eastbound flights, whereas the routing reduced the total AGTP by 20 % with an additional flight time of 3.0 % and with extra fuel use of 3.7 % for the westbound flights. Generally, aircraft operating costs depend on time and on fuel. Thus, those results indicate the aforementioned trade-off between climate impact and economic cost; this trade-off was also found for the short-term (25 years) and long-term (100 years) climate goals. Grewe et al. (2014a) compared the trade-off between economic costs and climate impact from the transatlantic air traffic simulations described above with respect to three climate metrics: the average temperature response with future increas-

ing emissions (F-ATR20) and the absolute global warming potential with pulse emissions at a 20-year time horizon (P-AGWP20) for short-term climate impacts and P-AGWP100 (time horizon of 100 years) for long-term climate impacts. The trade-offs obtained with the three metrics were very similar. Although many studies show the benefit of the climate-optimized routing, this routing is not used for today's flight planning; today's aircraft routing focuses on minimum economic cost. However, if additional costs, such as environmental taxes, for aviation climate impact of CO₂ and non-CO₂ effects are included in the operating costs, a cost increase due to the climate-optimized routing is possibly compensated for (Grewe et al., 2017b). This inclusion can change the current routing strategy and incentivize airlines to introduce a climate-optimized flight planning.

Here we present an air traffic simulation model which serves as a basis for the following ultimate two aims: to investigate an eco-efficient aircraft routing strategy that reduces the climate impact of global air traffic over the next few decades and to estimate its mitigation gain for different aircraft routing strategies. For these aims, the submodel AirTraf (version 1.0) was developed as one of the submodels of EMAC (Yamashita et al., 2015, 2016). AirTraf can simulate global air traffic in EMAC (online) for various aircraft routing strategies (options). Every flight trajectory is optimized for a selected routing option under daily changing local atmospheric conditions. AirTraf can take into account where and when aviation emissions are released or contrails form. The road map for our overall study has been shown elsewhere (Grewe et al., 2017b; Matthes et al., 2017).

This paper presents a technical description of the new version of the submodel AirTraf 2.0. The simple aircraft routing options of great circle (minimum flight distance) and flight time (minimum time) were developed in the previous version of AirTraf 1.0 (Yamashita et al., 2016). In AirTraf 2.0, seven new aircraft routing options have been introduced: fuel use, NO_x emissions, H₂O emissions, contrail formation, simple operating cost (SOC), cash operating cost (COC), and climate impact estimated by the algorithmic climate change functions (aCCFs) (Van Manen, 2017; Yin et al., 2018b, 2020; Van Manen and Grewe, 2019). The climate change functions were previously referred to as the climate cost functions mentioned above. These options represent the objects to be minimized. Overall the nine options have been integrated into AirTraf 2.0, which enables air traffic simulations for the ultimate aims of our study (hereinafter the aircraft routing options are referred to simply as, e.g., the "fuel option"). Thus, the development described in this paper is an indispensable update. Moreover, this paper provides example applications of AirTraf 2.0. Some simulations of the nine routing options were carried out for transatlantic routes for a typical winter day. Optimum flight trajectories and characteristics of the routing options were analyzed.

Here we mention the importance of the variety of the routing options. Various routing options have been made avail-

able in AirTraf 2.0 because not only the climate and the cost options but also the other options are important subjects for air traffic routing studies. The time option is useful for delay recovery. Because delays cause costs to airlines, pilots are often forced to temporarily use the time option during a flight to maintain flight schedules, although the use of this option increases fuel costs (Cook et al., 2009). The NO_x (Mulder and Ruijgrok, 2008) and contrail options (Fichter et al., 2005; Mannstein et al., 2005; Gierens et al., 2008; Sridhar et al., 2011; Schumann et al., 2011; Rosenow et al., 2017) have been examined as a routing strategy towards climate impact reduction. Moreover, conflicting scenarios (trade-offs) between different routing strategies have been studied; for example, avoiding contrail formation generally increases fuel use and CO₂ emissions. Irvine et al. (2014) assessed the trade-off between contrail avoidance and increased CO₂ emissions (~ increased fuel use) for a single flight. AirTraf 2.0 enables the analysis of those subjects all at once because all the options are integrated. Normally, one or two specific routing options are available for a flight trajectory optimization in other models. Another aspect to be emphasized compared to other models is that AirTraf performs air traffic simulations not under International Standard Atmospheric (ISA) conditions and not under a fixed atmospheric condition for a specific day but under comprehensive atmospheric conditions which are calculated by EMAC; that is to say that AirTraf can simulate air traffic for long-term periods in EMAC, which enables one to examine effects of aircraft routing strategies on climate impact on a long-term timescale. Last but not least, the aCCFs are new proxies for the climate-optimized routing. An important aim of the AirTraf development is to verify the aCCFs themselves and the routing strategy based on the aCCFs (i.e., the climate option) in multi-annual (long-term) simulations (Yin et al., 2018b).

This paper is organized as follows. Section 2 describes an overview of AirTraf 2.0. Particularly, key changes in the model components are stated. Section 3 presents the results and discussion for the example applications of AirTraf 2.0 using the nine routing options. Section 4 verifies the consistency of the results with literature data. Finally, Sect. 5 concludes this study.

2 Overview of AirTraf 2.0

2.1 Chemistry–climate model EMAC

The EMAC model is a numerical chemistry and climate simulation system that includes submodels describing tropospheric and middle atmosphere processes and their interaction with oceans, land, and influences coming from anthropogenic emissions (Jöckel et al., 2010, 2016). It uses the second version of the Modular Earth Submodel System (MESSy2) to link multi-institutional computer codes. The core atmospheric model is the fifth generation European Cen-

ter Hamburg general circulation model (ECHAM5; Roeckner et al., 2006). For the present study, we applied EMAC (ECHAM5 version 5.3.02 and MESSy version 2.53 updated from version 2.41 for AirTraf 1.0) in the T42L31ECMWF resolution, i.e., with a spherical truncation of T42 (corresponding to a quadratic Gaussian grid of approximately 2.8° by 2.8° in latitude and longitude) with 31 vertical hybrid pressure levels up to 10 hPa (middle of the uppermost layer). The namelist setup for ECHAM5 simulations (referred to the E5 setup, no chemistry) was employed. Moreover, the submodel AirTraf was coupled to the submodel CONTRAIL (version 1.0; Frömming et al., 2014) for the contrail option and to the submodel ACCF (version 1.0) for the climate option using the MESSy interfaces. Further information about MESSy, including the EMAC model system, is available from the MESSy Consortium website (<http://www.messy-interface.org>, last access: 17 September 2020).

2.2 Model components of submodel AirTraf

Figure 1 shows the flowchart of the submodel AirTraf 2.0. The present version is based on the model components of AirTraf 1.0, and thus this section outlines them (updates from AirTraf 1.0 are highlighted in Fig. 1). First, air traffic data and AirTraf parameters are read in the main entry point `messy_initialize` (Fig. 1, dark blue). They consist of a 1 d flight plan (including departure and arrival airport pairs, latitude and longitude of the airports, and departure time), EUROCONTROL's Base of Aircraft Data (BADA Revision 3.9; Eurocontrol, 2011), ICAO engine performance data (ICAO, 2005), a load factor, jet fuel price, an aircraft routing option, etc. Any arbitrary number of flight plans is applicable and is reused for AirTraf simulations longer than 2 d. Table 1 lists the relevant data of an A330-301 aircraft and constant parameters used in AirTraf 2.0 (the new parameters are listed in Table 1). Second, all the entries are distributed in parallel by the message passing interface (MPI) standard (called for the main entry point `messy_init_memory`; Fig. 1, blue). Third, the air traffic simulation (called the AirTraf integration; Fig. 1, light blue) is called in the main entry point `messy_global_end` considering local atmospheric conditions for every flight route. The AirTraf integration uses three modules: the aircraft routing module (Fig. 1, light green), the fuel–emissions–cost–climate calculation module (Fig. 1, light orange), and the flight trajectory optimization module (Fig. 1, dark green). The first module calculates flight trajectories corresponding to a selected routing option. The second module comprises a total energy model based on the BADA methodology (Eurocontrol, 2011; Schaefer, 2012) and the German Aerospace Center (DLR) fuel flow method (Deidewig et al., 1996). The third module consists of the Adaptive Range Multi-Objective Genetic Algorithm (ARMOGA version 1.2.0; Sasaki et al., 2002; Sasaki and Obayashi, 2004, 2005). Finally, simulation results are gathered from the MPI tasks. Optimum flight trajectories

and global fields of flight properties (four-dimensional Gaussian grid; Fig. 1, rose red) are output. The same assumptions made in AirTraf 1.0 are applied in AirTraf 2.0; e.g., only the cruise flight phase is considered, and trajectory conflicts and operating constraints (e.g., military air space) are neglected. Further details of the model components have been reported by Yamashita et al. (2016).

2.3 Calculation procedures of the AirTraf integration

AirTraf 2.0 follows the calculation procedures of AirTraf 1.0 described in detail in Sect. 2.4 of Yamashita et al. (2016). This section reviews the procedures of the AirTraf integration (Fig. 1, light blue) with emphasis on changes by introducing the new routing options.

