Abstract

This paper introduces a transformer-based generative network for rapid parameter estimation of Modelica building models using simulation data from a Functional Mock-up Unit (FMU). Utilizing the `MixedAirCO2` model from the Modelica Buildings library, we simulate a single-zone mixed-air volume with detailed thermal and CO_2 dynamics. By varying eight physical parameters and randomizing occupancy profiles across 100 simulated systems, we generate a comprehensive dataset. The transformer encoder, informed by room temperature and CO_2 concentration outputs, predicts the underlying physical parameters with high accuracy and without re-tuning (hence, "zero-shot"). This approach eliminates the need for iterative optimization or can be used to warm-start such optimization-based approaches, enabling real-time control, monitoring, and fault detection in FMU-based workflows.

Keywords: transformer networks, dynamic simulation, system identification, model calibration, functional mockup interface, machine learning.

1 Introduction

Accurate modeling of building energy systems is critical for the design and operation of advanced control strategies such as model predictive control (MPC), fault detection, and digital twins (Zhan, Chakrabarty, et al. 2023). Physics-based modeling tools, such as those based on the Modelica language, offer a powerful framework for capturing the thermal, ventilation, and air quality dynamics of buildings through component-based system representations. However, the reliability of these models depends heavily on accurate parameter values, which can be challenging to determine in practice due to limited access to detailed building specifications, aging infrastructure, or changes in operational conditions over time (Chakrabarty et al. 2021; Wüllhorst et al. 2022).

Parameter estimation methods bridge this gap by calibrating model parameters to match observed output data. In the context of Modelica models exported as Functional Mock-up Units (FMUs) (Blochwitz et al. 2011), parameter estimation typically involves executing repeated simulations while adjusting model parameters to minimize the mismatch between simulation outputs and measured signals, such as temperature or CO_2 concentration. Classical approaches—including gradient-based optimization (Cañas et al. 2023), Bayesian calibration (Li et al. 2025), and black-box global optimization methods—have been successfully applied in this domain (Chakrabarty et al. 2021). Tools like RAPID (Vanfretti et al. 2016) provide modular ways to link external optimization routines to FMU simulations, supporting a range of problem formulations from gray-box modeling to model order reduction (Bres 2021). Despite their success, these methods can be computationally expensive, particularly when applied to large-scale simulation studies or real-time control tasks, due to their reliance on iterative optimization loops (Balali et al. 2023). Additionally, the authors of (Zhang and Mikelsons 2023) present a sensitivity-guided, iterative framework that combines BayesFlow and a physics-enhanced variational auto-encoder to improve parameter identification and data generation for model calibration. Their method enhances efficiency and accuracy by focusing on the most sensitive parameters during each iteration.

Herein, we study a fundamentally different paradigm: using transformer networks to learn the mapping from system outputs to model parameters directly from Modelica simulations. The idea is rooted in the principle that, for a well-defined family of parameterized models, there exists a functional relationship between the parameters and the corresponding output trajectories under typical excitation. By simulating a large number of such model instances offline, varying both physical parameters and disturbance conditions, we can train a transformer network to approximate the inverse mapping: from observed outputs back to the parameters that generated them. This multi-source parameter estimation has been investigated in the context of Modelica-based dynamical simulation only recently (Zhan, Wichern, et al. 2022; Li et al. 2025).

We focus on the use of transformer architectures, which have recently emerged as state-of-the-art tools for modeling sequential data in natural language processing, time-series forecasting, and symbolic regression (Vaswani et al. 2017). Transformer networks are a generative machine learning tool that excel at capturing long-range dependencies and temporal patterns, making them well-suited for analyzing

building simulation data, which often involves complex interactions between building materials and fluid flows, occupancy, and external weather conditions over extended time periods. Moreover, transformers have demonstrated impressive "zero-shot" capabilities: they often generalize well to entirely new forecasting or control tasks even without any additional fine-tuning. By leveraging pretraining on diverse datasets, they can transfer learned representations of temporal structure and physical dynamics to novel scenarios (such as predicting thermal loads in previously unseen building types or adapting to different climate conditions) simply by framing the problem in a compatible input format. This flexibility not only accelerates deployment in new environments but also reduces the need for costly labeled data when extending models to emerging use cases.

To evaluate our transformer-based approach to parameter estimation, we consider a simplified room-level building model implemented in Modelica and exported as an FMU. The model simulates the dynamics of air temperature and CO_2 concentration in a mixed-air volume, subject to external disturbances such as solar radiation and time-varying occupancy. Eight key physical parameters are varied across 2000 simulations: floor area, room height, room volume, external wall thermal resistance, window U-factor, window solar absorption fraction, exhaust air mass flow rate, and CO_2 emission rate per person. In each simulation, occupant presence schedules are also randomized to introduce realistic variability in internal gains. The output signals from each run—specifically, the room air temperature and CO_2 concentration—are collected at five-minute intervals for a full week, resulting in multichannel time series of high resolution. These serve as inputs to a patch-wise transformer encoder, followed by a multi-layer regression head that predicts the underlying parameter vector.

Compared to traditional parameter estimation methods, our approach offers two key advantages. First, it decouples the expensive optimization loop from the online estimation process. Once trained, the model can infer parameters from new output signals in a single forward pass, enabling rapid estimation that is suitable for time-sensitive applications such as adaptive control or live performance monitoring. Second, the neural network can leverage the full temporal structure of the input signals, including cross-channel correlations and delayed dependencies, which may be difficult to exploit effectively with handcrafted objective functions or scalar error metrics used in classical methods. While this approach does not replace traditional calibration frameworks, particularly in applications requiring safety-critical design, it offers a complementary tool for use cases where speed and scalability are paramount. Moreover, since the method is data-driven but trained entirely on simulated data, it mitigates the need for large amounts of real-world measurement data, making it practical in warm-starting optimization-based parameter estimation algorithms.

By integrating modern machine learning with established Modelica modeling workflows, this work aims to expand the toolkit available for building energy analysis, enabling faster, scalable, and data-informed modeling workflows for real-world systems. Specific contributions of this paper include: (i) proposing a transformer-based neural architecture for estimating physical parameters from building simulation output time series; (ii) demonstrating the effectiveness of zero-shot parameter estimation on a dataset generated using a Modelica FMU of a mixed-air room model, with randomized physical parameters and occupancy profiles, and (iii) empirical validation of the trained model, showing that it can accurately recover eight key physical building parameters that may vary as the building ages, or are difficult to measure, despite significant climate and occupant-induced variation.

The remainder of this paper is organized as follows. Section 2 formulates the parameter estimation problem and describes our FMU-based simulation model, including the `MixedAirCO2` benchmark, the procedure for exporting it as an FMU, and the generation of a large, randomized dataset for pretraining. Section 3 details the design of our patch-wise transformer encoder and regression head, including embedding, positional encoding, attention layers, and pooling strategy. Section 4 presents the experimental setup and results: we begin by assessing zero-shot estimation accuracy across a range of context lengths (:= sequences of measurement data collected for parameter estimation, to be used as contextual inputs for the generative network), then benchmark our transformer against non-transformer baselines to highlight the superiority of attention-based models in achieving robust zero-shot performance under varying data quantities. Section 5 summarizes our conclusions and outlines directions for future work, including extensions to probabilistic transformers for uncertainty quantification.

2 Motivation

2.1 Problem Statement

We consider a parameterized dynamical system represented by a Modelica-based Functional Mock-up Unit (FMU):

$$\mathbf{y}(t) = f(\mathbf{p}, \mathbf{d}(t), t), \tag{1}$$

where $\mathbf{p} \in \mathbb{R}^m$ is a vector of unknown physical parameters, $\mathbf{d}(t)$ denotes time-varying disturbances (e.g., occupancy-driven internal gains), and $\mathbf{y}(t) \in \mathbb{R}^n$ are the observable outputs over time such as indoor air temperature and CO_2 concentration. Our goal is to learn a parameter estimator $\hat{g}_\theta : \mathbb{R}^{T\times n} \to \mathbb{R}^m$ that maps output trajectories $\mathbf{y}_{1:T} = \{\mathbf{y}(t_1), \ldots, \mathbf{y}(t_T)\}$ to estimates of the underlying parameters. Formally, we write this as

$$\hat{\mathbf{p}} = \hat{g}_\theta(\mathbf{y}_{1:T}) \approx \mathbf{p}, \tag{2}$$

where θ denotes some parameterization of the map $\hat{g}$, e.g., weights of a deep neural network. We reiterate that unlike traditional optimization-based parameter estimation methods which solve an inverse problem for each new instance

DOI
10.3384/ecp218469

of contextual data $\mathbf{y}_{1:T}$, we propose to learn this mapping directly from synthetic data generated offline.

2.2 FMU-based Multi-Source Data Collection

We use an FMU extracted from the `Examples.MixedAirCO2` model from the Modelica `Buildings 11.0` library (Wetter et al. 2014) as the simulation model with default TMY3 file for meteorological data; see Figure 1 for the graphical layer representation in Dymola. This model represents a single thermal zone with a detailed energy and CO_2 balance, incorporating contributions from internal gains, air infiltration, ventilation, and weather-driven boundary conditions. The model includes thermal mass, surface convection and radiation, and moisture dynamics, making it: (i) representative of building simulation use cases, and (ii) easily extendable to multi-zone office buildings.

The zone is served by a mixing box that supplies outdoor air and recirculated return air based on a CO_2-based control strategy. To perform parameter estimation under realistic operating conditions, we utilize closed-loop data, where the PI controller remains active with gain constants carefully tuned to balance tracking performance and disturbance rejection. We also add small-gain sinusoids to the control action in order to provide some excitation for the inputs. We already know that the outputs are sufficiently sensitive to the persistently exciting inputs and will induce persistently excited outputs that we will use for learning. This configuration preserves feedback actuation, as evident from the Fig. 1, and allows the system's response to exogenous inputs (e.g., occupancy profiles, weather disturbances, and internal loads) to be interpreted in the context of both the building's physical properties and the control dynamics. This setup is not only realistic, but the identification problem is challenging because of varying occupancy profiles and weather conditions.

The physical parameters varied in each simulation are summarized in Table 1. Each parameter is sampled uniformly within the specified range. Each simulation spans 1 year of operation, sampled every 60 minutes (3600 seconds), resulting in $T = 8760$ time steps per simulation. The output signal at each time step is the room air temperature T and the CO_2 concentration: $\mathbf{y}(t) = \begin{bmatrix} T(t) & CO_2\,(t) \end{bmatrix}$.

Occupant-driven internal gains are also randomized by varying: (i) occupant count (persons), (ii) start time and duration of occupancy, (iii) daily schedules. However, occupant information is not provided to the model at inference time, reflecting practical limitations.

2.3 FMU Export Procedure

To enable parameter estimation using external (to Modelica) optimization tools, we export the `MixedAirCO2` model as a functional mock-up unit (FMU) using Dymola 2024 (Dassault Systèmes 2023). The following steps summarize the FMU export process:

1. CONTROL CONFIGURATION. We disable the internal PI CO_2 controller.

2. PARAMETER EXPOSURE. Key physical parameters targeted for estimation are re-declared as `input Real` variables within the Modelica model. This allows external modification during estimation without having to continuously recompile the FMU.

3. SOLVER AND TIME SETTINGS. Simulation is configured for a 1-year period with a storage step size of 1 hr to match the measurement data resolution. The CVODE solver (Cohen, Hindmarsh, Dubois, et al. 1996) is selected for robust handling of stiff system dynamics during FMU export and tolerances and solver step-sizes are set to default.

4. FMU GENERATION. The FMU is generated using Dymola's `Advanced` menu with the following settings:

   - FMI version: `2.0`
   - FMI type: `Model Exchange`
   - Solver: `CVODE`

5. VERIFICATION. The resulting FMU is validated using `fmpy`[1] in Python 3.11 to confirm correct loading, access to exposed parameters, and consistency of simulated outputs with the original Modelica model under default disturbance input profiles.

In summary, this export procedure ensures that the physics-oriented Modelica model is encapsulated in a reusable and differentiable FMU format, suitable for integration with external state-of-the-art deep learning tools for which widespread Modelica support at the time of writing remains limited.

2.4 Multi-Source Dataset and Dataloader

Figure 2 presents multiscale building simulation outputs: daily temperature cycles with subtle day-to-day shifts, sharp occupancy-driven internal-gain spikes, multi-day ambient-temperature fronts, and a nonlinear, saturating heating response. This highlights the complex disturbances and actuator dynamics that make parameter estimation challenging.

The collected dataset is split into training (80 systems with uniquely sampled parameters), validation (10 systems), and test sets (10 systems). Channel-wise normalization is applied based on the training data statistics. During evaluation, model accuracy is assessed by comparing predicted parameter vectors $\hat{\mathbf{p}}$ to ground truth vectors $\mathbf{p}$ over the test set. We found it easier to work with logarithmic transforms of the parameters than the parameters themselves due to their values showing varying orders of magnitude.

Table 1. Physical parameters varied in simulation experiments. Each parameter is sampled uniformly within the specified range.

Parameter Name	Description	Unit	Range
`gaiCO2.k`	CO_2 emission rate per person	kg/s	$[6 \times 10^{-6},\ 1.2 \times 10^{-5}]$
`roo.AFlo`	Floor area	m^2	[60.0, 200.0]
`roo.hRoo`	Room height	m	[2.5, 4.0]
`roo.V`	Room volume	m^3	[40.0, 300.0]
`matExtWal.R`	External wall thermal resistance	$K \cdot m^2/W$	[0.5, 3.0]
`glaSys.UFra`	Window U-value	$W/m^2 \cdot K$	[1.0, 3.0]
`glaSys.absSolFra`	Window solar absorptance	–	[0.3, 0.7]
`mOut_flow`	Exhaust air mass flow rate	kg/s	[0.05, 0.5]

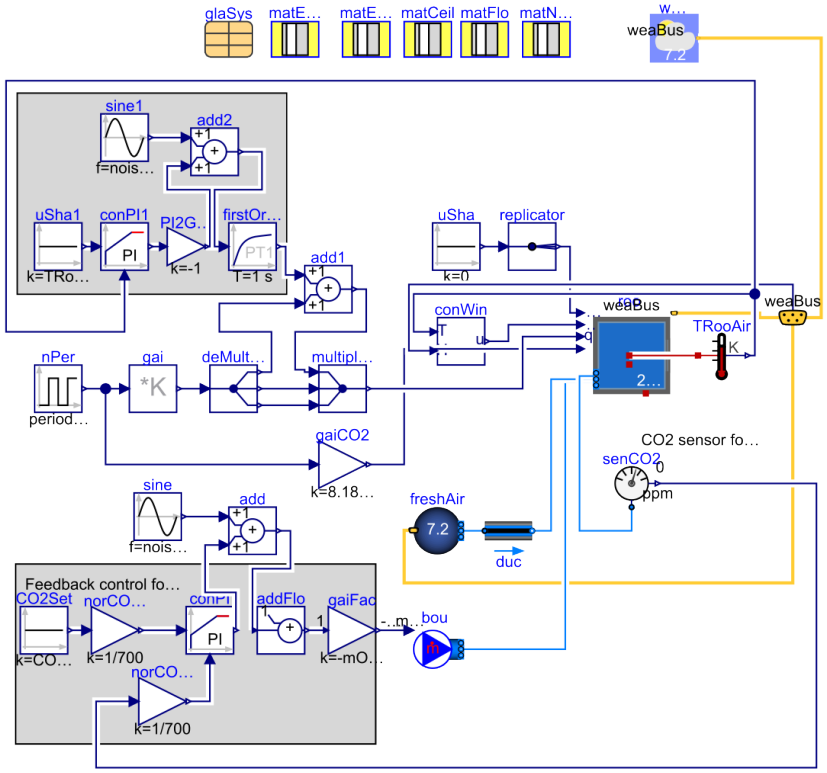

Figure 1. Graphical representation of adapted `MixedAirCO2.mo` model from Modelica `Buildings` Library, with additional PI control loop closed on room air temperature.

Data loading is implemented via `PyTorch 2.0`'s custom `Dataset` class that wraps the full collection of multivariate time-series records and their corresponding target vectors. Rather than returning entire sequences, the `Dataset`'s length is defined by a "virtual epoch" size, and each call to `getitem` randomly selects one series and then extracts a contiguous subsequence of fixed length from it. This subsequence is returned together with the associated target vector. By sampling both the series index and the time-window start position at each access, the `Dataset` generates a diverse set of training examples each epoch without explicit shuffling. We then wrap this `Dataset` in a standard `DataLoader` with a chosen batch size, yielding batches of subsequences and targets for efficient mini-batch training. Randomization inside the `Dataset` ensures variety in each batch.

More concretely, given contextualizing measurement inputs $\mathbf{Y} \in \mathbb{R}^{Q \times T \times n}$ and static outputs $\mathbf{P} \in \mathbb{R}^{Q \times m}$ across Q systems, each training sample is constructed as follows:

1. A system index $q \in \{1, \ldots, Q\}$ is drawn uniformly at random.
2. A start index $t_0 \in \{0, \ldots, T - L\}$ is sampled uniformly.
3. A temporal window $\mathbf{y}_{q,t_0:t_0+L-1} \in \mathbb{R}^{L \times n}$ is extracted.
4. The target is the corresponding output vector $\mathbf{p}_q \in \mathbb{R}^m$.

The dataset returns tuples $(\mathbf{Y}, \mathbf{P})$ with fixed window length L and configurable epoch size M.

10.3384/ecp218469

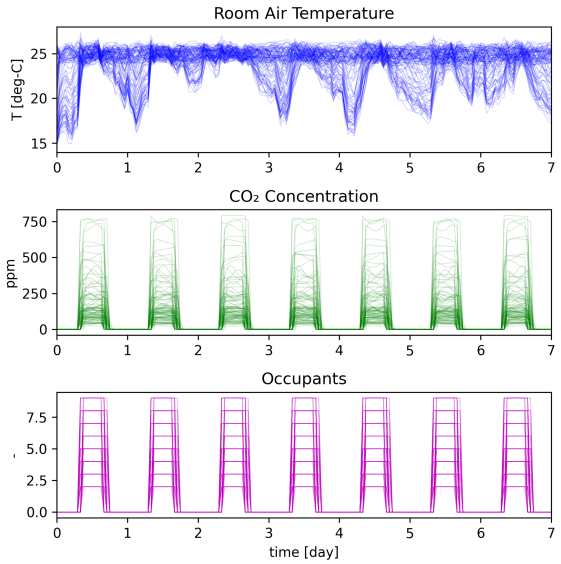

Figure 2. Example multi-system simulation outputs from FMU over one week; with loops closed on carbon dioxide and room air temperature. The outputs have been induced by time-varying disturbances, including fluctuating internal gains, multi-day ambient temperature fronts, and heating power responses.

3 Transformer-Based Parameter Estimator

We employ a patch-wise transformer encoder for parameter estimation from multivariate time series, followed by a deep multilayer perceptron (MLP) head for final prediction. The full architecture is referred to as the *patch transformer*, and is composed of five main components:

1. PATCH EMBEDDING. The input time series $\mathbf{Y} \in \mathbb{R}^{B\times T\times n}$ is separated into patches by a 1-D convolution: $\mathbf{z}_0 = \text{Conv1D}_{\text{stride}=\ell_p,\text{kernel}=\ell_p}(\mathbf{Y}^\top)$, where ℓ_p is the patch size and T is the sequence length. This transforms the input to $B \times (T/\ell_p) \times d$.

2. POSITIONAL ENCODING. A sinusoidal positional encoding $\mathbf{e} \in \mathbb{R}^{T/\ell_p \times d}$ is added to the patch embeddings, providing temporal awareness.

3. TRANSFORMER ENCODER BACKBONE. A stack of L standard transformer encoder layers as described in (Vaswani et al. 2017), each with H attention heads and feedforward width d_{ff}, processes the sequence $\mathbf{z}_L = \text{TransformerEnc}(\mathbf{z}_0 + \mathbf{e})$.

4. GLOBAL POOLING. A global average pooling layer aggregates the token outputs:

$$\mathbf{h} = \frac{1}{T/\ell_p} \sum_{i=1}^{T/\ell_p} \mathbf{z}_L^{(i)}.$$

5. REGRESSION HEAD. A MLP with LeakyReLU activations and LayerNorm at the input maps the pooled embedding to the target vector $\hat{\mathbf{p}} \in \mathbb{R}^{B\times m}$.

Our patch transformer is inspired by the Patcher model introduced in (Ou et al. 2022), which employs a patch-wise transformer encoder. Unlike the Patcher model, we replaced the mixture-of-experts decoder with a regression head, which is simply composed of fully connected layers.

The hyperparameters used in the patch transformer estimator are listed in Table 2. We did not perform extensive hyperparameter search, and expect that a smaller network will likely suffice if optimized by Bayesian neural architecture search (Nasrin et al. 2022) or an automated tool like Optuna (Akiba et al. 2019). All linear and convolutional layers are initialized using Xavier normal initialization (Glorot and Bengio 2010). Biases are zero-initialized.

Table 2. Patch Transformer Hyperparameters

Hyperparameter	**Value**
Input channels C	2
Patch size ℓ_p	12
Embedding dimension d	64
Number of Transformer layers L	4
Number of attention heads H	8
Feedforward dimension d_{ff}	256
Dropout	0.2
Output dimension d_{out}	8
Activation	LeakyReLU(α=0.2)
Positional Encoding	Sinusoidal (fixed)
Pooling	Global average pooling

The patch transformer parameter estimator combines localized feature extraction and global sequence modeling, which is critical for capturing the complex temporal dynamics inherent in multivariate time series from building systems. Patch embedding via 1D convolution reduces sequence length and emphasizes local temporal correlations, while the transformer encoder captures long-range dependencies using self-attention, avoiding the limitations of recurrence-based methods. The use of sinusoidal positional encoding preserves temporal order, and global average pooling enables efficient dimensionality reduction and regularization. A deep MLP regressor maps the aggregated latent representation to parameter estimates, allowing flexible modeling of non-linear, non-convex mappings typical in grey-box system identification.

Compared to alternatives, this architecture provides several advantages. Unlike RNN-based models (e.g., LSTM, GRU), it enables full parallelization during training and better handles long-range dependencies without gradient degradation. CNN-only approaches lack adaptability to temporal variation, and MLPs trained on raw sequences fail to encode temporal structure. The transformer's ability to dynamically attend across patches, combined with the efficiency of patch-wise tokenization, makes it more expressive and scalable. This inductive bias, along with its modular structure, is expected to offer improved accuracy and robustness over conventional baselines for zero-shot parameter estimation in building energy models.

4 Results and Discussion

All experiments were conducted on a MacBook Pro equipped with an Apple M3-Max system-on-a-chip featuring 16 cores (12 performance cores and 4 efficiency cores) and 64 GB of unified memory. Training on CPU for the patch transformer required between 1-2h. The Adamax optimizer is used for training with a learning rate of 0.001 for 2000 training iterations, the batch size is $B = 16$.

4.1 Test Setup

We evaluate the trained transformer regressor on held-out time–series snippets drawn from the same one-year simulation of 100 independent systems. Each snippet spans a fixed "context window" of length L (in hours), chosen from $\{24, 48, 96, 168, 360, 720\}$. For each L:

1. We randomly sample $N_{\text{win}} = 1000$ disjoint windows of length L from the full dataset, forming a *test* subset.

2. The network (whose inputs had been normalized and whose outputs were predicted in base-10 logarithmic scale) is applied in inference mode to each window, yielding $\widehat{\mathbf{p}}_{\log 10}$. We recover physical parameter estimates by
$$\widehat{\mathbf{p}} = 10^{\widehat{\mathbf{p}}_{\log 10}}.$$

3. The true parameter vector $\mathbf{p}$ for each system is likewise converted from $\log_{10}$ back to the original units.

4. We compute two metrics over the test set:

   - The coefficient of determination for each parameter
   $$\mathsf{R}^2 = 1 - \frac{\sum_{i=1}^{N_{\text{win}}} \left(p_i - \widehat{p}_i\right)^2}{\sum_{i=1}^{N_{\text{win}}} \left(p_i - \bar{p}\right)^2},$$
   where $\bar{p}$ is the sample mean of the true values.
   - The relative accuracy for each estimate,
   $$\mathsf{A}_i = 1 - \frac{\left|p_i - \widehat{p}_i\right|}{p_i}, \tag{3}$$
   which is 1 for a perfect match and is smaller as the absolute relative error grows.

4.2 Patch Transformer Results

In Fig. 3, we test the quality of the outputs generated by the FMU over 21 days. We first use 7 days as an input to the transformer model, as illustrated by the blue trace, and from this infer a set of predicted parameters for the model. Note that for this test we switch off persistently exciting noise on the controls to promote realism. By simulating with the predicted parameters for the 14 days after the 7 days of context input, we see that the error in the predictions is small, as is evident by the overlap between the orange dashed predicted trajectory and the blue solid true trajectory. Figure 4 presents scatter plots comparing predicted versus true values for eight key parameters of a thermal building model under varied contextual inputs. Each subplot corresponds to a distinct physical parameter. Red dots denote individual predictions, while the solid black line indicates the ideal identity mapping (i.e., perfect prediction). Each subplot reports the coefficient of determination (R^2) to quantify regression accuracy. The model demonstrates excellent predictive performance ($\mathsf{R}^2 \geq 0.95$) across most parameters, with only a modest drop in performance for the room height. The relatively lower score likely arises from its weaker influence on the observable outputs used for inference. Unlike parameters such as floor area or ventilation mass flow rate, which directly impact air volume exchange and thermal load profiles, room height has a more indirect effect, primarily through its contribution to overall room volume and stratification effects, which may not be strongly expressed in the measured outputs (e.g., temperature, CO_2 levels) under the simulation conditions. Additionally, identifiability may be confounded when both area and height jointly influence volume, making it difficult for the model to disentangle their individual contributions. This leads to a higher spread in predicted values for room height and hence a lower R^2 score. Overall, these results validate the model's high-fidelity parameter inference capability across diverse building configurations.

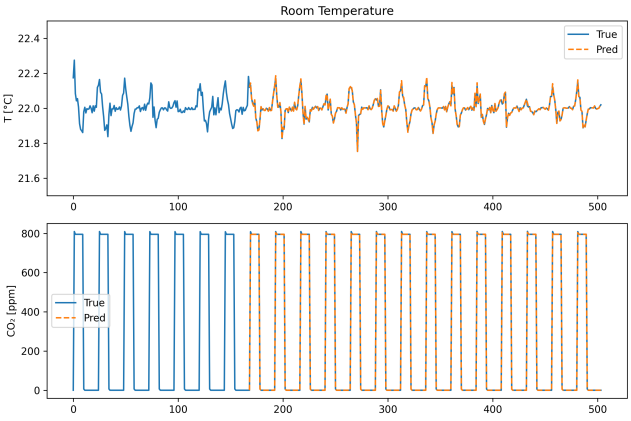

Figure 3. Predicted (orange) vs. true (blue) simulated outputs with a 7-day context set of measurements, and 14-day predictions.

Figure 5 presents boxplots of relative accuracy (3) for each parameter, evaluated over context windows of 1, 2, 4, 7, 15, and 30 days. Each box illustrates the interquartile range of relative accuracy across all test samples, with the median indicated by a horizontal line. As context length increases, inference accuracy improves consistently across all parameters, with median values approaching 1.0 and reduced variability. This trend is especially pronounced between 1 and 7 days, after which gains begin to saturate. Parameters such as exhaust mass flow rate (`mout.flow`) and CO_2 generation rate (`gaiCO2`) exhibit high identifiability even with short contexts, reflecting their strong observability through direct influence on air quality dynamics. In contrast, geometric and envelope-related parame-

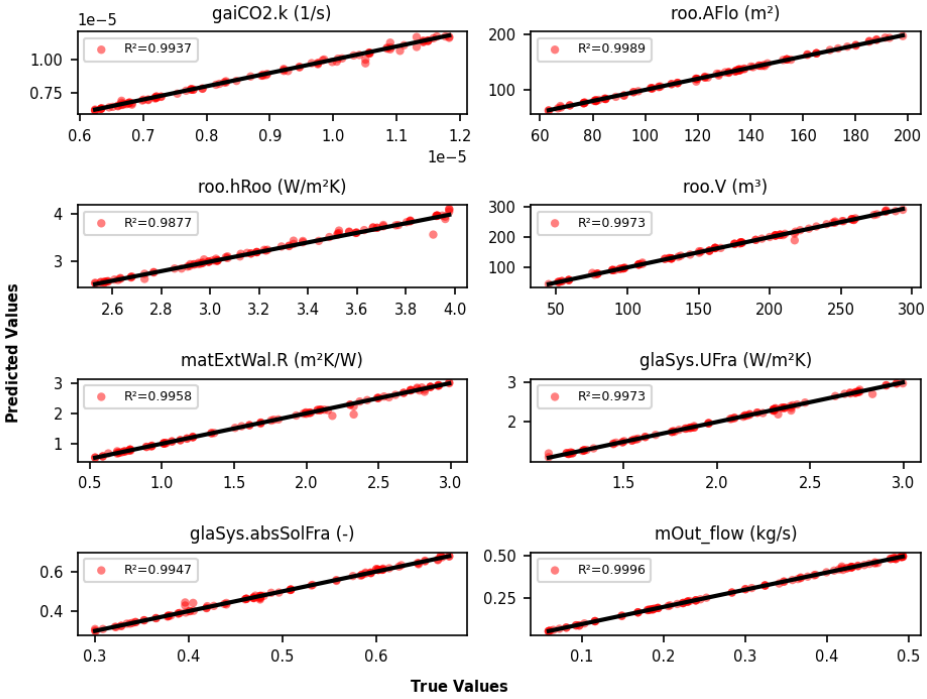

Figure 4. R^2 scatter plots (true vs. predicted) for each parameter, with 48 hr context windows.

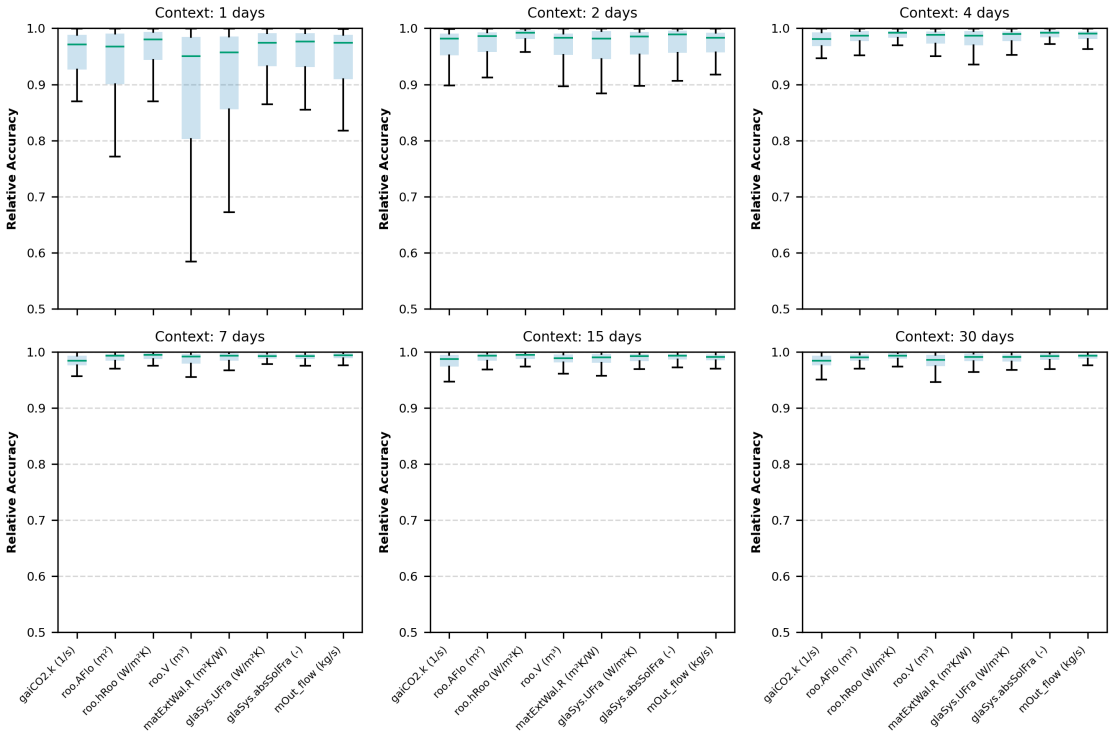

Figure 5. Boxplots of relative accuracy (3) versus context length.

ters (e.g., wall resistance `matExWal.R`, window U-factor `glsys.Ufrc`) benefit more from longer observation periods due to their slower thermal dynamics, indirect influence on measurable outputs, and entanglement with other physical properties. These factors lead to broader variance and reduced accuracy under short contexts. A 7-day context window offers a practical trade-off: it is short enough for deployment during commissioning while long enough to recover key physical parameters with high fidelity. This balance maximizes data efficiency and supports robust ini-

tialization of physics-based optimization routines in real buildings.

Table 3. Per-parameter R^2 on the test set for different transformer patch sizes for $N_{\text{win}} = 100$ parameter estimates.

Parameter	Patch 4	Patch 12	Patch 24
`gaiCO2.k`	0.9977	0.9947	0.9888
`roo.AFlo`	0.9989	0.9985	0.9975
`roo.hRoo`	0.9802	0.9979	0.9698
`roo.V`	0.9966	0.9982	0.9942
`matExtWal.R`	0.9850	0.9991	0.9913
`glaSys.UFra`	0.9950	0.9976	0.9931
`glaSys.absSolFra`	0.9976	0.9983	0.9949
`mOut_flow`	0.9997	0.9997	0.9997

In Table 3, we perform an ablation on the patch size of the proposed patch transformer; 1000 inputs are tested and the corresponding R^2 score is calculated. Overall, the network seems to be quite robust to patch-size selection. All three patch sizes deliver excellent predictive accuracy, with every parameter achieving $R^2 > 0.9$. The best performance in terms of average R^2 score across the paramaters is found with a patch size of 12, indicating it best balances capturing both fine-scale fluctuations and longer-range dependencies. Make the patch size smaller seems to improve estimates on more sensitive parameters such as `mOut_flow` and `gaiCO2.k` but shows poorer performance on the slower thermal dynamics (e.g. `matExtWal.R`). This trade-off suggests that very small patches lack sufficient context for slowly changing parameters, while very large patches dilute high-frequency signals. Note that a patch size of 12/24 corresponds to a 12h/24h window, which neatly aligns with the dominant diurnal cycles in building thermal and occupancy patterns. Smaller patches (4h) capture only very local fluctuations, leading to weaker performance. Consequently, a 12/24 patch size is recommended for uniformly high fidelity across all eight physical parameters.

4.3 Performance Comparison

We compare our patch transformer approach to two well-established time-series models: LSTM (Long Short-Term Memory) and TCN (Temporal Convolutional Network).

LSTM is a recurrent neural network variant designed to capture long-term dependencies in sequential data (Hochreiter and Schmidhuber 1997). It remains a common baseline for temporal modeling tasks due to its ability to handle variable-length inputs and learn from sequences with temporal correlations. We include LSTM as a representative of RNN-based architectures, which are widely adopted in forecasting and control settings.

In comparison, TCN is a convolutional alternative to RNNs that uses dilated causal convolutions to model temporal dependencies over long horizons (Lea et al. 2017). TCNs are attractive for their parallelizability, stable gradients, and competitive performance across time-series benchmarks. Their ability to capture hierarchical temporal structure without recurrence makes them suitable non-transformer baselines.

Table 4 summarizes the R^2 scores (mean and standard deviation) across models for varying context lengths. Overall, the Patch Transformer consistently outperforms both LSTM and TCN at short and medium horizons, validating its architectural design and inductive biases for learning from fine-grained temporal patterns.

Table 4. Performance comparison with TCN and LSTM.

Context	Model	Mean R^2	Stdev R^2
1 day	Our Transformer	0.8694	0.0818
	LSTM	-0.0284	0.4489
	TCN	0.0327	0.9633
3 days	Our Transformer	0.9679	0.0263
	LSTM	0.4266	0.2208
	TCN	0.4784	0.2382
7 days	Our Transformer	0.9669	0.0222
	LSTM	0.9664	0.0221
	TCN	0.6244	0.1410

At a short context length of 1 day, the transformer yields a mean R^2 of 0.8694, significantly outperforming LSTM and TCN, both of which under-perform with lower or even negative R^2 values. This highlights the transformer's superior capacity for modeling local dependencies via learned attention over patched segment: often, neither RNNs nor standard convolutions excel at this without larger receptive fields. At a medium context length (3 days), the performance gap improves, with our patch transformer achieving 0.9679, which is over double that of LSTM and TCN. This suggests that as the context window increases modestly, the transformer is uniquely capable of integrating more history without degradation, due to its global receptive field and ability to capture complex inter-dependencies. For a long context (7 days), both the transformer and LSTM perform similarly well, but the transformer's slightly higher mean and lower standard deviation suggest more stable generalization across samples. Notably, TCN remains behind, despite its design for long-range patterns, likely due to the difficulty of effectively tuning dilation rates and convolutional depths for diverse input dynamics.

Overall, our patch transformer-based regressor consistently outperforms or ties the strongest recurrent baseline across all tested window sizes. Its patch embeddings and self-attention mechanism enable more efficient contextual aggregation, particularly in low-data regimes (short windows), justifying its adoption for parameter regression tasks where context length may vary.

5 Conclusions

In general, the process of calibrating the parameters of physics-based models to experimental data often requires a large number of simulations to iteratively refine the parameters so that the model response matches the observations. Moreover, the number of simulations needed typically increases very quickly with the number of parameters being

DOI
10.3384/ecp218469

estimated, making this process quite time consuming. In comparison, this transformer-based approach enables the generation of parameter estimates directly from a set of experimental data in a zero-shot manner without the need for expensive iteration. This method uses offline simulation effectively in a massively parallel context during the training period to shift the burden of simulation from the time after data is collected to the time after the model is constructed. As engineers often desire information as soon as possible once experimental data is in hand, this is an attractive shift.

Furthermore, the proposed method shows strong promise as a warm-start initialization method for gradient-based parameter calibration algorithms when there is a significant simulation-to-real gap or further refinement of the values generated by the transformer-based method is desired. In many physical modeling settings, accurate initial guesses are critical for successful convergence of non-convex optimization routines. However, deriving such guesses analytically or heuristically is often infeasible. The transformer network helps fill this gap by rapidly providing good initial estimates that improve robustness and reduce computational overhead in subsequent calibration tasks.

We also demonstrate that this transformer-based architectures generalizes more effectively than conventional LSTM and TCN models when estimating system parameters from time-series data, particularly under conditions with limited temporal context. By leveraging the self-attention mechanism, the transformer can infer model parameters using significantly shorter time windows, thereby overcoming a longstanding limitation in traditional calibration tasks which typically require extensive input data for accurate estimation. This is especially beneficial for applications where measurement data is sparse or costly to collect.

As a promising direction for future work, we propose extending this approach to probabilistic transformers. This would allow the model to not only predict point estimates but also provide uncertainty quantification in the form of distributions over possible parameter values. Such capability could be instrumental in probabilistic calibration frameworks, for which prior distributions over parameters are required; e.g. Bayesian calibration.

Abstract

The development of Cyber-Physical Systems, particularly in the field of autonomous mobile robotics, often relies on proprietary environments, which limit flexibility and interoperability. This paper proposes a modular and open-source methodology that enables the modeling and simulation of such systems using non-proprietary tools. The methodology integrates Functional Mock-up Interface standard for model exchange, Open Neural Network Exchange standard for Convolutional Neuronal Networks algorithms integration, ROS2 as robotic middleware, and Gazebo as the simulation environment. To validate the approach, we applied it in the development of a mobile robot that navigates autonomously by following traffic signals. This implementation demonstrates that these open technologies can be effectively combined, overcoming common integration barriers among proprietary tools. The proposed workflow provides a practical alternative to proprietary solutions and demonstrates the feasibility of integrating open standards for the development of autonomous robotic systems. *Keywords: Autonomous robotic systems, FMI, ONNX, ROS2, Gazebo.*

1 Introduction

Model-Based Engineering (MBE) has transformed the way engineers and researchers design and develop complex systems (Holtmann, Liebel, and Steghöfer 2024). It is a strategy intended to reduce development time and to improve the quality of the system. To this end, the reuse of models and tests is promoted, thus avoiding iterative manual work and optimising the testing phase. Today, both industry and academia rely on MBE to predict system behavior, reduce the need of expensive physical prototypes, and drive advances in mobile robotics (Amorim 2019). At the same time, Convolutional Neural Networks (CNNs) are being increasingly applied in these systems, particularly for handling image processing tasks that support robot navigation and decision-making (Javaid et al. 2023).

Nowadays, many developments in robotics rely on commercial tools and proprietary platforms. While these tools offer powerful capabilities, their high cost and limited interoperability often restrict innovation (Haessler, Giones, and Brem 2023), increasing the demand for open-source alternatives that provide more flexible and accessible solutions.

In this context, the Modelica Association plays a key role in promoting and maintaining open standards for Cyber-Physical System (CPS) development, such as the Modelica Language for modeling dynamic systems and the Functional Mock-up Interface (FMI) (Modelica Association 2025) for ease the model exchange and co-simulation between different modeling and simulation (M&S) tools. These tools enable the development of complex systems, allowing for predictive modeling before physical prototyping, thus, reducing costs and minimizing development risks (Moshood et al. 2024). The integration of mathematical models with computer simulations has become a critical factor in ensuring the reliability and performance of modern systems (Idoko et al. 2024). However, applying these M&S capabilities to modern robotics frameworks is not exempt from challenges (Ray and Ramirez-Marquez 2020).