A 1 d flight plan includes departure time for every flight. A flight moves to the flying process (dashed box in Fig. 1, light blue) according to the individual departure time in the time loop of EMAC. The flying process comprises four steps: flight trajectory calculation, fuel–emissions–cost–climate calculation, aircraft position calculation, and gathering global emissions (bold black boxes in Fig. 1, light blue). The first step finds an optimum flight trajectory for a selected routing option by using the aircraft routing module (Fig. 1, light green) in which the seven new routing options are introduced in AirTraf 2.0. The flight trajectory optimization module (Fig. 1, dark green) executes the flight trajectory optimization under atmospheric conditions at the departure day and time of the flight. Thus, the optimum flight trajectory varies day by day. Note that the three-dimensional wind components (u , v , w) are considered in the flight trajectory optimization for all routing options. The resulting optimum flight trajectory consists of waypoints ($i = 1, 2, \dots, n_{\text{wp}}$) and flight segments ($i = 1, 2, \dots, n_{\text{wp}} - 1$), where i is the index arranged from the departure ($i = 1$) to the arrival ($i = n_{\text{wp}}$) and n_{wp} is the number of waypoints (see Fig. 3 of Yamashita et al., 2016). Table 2 lists flight properties calculated for the waypoints, the flight segments, and the whole trajectory. In AirTraf 2.0, 15 new properties are calculated, as highlighted in Table 2.

The second step, which is linked to the fuel–emissions–cost–climate calculation module (Fig. 1, light orange), calculates the flight properties of fuel, NO_x emissions, COC, etc. under the atmospheric conditions (Table 2, third group). This calculation is performed once at the departure time of the flight. The methodologies of the fuel and emissions calculation module developed in AirTraf 1.0 are expanded in AirTraf 2.0. Details of the fuel–emissions calculation module and its reliability have been reported in Sects. 2.5, 2.6, and 5 of Yamashita et al. (2016).

The third step moves the aircraft to a new position along the optimum flight trajectory corresponding to the time steps of EMAC by referring to the estimated time when the aircraft passes through the waypoints (called the estimated time over, ETO; Table 2).

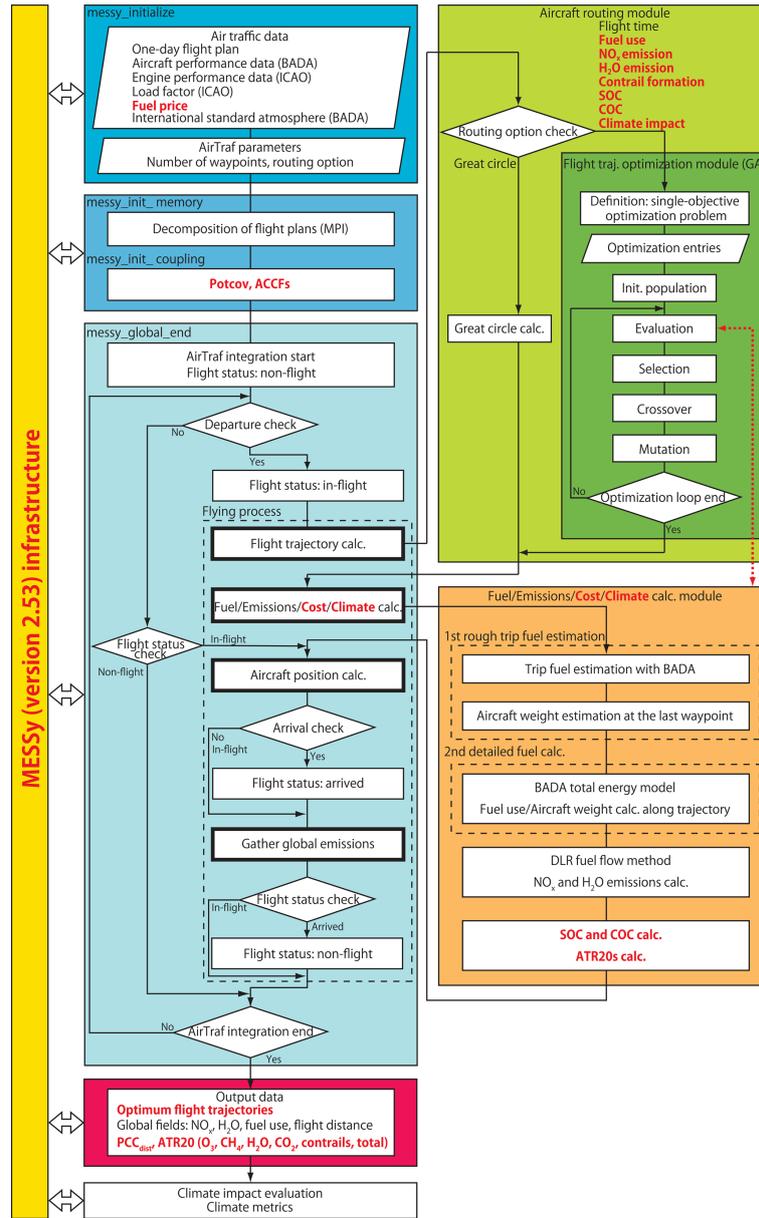

Figure 1. Updated flowchart of the MESSy submodel AirTraf 2.0 (updates from AirTraf 1.0 are highlighted by red texts and arrows). MESSy as part of EMAC provides interfaces (yellow) to couple various submodels for data exchange, run control, and data input/output. AirTraf 2.0 is coupled to the submodel CONTRAIL (version 1.0; Frömming et al., 2014) and the submodel ACCF (version 1.0). Air traffic data and AirTraf parameters are imported in the initialization phase (*messy_initialize*, dark blue). AirTraf includes the flying process in *messy_global_end* (dashed box, light blue), which comprises four main computation procedures (bold black boxes). AirTraf uses three modules: the aircraft routing module (light green), the fuel–emissions–cost–climate calculation module (light orange), and the flight trajectory optimization module (dark green). Resulting optimum flight trajectories and global fields of flight properties are output (rose red).

At the fourth step, the individual flight properties corresponding to a flight path for one time step of EMAC are gathered into the aforementioned global fields: NO_x emissions, H_2O emissions, fuel use, flight distance, contrail distance (PCC_{dist}), and average temperature responses for the time horizon of 20 years (ATR20s of ozone, methane, water vapor, CO_2 , contrails, and total climate impact; see Sect. 2.5.7)

are gathered along the flight segments (Table 2); the global fields of PCC_{dist} and ATR20s are newly calculated by AirTraf 2.0. If the aircraft reaches the last waypoint in the time loop of EMAC, the aircraft has landed (i.e., the flight ends), and the flying process ends for this flight.

Table 1. Relevant data of an Airbus A330-301 aircraft and constant parameters applied for AirTraf 2.0. The column “New in V2.0” denotes parameters newly introduced in AirTraf 2.0.

Parameter	Value	Unit	New in V2.0	Description
AFW	103 070	kg	×	Airframe weight estimated by $AFW = MEW - N_{eng}EDW$
c_t	0.75	(USD) s^{-1}	×	Unit time costs ^a
c_f	0.51	(USD) kg^{-1}	×	Unit fuel costs ^a
C_{D0}	0.019805	–		Parasitic drag coef. (cruise) ^b
C_{D2}	0.031875	–		Induced drag coef. (cruise) ^b
C_{f1}	0.61503	$kg \min^{-1} kN^{-1}$		First thrust specific fuel consumption (TSFC) coef. (jet engines) ^b
C_{f2}	919.03	kt		Second TSFC coef. ^b
C_{fcr}	0.93655	–		Cruise fuel flow correction coef. ^b
EDW	5091.62	kg	×	Engine dry weight; CF6-80E1A2 engine ^c
$EINO_{x,ref}$	4.88; 12.66; 22.01; 28.72	$g(NO_x) (kg(fuel))^{-1}$		Reference NO_x emission index at takeoff, climb out, approach and idle conditions (sea level); CF6-80E1A2 (2GE051) ^d
EIH_2O	1230	$g(H_2O) (kg(fuel))^{-1}$		H_2O emission index ^c
f_{ref}	0.228; 0.724; 2.245; 2.767	$kg(fuel) s^{-1}$		Reference fuel flow at takeoff, climb out, approach, and idle conditions (sea level); CF6-80E1A2 (2GE051) ^d
g	9.8	ms^{-2}		Gravity acceleration
JFD	0.804	kgL^{-1}	×	Jet fuel density at 15 °C (Jet A-1)
JFP	0.41	(USD) L^{-1}	×	Jet fuel price ^f
M	0.82	–		Cruise Mach number ^b
MEW	113 253	kg	×	Baseline manufacture empty weight ($MEW = 0.9053OEW$) ^g
MPL	47 900	kg		Maximum payload ^b
MTOGW	212 000	kg	×	Maximum takeoff weight ^h
N_{seat}	295	–	×	Number of seats (3 class) ⁱ
N_{eng}	2	–	×	Number of engines ^h
OEW	125 100	kg		Operational empty weight ^b
OLF	0.62	–		ICAO overall (passenger/freight/mail) weight load factor in 2008 ^j
P_0	101 325	Pa		Reference pressure (sea level)
r_{inf}	2.28	%	×	Ave. United States inflation rate (1994–2014) ^k
R	287.05	$JK^{-1} kg^{-1}$		Gas constant for dry air
S	361.6	m^2		Reference wing surface area ^b
SLST	268.7	kN	×	Thrust per engine (maximum continuous); CF6-80E1A2 ^h
SPD	86 400	sd^{-1}		Time (Julian date) \times SPD = Time (s)
T_0	288.15	K		Reference temperature (sea level)
Y_{pre}	2015	year	×	Present year for COC calculation
Y_{ref}	1993	year	×	Reference year for COC calculation
γ	1.4	–		Adiabatic gas constant

2.4 Flight trajectory optimization

The flight trajectory optimization methodologies described by Yamashita et al. (2016) are also used for the new routing options and are outlined in this section. The flight trajectory optimization module (Fig. 1, dark green) executes the optimization. The module consists of ARMOGA (version 1.2.0; Sasaki et al., 2002; Sasaki and Obayashi, 2004, 2005), which is a stochastic optimization algorithm.