Regarding the evolution of robotics middleware, ROS2 emerged as a leading development framework for robotic applications. Particularly, ROS2 Humble (Open Robotics 2025b) offers enhanced features, including improved capabilities, robust security measures, and better support for multi-robot systems. When combined with advanced simulation environments like Gazebo (Open Robotics 2025a), it enables the validation of control algorithms and vision systems in realistic scenarios. However, the integration of Modelica-based models with these robotics frameworks remains challenging (Bardaro et al. 2017).

Additionally, the use of CNNs introduces a new set of challenges for systems based on traditional M&S approaches. As AI-based perception becomes increasingly relevant in CPSs, developers face the need to integrate machine learning and deep learning models into existing robotics and control workflows. The Open Neural Network Exchange (ONNX) (ONNX community 2025) standard addresses part of this challenge by offering a common, open format for representing and deploying trained neural networks across different platforms. However, the seamless integration of AI models in simulation tools,

robotic middleware, and control systems remains an area of active research. This highlights the need for flexible and modular development methodologies that can facilitate the integration of AI capabilities into CPSs (Parwej 2024).

In summary, our research addresses these integration challenges by proposing an open-source methodology that uses:

- FMI standard for exchanging validated physical models via FMUs.
- ONNX standard for exchanging AI-validated models for image processing.
- ROS2 Humble as robotics middleware.
- Gazebo for 3D simulation.

By focusing on the integration of these non-proprietary components, our methodology offers a cost-effective, modular, and interoperable solution for the development of CPS, focusing in autonomous mobile robotics. This approach not only ensures effective communication between control algorithms, vision processing, and physical simulation while laying the foundation for future improvements in adaptive and AI-driven robotic systems.

The paper is organized as follows: Section 2 reviews the background and related work; Section 3 details the methodology and its architecture; Section 4 describes the proof of concept used to implement and demonstrate the proposed methodology, specifically focusing on the integration of 3D simulation, control, and image processing components; Section 5 presents the results and their implications; and Section 6 concludes with final remarks and directions for future research.

2 Background and Related Work

The integration of simulation, control, and image processing has become essential in developing modern robotic systems (Nevliudov, Tsymbal, and Bronnikov 2021). Recent open-source tools and integration developments have enabled innovative approaches for designing and validating complex systems (Santos et al. 2024; Robles, Martín, and Díaz 2023). However, ensuring seamless integration between the different components is still difficult. This section examines key technologies and related work, highlighting current limitations and opportunities for improvement in simulation in MBE, open-source tools in robotics, model exchange using FMI, and the integration of AI models through ONNX in robotic applications.

2.1 Simulation in Model-Based Engineering

MBE utilizes models as central tools to understand, design, and manage complex systems. This methodology enables effective analysis, early detection of potential issues, and improved efficiency through clear, structured information exchange (Holtmann, Liebel, and Steghöfer 2024). MBE supports critical tasks such as capturing requirements, system design, simulation-based validation, code generation, and result verification, focusing on specific system components to optimize key areas and mitigate development risks (Khandoker et al. 2022). For instance, (Sekar and Baras 2022) describe a model-based framework for robotic grasping, demonstrating how MBE facilitates iterative improvements and early error detection, ultimately reducing prototyping costs and risks.

Recent implementations, such as the one presented by Matlab/Simulink (MathWorks 2024) that combine ROS2 with control systems, show the potential and limitations of current approaches. In this use case, the system employs Simulink models to control simulated robots and manage data exchange, including camera feed, odometry, and speed commands; the focus of this use case involves an Image Processing subsystem for sign detection and a Sign Tracking Logic subsystem, implemented with a Stateflow chart, that translates detected sign information into linear and angular velocity commands.

While these implementations demonstrate MBE's capability for robust, iterative design, it is necessary to highlight the need for more flexible, platform-independent solutions (Corallo et al. 2022).

2.2 Open-Source Tools in Robotics

Open-source platforms have transformed robotics development by providing alternatives to traditional proprietary solutions. Authors of (Patel, Liarokapis, and Dollar 2022) discuss this transformation through open robotic hardware, documenting significant advances and diverse implementation practices across a range of applications. Similarly, (Soori, Arezoo, and Karimi Ghaleh Jough 2024) demonstrates how frameworks such as ROS2 accelerate industrial integration, particularly in Industry 4.0.

These advances in hardware and systems framework have prepared the way for the evolution of complementary software tools that further streamline robotics development. Market analyses by (Cornille 2024) confirm that including visualization tools like Rviz and Rerun.io, alongside physics simulators such as Gazebo and MuJuCo, it is possible to reduce development cycles and improve system reliability.

2.3 Model Exchange Using FMI

The FMI is an open standard that enables model exchange and co-simulation across different M&S environments, facilitating the integration of components from several domains, such as mechanical, electrical, and control systems. This capability is crucial for the development of complex systems where multiple M&S tools may work together. It defines a format for packaging such models, called Functional Mock-up Units (FMU). A FMU represents the practical implementation of the FMI standard, thus, it is a software component that complies with the FMI standard, making it portable and reusable across compatible simulation environments.

DOI
10.3384/ecp218479

Multiple studies have demonstrated the effectiveness of the FMI standard in practical applications and system simulations. For instance, (Oudart et al. 2020) present a model-based toolchain that leverages the FMI standard for CPS co-simulation. Their approach effectively separates physical and logical models, achieving up to 40% reduction in development time. Additionally, (Shahsavari et al. 2021) introduce MCX, an open-source framework for digital twins, highlighting the capability of FMUs to encapsulate system dynamics in a reproducible manner.

Building on these results, integrating FMI with robotics frameworks has emerged as a natural next step to bridge the gap between simulation and control. One notable contribution in this direction is the `fmi_adapter` package (Lange et al. 2020), which provides a concrete implementation for connecting FMI with ROS and Gazebo. This tool enables two primary approaches for incorporating FMUs into ROS-based architectures:

1. **Node-Based Use:** As shown in Figure 1, this approach represents how to create a ROS node containing an FMU. The architecture shows subscribers (left side) connected to the FMI adapter (middle, blue), which interfaces with the FMI library to communicate with the Application FMU (right, green). This implementation is helpful to create the necessary ROS subscribers and publishers to handle all model variables.

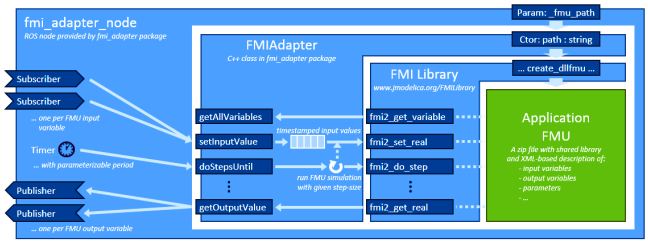

Figure 1. Node-Based Use
(Lange et al. 2020)

2. **Library-Based Use:** Figure 2 illustrates an alternative implementation using a C++ class (`fmi_adapter::FMIAdapter`). In this approach, the application node (left, green) directly interfaces with the FMI adapter components (blue). This method provides more direct control over the FMU lifecycle by eliminating the ROS node wrapper layer, allowing for more precise timing control and custom integration patterns.

Additionally, for Gazebo integration, (Lange et al. 2020) presented `gazebo-fmi` plugins, that enable the incorporation of FMU within the simulation environment. For co-simulation scenarios, `gazebo-fmi` components follow a master-slave architecture where one component, acting as the master, coordinates the execution of other components, which act as slaves. In this context, the main

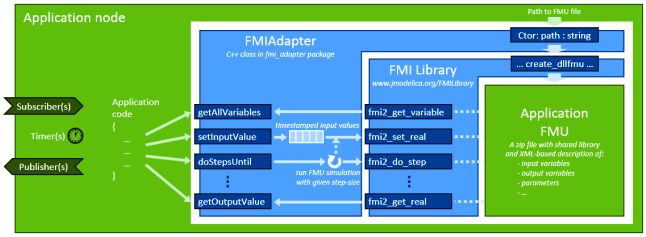

Figure 2. Library-Based Use
(Lange et al. 2020)

physics engine of Gazebo, acting as master, coordinates the overall simulation timing, while individual FMUs, acting as slaves, perform their specific calculations using their built-in solvers. The `gazebo-fmi` suite includes two key plugins:

1. **gazebo-fmi-actuator plugin:** For enabling the simulation of complex actuator dynamics such as reflected inertias, velocity/torque curves, and series elastic actuators.

2. **gazebo-fmi-single-body-fluid-dynamics plugin:** Designed to simulate fluid-body interactions, this plugin uses FMUs to compute lift, drag, and other fluid forces on a body.

2.4 AI Integration Using ONNX

Integrating artificial intelligence into robotic control systems presents significant opportunities in modern robotics, such as enabling adaptive decision-making, real-time optimization, and complex task automation. However, this integration also introduces technological challenges, including platform fragmentation, implementation complexity, and the need for reliable interoperability between AI models and robotic hardware (Patrício, Varela, and Silveira 2024). ONNX has emerged as a widely accepted standard for deploying AI models across various platforms. Its use enables standardized implementation of deep learning models, reducing dependence on customized and proprietary solutions. For instance, (El-Hussieny 2024) demonstrate a deep learning-based model predictive control strategy for a 3-DOF biped robot leg using ONNX, achieving real-time performance. Similarly, (Yue 2024) propose a real-time dynamic motion compensation design in vision-guided robots, that leverages ONNX to enhance task precision and system reliability, highlighting how standardized AI model deployment can improve task precision.

However, current approaches to integrating AI models with robotic control systems often rely on proprietary solutions or require complex custom implementations. This is particularly evident in applications that combine perception with dynamic control, where maintaining consistent performance across multiple subsystems can be difficult (Xu et al. 2024). Indeed, the robotics community has identified the need for more standardized, open approaches to AI integration that can reduce implementation

complexity while maintaining system reliability (Licardo, Domjan, and Orehovački 2024).

3 Proposed Methodology

To address the challenges outlined in Section 2, this paper proposes a development methodology for robotic systems based on open-source tools and following MBE principles. Our approach focuses on integrating physical and control models using FMUs, and AI algorithms via ONNX models, all within a Linux-based environment. ROS2 is proposed as the communication middleware, and Gazebo as the simulation platform. In this way, we aim to facilitate the development of such a complex systems in a cost-effective, modular, and interoperable manner.

It is important to note that our methodology assumes these models are already developed and available; therefore, the focus is on their integration into a robotic framework. This integration applies both to simulated environments and to deployment on physical hardware. The proposed methodology is guided by the following key principles:

Interoperability and Open-Source: The use of open-source tools and standards enables the development of a modular and scalable system architecture. This approach eliminates dependency on proprietary environments and promotes collaboration between robotic system developers.

Unified Integration of Physical and AI Models: This proposal unifies the integration of FMUs, containing physical models or control algorithms, with ONNX files, containing machine learning or deep learning algorithms. The integration is performed through ROS2, this way we obtain several advantages:

- As many robotic developments incorporate ROS2, integrating these components does not require modifying previously developed systems. Instead, adding new functionalities simply requires incorporating additional components.
- It reduces development time and costs, as predeveloped models can be incorporated into the system without the need to rewrite code. In other words, it acts as a code generation mechanism, with FMU and ONNX serving as the final code elements.
- It provides flexibility, allowing individual modules to be updated or replaced without affecting the entire system.

Modular Architecture: Our design adopts a modular appoach, where independent subsystems are wrapped within ROS2 nodes. ROS2 uses a communication model based on the publisher-subscriber pattern, where nodes can publish messages to topics or subscribe to them to receive information. This communication is built on top of Data Distribution Service (DDS), a middleware that enables automatic discovery of nodes and message exchange without requiring nodes to know each other directly. Gazebo provides the virtual environment for system simulation. This modular architecture reduces the complexity of integrating diverse technologies. As a result, our proposal is easily adaptable to a wide range of robotic applications.

4 Proof of Concept

To validate the effectiveness of the proposed methodology, we applied it to a scenario in which a robot navigates from point A to point B by following traffic signals that guide its path. We obtained this use case from a Simulink example originally designed to validate communication between Gazebo and Simulink. Our purpose is to reuse some of its elements to demonstrate how FMUs and ONNX models can be integrated for the development of CPS, showing that the same components and tools can be used both in virtual testing environments and in real hardware deployment.

As our approach does not involve the development of the models themselves, our initial intention was to reuse the odometry and signal-tracking logic by exporting them as FMUs, as well as exporting the image processing module as an ONNX model. However, we encountered some difficulties that required some adjustments. First, we were unable to generate FMUs directly from Simulink, since our development environment was Windows-based, while the final application is intended to run on Linux. FMUs generated on Windows cannot be seamlessly integrated into a Linux environment. To address this, we replicated these modules in OpenModelica under Linux and generated the FMUs from there.

Regarding image processing, Simulink relies on a proprietary toolbox that cannot be exported. To overcome this limitation, we recreated the functionality using a Python implementation, using PyTorch to enable ONNX export.

On the other hand, we were able to reuse the original Gazebo scenario. Therefore, our validation strategy is to test whether the robot behaves in the same way in both the original Simulink setup and our integration, now relying exclusively on non proprietary tools. This way, in this proof of concept, ROS 2 orchestrates the system, integrating FMUs for control and odometry tasks, and an ONNX model for image processing, with Gazebo serving as the simulation platform. The following subsections outline the processes involved in applying the proposed methodology.

4.1 Application Scenario

Figure 3 shows the simulated environment in Gazebo, where the map and layout of the simulation area can be appreciated. In this scenario, the mission of the mobile robot is to navigate from point A to point B while following visual signals. The yellow dashed line represents the expected path that the robot should follow based on the traffic signs positioned throughout the environment.

DOI
10.3384/ecp218479

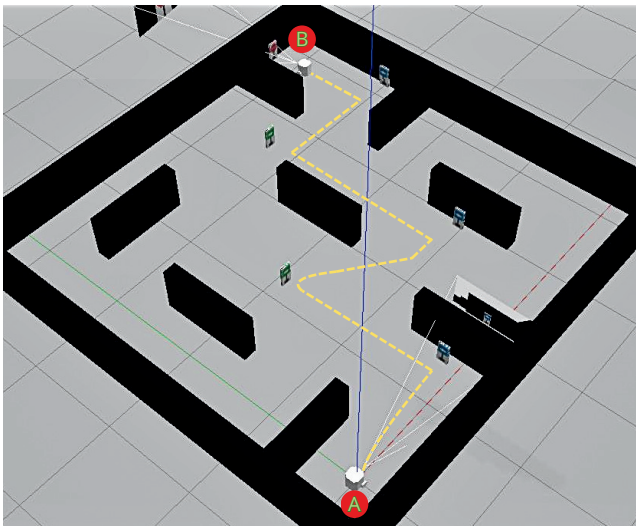

Figure 3. Simulated Gazebo environment showing the navigation path with traffic signs to guide the navigation of the robot.

The robot's navigation is guided by a set of traffic signals strategically placed throughout the environment, as shown in Figure 4. These signals provide the instructions for the robot's navigation behavior:

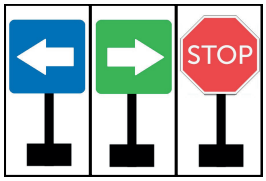

Figure 4. Traffic signals for robot navigation: Left arrow (blue) robot to turn left, right arrow (green) robot to turn right, and stop sign (red) robot to Stop.

4.2 Robot Pose Estimation (Odometry) FMU

The odometry management is handled via a two-stage process:

1. **Odometry Processing:** The system subscribes to the `/odom` topic in ROS2 to receive position and orientation data from the simulator. As shown in Figure 5, the FMU block `ReadOdometry` processes six input parameters: quaternion orientation (q_w, q_x, q_y, q_z) and cartesian position (x, y). The position coordinates (x, y) are directly mapped to the outputs ($posX$, $posY$), while the quaternion components are transformed into a 2D orientation angle ($theta$) using Euler angle conversion. This results in three output parameters ($posX$, $posY$, $theta$) that completely describe the robot's pose in 2D space.

2. **ROS2 Integration:** After understanding the functionality of the odometry FMU, we integrated it into a ROS2 node. This integration was performed by creating a node named (`fmu_odometry_node`) that subscribes to the robot's default `/odom` topic.

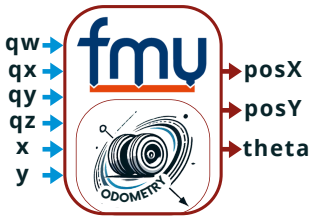

Figure 5. I/O port configuration of the odometry FMU block showing six inputs (four quaternion components and two position coordinates) and three outputs (2D position and orientation angle).

The node processes the odometry data and publishes the resulting pose information to a custom topic named `/fmu_odom_out`, as illustrated in Figure 6 the integration of the system is verified using rqt a ROS2's native introspection and visualization tool.

Figure 6. ROS2 node structure for the odometry FMU input subscription to `/odom` and output publication to `/fmu_odom_out`.

4.3 Traffic Sign Detection ONNX

The image processing subsystem employs a two-stage process:

1. **Vision System:** The ONNX model shown in Figure 7, processes RGB images with dimensions of 480×640×3 pixels received from the `/camera/image_raw` topic. The model takes this input tensor [1 480 640 3] and outputs two key parameters: `blobX` for the sign's horizontal position and `blobSize` for its dimensions.

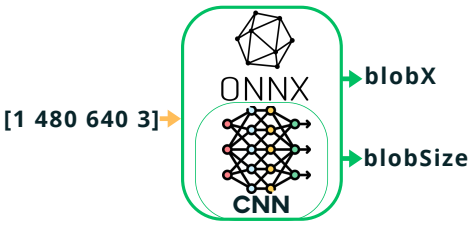

Figure 7. ONNX model structure showing the CNN architecture with its input tensor [1 480 640 3] (representing batch size, height, width, and RGB channels) and its two output parameters: `blobX` and `blobSize`.

2. **ROS2 Integration:** After understanding the functionality of the ONNX model, we integrated it into a ROS2 node. This integration was performed by creating a node that processes the camera input data and publishes the processed information through two custom topics: `/onnx_blobSize`, which provides

continuous updates of the traffic sign dimensions, and `/onnx_blobX`, which delivers the sign's horizontal position in the frame, as illustrated in Figure 8 the integration of the system is verified using rqt a ROS2's native introspection and visualization tool.

Figure 8. ROS2 node architecture for ONNX integration, illustrating input from the camera feed and output topics for sign detection parameters.

4.4 Autonomous Navigation Control FMU

The control system integrates the data from the FMU odometry model and the ONNX model subsystems through an FMU that manages the robot's control logic:

1. **Controller Design:** The SignTrackingLogic FMU incorporates decision-making logic to process visual inputs from the ONNX node and pose information from the odometry FMU. This FMU calculates the relative position of detected traffic signs and generates corresponding movement commands. Figure 9 shows the I/O configuration, where inputs include `blobSize`, `blobX`, and `pose` (i.e., *posX*, *posY*, *theta*), and outputs include linear velocity (`v`), angular velocity (`w`), and a stop command (`stopRobot`).

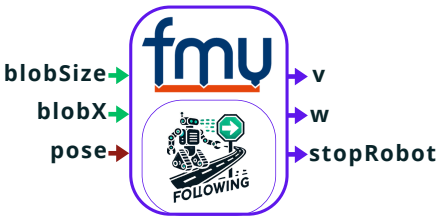

Figure 9. I/O port configuration of the SignTrackingLogic FMU block.

2. **ROS2 Integration:** After understanding the functionality of the SignTrackingLogic FMU, we integrated it into a ROS2 node. This integration was performed by creating a node named (`fmu_sign_tracking_node`) that subscribes to three topics: `/onnx_blobSize`, `/onnx_blobX`, and `/fmu_odom_out`. The node processes this information and publishes the resulting control commands to the `/cmd_vel` topic, as illustrated in Figure 10 the integration of the system is verified using rqt a ROS2's native introspection and visualization tool.

4.5 Integration of FMUs and ONNX

The final integration phase unifies the FMU-based control components and the ONNX-based image processing module within ROS2. This is accomplished through a layered architecture that ensures communication and synchronization between nodes while maintaining system modularity and scalability. The overall integration is validated using Gazebo as the simulation environment.

4.5.1 System Architecture in Linux

Figure 11 illustrates the complete system architecture, which comprises FMU Nodes for odometry processing and sign tracking logic, an ONNX Node for image processing and Gazebo Plugins for simulation interfacing through ROS2 as middleware.

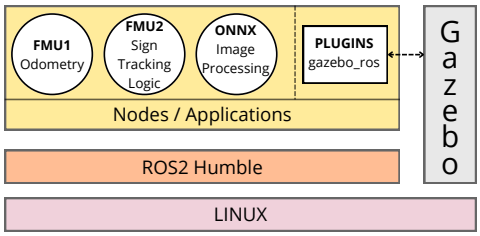

Figure 11. System architecture in a Linux environment.

4.5.2 Integration Implementation

The integrated system is deployed as follows:

1. **Component Deployment:** FMUs are executed within dedicated ROS2 nodes, the ONNX model is deployed within a computer vision node, and Gazebo interfaces with these components via the ROS2 bridge.

2. **Data Flow Management:** As shown in Figure 12, the system maintains synchronized communication through topic-based message passing between nodes, enabling coordinated execution of FMUs and ONNX models.

This integration setup shows the practical feasibility of combining ROS2, FMUs, ONNX models, and Gazebo within a Linux-based open-source environment. The resulting system supports modular development, clear separation of concerns, and synchronized communication across components, aligning with the principles outlined in our proposed methodology.

5 Results and Discussion

This section presents and analyzes the results from our implementation, evaluating both the performance of individual components and the overall system integration. In addition to the standard performance metrics, we compare the original outputs of the FMU and ONNX models with those obtained after integration within the ROS2 nodes, thereby validating that our integration preserves the model characteristics and enhances system's interoperability.

5.1 Odometry FMU Performance Analysis

To validate the accuracy of our solution, we compared the roll angle output from the original model with that of our integrated FMU-ROS2 implementation. The roll angle was chosen because it requires quaternion-to-Euler conversion, while x and y coordinates pass directly through the system without transformation. This comparison is essential for verifying that the mathematical operations and coordinate transformations are preserved after integration. Figure 13 shows the comparison of roll angle signals.

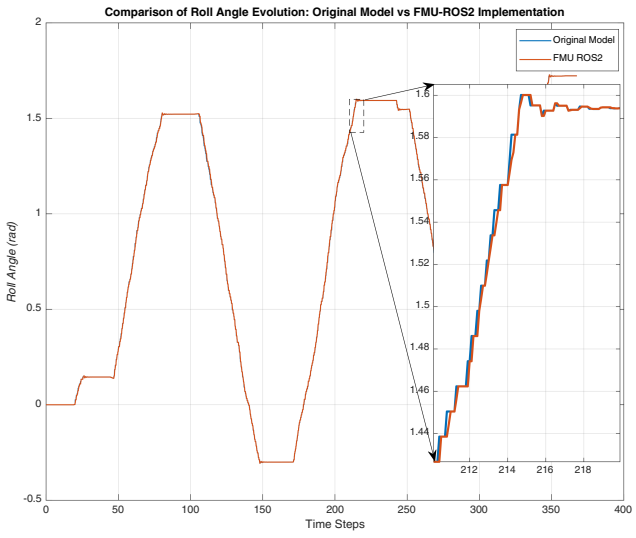

Figure 13. Comparison of roll angle evolution between the original model and FMU-ROS2 implementation.

From this comparison, we can conclude that the quaternion-to-Euler conversion accuracy is maintained. The signals exhibit slight variations, specifically on the order of 0.002 rad. These variations are acceptable, as the operational range goes from -0.4 rad to 1.8 rad. They are likely caused by differences in floating-point computations or by the overhead introduced during ROS 2 message passing.

5.2 ONNX Vision Processing Performance

To validate the accuracy of our ONNX implementation for sign detection, we compared the blobSize(3) output of the original ONNX model with our ONNX-ROS2 solution. This output was chosen as a representative measure since similar detection patterns are observed in other components of the blobSize and blobX vectors. Figure 14 shows the blob size signals.

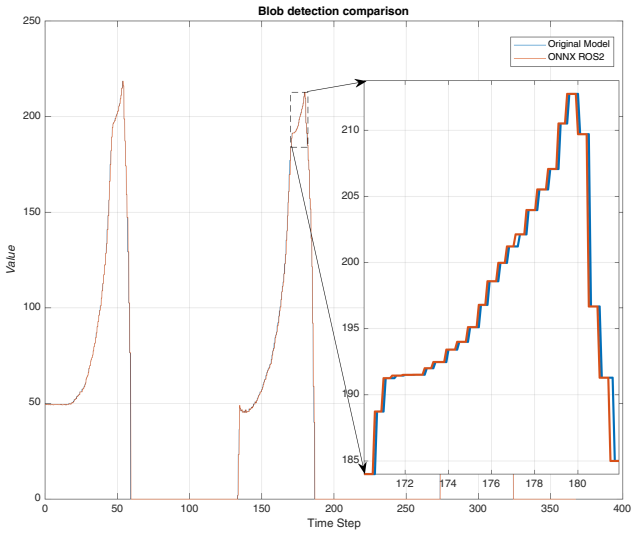

Figure 14. Comparison of blob detection between the original model and the ONNX-ROS2 implementation.

The comparison reveals that the detection accuracy is preserved. Similar to previous comparison, the signals also exhibit slight variations, specifically on the order of 1 pixel. These variations are acceptable, as the operational range goes from 0 to 215 pixels. They are likely caused by differences in floating-point computations or by the overhead introduced during ROS 2 message passing.

5.2.1 ROS2-Based System Integration

The overall system integration was verified using rqt, ROS2's native introspection and visualization tool. Figure 15 displays the runtime communication graph generated by rqt, validating the proposed system architecture as depicted in Figure 12.

The comparison between the proposed architecture and the actual implementation shows successful architecture validation, including the establishment of all intended communication pathways, correct node relationships, and proper topic naming and message routing. In terms of sys-

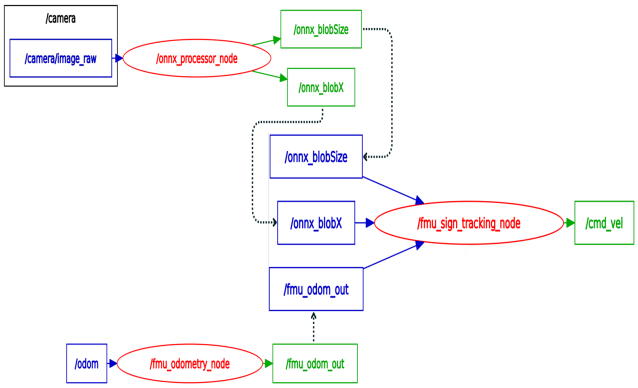

Figure 15. Runtime communication graph generated by rqt, showing node interactions and topic connections in the ROS2 environment.

tem integration, the data flow between the ONNX vision processing and FMU nodes is effective, and synchronization between odometry and control components is maintained, ensuring reliable message passing across the system.

5.2.2 Trajectory Analysis and Navigation Performance

To evaluate the effectiveness of the integrated system, we first analyzed the robot's trajectory through its X-Y position data. Figure 16 shows the complete path, where we can identify the navigation phases.

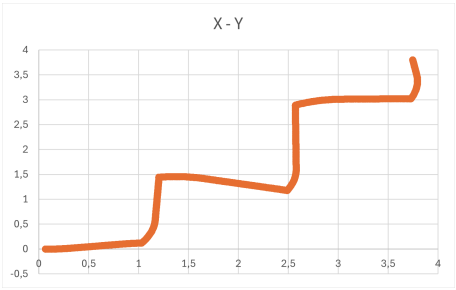

Figure 16. X-Y position plot showing the robot's trajectory.

When this recorded trajectory (orange line) is overlaid onto the simulation environment, as shown in Figure 17, we can verify the robot's successful navigation from point A to point B while following the traffic signs.

The comparison between the expected path (yellow dashed line in Figure 3) and the actual trajectory demonstrates that the robot successfully executed all required turns and maintained proper alignment during straight segments. The transitions observed in both representations validate the effectiveness of the SignTrackingLogic FMU in interpreting visual signals and generating appropriate control commands.

6 Conclusions and Future Work

In this work, we propose a cost-effective, modular, and interoperable methodology for developing CPSs using FMI

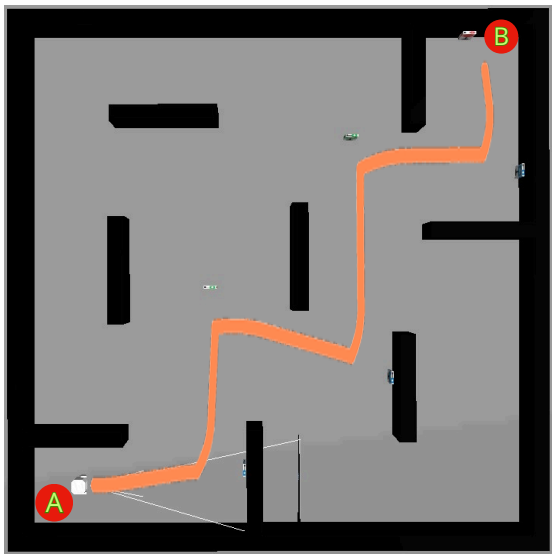

Figure 17. Actual trajectory (orange line) overlaid on the simulation environment, demonstrating precise path following and successful navigation through the course.

2.0 standard. We tested our solution with an autonomous robot navigation use case, integrating FMUs and ONNX models to establish the robot's behavior. The experimental results demonstrate that the system maintains precision while ensuring component independence. Specifically, our tests show accurate odometry tracking, reliable vision-based detection, and control behavior evidenced by consistent velocity patterns and effective trajectory adjustments.

The modular design, which wrappers FMUs and ONNX models as independent ROS2 nodes, offers significant benefits in terms of scalability, maintainability, and interoperability. The implementation demonstrates robust performance in both simulation and real-world environments, with the FMU-based control loop and ONNX inference running effectively within the computational constraints of the embedded platform. The ROS2 middleware proves efficient in handling the communication between components, maintaining system stability and responsiveness throughout operation.

The successful transition from simulation to physical implementation validates the practical applicability of our approach. As shown in Figure 18, while the real environment didn't exactly match the virtual scenario's measurements, the system demonstrated robust adaptability. This flexibility stems from the algorithm's fundamental reliance on traffic sign recognition and following, enabling effective operation in any environment where the standardized signs are present.

By relying on open and interoperable standards, our approach allows easy module replacement and simplifies system updates. This openness not only removes dependencies on proprietary tools but also fosters collaboration among robotic system developers. Moreover, our methodology significantly reduces development time and costs by

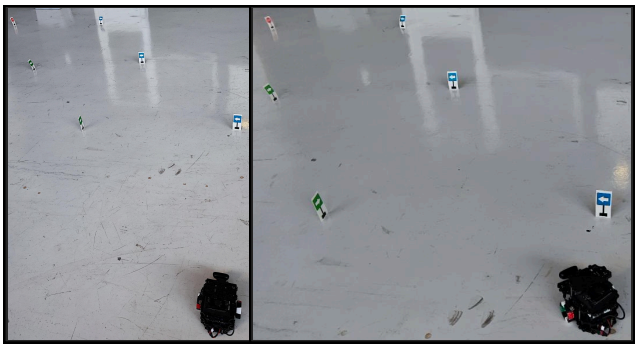

Figure 18. Implementation in physical robot demonstrating system adaptability in real-world conditions

allowing seamless code reuse between the simulation environment and the final hardware deployment. The same ROS2-based modules used for testing and validation in simulation can be directly integrated into the target robotic platform, eliminating the need for reimplementation.

Regarding future research, we identified the following aspects:

- **Advanced AI algorithms:** Development of efficient convolutional neural networks through dynamic neural architecture search and adaptive pruning techniques, focusing on minimizing computational overhead while preserving detection accuracy in vision-based navigation tasks.
- **Use of Zenoh as communication middleware:** Integration of the Zenoh protocol to enhance real-time data distribution in distributed CPS deployments. Zenoh's inherent support for time-sensitive networking and decentralized pub/sub patterns could reduce end-to-end latency while improving interoperability across heterogeneous hardware.

Overall, the current results suggest that our architecture is well-suited to accommodate such extensions while maintaining its core reliability and performance. This work opens new paths for integrating simulation, control, and AI-driven perception, contributing to the advancement of autonomous robotic systems.

Hybrid reinforcement learning enhanced trajectory planning for an ADR scenario for combined control of a satellite with a 7-axis robotic arm using Modelica/FMI

Matthias J. Reiner[1]

[1]DLR, Institute of Robotics and Mechatronics, Oberpfaffenhofen, Germany, Matthias.Reiner@dlr.de

Abstract

This work presents a novel hybrid trajectory planning algorithm that leverages reinforcement learning (RL) to address the challenges of active debris removal (ADR) in space, specifically for the combined control of a satellite and its 7-axis robotic arm. The proposed approach integrates a lightweight RL policy with correction algorithms and classical trajectory planning, enabling robust and collision-free maneuvering of the chaser satellite and precise placement of the robotic gripper near the target grasp point. This hybrid method is designed to handle uncertainties in target dynamics and sensor measurements, while remaining feasible for implementation on space-grade hardware. The effectiveness of the algorithm is demonstrated through comprehensive simulation studies using Modelica/FMI, validating its capability to generate safe and reliable trajectories in complex ADR scenarios.

Keywords: Reinforcement Learning, Trajectory Planning, Active Debris Removal, Combined Control, Robotics, Modelica, FMI

1 INTRODUCTION

Inactive satellites and debris, especially in the most used Low Earth Orbits (LEO), have been known to be a potential problem for a long time. The number of satellites increases every year, which increases the chance of a collision. Active Debris Removal (ADR) using satellites (chaser) equipped with a robotic arm is a possible technical solution to reduce this risk (Liou and Johnson 2006). ADR missions with robotic arms are very challenging, because they involve complex systems consisting of a satellite with a robotic arm with many degrees of freedom, while the information about a debris target is not always perfect (Weiss and Sarli 2014). Recent advances in the field of reinforcement learning (RL) could help solve problems in the field of ADR, especially when large uncertainties are involved. RL algorithms can adapt to changing environments, making them suitable for such tasks (Arulkumaran, Deisenroth, Miles Brundage, et al. 2017). However, the onboard hardware of satellites is usually very limited in its computational capabilities, and questions about the robustness of RL algorithms are still not completely solved (Kober, Bagnell, and Peters 2013; Han et al. 2023; Arulkumaran, Deisenroth, Michael Brundage, et al. 2017). In this paper, a hybrid trajectory planning algorithm is presented, which tries to combine conventional path planning methods and control strategies with an RL algorithm to address uncertainties in the ADR scenario.

Reinforcement learning (RL) is particularly attractive for ADR because it can learn adaptive strategies for collision avoidance and trajectory planning in the presence of nonlinear dynamics and uncertainty, where classical methods often face limitations.

The field of reinforcement learning (RL) for satellite on-orbit servicing (OOS) has witnessed notable advancements, particularly in the area of robotic arms on satellites. RL-based approaches have been developed to autonomously detect potential collisions, rendezvous with target satellites, and execute optimal collision avoidance maneuvers (CAMs) (Patnala and Abdin 2024). In addition, deep reinforcement learning (DRL) has been employed for autonomous guidance of redundant space manipulators. These approaches focus on solving path planning during the motion-synchronization phase with the mission target, using algorithms like Proximal Policy Optimization (PPO) to optimize the manipulator's guidance law (Ambrosio et al. 2024).

Furthermore, reinforcement learning algorithms with fast convergence have been proposed for routing in Low Earth Orbit (LEO) satellite networks. These algorithms address the dynamic topology changes and transmission requirements of LEO networks, enabling satellites to quickly adapt their routing strategies based on network link status updates (Ding et al. 2023).

Additionally, reinforcement learning techniques have been applied to path-planning for smart imaging of uncooperative space objects, enhancing the precision and efficiency of on-orbit servicing missions (Brandonisio, Lavagna, and Guzzetti 2021).

2 MODELLING AND SCENARIO

This paper focuses on a simulation study of an ADR scenario that is based on the inactive (target) satellite Envisat and a (chaser) satellite equipped with a robotic arm. The scenario starts with the chaser already in close proximity with variable initial conditions with respect to the starting distance and target spinning rate to Envisat. The angular

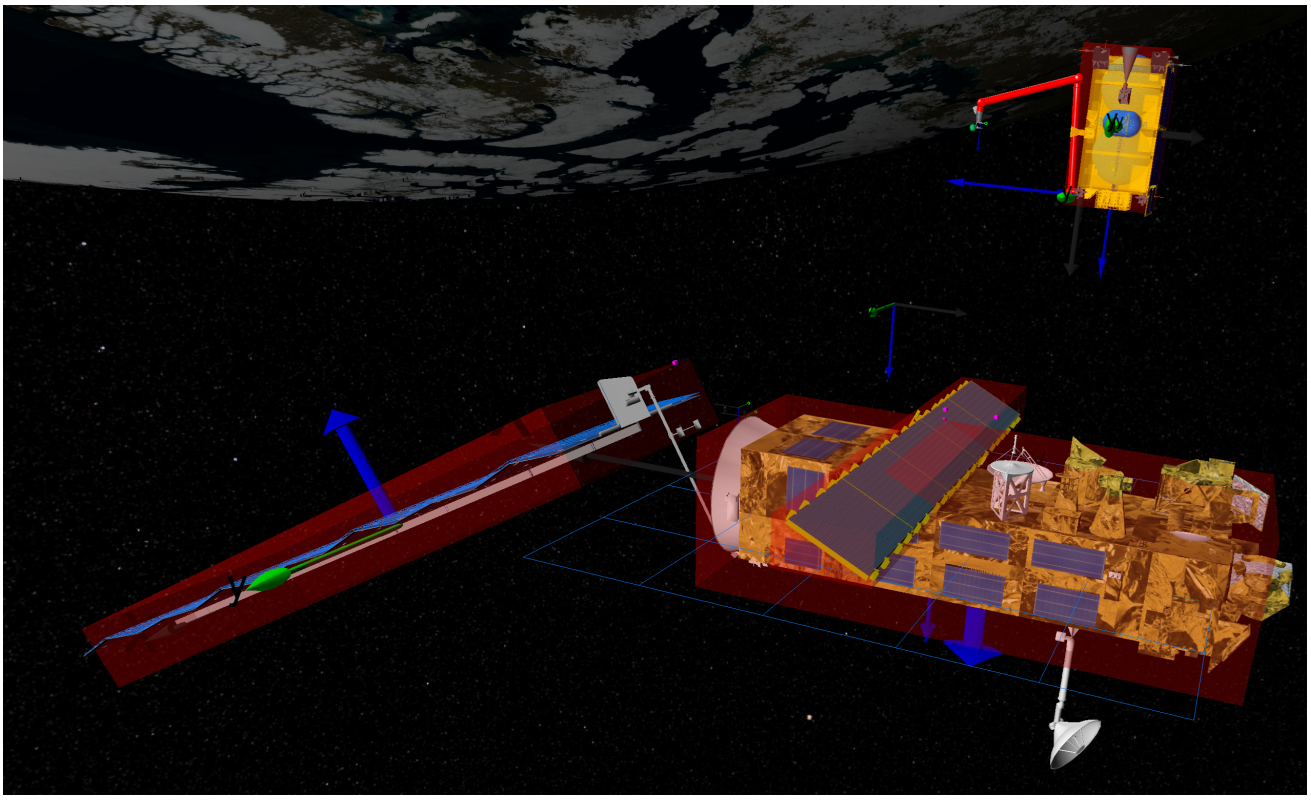

Figure 1. Visualization of the ADR scenario with Envisat and the chaser satellite with its 7-axis robotic arm and gripper. The four red bounding boxes around the target and chaser satellite are used for the collision avoidance of the RL algorithm. The computed critical closest points on the bounding boxes are shown as small pink spheres.

rates between target and chaser are assumed to be synchronized at the start of the simulation.

The scenario consists of multiple phases with different control modes. The first phase, which is the main focus of this paper, is the collision-free approach of the chaser satellite above Envisat's adapter ring and placing the gripper (also collision free) very close to the grasping point on the adapter ring.

This phase is handled by the hybrid RL algorithm which will be described in section 3. After this phase classical trajectory planning is used to stay synchronized with the spinning target using the combined control and grasping the adapter ring. After the gripper at the robot's tool center point (TCP) is closed, a detumbling mode is activated to reduce the angular rate of the target. After the detumbling is completed the deorbiting of the target would be started, but these phases are not considered in this work.

The models and scenario used are based on previous simulation studies, which were performed together with ESA (M. Reiner 2021; M. Reiner, Fernandez, and Ortega 2017; M. Reiner 2016), but were extended by additional uncertainty parameters for this scenario with respect to the tumbling (spinning) rate of the target and the starting distance for the trajectory planning.

The simulation models are created using the equation-based modeling language Modelica and dedicated Modelica-based libraries, the DLR Space Systems Library (M. Reiner and Bals 2014) and the DLR Environment Library (Briese, Klöckner, and M. Reiner 2017) and consider the following aspects (more details are given in the previous publications):

- Orbit dynamics for Envisat's sun synchronous orbit (LEO).
- First order approximation for the elasticity of Envisat's large solar array.
- Chaser satellite with 3D-pendulum models to approximate the fuel and oxidizer sloshing of the large tanks.
- Detailed control thruster array with 24 individual 22 N thrusters. The thruster firing pulse sequencing is implemented using a Pulse Width Pulse Frequency (PWPF) control in addition to a constrained least square (CLS) force and torque allocation.
- 7-Axis robotic arm mounted on top of the chaser with a fourth order approximation for each of the seven joints which approximate the flexibility of the gearboxes and friction as well as the internal high frequency torque control.
- Coupling and reaction forces between all elements are automatically considered by the multibody im-

DOI
10.3384/ecp218489

plementation supported by the Modelica Standard Library.