A solution \mathbf{x} (the term is synonymous with the flight trajectory) is a vector of n_{dv} design variables: $\mathbf{x} = (x_1, x_2, \dots, x_{n_{dv}})^T$, here $n_{dv} = 11$. With the design variable index j ($j = 1, 2, \dots, n_{dv}$), x_j ($j = 1, 2, \dots, 6$) indicate lati-

tudes and longitudes, and x_j ($j = 7, 8, \dots, 11$) indicate altitudes. The j th design variable varies between lower and upper bounds $[x_j^l, x_j^u]$. The bounds of $[x_j^l, x_j^u]$ ($j = 1, 2, \dots, 6$) are automatically set for a given airport pair, whereas those of $[x_j^l, x_j^u]$ ($j = 7, 8, \dots, 11$) are set as $[x_j^l, x_j^u] = [FL290, FL410]$ (flight levels; FL290 and FL410 denote 29 000 and 41 000 ft, respectively). Geographic locations of the airport pair are set according to the flight plan; altitudes of the airport pair are set to FL290. Given values of x_j ($j = 1, 2, \dots, n_{dv}$), a three-dimensional flight trajectory is represented by a B-spline curve (third-order) between the air-

Table 2. Properties assigned to a resulting flight trajectory. The properties of the three groups (divided by rows) are obtained from the nearest grid box of EMAC at the departure time of the flight, the flight trajectory calculation (Fig. 1), and the fuel–emissions–cost–climate calculation (Fig. 1; some properties are calculated in flight trajectory optimizations depending on a selected routing option). The attribute type indicates where the values of properties are allocated. “W”, “S”, and “T” stand for waypoints ($i = 1, 2, \dots, n_{wp}$), flight segments ($i = 1, 2, \dots, n_{wp} - 1$), and a whole flight trajectory in column 3, respectively. The column “New in V2.0” denotes properties newly introduced in AirTraf 2.0.

Property	Unit	Attribute type	New in V2.0	Description
aCCF _{O₃}	K (kg(NO ₂)) ⁻¹	W	×	Algorithmic climate change function of ozone ^{ab} ; see Eq. (A1)
aCCF _{CH₄}	K (kg(NO ₂)) ⁻¹	W	×	Algorithmic climate change function of methane ^{ab} ; see Eq. (A2)
aCCF _{H₂O}	K (kg(fuel)) ⁻¹	W	×	Algorithmic climate change function of water vapor ^{ab} ; see Eq. (A3)
aCCF _{CO₂}	K (kg(fuel)) ⁻¹	W	×	Algorithmic climate change function of CO ₂ ^c ; see Eq. (A4)
aCCF _{contrail}	K (km(contrail)) ⁻¹	W	×	Algorithmic climate change function of contrails ^d ; see Eq. (A5)

port pair (an illustration is given in Fig. 6 of Yamashita et al., 2016).

The initial population operator (Fig. 1, dark green) generates initial values of $x_j (j = 1, 2, \dots, n_{dv})$ at random within the lower and upper bounds and creates an initial “population” which represents a random set of solutions. The population size is set by n_p , and ARMOGA starts its search with the solutions. An evaluation function f (called an objective function) is defined depending on a selected routing option (see Sect. 2.5), and a single-objective optimization problem

can be written as follows:

$$\left. \begin{aligned} &\text{Minimize } f \\ &\text{Subject to } x_j^l \leq x_j \leq x_j^u, \quad j = 1, 2, \dots, n_{dv} \end{aligned} \right\}, \quad (1)$$

where no constraint function is used. The ARMOGA solves the optimization problem by the following genetic operators: evaluation, selection, crossover, and mutation (Fig. 1, dark green; Holland, 1975; Goldberg, 1989). A value of f is calculated for each of the solutions by the evaluation operator. In this study, good solutions were identified in the population by the Fonseca–Fleming Pareto ranking method (Fonseca and Fleming, 1993), the stochastic universal sampling selection (Baker, 1985) was used for the selection operator

to pick two solutions (parent solutions) from the population, the Blend crossover operator (BLX-alpha; Eshelman, 1993) was applied to the parent solutions to create new solutions (child solutions), and the revised polynomial mutation operator (Deb and Agrawal, 1999) was used to add a disturbance to the child solutions. When those processes are iterated for a number of generations (the term “generation” represents one iteration of ARMOGA; this is set by n_g), the population of solutions is improved by reducing f , and another superior population is created in subsequent generations. Finally, the ARMOGA finds the best solution (one optimum flight trajectory) with the minimum value of f through the whole generations; the flight properties of the solution are stored, as shown in Table 2. The flight trajectory optimization stated above is executed for every airport pair. Detailed descriptions of the optimization methodologies, appropriate ARMOGA parameter settings, and the accuracy of the optimization module have been presented in Sect. 3.2 of Yamashita et al. (2016).

2.5 Formulations of objective functions for new aircraft routing options

In AirTraf 2.0, seven new objective functions were developed for the new aircraft routing options. The following subsections describe formulations of the objective function f for those options. To calculate f , the fuel–emissions–cost–climate calculation module (Fig. 1, light orange) is used as necessary by the evaluation operator (Fig. 1, dark green) in the flight trajectory optimization.

2.5.1 Fuel use

The objective function for the fuel option represents the sum of fuel use – kg(fuel) – of a flight:

$$f = \sum_{i=1}^{n_{wp}-1} \text{FUEL}_i, \quad (2)$$

where FUEL_i is the fuel use of the i th flight segment (Table 2).

2.5.2 NO_x emissions

The objective function for the NO_x option represents the sum of NO_x emissions – g(NO_x) – of a flight:

$$f = \sum_{i=1}^{n_{wp}-1} \text{NO}_{x,i} = \sum_{i=1}^{n_{wp}-1} (\text{FUEL}_i \text{EINO}_{x,a,i}), \quad (3)$$

where $\text{NO}_{x,i}$ is the NO_x emissions of the i th flight segment; $\text{EINO}_{x,a,i}$ is the NO_x emission index under actual flight conditions at the i th waypoint (Table 2) and is calculated using the ICAO engine performance data (ICAO, 2005; see Sect. 2.6 of Yamashita et al., 2016).

2.5.3 H₂O emissions

The objective function for the H₂O option represents the sum of H₂O emissions – g(H₂O) – of a flight:

$$f = \sum_{i=1}^{n_{wp}-1} \text{H}_2\text{O}_i = \text{EIH}_2\text{O} \sum_{i=1}^{n_{wp}-1} \text{FUEL}_i, \quad (4)$$

where H_2O_i is the H₂O emissions of the i th flight segment (Table 2); EIH_2O is the emission index of H₂O and was set as $\text{EIH}_2\text{O} = 1230 \text{ g}(\text{H}_2\text{O})/(\text{kg}(\text{fuel}))^{-1}$ (Table 1). The H₂O emissions are proportional to the fuel use by assuming an ideal combustion of jet fuel. Thus, this option yields the same results as the fuel option in AirTraf 2.0. If an alternative fuel option is introduced, the H₂O option probably differs from the fuel option because the emission index may not be constant.

2.5.4 Contrail formation

Yin et al. (2018a) developed the routing option to avoid contrail formations by using the submodel CONTRAIL (version 1.0; Frömming et al., 2014) which calculates the potential persistent contrail cirrus coverage Potcov (Ponater et al., 2002; Burkhardt et al., 2008; Burkhardt and Kärcher, 2009; Grewe et al., 2014b) within an EMAC grid box. The Potcov represents the fraction of the grid box which can be maximally covered by contrails under the simulated atmospheric condition. The threshold for contrail formation is determined from a parameterization scheme based on the thermodynamic theory of contrails, i.e., the Schmidt–Appleman theory (Schmidt, 1941; Appleman, 1953; Schumann, 1996). In the CONTRAIL submodel, Potcov indicates the difference between the maximum possible coverage of both contrails and cirrus and the coverage of natural cirrus alone; values of Potcov along the waypoints are taken from the nearest grid box (Table 2). With that, we define a contrail distance (PCC_{dist}) – in km(contrail) – as Potcov multiplied by the flight distance in kilometers. The corresponding routing option minimizes the total contrail distance of a flight, and thus the objective function is formulated as follows:

$$f = \sum_{i=1}^{n_{wp}-1} \text{PCC}_{\text{dist},i} = 10^{-3} \sum_{i=1}^{n_{wp}-1} (\text{Potcov}_i d_i), \quad (5)$$

where $\text{PCC}_{\text{dist},i}$ is the contrail distance of the i th flight segment, Potcov_i is the potential persistent contrail cirrus coverage at the i th waypoint, and d_i is the flight distance of the i th flight segment (Table 2). Note that the objective function is formulated in the simple form to consider only the contrail distance. Thus, further physical processes such as contrail spreading, changes in contrail coverage area, contrail lifetime, and the contrail radiative forcing are not included.

2.5.5 Simple operating cost (SOC)

The cost index (CI) is set during a real flight to manage airline operation costs and is defined as the ratio of time cost to fuel cost (CI = time cost/fuel cost). A low CI value causes an aircraft to minimize fuel use with a sacrifice of flight time, which enables a long-range flight. Conversely, a high CI value causes the aircraft to minimize flight time with extra fuel use. Generally, the operating costs are a function of flight time and fuel. Thus, the minimum cost solution lies in a trade-off between flight time and fuel (Cook et al., 2009; Marla et al., 2016). Here the objective function simply represents the sum of the time and the fuel costs on the basis of the CI features:

$$f = \text{SOC} = c_t \sum_{i=1}^{n_{\text{wp}}-1} \frac{d_i}{V_{\text{ground},i}} + c_f \sum_{i=1}^{n_{\text{wp}}-1} \text{FUEL}_i, \quad (6)$$

where c_t and c_f are the unit costs of time and fuel, respectively (Table 1), and $V_{\text{ground},i}$ is the ground speed at the i th waypoint (Table 2). Note that the c_t includes the cost elements for flight crew, cabin crew, and maintenance for both airframe and engines.

2.5.6 Cash operating cost (COC)

The COC is a comprehensive economic criterion for evaluating airline operation costs (Liebeck et al., 1995). The COC includes the cost elements for flight crew, cabin crew, landing fee, navigation fee, fuel, and maintenance for both airframe and engines (no costs for depreciation, insurance, and interest are included). The COC calculation method for international flights (Liebeck et al., 1995) was employed. Those cost elements were calculated on the basis of the price in 1993 and were scaled to 2015 by the average United States inflation rate of average consumer prices r_{inf} (Table 1; IMF, 2016). Only the fuel cost was directly calculated with the current jet fuel price (JFP) (Table 1; IATA, 2017). A block time and a block fuel originally used in the method were replaced by the total flight time (FT) and the fuel use of $\sum_{i=1}^{n_{\text{wp}}-1} \text{FUEL}_i$ in AirTraf 2.0, respectively (Table 2). The objective function can be written as follows:

$$f = \text{COC} = C_{\text{flightcrew}} + C_{\text{cabincrew}} + C_{\text{landing}} + C_{\text{navigation}} + C_{\text{fuel}} + C_{\text{airframe}} + C_{\text{engine}}, \quad (7)$$

where C denotes a cost. A detailed description of the COC calculation method has been reported in Liebeck et al. (1995). Given the parameters and variables listed in Tables 1 and 2, Eq. (7) becomes a function of the flight time and the fuel.

2.5.7 Climate impact

The climate-optimized routing was carried out by using the aCCFs (Van Manen, 2017; Yin et al., 2018b, 2020; Van Manen and Grewe, 2019) calculated by the submodel ACCF.

The aCCFs are approximation functions based on regression analyses for the CCF data set which was obtained from detailed EMAC model simulations including radiative impacts (see Sect. 1); the CCF data set for contrails was exceptionally obtained from contrail RF calculations based on the European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis Interim (ERA-Interim) data (Dee et al., 2011) and contrail trajectory data (Yin et al., 2020; the definition of the aCCFs is provided in the Appendix, and examples are shown in Fig. S1 in the Supplement). The aCCFs represent a correlation of meteorological variables at the time of flight with anticipated climate impacts; i.e., ATR20s of ozone, methane, water vapor, CO₂, and contrails are estimated on a per unit basis by

$$\text{ATR20}_{\text{O}_3,i} = \text{aCCF}_{\text{O}_3,i} \times \text{NO}_{x,i} \times 10^{-3}, \quad (8)$$

$$\text{ATR20}_{\text{CH}_4,i} = \text{aCCF}_{\text{CH}_4,i} \times \text{NO}_{x,i} \times 10^{-3}, \quad (9)$$

$$\text{ATR20}_{\text{H}_2\text{O},i} = \text{aCCF}_{\text{H}_2\text{O},i} \times \text{FUEL}_i, \quad (10)$$

$$\text{ATR20}_{\text{CO}_2,i} = \text{aCCF}_{\text{CO}_2} \times \text{FUEL}_i, \quad (11)$$

$$\text{ATR20}_{\text{contrail},i} = \text{aCCF}_{\text{contrail},i} \times \text{PCC}_{\text{dist},i}, \quad (12)$$

where the respective aCCF values of ozone, methane, water vapor, CO₂, and contrails are given as flight properties at the i th waypoint. These five ATR20s are calculated for flight segments (Table 2) and are combined into an objective function to represent an anticipated climate impact of a flight (in K):

$$\text{ATR20}_{\text{total},i} = \text{ATR20}_{\text{O}_3,i} + \text{ATR20}_{\text{CH}_4,i} + \text{ATR20}_{\text{H}_2\text{O},i} + \text{ATR20}_{\text{CO}_2,i} + \text{ATR20}_{\text{contrail},i}, \quad (13)$$

$$f = \sum_{i=1}^{n_{\text{wp}}-1} \text{ATR20}_{\text{total},i}, \quad (14)$$

where $\text{ATR20}_{\text{contrail},i}$ can take positive and negative values because the $\text{aCCF}_{\text{contrail}}$ consists of two formulas for the daytime and nighttime contrail effects (see Eq. A5 in the Appendix). We acknowledge the large uncertainties in the global temperature response especially from contrails ($\text{ATR20}_{\text{contrail}}$) due to uncertainties in the efficacy of the contrail forcing (Hansen et al., 2005; Ponater et al., 2005). In addition, the aCCFs are derived based on the CCF data of the North Atlantic region and are applicable to the northern and high latitudes. Further details of the aCCFs have been reported in the literature mentioned above.

3 Example application: 1 d simulation with new aircraft routing options

3.1 Simulation setup

Nine 1 d simulations were carried out for a demonstration of AirTraf 2.0. Table 3 lists the simulation setups. The same setups that we used for the consistency check for AirTraf 1.0 simulations (Yamashita et al., 2016) were employed; only the

Table 3. Setup for AirTraf 1 d simulations. The setups of the two groups (divided by rows) are used for AirTraf/EMAC and for ARMOGA (Sasaki et al., 2002; Sasaki and Obayashi, 2004, 2005). The user-specified crossover parameter is α , r_m is a mutation rate, and η_m is a parameter controlling the shape of a probability distribution. Details of these parameters are described in Yamashita et al. (2016).

Parameter	Description
ECHAM5 resolution	T42L31ECMWF (2.8° by 2.8°)
Simulation period	1 December 2015, 00:00:00–2 December 2015, 00:00:00 GMT
Time step of EMAC	12 min
Flight plan	103 transatlantic flights (eastbound 52 and westbound 51) ^a
Aircraft type	A330-301
Engine type	CF6-80E1A2, 2GE051 (with 1862M39 combustor)
Flight altitude changes	[FL290, FL410] (fixed at FL350 for the great circle option)
Mach number	0.82
Number of waypoints, n_{wp}	101
Design variable, n_{dv}	11 (6 locations and 5 altitudes)
Population size, n_p	100
Number of generations, n_g	100
Selection	Stochastic universal sampling
Crossover	Blend crossover BLX-0.2 ($\alpha = 0.2$)
Mutation	Revised polynomial mutation ($r_m = 0.1$; $\eta_m = 5.0$)

^a Grewe et al. (2014a) and REACT4C (2014).

simulation period was changed to a recent day which showed a typical weather condition in winter with a strong jet stream (see Fig. S2 in the Supplement). The flight altitude for the great circle option was set to FL350; the altitude for the other options was calculated in the trajectory optimization within [FL290, FL410], as mentioned in Sect. 2.4. The transatlantic flight plan (103 flights) of an Airbus A330 aircraft was provided by Grewe et al. (2014a) and REACT4C (2014). The setups for the optimization parameters were determined by the benchmark tests (Yamashita et al., 2016).