- The grasping of the robotic gripper of the adapter ring of Envisat is approximated by a switchable force and torque constraint with Baumgarte-like stabilization (Acquatella B. and M. J. Reiner 2014)
- Approximated IMU uncertainty using randomized simulated measuring noise and a simplified Exponentially Correlated Random Variable (ECRV) based camera performance model for the on-board camera and Light Detection and Ranging (LIDAR) system uncertainty.
- Robust H-infinity-based controller with outer Quaternion feedback loop for the combined control of the chaser and its 7-axis robotic arm.

To account for the uncertainty of the target's spinning rate, the initial angular velocity is allowed to vary within the following range:

$$\omega_{\mathrm{ta},0} = (\omega_{\mathrm{ta},0,x}, \omega_{\mathrm{ta},0,y}, \omega_{\mathrm{ta},0,z})^T \tag{1a}$$

$$\text{with: } -1^\circ/s <= \omega_{\mathrm{ta},0,x} <= 1^\circ/s, \tag{1b}$$

$$-1^\circ/s <= \omega_{\mathrm{ta},0,y} <= 1^\circ/s, \tag{1c}$$

$$-5^\circ/s <= \omega_{\mathrm{ta},0,z} <= 5^\circ/s \tag{1d}$$

Similarly, the (relative) starting distance of the chaser to the target (with respect to the target's CoM) is allowed to vary within the following range:

$$r_{\mathrm{ta},0} = (r_{\mathrm{ta},0,x}, r_{\mathrm{ta},0,y}, r_{\mathrm{ta},0,z})^T \tag{2a}$$

$$\text{with: } -2.0\,\mathrm{m} \leq r_{\mathrm{ta},0,x} \leq 2.0\,\mathrm{m} \tag{2b}$$

$$-2.0\,\mathrm{m} \leq r_{\mathrm{ta},0,y} \leq 2.0\,\mathrm{m}, -7.0\,\mathrm{m} \leq r_{\mathrm{ta},0,z} \leq -3.0\,\mathrm{m} \tag{2c}$$

For the RL algorithm, which requires many simulation steps, this model is too complex, and the training of the RL-algorithm would take an extremely long time on the available hardware (a single laptop with an Nvidia GeForce RTX 4090 GPU and Intel i9-13950HX CPU). Therefore, a simplified model is derived from the complex model for the training phase of the RL algorithm. However, the full model is later used for verification and validation (V&V). The simplified model only considers the kinematics for the chaser satellite and robotic gripper (at TCP). The spinning target is approximated as a rigid body with given initial conditions in a perfect zero gravity environment. The inputs to the model are direct kinematic translations for the chaser and robot TCP (without controller or actuator/sensor models). The outputs of the model are the observations and reward functions for the RL algorithm, which will be described in detail in sec. 3. This model can be computed very quickly, and is suitable for the time-consuming training process of the RL algorithm.

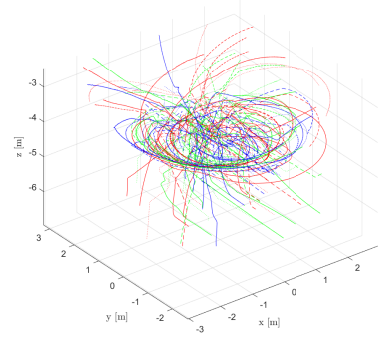

Figure 2. 3D-Visualization for the generated reference trajectories for the chaser satellite $r_{\mathrm{CH,ref}}$ (in relative target coordinate system) for the 100 random scenarios. From a random start location the trajectories convert to the desired position close to the grasping point on the target.

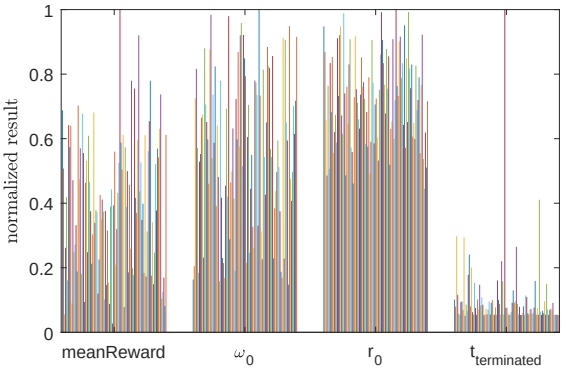

Figure 3. Visualization of the result of 100 random scenarios for different start values for the initial target angular velocity (vector length ω_0) and distance to target (vector length r_0).

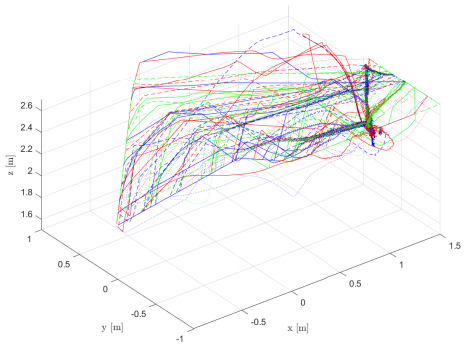

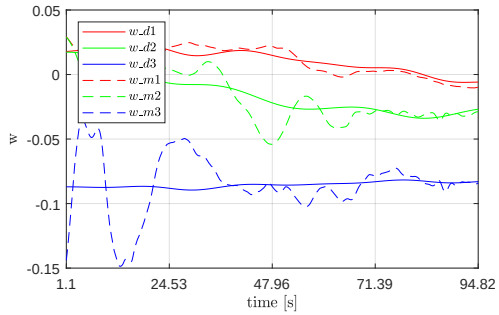

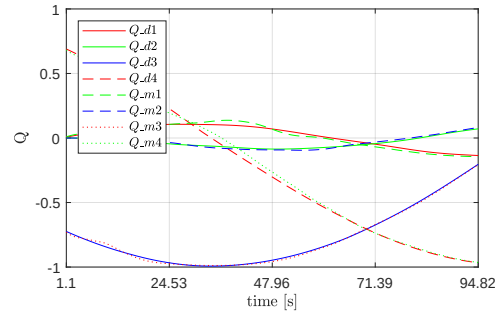

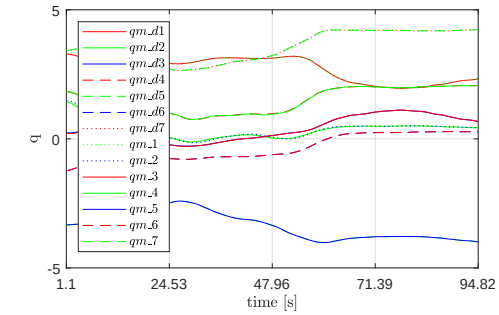

Figure 4. 3D-Visualization for the generated reference trajectory for the robot TCP $r_{\mathrm{TCP,ref}}$ (in local robot coordinate system) for the 100 random scenarios. The start location for all cases is $(-0.99, -0.01, 2.01)$m. The limitations for the TCP position given by $r_{\mathrm{TCP},min}$ and $r_{\mathrm{TCP},max}$ can be seen for some trajectories, that move along the given limits.

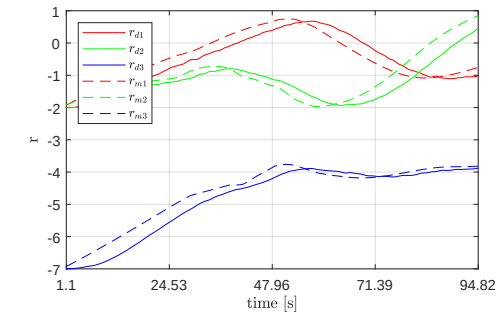
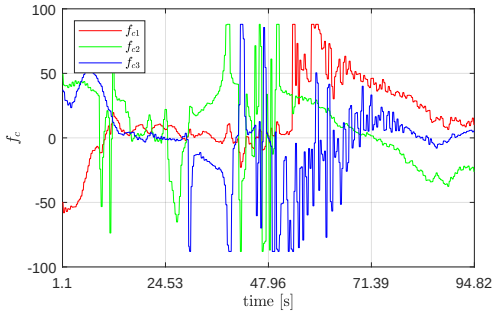
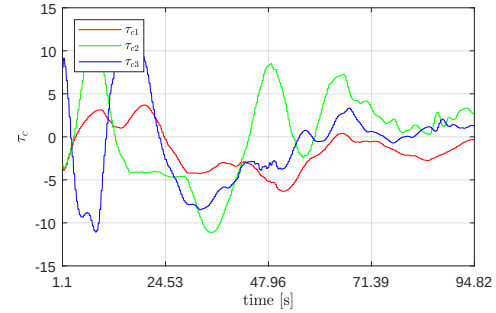


(a) Comparison of the commanded (ω_d) and measured (ω_m) angular velocity (including correction) to the combined controller in rad/s.

(b) Comparison of the commanded (Q_d) and measured (Q_m) Quaternion (including correction) to the combined controller.



(c) Comparison of the commanded ($q_{m,d}$) and measured (q_m) robot motor position (including correction) to the combined controller in rad.



(d) Comparison of the commanded (r_d) and measured (r_m) chaser relative distance to the target in m.

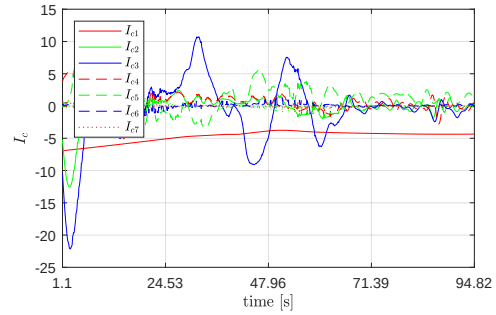


Figure 5. Simulation results for the generated command inputs and measured results for the combined controller for an example simulation case with high starting target angular velocities $\omega_{\text{ta},0} = (-1,-1,-5)^T\,^\circ/s$ and starting distance $r_{\text{ta},0} = (-2,-2,-7)^T\,m$.

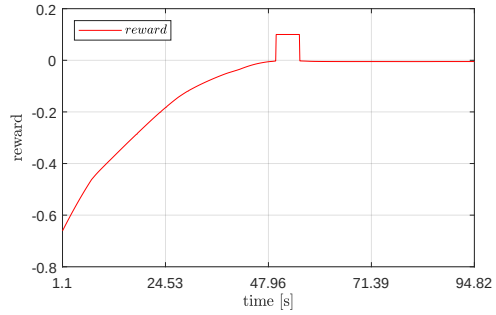

(a) Resulting thrust forces f_c commanded by the combined controller which are input for the force allocation to assign them to individual thrusters.

(b) Resulting thrust forces τ_c commanded by the combined controller which are input for the force allocation.

(c) Commanded motor torques for the 7-axis robot by the combined controller.

(d) PPO reward for the simulation case. The peak in the reward function (48 s) triggers the terminal condition C_{ter} and the classical trajectory planing takes over from the PPO algorithm.

3 HYBRID REINFORCEMENT LEARNING ENHANCED TRAJECTORY PLANNING

The basic idea behind the hybrid reinforcement learning enhanced trajectory planning is to combine the advantages of the flexibility of an RL algorithm with classical trajectory planning for the chaser including an optimization-based inverse kinematics for the robot arm and correction terms for the simplified RL model.

Since the computational power of today's satellites is still limited, the algorithm is designed such that a simple RL part with relatively small neural network sizes is sufficient. It is then combined with correction terms and classical trajectory planning to achieve good accuracy and robustness with respect to the initial conditions and spinning behavior of the target satellite, sensor noise, as well as actuator and control limitations.

The RL base algorithm is a Proximal Policy Optimization (PPO) (Schulman et al. 2017) as implemented in DLR's Stable Baseline 3 (SB3) Python software package (Raffin, Hill, et al. 2021). PPO is widely used and has proven its capabilities in many applications, especially in the field of robotics (Arulkumaran, Deisenroth, Miles Brundage, et al. 2017; Kober, Bagnell, and Peters 2013; Han et al. 2023; Arulkumaran, Deisenroth, Michael Brundage, et al. 2017).

$$L^{\mathrm{CLIP}}(\theta) = \mathbb{E}_t\left[\min\left(\frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_{\mathrm{old}}}(a_t|s_t)}\hat{A}_t,\right.\right.$$
$$\left.\left.\mathrm{clip}\left(\frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_{\mathrm{old}}}(a_t|s_t)}, 1-\varepsilon, 1+\varepsilon\right)\hat{A}_t\right)\right] \tag{3}$$

The objective function for the Proximal Policy Optimization (PPO) algorithm can be expressed by Equation 3, were θ represents the parameters of the current policy, $\pi_\theta(a_t|s_t)$ is the probability of taking action a_t given state s_t under the current policy, $\pi_{\theta_{\mathrm{old}}}(a_t|s_t)$ is the probability of taking action a_t given state s_t under the old policy, $\hat{A}_t$ is the estimated advantage at time t and ε is a hyperparameter that controls the extent of clipping (which limits extreme changes). The policies are implemented as neural networks.

CATIA-Systems FMPy Python software package is used to simulate Functional Mockup Units (FMUs) in Python, which are generated by Dymola from Modelica Code for the models described in sec. 2. SB3 allows many models (environments) to be computed in parallel. This feature was extended to use FMPy and underlying Modelica models. For a fast and efficient implementation, Modelica/Dymola's feature of inline integration (Elmqvist, Otter, and Cellier 1995) is used, so that the numerical solver is directly part of the Modelica model inside the FMU. As a result, from the outside (SB3), the model can be used as a model with discrete step size and no additional integrator in SB3 is needed.

The basic idea for the RL part of the hybrid algorithm is to train a network to find a collision free trajectory for both the chaser satellite and the gripper, mounted at the TCP of the 7-axis robot arm, from a varying initial distance to the target, which can spin with different rates as defined in Equation 1 and Equation 2.

To simplify the collision avoidance problem, the target satellite is approximated by bounding boxes for the collision algorithm. For the target three different collision boxes are used. One for the main satellite bus and two for the solar arrays. Figure 1 shows the bounding boxes in transparent red. It is assumed, that the onboard cameras can accurately (with the modeled measurement noise) track these boxes for the target. The chaser itself is approximated by using an additional safety offset for the distance calculation (with respect to the chaser's CoM) according to its largest dimension, in addition, for the TCP a smaller offset is used to account for the size of the gripper.

For both the chaser and the robot's TCP the closest points on these collision boxes are computed (some are visible as small pink spheres in Figure 1) as well as the distance of these critical points to the TCP and chaser including the safety offsets for chaser and TCP.

Since the rotation of the chaser is controlled such that it tries to stay synchronized to the spinning target, only the translational part is of interest for the PPO algorithm (a correction described later will handle occurring deviations).

As observation inputs for the PPO algorithm, a series of normalized vectors are used. All are given as relative vectors with respect to the robot's mounting frame.

- The actual position of the TCP.
- The vector between the TCP and the target grasp point (with safety offset) shown in Figure 1 as small visual coordinate system (cosys) above the grasp point on the adapter ring.
- The vector between the chaser CoM and the chaser goal position close to the grasp point shown in Figure 1 as a local coordinate system above the central solar array.
- A set of $n_{vec} = 6$ vectors $d_{\mathrm{vec},i}$ describes the distance between the computed closest critical points for the three bounding boxes relative to the TCP and chaser center (with safety offsets).

The termination condition C_{ter} is achieved when both the TCP and the chaser CoM are within a given distance limit to the target positions as given in Equation 5, where $k_{\mathrm{safe}} < 1$ is just a safety factor to ensure the TCP is not very close to a bounding box and $k_{\mathrm{col,TCP}}$ is a scaling factor, to ensure the TCP is allowed to be closer to a bounding box than the chaser itself. $d_{TCP,Gr}$ is the distance between the TCP and the grasping end position (with safety offset), $d_{TCP,\max}$ is the maximum allowed deviation, $d_{\mathrm{CH},Gr}$ and $d_{\mathrm{CH,max}}$ are similar terms for the chaser. C_{col} is a criterion

for collision avoidance as defined in Equation 4. The reward r_t^{PPO} for the PPO is computed by Equation 6 if the termination is not reached yet. If the termination criterion is reached it is set to a constant high termination reward $r_t^{\text{PPO}} = R_{PPO,ter}$, which helps the PPO optimization to quickly find and keep the termination condition C_{ter}.

$$C_{\text{col}} = \sum_{i=1}^{n_{vec}} \frac{1}{\max(\varepsilon_d, \|d_{\text{vec},i}\|)} \tag{4}$$

$$\begin{aligned} C_{ter} \implies & d_{\text{TCP},Gr} < d_{\text{TCP,max}} \\ & \wedge\ d_{\text{CH},Gr} < d_{\text{CH,max}} \\ & \wedge\ C_{\text{col}}\, k_{\text{col,TCP}} < C_{\text{max,col}}\, k_{\text{safe}} \end{aligned} \tag{5}$$

$$\begin{aligned} r_t^{\text{PPO}} = \\ -\left(d_{\text{TCP,Gr}} + d_{\text{CH,Gr}} + \min\left(C_{\text{max,col}}, C_{\text{col}} k_{\text{col,TCP}}\right)\right) \end{aligned} \tag{6}$$

Since the optimization of the neural networks inside the PPO algorithm works better with scaled values, the reward and the observation vectors are normalized element-wise between zero and one using a scaling function $\text{f}_s()$ with predefined minimum and maximum values which scales an input vector using a combination of linear and sigmoid functions (near the limits), with adjustable bounds and smoothing.

The PPO neural networks consist of two networks (actor and critic value-function), each with two layers and 128 neurons per layer. The hyper-parameters for the PPO tuning were found using a hyper-parameter optimization implemented in Optuna (Akiba et al. 2019). In addition, generalized State Dependent Exploration (gSDE) (Raffin, Kober, and Stulp 2022) is used instead of action noise exploration.

The resulting action a_t of the PPO algorithm (Equation 7) is also a normalized vector with six elements (with each element between -1 and 1). The first three elements are the translation command for the gripper at the robot's TCP. The last three elements are the translation vector for the chaser satellite for the next time step. Both vectors are given with respect to the robot's mounting frame. A predefined scaling vector k_s is used to account for the faster dynamics of the robot arm compared to the chaser satellite (Equation 8). k_s is chosen such, that the robot and chaser should be able to handle the resulting translation movement in most cases. The actual agility depends on the current pose of the robot arm and the satellite, and is limited by the required thrust to achieve rotational synchronization, so k_s is an approximation. In addition, $a_{t,s,rob}$ is set to zero if the sum over all actions would move the relative TCP location outside the allowed bounds $r_{\text{TCP,min}} = (-1.5, -1.0, 1.0)\text{m}$ and $r_{\text{TCP,max}} = (1.5, 1.0, 2.7)\text{m}$. These bounds ensure that the robot arm is able to reach the location and that no self-collision with the chaser can occur.

$$a_t = \left(a_{t,\text{rob}}, a_{t,\text{ch}}\right)^T \tag{7}$$

$$a_{t,s} = a_t \circ k_s = \left(a_{t,s,\text{rob}}, a_{t,s,\text{ch}}\right)^T \tag{8}$$

For the PPO algorithm, the only measured sensor inputs are the target rotation matrix in each time step relative to the chaser, which is assumed to be measurable with the onboard sensors. Also available for the PPO algorithm is the relative distance vector between chaser and target at the start of the first phase. With this information and the geometric data for the bounding boxes, the PPO algorithm can compute a trajectory (and internally also the required observations and reward). The actual states of the chaser and robot arm are not fed back to the PPO algorithm. This has the advantage that the PPO algorithm works much more stably, since no instability due to feedback can occur; in some sense, it works as a feed-forward control for trajectory planning.

Since the actual states of the chaser and the robot arm can deviate from the internal state of the PPO (mainly because of actuation limitations and sensor noise and disturbance effects), a correction is needed. Thus, using the measured relative orientation $R_{\text{rob,base},m}$ and measured (relative) position of the chaser robot mounting frame $r_{\text{base},0,m}$, a corrected action $a_{t,\text{cor,rob}}$ is computed and transformed in the actual measured robot mounting frame Equation 9.

$$a_{t,\text{cor,rob}} = R_{\text{rob,base},m}\left(a_{t,s,\text{rob}} - r_{\text{base},0,m}\right) \tag{9}$$

For the position of the chaser, no such correction is made, since the TCP can be moved faster and errors in the rotation have only a small effect on the actual CoM position. The chaser directly follows the trajectory given by $a_{t,s,ch}$. Since $a_{t,cor,rob}$ is a Cartesian translation, an inverse kinematics algorithm is used to transform the trajectory in the robot joint space. As desired orientation for the TCP the orientation of the target grip point is used. A discrete implementation using a least squares algorithm, instead of the original constrained least squares (CLS) implementation from (Bellmann 2014), with additional limitations is used for performance reasons.

The PPO trajectory is followed until the condition C_{ter} is true. In this state the gripper is very close to the grasp point and the chaser close at a defined location near the grasp point.