3.2 Optimized flight trajectories and global fields

To display typical simulation outputs, the obtained optimized trajectories and global fields for the contrail, the COC, and the climate options are shown. Figure 2 shows the optimized trajectories for those options (optimized trajectories for other options are shown in Supplement Fig. S3). Obviously, the optimum trajectories vary with the routing options. Figure 2c and d show that the COC optimum trajectories of the eastbound flights leap up over the North Atlantic Ocean, whereas the trajectories of the westbound flights are shifted northward. As the jet stream is located at around 40° N and 50° W (see Fig. S2 in the Supplement), the eastbound trajectories are optimized to benefit from tailwinds of the jet stream and the westbound trajectories avoid headwinds of the jet stream by detouring northward. In addition, most of those trajectories are located at high flight altitudes (\sim FL410, 12.5 km). Figure 3 shows the mean fuel consumption – in $\text{kg}(\text{fuel})\text{min}^{-1}$ – vs. mean flight altitude (in km) for individual flights for the three routing options. Because fuel consumption decreases as a result of aerodynamic drag

reduction at high altitudes (Fichter et al., 2005; Schumann et al., 2011; Yamashita et al., 2016), the COC optimum trajectories select the high flight altitudes, as shown in Fig. 3. We acknowledge that limitations of BADA 3 affect the selection of the flight altitudes (the same applies to the fuel, the NO_x , the H_2O , and the SOC options; see Fig. S3 in the Supplement). According to Nuic et al. (2010), BADA 3 has a tendency to underestimate aircraft fuel consumption at high altitudes and Mach numbers as the compressibility effect and wave drag are not modeled. These effects will cause differences in the selection of the flight altitudes. In contrast, the contrail and the climate options show complex-shaped trajectories with various flight altitude changes (see Fig. 2a, b, e, and f).

The global fields of fuel use, contrail distance, and climate impact indicated by $\text{ATR}_{20,\text{total}}$ for the three options are shown in Fig. 4, in which distributions represent the sum of all the flights during the day. We see from Fig. 4b, e, and h that the contrail option certainly decreases the contrail formation, which is mostly located over northwest Europe and over the east coast of the United States. A comparison of Fig. 4a, d, and g shows that the COC option produces a narrower fuel distribution than that of the contrail and climate options. In addition, Fig. 4c, f and i show that the climate option decreases the positive values of $\text{ATR}_{20,\text{total}}$ (warming effects) over northwest Europe and over the east coast of the United States and produces regionally negative values (cooling effects) near Iceland and over eastern Canada, which result in the net climate impact reduction. A comprehensive analysis of the optimized trajectories for the calculated fields is beyond the scope of this paper. However, it is apparent from Fig. 4 that the optimized trajectories success-

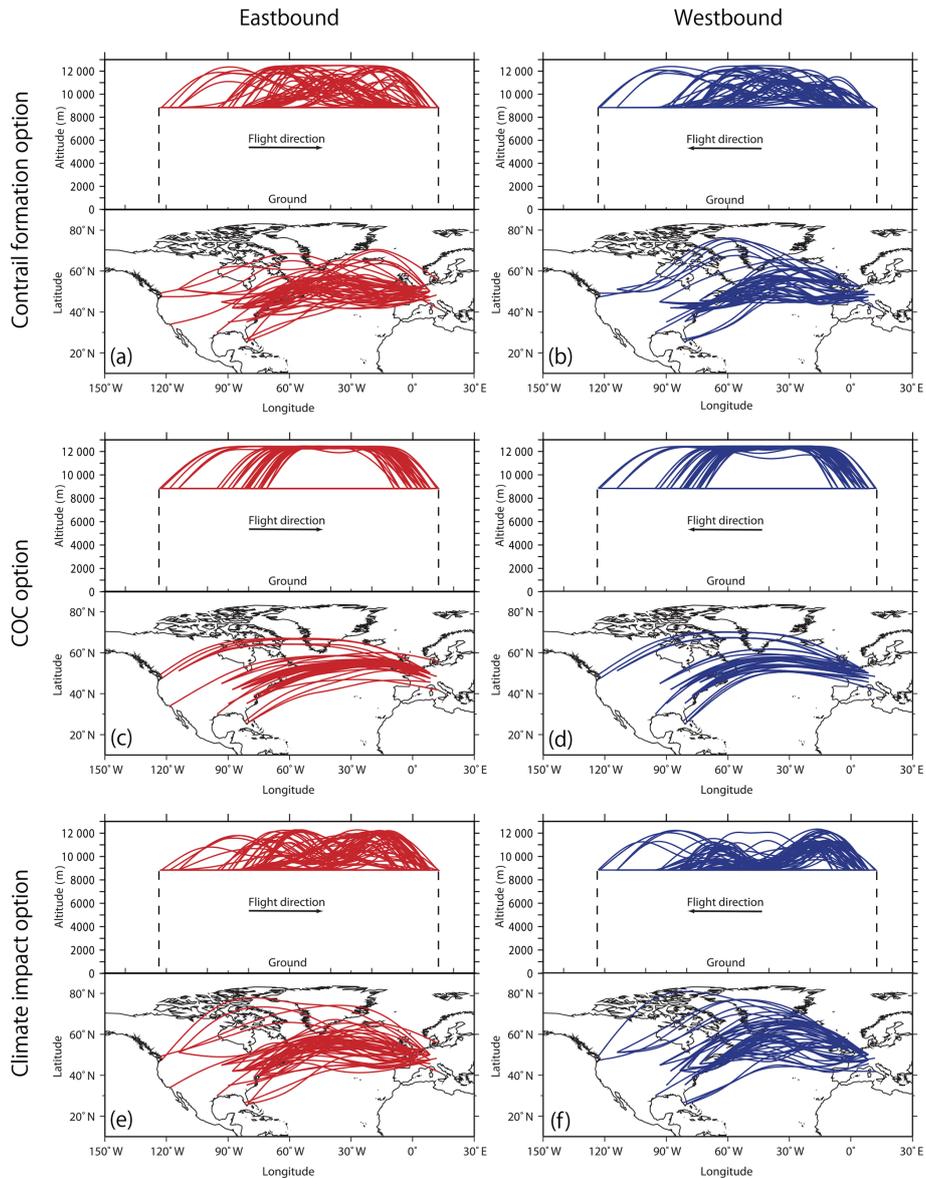

Figure 2. Optimized flight trajectories from a 1 d AirTraf simulation (52 eastbound and 51 westbound flights) for the contrail formation (a, b), the COC (c, d), and the climate impact routing options (e, f). For each figure, the trajectories are shown in the vertical cross section (top) and projected on the ground (bottom).

fully decrease the respective objects (target measures) which should be minimized (this point is discussed quantitatively in Sect. 3.3).

3.3 Characteristics of aircraft routing options

To examine the characteristics of the routing options, Table 4 lists a summary of nine performance measures of the 1 d air traffic (total 103 flights) for specific routing options (bar charts are given in Supplement Fig. S4). Relative changes (in %) to the COC option are also listed in Table 4, considering this option as a reference (the COC option is assumed to be the current aircraft routing strategy). Table 4 shows that indi-

vidual options successfully minimize their own object (target measure; see measures marked with an asterisk in Table 4). These results confirm that the new routing options work correctly in AirTraf 2.0 since we solve a single-objective minimization problem defined by Eq. (1) for each routing option.

The individual routing options are now discussed in turn. We see from Table 4 that the great circle option has the minimum flight distance of 660.3×10^3 km, whereas this option increases the other measures. The time option shows the minimum flight time of 739.4 h with a large penalty on fuel use, NO_x emissions, H_2O emissions, SOC, COC, and $\text{ATR}_{20\text{total}}$ (further discussion in Sect. 4). The fuel option shows the

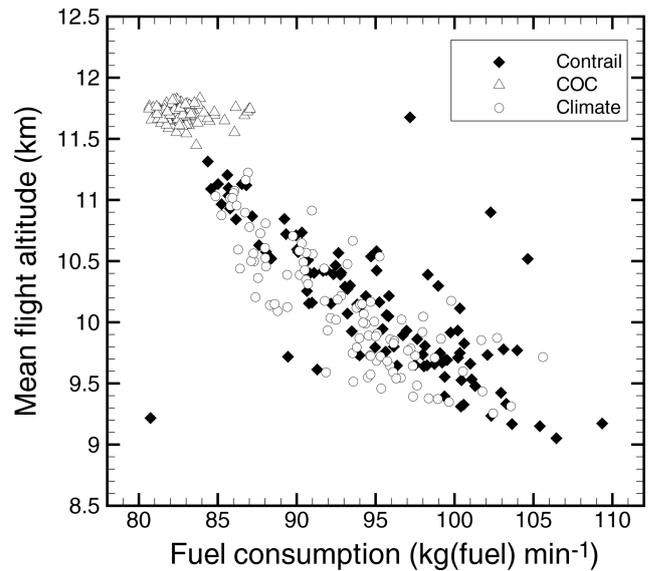

Figure 3. Mean fuel consumption vs. mean flight altitude for 103 individual flights obtained by the contrail formation, the COC and the climate impact routing options.

minimum fuel use of 3758.5 t. Of the nine routing options, the fuel (and also the H₂O), the NO_x, the SOC, and the COC options obtain similar values on all the measures (see also Supplement Fig. S4); these options show decreased fuel use, NO_x and H₂O emissions, SOC, and COC, whereas contrail distance and ATR20_{total} increase. The difference among these options is considered significant for airline operations and thus is discussed in more detail in Sect. 4. The contrail option shows the minimum contrail distance of 26.3×10^3 km and the second-lowest ATR20_{total} of 3.45×10^{-7} K, whereas the other measures increase considerably. This option allows aircraft to widely detour the potential contrail regions (because no constraint function is used in Eqs. 1 and 5; see below for more discussion). Thus, the flight distance, the flight time, and the fuel use increase drastically, which results in the increase of NO_x and H₂O emissions, SOC, and COC. In particular, the contrail option shows the highest COC of 5.99 million USD of the nine routing options. Comparing the contrail option with the COC option indicates that the contrail distance decreases with an additional fuel use of $8.3 \text{ kg(fuel)(km(contrail))}^{-1}$, i.e., the additional COC of $6.20 \text{ USD(km(contrail))}^{-1}$. The SOC and the COC options are comparable. The two options show similar values for all the measures and have the same minimum SOC of 3.96 million USD and COC of 5.35 million USD. In fact, the obtained optimum trajectories for those options are approximately the same (see Fig. 2c, d and Supplement Fig. S3k, l). This is because the objective function of the two options is a function of flight time and fuel, as defined in Eqs. (6) and (7). An interesting aspect of their performance measures is that both options do not correspond to the minimum

Table 4. The nine performance measures obtained from the 1d AirTraf simulations with different aircraft routing options (the values indicate the sum of 103 flights). The minimum values of each performance measure are marked with an asterisk; changes (in %) relative to the COC option are given in parentheses. Bar charts of the same data are given in Fig. S4 in the Supplement.

Routing option	Flight distance (10 ³ km)	Flight time (h)	Fuel use (t)	NO _x emissions (t)	H ₂ O emissions (t)	Contrail distance (10 ³ km)	SOC (million USD)	COC (million USD)	ATR20 _{total} (10 ⁻⁷ K)
Great circle	660.3* (-0.4)	757.4 (+0.1)	3979.1 (+5.8)	44.6 (+5.5)	4894.2 (+5.8)	154.9 (+19.1)	4.072 (+2.9)	5.463 (+2.1)	6.85 (+12.5)

SOC	663.2 (+0.02)	756.6 (+0.03)	3760.4 (-0.02)	42.2 (-0.1)	4625.3 (-0.02)	130.2 (+0.1)	3.959* (0.0)	5.349 (0.0)	6.02 (-1.1)
COC	663.1	756.4	3761.1	42.3	4626.2	130.1	3.959	5.349*	6.09
Climate impact	703.2 (+6.0)	801.4 (+5.9)	4474.0 (+19.0)	52.3 (+23.8)	5503.1 (+19.0)	92.6 (-28.8)	4.443 (+12.2)	5.874 (+9.8)	1.96* (-67.9)

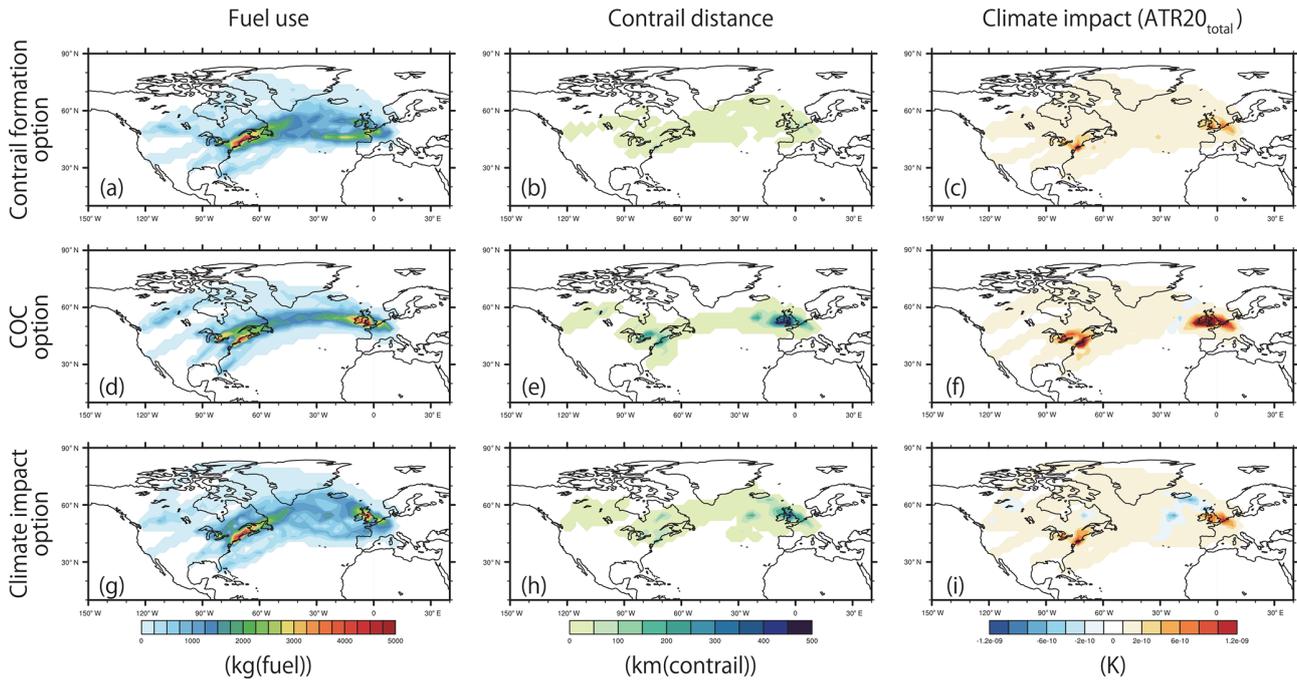

Figure 4. Vertically integrated distribution of fuel use, contrail distance, and climate impact indicated by $ATR20_{total}$ during the day (from 1 December 2015, 00:00:00 to 1 December 2015, 00:00:00 GMT). (a–c) Contrail formation option. (d–f) COC option. (g–i) Climate impact option. These distributions were obtained with the optimized flight trajectories shown in Fig. 2 (sum of 103 flights).

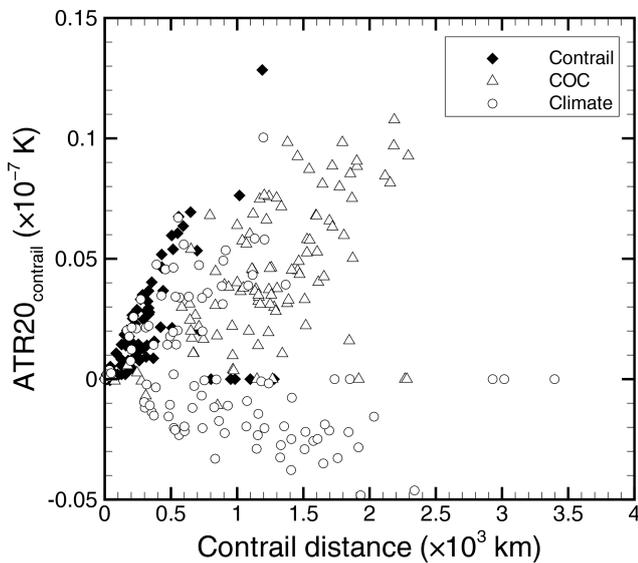

Figure 5. Contrail distance vs. $ATR20_{contrail}$ for 103 individual flights obtained by the contrail formation, the COC, and the climate impact routing options.

flight time and fuel use (see further discussion in Sect. 4). The climate option achieves the minimum $ATR20_{total}$ of 1.96×10^{-7} K and shows the second-shortest contrail distance of 92.6×10^3 km, whereas the other measures increase; this option in particular shows the second-highest COC of

5.87 million USD. The present results indicate that the contrail and the climate options considerably reduce the climate impact indicated by $ATR20_{total}$; however, these options increase COC. The cost–benefit performance (i.e., the COC increment per $ATR20_{total}$ reduction) for the contrail and the climate options are 0.24 and 0.13 million USD $(10^{-7} K)^{-1}$, respectively. Thus, the climate option seems to be a more cost-effective option. Note that this performance is a narrow result obtained using AirTraf 2.0 under specific conditions (e.g., the simulations were carried out with the 103 North Atlantic flights on 1 December 2015, as shown in Table 3). Figure 5 shows the contrail distance (in 10^3 km) vs. $ATR20_{contrail}$ (in 10^{-7} K) for individual flights for the contrail, the COC, and the climate options. We see that the contrail option decreases the contrail distance drastically and shows the positive values of $ATR20_{contrail}$ for almost all the flights. On the other hand, the climate option has longer contrail distances than those of the contrail option (although the climate option achieves the second-shortest total contrail distance, as shown in Table 4) and shows the negative values of $ATR20_{contrail}$ for many flights. These results imply that the contrail option minimizes the overall contrail distance at all times, whereas the climate option actively forms cooling contrails during the day and avoids the formation of warming contrails during the day and night. Finally, we believe that the climate benefits described above are most likely an upper limit because airspace congestion and air traffic management could reduce the flexibility for flights to perform these trajectory optimizations.

4 Discussion: verification of the 1 d AirTraf simulation results

This paper presents the extended version of the submodel AirTraf which offers additional aircraft routing options for defining overall target functions for the flight trajectory optimization. To confirm the consistency of AirTraf simulations, the relative changes in the performance measures among the routing options (listed in Table 4 in parentheses) are compared with previous studies. The quantitative values of the changes in the performance measures vary depending on different methodologies, atmospheric conditions, simulation periods, flight plans, aircraft/engine types, cost/climate impact metrics, etc. Thus, a direct comparison in magnitude of our results with published studies is difficult; the sign of the relative changes in the measures is compared. Note that the great circle and the time options have been verified before (Yamashita et al., 2016). In addition, the H₂O option yields the same results as the fuel option (see Sect. 2.5.3 and Table 4); the SOC option is comparable to the COC option (see Sect. 3.3 and Table 4). Thus, we omit any discussion of the H₂O and the SOC options here.