From there classical trajectory panning algorithms are used for the grasping, detumbling and de-orbiting, as described in (M. Reiner 2021; M. Reiner, Fernandez, and Ortega 2017; M. Reiner 2016).

4 SIMULATION EXPERIMENT RESULTS

To test the proposed hybrid algorithm, a series of 100 simulations of the ADR scenario were performed, using the full complex model (instead of the simplified model used for training the PPO algorithm) as described in sec. 2.

Figure 2 shows the trajectories for the chaser satellite generated by $a_{t,s,\text{rob}}$. For the 100 simulations, the start values for the initial target angular velocity and distance to target were randomized within their respective bounds

DOI 10.3384/ecp218489

as defined in Equation 1 and Equation 2. For all 100 simulation the algorithm was successful and collision free.

Figure 3 shows the results for the mean achieved reward which is normalized with the minimal reward achieved (meanReward in the bar plot). The plot also shows the vector length of the initial target angular velocity and distance to target (normalized to the maximal values). The last bar shows the time it took for the termination, normalized to the longest time. The mean time for a termination was $40.99s$. The large visible outlier was a case were the algorithm was able to move both gripper and chaser very close to the target, but not close enough to achieve the terminal condition C_{ter}, only after $404.35s$ the condition C_{ter} was achieved. For such cases the algorithm could be improved in the future with a more adaptive terminal condition C_{ter} or an abort criterion if the phase takes too long.

Figure 4 shows the trajectory for the gripper at the TCP, which result from $a_{t,s,\text{rob}}$ for the 100 simulations.

Figure 5 and Figure 6 show some detailed results for one simulation case which is at the limit for the allowed initial target angular velocity. The trajectory, generated by the hybrid algorithm, is used as input for the combined controller which is used to control the chaser satellite and robot arm. The plots show the approach with the PPO algorithm and the transition to the grasping (using a classical approach). The de-tumbling and de-orbiting is not shown. The combined controller and classical trajectory planning used are described in more detail in the previous publications (M. Reiner 2021; M. Reiner, Fernandez, and Ortega 2017; M. Reiner 2016).

5 CONCLUSION AND OUTLOOK

This work describes a novel hybrid reinforcement learning enhanced trajectory planning for an ADR scenario for combined control of a satellite with a 7-axis robotic arm. A PPO algorithm is combined with a correction algorithm and classical trajectory planning to handle the collision free approach of a chaser satellite to a target and placing the gripper at the robots TCP near the grasping point for use with a combined controller, which commands the satellite and its robotic arm simultaneously.

The algorithm was tested in a complex simulation ADR scenario with 100 randomized initial conditions, and was able to generate collision free trajectories for all cases.

The PPO part of the algorithm is trained using a simplified model of the scenario, which allows fast training times and leads to small neural networks, which could be run on weaker space computing hardware. It acts as a feed-forward component to a correction algorithm, which helps to reduce instability caused by uncertain measurement feed-back and model mismatch.

In the future the algorithm could be extended to use a more complex model for the training if more computing power would be available and larger neural networks on board of the satellite.

The space industry is very restrictive in regards to use neural networks as part of the control but a hybrid algorithm, as presented here, which can be more easily supervised and extended with a fall-back solution could help the acceptance.

As potential directions for further work, systematic comparisons with other RL algorithms and classical control baselines could be explored, along with more detailed statistical analyses and ablation studies. It may also be valuable to investigate advanced domain adaptation and sim-to-real transfer techniques, as well as formal safety and stability guarantees, to further broaden the applicability of the proposed approach.

Automatic Modelica Package and Model Generation from Templates and Data Files with Python, Exemplified with URDF

Antoine Pignède[1] Carsten Oldemeyer[1]

[1]German Aerospace Center (DLR), Institute of Robotics and Mechatronics, 82234 Weßling, Germany
{Antoine.Pignede,Carsten.Oldemeyer}@dlr.de

Abstract

Creating correct Modelica models and packages from templates and data files describing a multi-physics system is useful in numerous situations. For example, in laying out power plants, designing airplane air conditioning or chemical reactions (Barth and Fay 2013; Santillan Martinez et al. 2018; Ramonat et al. 2025). This publication shows two possibilities of doing this with an example from robotics design and simulation. The `URDFModelica` library contains templates for links, joints and whole robots that can be mobile or stationary. The library also has a Python script that takes a valid URDF file as input. With minimal manual processing of this input file, a complete robot simulation package is created automatically. Alternatively, the input file, translated to a Modelica record, can be used to set the parameters and connections of a generic robot model. The `URDFModelica` library has already been successfully used for quick generation of first Modelica simulations of existing robots or robots yet to be fully developed. The general structure and approach can be adapted to other application domains without much effort. `URDFModelica` has been released as open source Modelica library on GitHub.

Keywords: model and package generation, Python Modelica processing, URDF, robotics

1 Introduction

There are numerous examples through all domains where Modelica is one among several tools for design, development, modeling, simulation, analysis etc. Keeping a consistent set of parameters through all tools is crucial but can be challenging and the same also holds for model structures and elements interaction. Ideally, there is one data file or set of files that compiles all this information in usable form and with consistent units. Examples of widely accepted data formats are **J**ava**S**cript **O**bject **N**otation *JSON*[1], E**x**tensible **M**arkup **L**anguage *XML*[2] and **Y**AML **A**in't **M**arkup **L**anguage™*YAML*[3].

But even if the data file fulfills these requirements, there needs to be some function in the tools to read and possibly write the data file. The `ExternData`[4] Modelica library (Beutlich and Winkler 2021) for example, does that. It reads files at initialization to set parameters, initial values and lookup tables. But the Modelica user still needs to create the models.

Taking robotics as example, there are situations when one data file can contain more information than just parameter and initial values. The **U**nified **R**obot **D**escription **F**ormat *URDF*[5] [6], introduced by the **R**obot **O**perating **S**ystem *ROS*[7] (Macenski et al. 2022), describes a robot as a set of links with appropriate attributes and joints that connect links together, more details in subsection 2.1. As such it can not only be used to set parameters but to create whole packages automatically. This works well because the model structure is fixed before initialization. URDF is supported by many CAD software packages. Simulation tools, e. g. CoppeliaSim[8] and Isaac[9], can build simulation models starting from a URDF file. The similar capability for Modelica is newly introduced in this work. The new `URDFModelica` library developed at the German Aerospace Center (DLR) parses a valid URDF file and automatically creates a complete robot simulation model as a new Modelica package or as a Modelica record that configures one model using variable-length arrays. For the simulation model as Modelica package, it creates separate models and parameter records for each link and joint as well as the robot model, that collects all elements and connects them to chains. It is thus possible to adapt all elements individually whenever needed without affecting all elements of the same kind. The separation between parameters and models also permits an update function that only rewrites parameter values. For the simulation model as single Modelica record, a generic robot model is contained in the library. This has two arrays of variable length for links and joints. Connections between these and for the flanges of active joints are managed by two matrices generated from the URDF source by the Python script. This way to automatically create a robot simulation needs

considerably less code but one cannot change individual elements in contrast to the simulation as new package.

Translation in the other direction, i. e. from Modelica to URDF, is currently not implemented and not planned for the near future because no application has been identified.

`URDFModelica` is different from `ExternData`, but also different from `Modelica-Builder`[10]. It does not manipulate arbitrary Modelica files, but only translates from one format to Modelica syntax for the special application type of robotics simulation. It also is different from the supported automated design (Matei et al. 2024) whose aim is to automatically create Modelica models, too. But, `URDFModelica` only translates an existing design from one description language to another while the supported automated design uses optimization from basic elements to create new models fulfilling specific tasks.

All three categories, read parameters defined externally, manipulate individual Modelica files externally, create whole packages for special applications automatically, have their area of applications and are useful in many fields. The approach and structure of the new library explained here can be adapted to other application domains without much effort. Therefore, the interest of this publication may go beyond the Modelica robotics community.

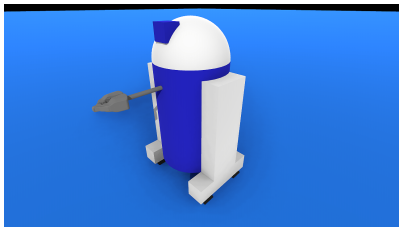

Figure 1. DLR Visualization 2 of the example mobile robot described in URDF and simulated in Dymola.

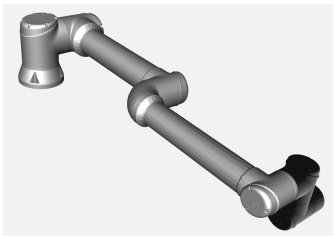

Figure 2. Standard Library Animation of the example stationary robot described in URDF and simulated in OpenModelica.

As appetizer, Figure 1 and Figure 2 show a mobile and a stationary robot created and simulated with `URDFModelica`. These are the R2D2-inspired example robot of the official ROS 2 documentation and the UR10e manipulator from Universal Robots[11]. They are contained as examples in the library, that has been released as open source Modelica library in Summer 2025: **`https://github.com/DLR-RM/urdfmodelica`**.

[10] `https://github.com/urbanopt/modelica-builder`

[11] `https://www.universal-robots.com/products/ur10e/`

The purpose of this publication is twofold. The first purpose is to generally explain how package and model generation can be done. The methodology is adaptable to other domains and other similar research questions.

The second purpose is to introduce the new `URDFModelica` library. This is split into two sections because two approaches for simulating robots based on URDF are implemented. The *package* approach and the *model structure defining record* approach. Independent of this, there are two variants for visualization, either with multibody animation from the Standard Library or the DLR Visualization 2 (Kümper et al. 2021).

Therefore, the text is structured along the two approaches, first the package then the record approach. Each time, a concept is explained theoretically first and then exemplified. Before this, the data source file and a general overview of `URDFModelica` are explained because they are the basis for both approaches.

2 Data Source File

Automatic package or model generation at first needs a good data source. There are numerous formats for this that cannot be covered entirely here, but some general guidelines with Modelica in mind can be given.

Ideally, one should adapt a few things before the Modelica package is created. For example, the export may result in wrong data types like real-valued color triplets instead of the integer-valued triplets required by Modelica. Most probably, file paths to resources such as lookup tables or CAD files for visualization must be changed in order for Modelica to find them. The recommendation is to put all these files in the resources directory of the Modelica package and refer to them relatively following the pattern `filename="modelica://Package/Resources/..."`. These steps are easier if the format is human-readable, but that is not a hard requirement.

Unfortunately, users tend to stretch, go beyond or abuse the capabilities or intentions of the data formats even if they are standardized. For example, JSON does not include comments, although they are occasionally seen in practice. YAML, as a second example, is not standardized. This makes handling, especially of large files, difficult and checking correctness is nearly impossible.

Based on experience of the authors, it often is beneficial not to include absolutely everything in the data file but rather restrict to the minimum that everybody agrees on. The automatically created package will almost always need post processing anyway.

2.1 Example: URDF and Modelica

> «*URDF* (**U**nified **R**obot **D**escription **F**ormat) is a file format for specifying the geometry and organization of robots in ROS.»[12]

DOI 10.3384/ecp218497

URDF is in XML style and thus human-readable. A robot is a set of interconnected links and joints. Links have inertial properties, and optionally visual or collision properties. Joints have a type (fixed, rotational, translational, etc.), an axis, a parent link, a child link and a few other optional properties. URDF reserves keywords for more elements such as sensors and special Gazebo[13] elements, but these are not adopted by every software. For example, the `urdf_parser_py`[14] Python module, on which the conversion from URDF to Modelica is based on, only parses links and joints.

URDF has become one of the most popular formats in the robotics community (Tola and Corke 2023). Tola and Corke (2024) lists and discusses a comprehensive compilation of URDF robot models through the world. A large number of known CAD software are able to export their models as URDF, the ROS 2 documentation export page has a good overview with links to respective manuals.[15]

Thanks to the already existing Python parser for URDF, minimal preprocessing of the data source file is needed. Most important is that file paths point to resources that Modelica can find. The parser does not check for consistent values, e. g. whether an axis attribute is a unit vector, and recognizes only the minimal set of elements and attributes that everybody agrees on. For example, the ROS 2 documentation defines contact coefficients for the link collision model that are not recognized by `urdf_parser_py`.[16]

3 `URDFModelica` Library

The `URDFModelica` library contains records, models and resources to easily set up a simulation from an existing URDF file. See the library tree Figure 3. The two approaches described here, are contained in the library.

3.1 `URDFModelica` Links

The link model can be any rigid robot body or represent some other important robot part like a camera position or a measurement point. Associated with a link model is a link parameter record that has three records: inertial, visual and collision. These three parameter records themselves contain further records down the hierarchy until primitive data types such as mass and inertia real values, integer color vectors or strings for paths to CAD files.

A link always has an inertial component, that is a `Body` from the multibody Standard Library with parameters from the corresponding record, which can be zero.

Link visualization is optional. It is always included, but only active if a Boolean parameter is true. In the "main" variant, it is simulated using the visualizers from the Modelica multibody visualizers. The `geometry` type that is part of the link parameter record specifies which visualizer to conditionally include. The user may also choose to replace the Standard Library visualizers with the corresponding elements from the DLR Visualization 2 library with a simple script option.

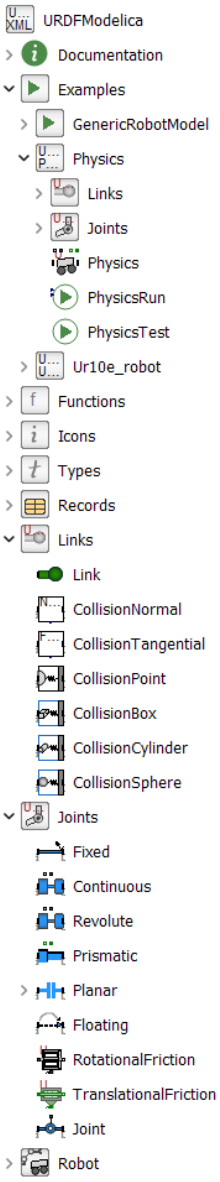

Figure 3. URDFModelica library tree.

Collision of links is optional, too. Again, it is always included in the template and active only if a Boolean parameter is true. Because the focus of `URDFModelica` is on the package generation and translation from URDF but not on contact detection and dynamics, collision is not simulated but only visualized. The same visualizers from Standard Library or DLR Visualization 2 as for link visualization are included equally in each link that has collision information. Color is pink for easier distinction. Collision can be globally turned off with a parameter that is propagated through the whole robot.

The link model stands as is and does not need to be processed by the automatic package generation to work. One can add a link to any multibody model of Modelica because all parameters have default values and optional components are conditional. The advantage of the URDF link compared to a Standard Library body is the attached parameter record with which it is easy to have different rigid bodies with optional visual and collision models. Additionally, the resulting Modelica model uses the same parameters as defined by URDF, which makes the backwards translation (currently not automatized) simple.

3.2 `URDFModelica` Joints

Joints connect links together. Different from links, there is not one joint with conditional components, but different models for each type. Still, all joint models have an instance of the same joint parameter record. This record has an enumerated type and nine records, e. g. for the parent and child link names, the joint axis, limits for effort and velocity, friction and calibration information. Note that not all information contained in the URDF joint description (and `URDFModelica` joint parameter record) are used in Modelica simulations.

[13] `https://gazebosim.org/home`

[14] `https://github.com/ros/urdf_parser_py`

[15] `http://docs.ros.org/en/jazzy/Tutorials/Intermediate/URDF/Exporting-an-URDF-File.html`

[16] `http://docs.ros.org/en/jazzy/Tutorials/Intermediate/URDF/Adding-Physical-and-Collision-Properties-to-a-URDF-Model.html#contact-coefficients`

There are six types. All of them first apply a Standard Library `FixedRotation` to set their origin.

- `Fixed` joints rigidly connect two links together without any degree of freedom.
- `Continuous` joints connect two links around a `Revolute` from the multibody Standard Library whose axis is set by the `Axis` parameter record. The joint flanges are also propagated to the outside such that the angle can be controlled. An integer parameter can optionally be set to mark the flange number for easier reference in a robot diagram.
- `Revolute` is the same as `Continuous` with the difference that limits for angle (upper and lower limit), angular velocity absolute value and effort (torque) absolute value are checked against at. A warning is output if a limit is violated.
- `Prismatic` is the same as `Revolute` for translational connection between links using `Prismatic` from the multibody Standard Library. All prismatic joints have limits for position (upper and lower limit), velocity absolute value and effort (force) absolute value. These are zero by default as defined by URDF. A warning is output if a limit is violated.
- `Planar` joints connect two links together with three degrees of freedom around a `Planar` from the multibody Standard Library. The `Axis` parameter record from URDF is perpendicular to the unconstrained degrees of freedom. A function calculates the simplest possible required n_x parameter by exchanging two vector elements of which one is not zero such that it can be negated.
- `Floating` joints connect two links together with all six degrees of freedom around a `FreeMotion` from the multibody Standard Library.

`Revolute` and `Prismatic` joints may have friction. URDF reserves two parameters for this: a friction and a damping coefficient. Therefore, simple friction models are also contained in `Joints`. The friction force f_r depending on velocity v is

$$f_r = R_v v + \frac{2R_h}{1+\exp(-sv)} - R_h$$

that is continuously differentiable. Parameters are the viscous friction coefficient R_v (URDF damping), stiction coefficient R_h (URDF friction) and steepness s of stiction (default is 100). Rotational friction is the same with torque and angle replacing force and position.

The joint models stand as is and do not need to be processed by the automatic package generation to work. One can add any joint to any multibody model of Modelica because all parameters have default values and optional components are conditionally included.

3.3 `URDFModelica` Background Information

`URDFModelica` only relies on the Modelica Standard Library (`4.0.0`) and needs Python to translate from URDF to Modelica. It has been developed and tested on OpenModelica `v1.24.0`[17] (Fritzson et al. 2020) and Dymola `2024x`[18]. The *model structure defining record* approach however does not yet work with OpenModelica. Instead of the default Standard Library visualizers, one may also choose to do object visualization with the DLR Visualization 2 library (Kümper et al. 2021). Both variants are provided in the library and an option on translation lets the user decide which variant to take. The "visualization 2" version has been developed and tested only with Dymola because DLR Visualization 2 currently does not support OpenModelica. The restricted free community edition[19] suffices to run the examples.

The Python code has been developed and tested with Python `3.12` from the official sources[20]. The module `urdf_parser_py` has been installed with `pip`.

4 Automatic Package Generation in Modelica

Creating a Modelica package automatically is not a trivial undertaking, even with well-defined data source and templates. A general approach that is adaptable to many domains and situations is explained in this section. This is the first approach of this publication subsequently referred to as *package* approach.

In overview terms, there is a Modelica library that contains template models, parameter records definitions and resources. Among the resources is a Python translation script and space for necessary files for the automatically created package to work correctly. These can be lookup tables, CAD files, JSON initialization files, etc. The separation of parameter records and Modelica models is an important part of the proposed automatic package generation. Counterintuitively, created records and files do not extend form the templates but do full copies of their content. The advantage of individual model alteration is judged higher than the drawback that one cannot simply change all similar models in one step. This and more aspects will be elaborated in the following subsections.

4.1 Modelica Records

A central part of the suggested package structure is to separate parameters from models, a general pattern that is widely applied in modeling and simulation. Thus, the first task is the definition of Modelica records. Here, one must replicate the elements contained in the data source file that

[17] `https://openmodelica.org/`

[18] `https://www.3ds.com/products/catia/dymola`

[19] `https://www.sr-scil.de/simulationsbibliotheken/kommerziell-verfuegbar/visualization/`

[20] `https://www.python.org/`

DOI 10.3384/ecp218497

are potentially needed for the simulation model in Modelica syntax. A hierarchical approach and providing default values is recommended.

When the automatic package generation is run, instances of the parameter records are created and given the values of the data source file. These copies are given the same name as the model they refer to, with "Parameters" as suffix and saved as single files in the new package.

4.1.1 `URDFModelica` Records

A URDF-described robot is a set of links and joints. Thus, there is not one but two records on the top of the hierarchy.

4.2 Modelica Template Models

Having template Modelica models helps to automatically create useful Modelica packages. One could create partial templates and then extend the concrete instances. However, a different approach is put forward here. Having copies of the templates allows to change individual models after generation. The drawback that changes cannot be applied to all models at once, is deemed less important. If needed, packages can be recreated at any moment, but this comes at the cost of losing individual modifications.

A design choice concerns the number of template models and enumerated types. One can decide to have one template model that fits all purposes and selects its conditional components based on the variant. Otherwise, one can choose to define one, generally simpler, template model for each variant. The decision which approach to use, depends on preference, data source, and mainly on the interface to other parts of the model. Less important for the decision are the icons and number of components in each template. Both approaches are implemented in the example of this publication. There is one template for all links, regardless whether they are boxes or cylinders, and six templates for joints, one for each joint type defined by the data source standard. All joint types have their own template because some of them have flanges in addition to the two multibody frames needed by all joints. All links use the same template because they all only have one multibody frame to attach them to joints or other links. Conditional components inside a link do not introduce much complexity. On the contrary, adaptation to other link types, e. g. converting a CAD defined wheel to a cylinder, is made easy.