First, the time, the fuel, and the COC options are analyzed. As defined in Sect. 2.5.6, COC is a combined function of flight time and fuel. To minimize COC, one may attempt to reduce both factors simultaneously; however, a trade-off between the flight time and the fuel generally exists. Table 4 shows that the time penalty of flying minimum fuel trajectories is 2.4 percentage points, whereas the fuel penalty of flying minimum time trajectories is 20.3 percentage points. A similar trade-off was reported by two published studies. Celis et al. (2014) addressed a single-objective flight trajectory optimization on total flight time and fuel use under ISA conditions. A typical single-aisle aircraft (150 passengers) with twin turbofan engines was assumed; the aircraft speed and the flight altitude in eight flight segments were optimized for a given flight trajectory (a quasi-full flight profile optimization). Compared to the minimum time trajectory, the fuel optimum trajectory decreased the fuel use by 31.7 percentage points with an increased flight time of 14.0 percentage points. Rosenow and Fricke (2016) compared performances for the minimum time and the minimum fuel trajectories for a flight from Frankfurt (Main) to Dubai for a Boeing B777 freighter on 2 February 2016 at 12:00 GMT. The comparison showed that the fuel optimum trajectory decreased fuel use by 8.0 % with an increased flight time of 3.7 %. These studies imply that the minimum COC solution lies between the minimum time and the minimum fuel solutions. In fact, Table 4 shows that the COC option has more flight time than that of the time option and that the COC option consumes more fuel than that of the fuel option. The COC option yields the values of compromise (i.e., not minimum) of flight time and fuel. Nonetheless, this option achieves the minimum COC. The submodel AirTraf 2.0 can consistently differentiate those three solutions.

To support the discussion above, the fuel and the COC options are compared in detail. Erzberger and Lee (1980) compared the minimum fuel and the minimum direct operating cost (DOC) trajectories for a short-haul route for a Boeing 727-100 aircraft on the basis of optimum control theory (Bryson and Ho, 1969) under United States standard atmospheric conditions. They showed that flying “minimum fuel” reduced fuel use by 6.9 %, whereas the time and the DOC penalties of the trajectory were 23 % and 6 %, respectively (constrained thrust case). Our results in Table 4 show that the fuel option reduces fuel use by 0.1 %, whereas the time and the COC penalties of the option are 0.1 % and 0.03 % compared to those measures of the COC option. The signs of these relative changes obtained from our results agree with those shown by Erzberger and Lee (1980). In addition, the time and the COC options are compared in a perspective of airline operating economics. Although the time option increases fuel use, NO_x emissions, H₂O emissions, SOC, COC, and ATR20_{total} (fuel use and COC increase by 20.2 % and by 6.1 %, respectively), the option decreases flight time by 2.3 % compared to that of the COC option. In other words, the time option reduces flight time with the extra cost of 19 034.74 USD h⁻¹ (= 269.66 EUR min⁻¹, converted as 1 USD = 0.85 EUR on 18 September 2018; European Central Bank, 2018). In a context of delay recovery, this extra cost is the same order of magnitude to flight delay costs. If the flight delay costs exceed the extra cost due to the time option, operators would determine to fly faster by using the time option to recover the delay. Cook et al. (2004, 2009) reported that the flight delay costs, which are associated with delayed passengers, additional fuel use, flight crew, cabin crew, and marginal maintenance costs, reached several hundred Euros per minute. The extra cost calculated from our results agrees well with this report.

Compared to the COC option, the NO_x option decreases the NO_x emissions by 0.5 %, leading to a COC increase of 0.2 %. Mulder and Ruijgrok (2008) analyzed the effects of varying cruise conditions on NO_x emissions and on DOC from the cruise NO_x simulation model (Bremmers, 1999) by assuming a cruise range of 5800 km with a Boeing 747-400 aircraft under ISA conditions. They clearly concluded that a reduction of NO_x emissions caused a cost increase. Our results agree well with this conclusion. Moreover, the NO_x option differs from the fuel option because the amount of NO_x emissions depends not only on fuel use but also on the NO_x emission index, as defined in Eq. (3). The emission index depends strongly on the ambient atmospheric conditions at every waypoint (see Sect. 2.6 of Yamashita et al., 2016). Table 4 shows that the NO_x option decreases the NO_x emissions by 0.3 percentage points, whereas this option increases flight time by 0.2 percentage points and fuel use by 0.2 percentage points compared to those measures of the fuel option. Celis et al. (2014) addressed a single-objective flight trajectory optimization on total fuel use and on NO_x emissions with the same simulation setup described above. Com-

pared to the minimum fuel trajectory, the minimum NO_x trajectory decreased NO_x emissions by 10.4 percentage points, whereas the trajectory increased time by 1.0 percentage point and fuel use by 3.9 percentage points. The signs of the relative changes obtained from our results are in good agreement with those shown by Celis et al. (2014).

The contrail option drastically decreases contrail distance by 79.8 % and $\text{ATR}_{20\text{total}}$ by 43.4 %, whereas this option increases fuel use by 23.0 % and COC by 12.0 % compared to those measures of the COC option. The contrail option is effective in order to reduce the climate impact, as pointed out by previous studies introduced in Sect. 1. Here those relative changes in the measures are compared with two published studies. Rosenow et al. (2017) performed a 1 d European air traffic optimization on 25 July 2016. The total number of 13 584 flights over Europe (containing 16 aircraft types) was employed; their three-dimensional flight profiles were optimized for airline costs (termed as the cost performance indicators, CPI) and environmental impacts (termed as the ecological performance indicators, EPI). They revealed that an additional contrail avoidance intent decreased contrail costs by 31.5 % (contrail formations were converted into a monetary value) and EPI by 5.2 %, whereas the intent increased fuel use by 0.05 % and CPI by 0.5 % over those of the minimum cost strategy. The signs of the relative changes obtained from our simulations are consistent with those shown by Rosenow et al. (2017). Furthermore, Sridhar et al. (2013) applied a contrail reducing strategy to aircraft flying between 12 airport pairs (287 flights) in the United States on 12 April 2010. The three-dimensional contrail reducing strategy showed a trade-off between contrail formation time (time spent in traveling through contrail formation regions) and fuel consumption. Representative points on the trade-off curve showed that the contrail formation time decreased by 4415 and by 5301 min with an additional fuel use of 20 000 and of 131 000 kg (fuel), respectively, over those of a wind-optimal strategy (this strategy is regarded as an economically optimal strategy; see Sect. 2.4 of Yamashita et al., 2016). This study clearly indicated the fuel increase by avoiding contrail formations. Our results agree well with the finding of Sridhar et al. (2013).

Table 4 clearly shows a trade-off between economic cost and climate impact (see also Supplement Fig. S4). Compared to the COC option, the climate option decreases $\text{ATR}_{20\text{total}}$ by 67.9 % with an additional COC of 9.8 %. A similar trade-off certainly exists between the minimum COC and the minimum climate impact trajectories for each airport pair. The trade-off obtained from our results agrees with that indicated by many studies (see Sect. 1). Moreover, Niklaß et al. (2017) performed an aircraft trajectory optimization for nine North Atlantic flight routes varying weighting factors on average temperature response over 100 years (ATR_{100}) and on COC under ISA conditions. They showed a clear trade-off between the cost and the climate impact. The minimum climate impact trajectories, on average, reduced ATR_{100} by 28.4 %

with an additional COC of 7.1 % compared to those measures of the minimum COC trajectories. Our results agree with those shown by Niklaß et al. (2017). As discussed above, many previous studies corroborate the consistency of the AirTraf simulations.

5 Conclusions

We introduced updates to the air traffic simulation model AirTraf in the chemistry–climate model EMAC. The submodel AirTraf 2.0 was developed according to the MESSy standard and was described in detail in this paper. This submodel introduces seven new aircraft routing options for air traffic simulations: the fuel use, the NO_x emissions, the H_2O emissions, the contrail formation, the simple operating cost, the cash operating cost, and the climate impact options. Our flight trajectory optimization methodology consists of genetic algorithms; the methodology was similarly used and was validated beforehand (Yamashita et al., 2016). The particular strength of AirTraf is to enable a flight trajectory optimization for a global flight movement set in the atmosphere which is comprehensively described by EMAC. The novel routing option, i.e., the climate impact option, has been integrated in AirTraf 2.0. This option uses meteorological variables in terms of (spatially and temporally varying) aviation climate impact estimated by the aCCFs, and optimizes flight trajectories by minimizing their anticipated climate impact. As the aCCFs are new proxies for the climate-optimized routing, AirTraf takes a role in verifying the aCCFs themselves and the climate impact option based on the aCCFs in multi-annual (long-term) simulations.

To test the submodel AirTraf 2.0, example simulations were carried out with 103 North Atlantic flights of an Airbus A330 aircraft for a typical winter day. AirTraf 2.0 simulates the 1 d air traffic successfully for the newly developed routing option concerning different optimization objectives, e.g., contrail avoidance, cash operating cost, and climate impact (represented by average temperature response over 20 years) and finds the different families of optimum flight trajectories which minimize the corresponding objective functions. The characteristics of these routing options include that aircraft are flown as the minimum economic cost with both the SOC and the COC options. These options are comparably effective for economic cost indices. AirTraf 2.0 differentiates the minimum time, the minimum fuel, and the minimum COC options. The COC option lies between the minimum time and the minimum fuel options and thus minimizes COC by taking the best compromise between the flight time and the fuel use into account. The NO_x option minimizes NO_x emissions; this option differs from the fuel and the COC options. The contrail and the climate options decrease the climate impact (indicated by $\text{ATR}_{20\text{total}}$), which causes extra operating costs. A trade-off between the cost and the climate impact certainly exists. Compared to the COC option,

the climate and the contrail options decrease $ATR_{20_{total}}$ by 67.9 % and by 43.4 % with an increase of COC of 9.8 % and of 12.0 %, respectively. Thus, the climate option seems to be more effective on the cost–benefit performance than the contrail option. We believe that these climate benefits are most likely an upper limit. The simulation results were compared with literature data. The relative changes in the performance measures among the various routing options agree well with those shown by many previous studies. This comparison has limitations because of different methodologies, different atmospheric conditions, etc. Nonetheless, a lot of literature data offer evidence to indicate the consistency of the AirTraf simulations.

The integration of AirTraf into EMAC allows one to optimize flight trajectories and to study aircraft routings under historical, present-day, and future conditions of the climate system. We acknowledge that the simulation results depend on the atmospheric conditions of the target day. Thus, it is important to examine whether the findings, e.g., the trade-off between the cost and the climate impact, are common under any atmospheric conditions. Recently, Yamashita et al. (2020) examined this for representative weather types over the North Atlantic by using EMAC with AirTraf 2.0. Furthermore, the integrated aircraft routing options could be extended to conflicting scenarios. Yin et al. (2018a) investigated a trade-off between flight time and contrail formation for transatlantic flights by combining the time and the contrail options. Another option could easily be created by adding a corresponding objective function. The AirTraf development presented in this paper leads to a further detailed understanding of characteristics of various aircraft routing strategies.

Appendix A: The algorithmic climate change functions

The aCCFs are calculated by the submodel ACCF (version 1.0). The derivation and validation of the aCCFs of ozone, methane, and water vapor have been published by Van Manen (2017), Yin et al. (2018b), and Van Manen and Grewe (2019); the aCCF of contrails is described by Yin et al. (2020). The aCCFs for ozone, methane, water vapor, CO₂, and contrails are formulated as follows:

$$\text{aCCF}_{\text{O}_3} = \begin{cases} -5.20 \times 10^{-11} + 2.30 \times 10^{-13} T \\ + 4.85 \times 10^{-16} \Phi \\ - 2.04 \times 10^{-18} T \Phi, & \text{if } \text{aCCF}_{\text{O}_3} > 0, \\ 0, & \text{if } \text{aCCF}_{\text{O}_3} \leq 0, \end{cases} \quad (\text{A1})$$

$$\text{aCCF}_{\text{CH}_4} = \begin{cases} -9.83 \times 10^{-13} + 1.99 \times 10^{-18} \Phi \\ -6.32 \times 10^{-16} F_{\text{in}} \\ + 6.12 \times 10^{-21} \Phi F_{\text{in}}, & \text{if } \text{aCCF}_{\text{CH}_4} < 0, \\ 0, & \text{if } \text{aCCF}_{\text{CH}_4} \geq 0, \end{cases} \quad (\text{A2})$$

$$\text{aCCF}_{\text{H}_2\text{O}} = 4.05 \times 10^{-16} + 1.48 \times 10^{-16} |\text{PV}|, \quad (\text{A3})$$

$$\text{aCCF}_{\text{CO}_2} = 6.35 \times 10^{-15}, \quad (\text{A4})$$

$$\text{aCCF}_{\text{contrail}} = \begin{cases} 1.0 \times 10^{-10} (0.0073 \times (10^{0.0107T} - 1.03)) \\ \times 0.114, & \text{if } \text{Potcov} > 0 \text{ and nighttime,} \\ 1.0 \times 10^{-10} (-1.7 - 0.0088\text{OLR}) \times 0.114, \\ & \text{if } \text{Potcov} > 0 \text{ and daytime,} \\ 0, & \text{if } \text{Potcov} \leq 0, \end{cases} \quad (\text{A5})$$

where T is the atmospheric temperature (in K), Φ is the geopotential (in $\text{m}^2 \text{s}^{-2}$), F_{in} is the incoming solar radiation at the top of atmosphere (in W m^{-2}), PV is the potential vorticity (in PVU; $1 \text{ PVU} = 10^{-6} \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$), and OLR is the outgoing longwave radiation (in W m^{-2}). Given values of these meteorological variables, Eqs. (A1) and (A2) yield aCCF_{O_3} and $\text{aCCF}_{\text{CH}_4}$ (in $\text{K}(\text{kg}(\text{NO}_2))^{-1}$), Eqs. (A3) and (A4) yield $\text{aCCF}_{\text{H}_2\text{O}}$ and $\text{aCCF}_{\text{CO}_2}$ (in $\text{K}(\text{kg}(\text{fuel}))^{-1}$), and Eq. (A5) yields $\text{aCCF}_{\text{contrail}}$ (in $\text{K}(\text{km}(\text{contrail}))^{-1}$). The $\text{aCCF}_{\text{CO}_2}$ is the sole constant value (K. Dahlmann: Personal communication, 2018). The $\text{aCCF}_{\text{CO}_2}$ is calculated by using the nonlinear climate–chemistry response model AirClim (Grewe and Stenke, 2008; Dahlmann, 2012; Dahlmann et al., 2016) assuming a 1 Tg fuel use in 2010 with the annual

growth rate according to the future global aircraft scenario Fa1 (Penner et al., 1999). The $\text{aCCF}_{\text{CO}_2}$ is the averaged temperature response of CO₂ for the period 2010–2029 (in K per kilogram of fuel) calculated by AirClim. The $\text{aCCF}_{\text{contrail}}$ for the nighttime contrails takes positive values; if the temperature is less than 201 K, $\text{aCCF}_{\text{contrail}}$ for the nighttime contrails is set to 0. The $\text{aCCF}_{\text{contrail}}$ for the daytime contrails can take positive and negative values depending on the OLR (the threshold is -193.18 W m^{-2}). As for the time boundaries of day and night, the local time and solar zenith angle are calculated for locations where contrails could form ($\text{Potcov} > 0$). For locations in darkness, the time of sunrise is then calculated. If the time between the local time and sunrise is greater than 6 h, the $\text{aCCF}_{\text{contrail}}$ for the nighttime contrails is applied. If the contrail forms in daylight, or in darkness but with less than 6 hours before sunrise, the $\text{aCCF}_{\text{contrail}}$ for the daytime contrails is applied. These calculations are performed online in EMAC by the submodel ACCF. In AirTraf 2.0, those five aCCFs are calculated as flight properties for waypoints, and then the corresponding ATR20s are calculated for flight segments (see Table 2).

Code and data availability. AirTraf is implemented as a submodel of the Modular Earth Submodel System (MESSy). MESSy is being continuously developed and applied by a consortium of institutions. The usage of MESSy and access to the source code are licensed to all affiliates of institutions which are members of the MESSy Consortium. Institutions can become a member of the MESSy Consortium by signing the MESSy Memorandum of Understanding. More information can be found on the MESSy Consortium website (<http://www.messy-interface.org>). The submodel AirTraf 2.0 presented here has been developed on the basis of MESSy version 2.53 and has been available since the official release of MESSy version 2.54. The status information for AirTraf including the license conditions is available on the website. The data from the simulations will be provided by the authors on request.

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/gmd-13-4869-2020-supplement>.

Author contributions. HY, FY, and VG designed the submodel AirTraf 2.0. HY, FY, PJ, SM, and BK implemented the coupling of AirTraf 2.0 with the Modular Earth Submodel System (MESSy). FY, VG, SM, KD, and CF developed the algorithmic climate change functions (aCCFs). FY and VG designed the submodel ACCF. HY performed the simulations and analyzed the results presented in this paper.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This study was supported by the DLR project WeCare (Utilizing Weather Information for Climate Efficient and Eco Efficient Future Aviation) and Eco2Fly. The flight plan was provided by the European Union FP7 project REACT4C (Reducing Emissions from Aviation by Changing Trajectories for the Benefit of Climate; <https://www.react4c.eu/>, last access: 17 September 2020). We gratefully acknowledge the computational resources for the simulations which were provided by the Deutsches Klimarechenzentrum (DKRZ). We wish to acknowledge the valuable contributions of the Department of Meteorology at the University of Reading, especially Emma Irvine for her development of the aCCF_{contrail}. We also wish to acknowledge our colleagues, especially Robert Sausen for his support of the projects. We wish to thank Malte Niklaß for providing comparison data on the trajectory optimization. We wish to thank Duy Sinh Cai for his invaluable help with the model development. We would like to thank Anton Stephan for providing an internal review. We would like to express our gratitude to two anonymous reviewers for their helpful comments and discussion.

Financial support. This research has been supported by the European Union's Horizon 2020 program ATM4E (Air Traffic Management for Environment; <https://www.atm4e.eu/>, last access: 17 September 2020; grant no. 699395).