A model always needs the corresponding parameter record. The template itself has its parameter record as replaceable component. This permits instances of the template model to stand for themselves and be added manually to any Modelica model. Then, one can select existing records, possibly overwrite the defaults and instantiate new models. When the automatic package generation is run, the replaceable parameter record is not copied. Instead, the correct record, that is the one with the same name plus "Parameters" suffix, is added without the "replaceable" keyword because one should not need to replace the parameter record with another one in post processing. The instance name is always "parameters" for easy reference.

Other contents of templates can be divided in required and optional components. Required components, e. g. interface, are simply copied when automatically created. Optional components are declared conditional. This is a second requirement so that instances of a template can stand for themselves. When the automatic package generation is run, one could copy all optional components relying on Modelica conditional components. However, the Python script only copies the needed optional components to make the new model smaller.

4.2.1 `URDFModelica` Templates

Because a URDF-described robot is a set of links and joints, there are two packages with templates. Thus, the automatic package generation will create two subpackages for links and their parameters as well as for joints and their parameters.

Link Template

The link model described in subsection 3.1 serves as template for links described by URDF.

When a new package is created, copies of the link template and record are put in a new `Links` subpackage for each link. Thus, the link models can be adapted independently of the parameter definitions. Similarly, parameter values can be updated without modifying the link models.

The correct visualization and collision components (box, cylinder, sphere, CAD file), if any, are selected from all components contained in the template based on the `geometry` type that is part of the link parameter record.

Joint Templates

The joint models described in subsection 3.2 serve as template for joints described by URDF.

When a new robot package is created, copies of joints of appropriate type are put in the new `Joints` subpackage for each joint. A joint parameter record copy is added for each joint, too. Thus, the joint models can be adapted independently of the parameter definitions, parameters which can be updated at any time without modifying the joint models.

Different from links, joints have no conditional components because there is not one general joint template, but six more specialized joint templates.

4.3 Aggregate Modelica Template Model

The last required template is the one that combines all elements together to the whole system. This template is mostly empty apart from the interface. When the automatic package generation is run, the previously created models of the subsystems are added to a new system model and connected together based on the data source file. This is done in the Python script with string manipulation functions that create correct Modelica syntax before and after the "equation" keyword.

4.3.1 `URDFModelica` Robot Template

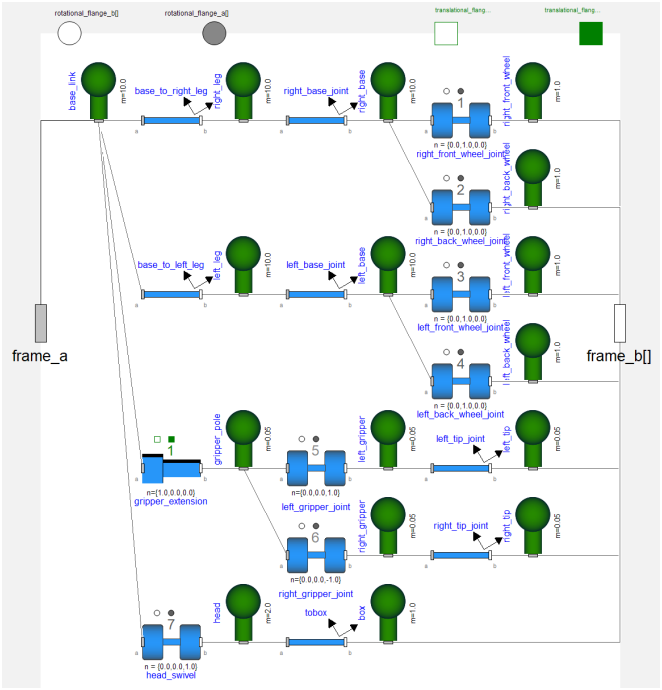

Figure 4. Graphics view of the example mobile robot.

The `Robotname` model puts all links and joints together and connects them according to the parent and child link string contained in each joint record. The graphics view of the R2D2-inspired example (Figure 1) is shown in Figure 4. The first link is connected to a `frame_a` on the left. All links that are leaves of chains are connected to a vector of `frame_b` on the right of the model to allow for interaction with external components. Additionally, rotational and translational flanges are propagated to the outside for every continuous, revolute and prismatic joint. The correct array sizes are calculated automatically. For easier reference in the joint icons, the flange number is also given as parameter to the concerned joints. The robot model diagram size is automatically adjusted to show all elements. This is the last model relying on the URDF source description, the further two Modelica models are suggestions for usage.

4.4 Modelica Usage Models

Further templates for how to create example models or FMUs may also be convenient for users.

4.4.1 `URDFModelica` Usage Models

For example, `RobotnameRun` builds an environment around `Robotname`. There is a multibody `World`, and outside inputs for position and angle of joints. `RobotnameRun` is one possible model to compile as FMU[21] (Blochwitz et al. 2012).

`RobotnameTest` is a model to quickly check that the package has been created correctly by providing some simple inputs to all needed signals.

[21] `https://fmi-standard.org/`

4.5 Python Script

The actual generation of the Modelica package is done with a Python script. Modelica also has text and file manipulation functions, but lacks the versatility and ease of Python. For example, there are parser modules for XML or JSON files that make the translation from these formats to Modelica syntax a lot easier.

Inputs to the Python script are the data source file and the location where to save the new package. The latter must be divided into two inputs, the path to the directory where the Modelica package structure begins, and the Modelica package inside this package structure. This is needed because each Modelica file begins with the keyword “within” and the Modelica package structure.

4.5.1 Package Generation

The Python script in general performs the following tasks.

1. Parse the input file. This is one of the main reasons to use Python because there already are modules for many data formats such as JSON, XML or YAML.
2. For each element
   (a) Create a new parameter record by translating the parsed information to Modelica syntax. Save the parameter record in the given package structure, possibly in further subpackages, with element name plus “Parameters” suffix.
   (b) Create a new model by copying only the needed contents of the template. Add the parameter record as “parameters” instance. Save the model in the given package structure, possibly in further subpackages, with element name.
3. Create the model that combines all elements to the system. Add all elements and connect them based on the actual source. Save this model in the given package structure with system name.
4. Optionally create and save a model that shows how to use the system.
5. Create the package order file of the new package.
6. Create the package definition file of the new package.
7. Update the package order one hierarchy level higher.

Note also that it is recommended to convert all names to title case, i. e. first letter upper case and the rest lower case, and that they should not contain "-" (minus) signs or be reserved keywords.

4.5.2 Parameter Update

One main reason for the division between parameters and models is to be able to update parameters without rewriting the whole package. This is possible if only numerical parameter values change in the data source file. In that

DOI 10.3384/ecp218497

case, the same Python script as above only recreates the parameter record files and skips all the rest.

Because the models of elements and the overall system model remain unchanged, it is not possible to change element types or connections in update mode. If the data source has such changes, one must completely rewrite the whole package or create a new one.

4.5.3 `URDFModelica` Python Script for Package Approach

The Python script `urdf_to_package.py` in the resources does the translation from URDF to Modelica syntax and creates or updates the Modelica package. It relies on the existing Python URDF parser but does not need further information or other non-standard modules otherwise.

Given a URDF file it first translates all information into one Modelica record exactly replicating the URDF contents. Then it writes, or rewrites, the parameter records of links and joints in the specified package. If the user chooses the update mode, the script terminates. Otherwise the entire package structure, with joints models, link models, robot model and example files, is recreated. Details about specific steps in this process are given in the respective paragraphs about links, joints, etc. further above.

5 Simulation Based on Modelica Record

Instead of generating new packages for every source file, an alternative way is a model that adapts to the structure during translation. While Modelica is not capable of handling systems with variable structure during simulation, it supports component arrays with varying sizes as long as those are known during translation. This is the second approach of this publication subsequently referred to as *model structure defining record* approach.

While retrieving the connection information from the data source file with a Modelica function is theoretically possible, it does not work with the Dymola version used by the authors. The tool must be able to expand the subscripts of connected variables into literals. Hence, a `connectionMatrix` containing that information is written into the single, complete record by the Python script as a workaround and used as shown in Listing 1. Each connection corresponds to a matrix row containing the indices of connected elements in its columns. Note that Listing 1 is adapted to the URDF and Modelica example and thus has two arrays of different elements (links and joints) and one connection matrix, because URDF defines parent links and child links to each joint.

Similarly, matrices for outside connections must be retrieved from the data source file and added to the model. In the robotics example of this text, it is the flanges of rotational or translational joints.

Finally, knowing the base and end elements of chains is usually necessary for interfacing with the environment. Roots and leaves can be determined relatively easily from the `connectionMatrix`.

Compared to the package generation approach of section 4, the simulation based on a single record reduces the amount of generated code and therefore maintenance effort considerably. In fact, the same few lines of Modelica code are enough to simulate all translated data source files. This implementation lends itself to use-cases where the system is frequently changed and used without modifications, e. g. when choosing the right system for a given task based on a simulation study.

A drawback is the lack of accessible presentation of the mapping from component name to index in the component vector that is more user-friendly with the package generation approach, see Figure 4. Changes in individual components are not possible either. As of writing model translation fails with OpenModelica with preliminary analysis indicating an error in component array handling.

5.1 `URDFModelica`: Simulation Based on Modelica Record

The `URDFModelica` library also does simulation from URDF source in a generic form following the *model structure defining record* approach. The source file rigidly defines the number of joints and links as well as their connections. A literal URDF robot implementation consists of two variable size arrays of links and joints whose size is the same as their respective records in the `Robot` record. The DLR Robots library (Bellmann et al. 2020) frequently uses this alternative way to create robots from URDF.

Listing 1. Simplified Excerpt of Robot Model.

```
model GenericRobot
 (...)
 Records.Robot data;
 Integer nJ = size(data.joint, 1);
 Integer nL = size(data.link , 1);
 Integer cM[nJ, 2] = data.connectionMatrix;
 Joint joint[nJ](jointParams = data.joint);
 Link  link [nL](linkParams  = data.link);
equation
 for iJ in 1:nJ loop
  connect(link[cM[iJ, 1]].frame_a,
   joint[iJ].frame_a);
  connect(joint[iJ].frame_b,
   link[cM[iJ, 2]].frame_a);
 end for;
 (...)
end GenericRobot;
```

The Python script of subsubsection 4.5.3 also creates a parameter record `Robot`, that contains the complete translation in one file. The translated links and joints that are used individually in the *package* approach, first are compiled to two arrays. Then, two additional matrices are generated from the joint information.

- `connectionMatrix[numJoints,2]`, theoretically explained in section 5, in practice becomes an array where each joint corresponds to a matrix row containing parent and child link indices in its columns. Usage is shown in Listing 1.

- `moveableJoints[numAxes,2]` has the joint number and movable axis number for every `Continuous`, `Revolute` and `Prismatic` joint. This sets connection of joint flanges to outside components at model translation.

Another part of the interface is a base frame that is used to place the robot in its environment. Which link to connect to the base frame is determined based on the `connectionMatrix` with a Modelica function that searches for the single root of the connection tree.

Higher level components need to provide the URDF robot record to the robot model via modifier.

6 Conclusion and Further Work

Automatic package generation or parameterization of generic models can be very useful, especially to keep consistent parameters and structures of models. It simplifies the initial setup and encourages good modeling practices, such as separating parameters from models.

This text explains two approaches, *package* and *model structure defining record*, that are adaptable to many domains and applications without much effort. The new `URDFModelica` library implements both approaches. It exemplifies the approaches and shows their practicality. The library has been released open source under BSD license on GitHub in Summer 2025. First users report quick translation, even of large robots (> 25 joints), and in general stable execution.

Further work can go in different directions. While there is not much to add to the general and more theoretical terms, `URDFModelica` can be expanded for example for proper collision models (Buse et al. 2023) or include more advanced drives or expand the range of robot elements. Although the Python parser does not recognize sensors, the URDF documentation reserves keywords for IMUs, cameras etc. An in-house extension to the library that also considers this, is already in use at DLR. Once `URDFModelica` has been released as open source Modelica library, efforts for extending `urdf_parser_py` will be undertaken. More examples of how to use the created Modelica models is another possibility for further work. For example, calculation of Jacobian or Coriolis matrices are important in robotics research.

Finally, the claim that the approach can be adapted to other domains, remains to be proven.

Acknowledgements

The authors would like to thank Robert Reiser for being the first person to test the library and Bernhard Thiele for proof reading the manuscript.

Modelica Meets ASHRAE: Towards A Digital Standard for Building Control

Abstract

Today's process for designing, specifying, installing and testing building HVAC control is not digitalized, leading to expensive manual workflows and missed operational performance. To digitalize the design-build-operate process for building HVAC control, the authors developed a process, associated tools and initiated the voluntary ASHRAE Standard 231P. This paper describes this process and tools, which are both based on Modelica. Standardization through a proposed voluntary ASHRAE Standard and the existing Modelica Language Specification provides a robust technology foundation for industry investment. It is based on declarative specification of the control logic, and allows reuse of existing technologies for open-loop and closed-loop control testing through coupling with an HVAC system or a whole building energy model. It supports control testing using MIL, SIL and HIL, and export of digital twins for operational support. The process and ASHRAE Standard 231P have been designed to accommodate existing Building Automation Systems product lines, while also enabling direct code generation such as by using FMI or eFMI. Control deployment can be digital or manual and conformance to the digital specification can be tested formally and programmatically at each step of the control delivery.

Keywords: Controls, Digitalization, Modelica Buildings Library, ASHRAE Standard 231P

1 Introduction

Design and implementation of control sequences for building and district energy systems has shown to be problematic. Barwig et al. (2002) showed that about one third of the errors in control systems for built-up HVAC systems, those that typically serve medium and large buildings that cover more than half of the floor area of the building stock, are attributed to programming errors. The problem of programming errors remains also today, as more recent literature shows (Crowe et al. 2020; Torabi et al. 2022). HVAC designers usually lack funding and skills needed to develop control logic. Rather than providing the control logic, they write the control intent, typically in the form of a 20 to 50 page untested Word document that has ambiguous formulations. The control provider then interprets this English language text and implements the control logic in software, often by reusing code from previous projects. This process has proven problematic even for the older HVAC systems, which have generally much simpler sequences than today's high performance control sequences. Modern controls are tasked with integrating heat pumps, chillers, and storage to not only meet temperature setpoints but also improve efficiency and shift energy use to periods with lower energy rates. The current control design and delivery process has not kept pace with digitalization. It remains highly manual, based on ambiguous specification, with minimal testing beyond spot checks during commissioning. While control providers have product lines that support communication standards, such as ASHRAE Standard 135 (BACnet, ASHRAE (2024)) or KNX, there is no standard for expressing the control logic.

To address these gaps, the authors have been developing a process and underlying tools for the digitalization of the controls design, delivery, implementation and commissioning. In support of this effort, the authors created a language for expressing control logic, called Control Description Language CDL (Wetter, Grahovac, and Hu 2018). Together with Modelica template models for HVAC systems and tools for configuring and translating CDL, CDL forms the foundation for control digitalization. CDL is defined as a small subset of Modelica, chosen in a way that allows translation to many legacy control languages, yet expressive enough to build configurable control sequences that allow for example specifying the type of sensors (e.g., a room CO_2 sensor), the type of equipment (e.g., water-based cooling coil, direct expansion cooling coil, presence of a heat recovery chiller etc.) and then automatically configure a control logic for the specified system.

Some of the authors also initiated an ASHRAE Standards Committee, and further developed CDL into the proposed ASHRAE Standard 231P[1].

This paper provides an overview of the CDL language,

[1]See https://www.ashrae.org/technical-resources/standards-and-guidelines

the control libraries that are being developed based on CDL, and the tools to configure controls and to translate CDL to target environments, which can be new or legacy Building Automation Systems (BAS) or Energy Information Management Systems (EMIS). As recent EMIS can also provide control capabilities (Pritoni et al. 2022), we collectively call them BAS below. The paper also describes verification of control logic implemented in a BAS to test conformance to the control specification that is expressed in CDL. Additionally, it highlights companies that have been incorporating CDL into their products and processes. Further information on earlier work related to this project can be found at `https://obc.lbl.gov`.

Assuming a widespread adoption of the digital control design-build-operate process presented here, the annual US electricity cost savings would be $8.2*B* and the natural gas savings $1.07*B* (CEC 2021).

2 Methodology

The development of the digital workflow started with the identification of key problems in today's building control design-build-commission-operate process, followed by stakeholder interviews and the development of use case and requirements. For industry adaption, the new workflow needs to reduce time and cost, address the lack of skills and budget among mechanical designers tasked with specifying controls, and ensure that the software solution is easy to support with existing control product lines. Additionally, it must be future-proof to enable more modern software solutions than those currently available in many automation product lines. Further, it has to enable rigorous sequence verification in a formal, programmatic way, which the authors believe is a core requirement that few control providers recognize today.

For this digital workflow, we developed the Control Description Language (CDL) (Wetter, Grahovac, and Hu 2018), which is a subset of Modelica. CDL prescribes basic blocks that are easy to support by legacy control systems, and it prescribes rules to compose such blocks hierarchically to implement control logic. The use of Modelica allows to perform simulations for design and verification of control and mechanical system operation coupled to a whole building or district energy model. It also allows code generation for future control product lines such as via the FMI or eFMI standard (Blochwitz et al. 2011; Lenord et al. 2021).

We validated CDL by creating HVAC control libraries, and using these libraries for closed-loop performance assessment with whole building energy simulation, using either Modelica or Spawn of EnergyPlus to simulate the building envelope model (Wetter, Ehrlich, et al. 2022; Zhang et al. 2022; Wetter, Benne, et al. 2023). Additionally, we developed a new workflow for digital control delivery, and we prototyped each step of the process, from design to code generation for WebCTRL, a commercial control product line from ALC (Automated Logic, a Carrier company) and verification of as-installed control logic in a real building (Wetter, Gautier, et al. 2019). See Wetter, Ehrlich, et al. (2022) for an overview.

To standardize the underlying language for control representation, in 2020, a formal application was submitted to ASHRAE to establish a standards committee, resulting in the proposed ASHRAE Standard 231P "CDL - A Control Description Language for Building Environmental Control Sequences." This standard aims to define a declarative graphical programming language for building environmental control sequences that is both human- and machine-readable, designed for specification, implementation via machine-to-machine translation, documentation, and simulation. The ASHRAE Standard 231P committee held its kick-off meeting in September 2020, and the proposed standard is expected to undergo a second, and potentially final, public review in 2025.

In the meantime, various control libraries and support tools have been implemented, and they are described in the following sections.

3 Workflows

Figure 1 shows a simplified flow chart of the digital workflow enabled by CDL. The figure is based on the more comprehensive workflow shown in Figure 2 in Wetter, Ehrlich, et al. (2022). Depending on the HVAC characteristics, energy code and project requirements, a mechanical engineer uses ctrl-flow (see Section 3.5), a web-based tool, to select and configure the HVAC system and control sequence through menu options. Then, the ctrl-flow software outputs the sequence specification. This consists of the English language sequence description, the digital control sequence conforming to ASHRAE Standard 231P, (essentially a hierarchical block-diagram in Modelica), and the semantic model conforming to ASHRAE Standard 223P. These steps are achieved using the modelica-json software described in Section 3.4.[2] A control provider then implements this control logic in a BAS. This can either be done manually using today's workflow, or preferably through software translation, which we prototyped and explained in Section 4.2 in Wetter, Ehrlich, et al. (2022). The control provider then instantiates the control logic in a controller and links inputs and outputs to physical devices or virtual control points. Regardless of whether the control logic was implemented through software translation or through manual programming, a commissioning agent then trends BAS inputs and outputs, and compares them against outputs computed by the CDL representation for the same control input and parameters. This verification test can be done using the funnel software [3], and prototype code for such verification is described in Section 4.3 in Wetter, Ehrlich, et al. (2022).

[2] modelica-json generates these outputs based on a configured Modelica model. The ability to export the configured Modelica model, as an additional output, is a planned feature for 2025.

[3] See `https://github.com/lbl-srg/funnel`.

DOI 10.3384/ecp218505

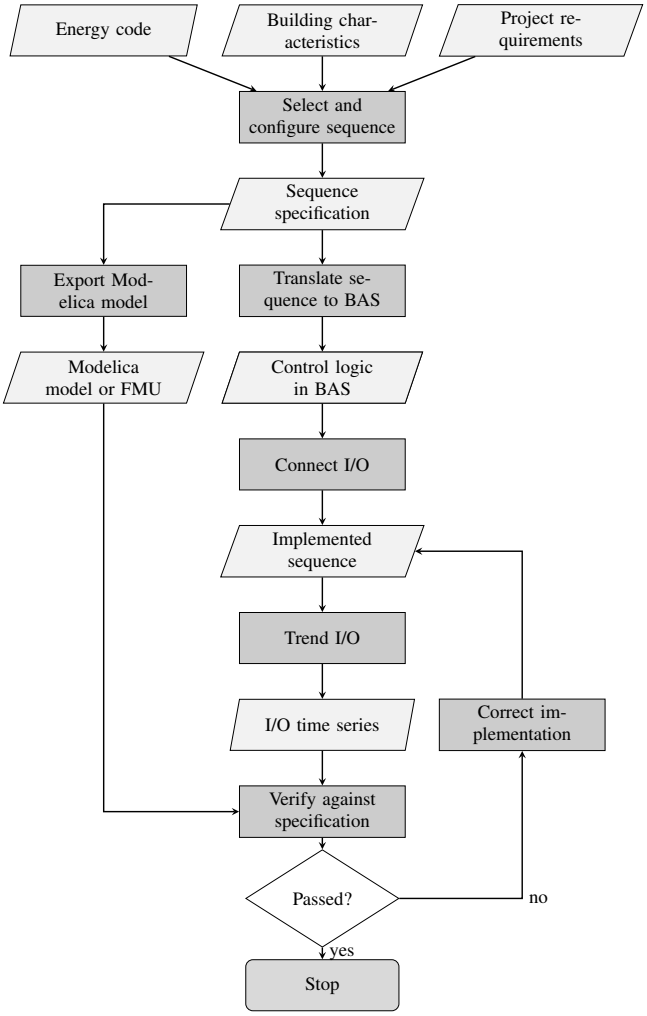

Figure 1. Workflow from control sequence configuration to export of a specification, implementation on a BAS and verification during commissioning. (Simplified representation based on Wetter, Ehrlich, et al. (2022).)

This final step of the workflow provides formal verification ensuring that the as-implemented control logic reproduces the control signal in accordance with the specification that was exported by the mechanical designer. Thus, we give the control vendor the option to use software translation, but don't require to do so, and regardless, we offer the ability to test the implemented control logic for compliance with the CDL specification.

While the above workflow is for an actual building, the above cited publication shows a variant that is applicable for control providers to conduct open-loop tests to verify that they implemented the control logic correctly.

3.1 CDL

CDL is a small subset of Modelica that is needed to implement block diagrams that are sufficient for use in Modelica templates (Gautier et al. 2023), yet simple to implement and modify by non-Modelica experts. CDL defines permissible data types (`Real`, `Integer`, `Boolean`, **`enumeration`**). It also defines immutable, so-called *Elementary Blocks*, such as the `Reals.Add` block that outputs the sum of two real-valued input signals. The language allows single inheritance blocks and the composition of blocks to form a *Composite Block* that may encapsulate a complex hierarchical control logic. It also allows for conditional connectors and instances, enabling the implementation of a room controller that may include, for example, an optional input and associated control logic for the room CO_2 concentration.

To reduce complexity of CDL, and because legacy BAS may not support advanced Modelica concepts, we excluded various Modelica constructs. Excluded constructs are, for example, `Clock`, **`inner`**/**`outer`**, physical ports such as a fluid port, and finite state machines. However, CDL has the concept of an *Extension Block* that allows to encapsulate any Modelica construct. Originally implemented to satisfy the requirement of calling compiled proprietary control logic, an `Extension Block` also allows, for example, the implementation of a finite state machine. ASHRAE Standard 231P requires each *Extension Block* to be exported to an FMU-ME 2.0 when exporting CDL to CXF, which is an exchange format described below. Control vendors are allowed to implement *Elementary Blocks* and *Extension Blocks* in their language of choice, as long as the mapping from inputs, parameters and states produces the same outputs. Thus, these blocks are defined through their inputs, outputs and the mapping from inputs and current states to outputs.

CDL also specifies the Modelica vendor annotation `__cdl`, which is used, among other things, to declare semantic information, or to specify whether an input needs to be hardwired or networked, such as through the BACnet protocol.

3.2 Standardization via ASHRAE Standard 231P

One critical step to digitalizing control delivery is to develop a standard which then provides a solid foundation for industry to adopt and invest in the technology. Approved standards are widely used by government and industry. We chose to develop an ASHRAE/ANSI standard, to facilitate potential future ISO recognition. The ASHRAE/ANSI process is consensus-based and involves various stakeholders. In 2020 the CDL team approached ASHRAE with a proposal and received approval to initiate a standards project. This effort was titled "ASHRAE 231P, Controls Description Language." The project committee consists of 30 members, including a diverse mix of control system manufacturers, HVAC control system designers, and researchers. The committee has been meeting regularly and reviewing and discussing the structure and format of the standard. This has resulted in discussions related to key differences between how control logic is handled in simulation and in building automation product lines. For example, Modelica distinguishes between real and integer data types while many BAS represent integers as integer-valued real data types. Additionally, many BAS lack mechanisms for event iteration, or for synchronizing simultaneous time events. The standards committee discussed and reached an agreement on what blocks should be supported as *Elementary Blocks*.

ASHRAE Standard 231P also specifies the Control eXchange Format (CXF), a representation of CDL in a JSON-LD format that is intended to be used as an intermediate format when importing CDL to a BAS, as JSON-LD is easier to parse than Modelica. For example, a control provider might utilize JSON-LD to import control logic from a design tool and deploy it to their commercial BAS for a particular project. While CDL has language constructs that are used to build library of sequences, CXF was designed to only represent a specifically configured logic. For example, CXF has no mechanism to conditionally remove a block and all its connections, as is provided by Modelica and allowed in CDL. CXF can be exported from CDL using the modelica-json software described below.

In 2024 the committee released an initial draft standard for public review. It is anticipated that a second review will occur in 2025 which, depending on feedback, could result in the publication of an ASHRAE/ANSI Standard in early 2026, which could then be submitted for ISO approval.

3.3 Sequence library and HVAC templates

Concurrently with developing CDL, the authors have created CDL compliant reference implementations of control sequences published in ASHRAE Guideline 36 (ASHRAE 2018), along with the accompanying HVAC system models.[4] These parallel developments created valuable feedback where practical implementation challenges directly informed the CDL specification. One example of such feedback is the introduction of the *Extension Block* concept which provides support for finite state machines (see Section 3.1). This addition helped address one of our main difficulties: using discrete event modeling to represent synchronous logic, as described hereafter.

In sequence documentation, the word "when" (as opposed to "if") typically signals such event-based patterns. Consider the following clauses that handle availability conditions in the staging logic of a plant: "Any unavailable stage is skipped during staging events. *When* the current stage *becomes* unavailable, the transition to the next higher available stage is triggered." We first implemented these clauses by merging them into a single state-based condition: "*If* a stage *is* unavailable, the transition to the next stage is triggered." Now, if the plant is in stage 1 while stage 2 is unavailable and a stage-up command is generated, a simple test shows that, in the model time domain, the plant effectively transitions directly to stage 3. However, issues appear in the event domain where an intermediate step is taken, during which stage 2 is enabled before being disabled at the next event. This intermediate zero-time event triggers all the staging sequence at stage 2, which is unwanted. Refactoring the implementation to be event-safe proved challenging when using only CDL *Elementary Blocks*, but was greatly simplified by using finite state machines. This also improved the block diagram readability, facilitating maintenance tasks. [5]

With our studies involving closed-loop simulations (Wetter, Ehrlich, et al. 2022; Zhang et al. 2022), we realized both the value and the difficulty of integrating equipment models and detailed controls into models that can be easily configured and parameterized. Depending on the system configuration and control options, the set of required actuators and sensors changes. The corresponding components and their connections must be updated consistently, while ensuring that the model remains well formulated for simulation. For example, lumping flow resistances is a good practice that reduces the size of nonlinear algebraic loops when modeling pressure-flow networks (Jorissen, Wetter, and Helsen 2015). But this approach becomes error-prone when the system configuration changes, e.g., when actuated isolation valves are removed, knowing that these are typically the components used to merge the fixed flow resistance of a chiller evaporator and condenser. Parameterizing hydronic system models brings further requirements, such as flow balanc-

[4] Both developments are released as part the Modelica Buildings Library, in the packages `Buildings.Controls.OBC.ASHRAE` and `Buildings.Templates`.

[5] The resulting *Extension Block* `StageIndex` in the Modelica Buildings Library shows the complexity of simply computing the current stage index of a multiple-unit system based on stage change commands. The discussions in the issues #3787, #3952 and #3966 further illustrate the iterations it took to find event-safe implementations for CDL *Elementary Blocks*.

DOI 10.3384/ecp218505

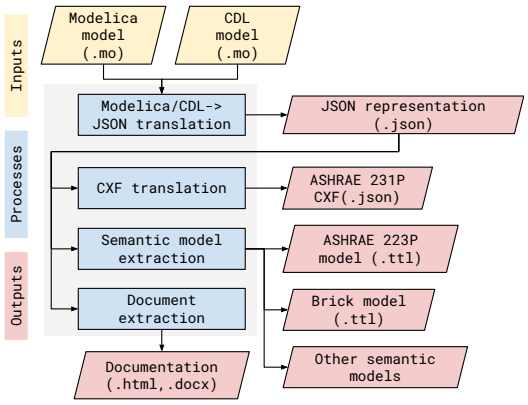

Figure 2. Inputs and outputs supported by modelica-json.

ing between unequally sized equipment in constant primary flow systems. This involves calculating the flow coefficient of balancing valves in case of constant speed pumps, or the pump speed (potentially at each plant stage) in case of variable speed pumps operated at fixed speed. Templates have been developed to programmatically address such tasks, enabling users to configure detailed closed-loop models by simply specifying top-level parameters. The templates handle all the complexity of model creation and parameterization, while embodying modeling best practices and making state-of-the-art control sequences broadly accessible. This is achieved exclusively with Modelica code, leveraging advanced class parameterization features of the language (Gautier et al. 2023).

The templates distributed with version 12.0.0 of the Modelica Buildings Library cover variable-air-volume systems and air-to-water heat pump plants. Templates for boiler and chiller plants are planned for release with the next version of the Library.

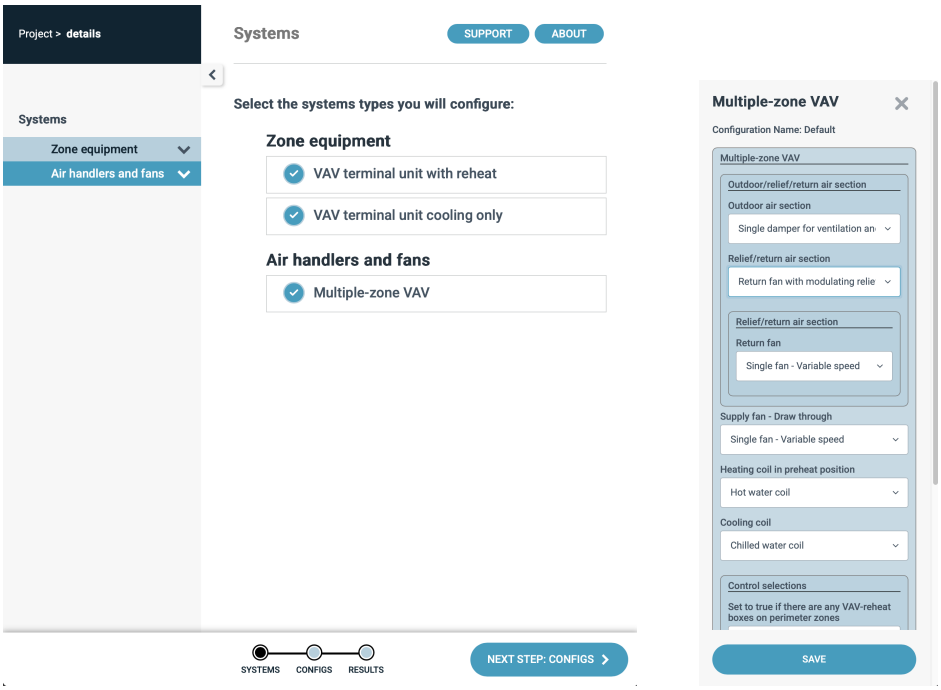
3.4 Modelica-json translator

Figure 2 shows modelica-json, a software that can be used to translate Modelica models into a JSON representation (Wetter, Hu, et al. 2021), and from there to generate various other outputs. The JSON representation is used to generate CXF, the representation of the control logic, and to generate a semantic model (see Section 3.4.2). As Modelica and CDL classes support the inclusion of semantic information (Fierro and Pauwels 2022), modelica-json allows the extraction of semantic models for ontologies such as Brick and ASHRAE 223P, as well as other schemas such as Project Haystack. Modelica-json is also used to generate documentation in html or Microsoft Word.

3.4.1 CDL-CXF translation

CXF is a semantic, graph-based representation of a CDL control logic serialized in JSON Linked Data (JSON-LD). Based on JSON-LD and using classes such as `S231:Block`, `S231:Connector` and `S231:Parameter`, and using relationships such as `S231:hasInput`, `S231:containsBlock` and `S231:isConnectedTo`, modelica-json constructs the CXF representation of the CDL control logic. Structurally the content of a logic in CDL and CXF are identical, in that both utilize the same *Elementary Blocks*, *Composite Blocks*, and *Extension Blocks* as well as `Constants`, `Parameters`, `InputConnectors` and `OutputConnectors`. There are, however, a few differences: First, for *Elementary Blocks* in CDL, their CXF representation does not include the implementation (equation section) of the particular block. Second, CXF allows translation tools to either retain array references and expressions present in CDL or to flatten the arrays and evaluate the expressions.

3.4.2 Semantic model extraction



CDL supports the inclusion of semantic information (Fierro and Pauwels 2022) in a control logic using the `__cdl(semantic(...))` Modelica vendor annotation. While, as with other Modelica annotations, these annotations have no influence on the behavior of the control logic, they can be used to add information that is helpful for trending and communication, and for specifying semantic information. These items all support streamlining the configuration of control and communication, connecting or configuring energy analytics programs, and exporting natural language documentation.

Through the `__cdl(semantic(...))` annotation, semantic information can be added to blocks (both the class and the instance definitions), packages, parameters and input and output connectors. Controls developers can include information adhering to a particular semantic ontology or data schema using the `semanticLanguage` keyword. In this case, the included information must conform to the `semanticLanguage` and a supported format, such as `text/turtle`, `application/json` or `application/ld+json`. They can also add documentation in a natural language using the `naturalLanguage` keyword, with the documentation in the `text/plain` format. Similarly, semantic information can also be added to models developed with the Modelica Buildings Library, beyond CDL, by using the `__Buildings(semantic(...))` vendor annotation.

Modelica-json enables the export the semantic information as a separate file that can be shipped along with the CDL (or CXF) control logic or the Modelica model. For example, if a CDL control logic contains semantic shape requirements for the input and output points, described using ASHRAE Standard 223P and SHACL (W3C 2008), modelica-json can export these shapes for each of the connectors. These semantic shapes could then be used to integrate the sequences with BACnet communication points within a BAS.

3.5 ctrl-flow

Figure 3 shows ctrl-flow, a web-based application that aims to facilitate the adoption of the digital workflow by the HVAC designers. The tool is open-source and available at `https://ctrl-flow.lbl.gov`. It solicits user inputs to specify the characteristics of HVAC systems

(a) System selection. **(b)** Configuration panel.

Figure 3. ctrl-flow user interface.

and controls as shown in Figure 3, and outputs standardized specification documents. In its current state of development, the tool enables creating the control sequence documentation for variable-air-volume systems compliant with ASHRAE Guideline 36 (ASHRAE 2018). Ongoing projects are extending both the scope of supported systems and the generated content to include control schematics, point lists, equipment schedules and Modelica models of the specified systems.

At its foundation, ctrl-flow uses templates from the Modelica Buildings Library (see Section 3.3) and can accommodate any Modelica model that conforms to the guidelines available at `https://lbl-srg.github.io/modelica-buildings-templates`. On the server side (*Node Backend* in Figure 4) the tool invokes modelica-json and further processes the JSON representation of the template abstract syntax tree into an intermediate format (*ctrl-flow Schema*) that is more tractable by the React frontend. This schema is then populated by user selections and written back to the *Node Backend*, from where it is returned to the *Python Doc Pipeline*. The *Python Doc Pipeline* creates the sequence documentation using a DOCX template file, and then sends it to the *React Frontend* for user download.

Since templates often rely on advanced Modelica constructs, the tool required an interpreter layer capable of handling Modelica grammar's intricacies such as replaceable elements (instance or class) with optional constraining clauses, conditional declarations or composite bindings with `record` instances. Additionally, the frontend needed an integrated expression evaluation engine to process Boolean expressions used in user interface annotations that control the visibility of input fields.

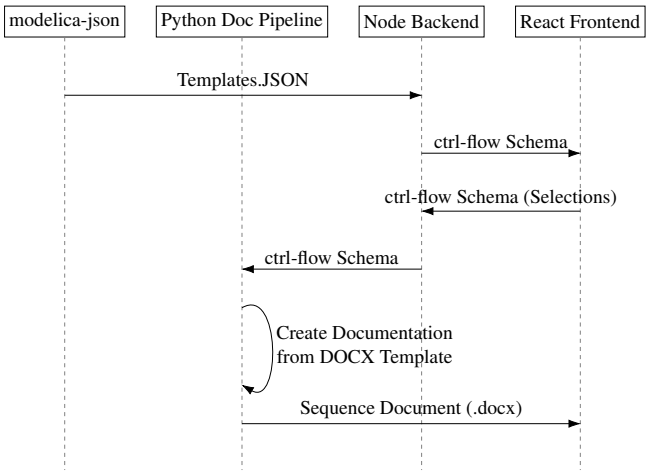


Figure 4. Data flow diagram of ctrl-flow.

In practice, this translates into handling an object of roughly 20 MB in size that gets regenerated at each user interaction while maintaining both responsiveness in the interface and simplicity in the user experience.

3.6 Import of CDL in BAS

Today's BAS generally do not accommodate generating C code and executing the compiled code, as is done, e.g., in embedded systems. Therefore, CDL was designed so that its mathematical mapping of inputs and states to outputs can be replicated by a BAS, and the declarative specification of the block diagram be translated to the programming

DOI
10.3384/ecp218505

language of the target environment. Hence, supporting CDL can be accomplished either through code generation, or through translation of CDL. The translation of CDL consists of mapping the CDL block diagrams to a representation in the target platform that given the same inputs and states, produces the same outputs. Our ongoing collaboration with various BAS providers indicate that only minor changes if any are needed in the target BAS. This requirement for compatibility with existing BAS product lines was the reason for excluding Modelica constructs such as `inner`/`outer`, `expandable connector` and `Modelica.Clocked`.

For a translation from CDL to a BAS, control providers seem to favor the JSON-LD representation rather the CDL representation, as it avoids having to implement a Modelica parser, although we encountered a company that started doing so. If one designs a new control product line, we recommend exploring the use of the eFMI Standard (Lenord et al. 2021) and the SSP standard (Modelica Association 2019) for using code in a BAS.

3.7 Verification

The proposed digital workflow supports the verification of the control logic relative to the original specification, which is expressed as a model in the CDL language. The verification compares the difference between the outputs of the controller minus the outputs computed by the specification, both using the same control inputs, parameters and constants.[6] The verification uses the funnel software to verify that the differences are within user-specified tolerances in time and in signal value. If all differences are within the tolerances, the tested control logic conforms to the specification.

Note that this verification process only tests the control logic implementation relative to the specification. It neither evaluates the suitability of the control intent as specified in the control specification, nor does it test the performance of the closed loop system or the proper operation of the HVAC components. Such functional tests and performance tests have been deliberately excluded from the control logic verification, and should be done separately.

We will now describe two distinct use cases, the first being the verification of a control logic implemented in a building system, and the second being the testing of a control logic as part of product development during which a controller can be run open loop. Both use cases are also described in more detail in Wetter, Gautier, et al. (2019) and Wetter, Ehrlich, et al. (2022)

3.7.1 Controller installed in a building system

If a controller is installed in a building system, it may not be possible to arbitrarily change the control inputs without detrimentally affecting the safe operating of the building system. Therefore, in this workflow, a commissioning agent can run the building system through acceptable operational scenarios and trend the inputs and outputs of the controller. Next, the CDL model is simulated with the same parameters and inputs, and its outputs are recorded. Using the funnel software, tests can be run to verify that the differences between trended and simulated outputs are within a user-set tolerance.

3.7.2 Open loop testing of a controller

Prior to installation in a building system, a controller could also be executed open loop to test its response to different sets of parameters and inputs. Therefore, in this workflow, a control technician executes the CDL model for a variety of parameters and inputs, and records the output. Next, the actual controller is executed for the same parameters and inputs, and its outputs are recorded. As in the previous use case, the outputs of the simulated and actual controller are compared.

4 Industry collaboration

The control industry has shown significant interest in developing and adopting standards for digitalization of control as described above. All of the major US BAS vendors have been actively participating in the creation of ASHRAE Standard 231P, with representatives being voting members of the committee. The authors have been collaborating with Carrier's Automated Logic to prototype a translator from CDL to the EIKON language, as described in Wetter, Ehrlich, et al. (2022), which is now being further developed. Additionally, another BAS vendor, Tridium, and two EMIS vendors, Skyfoundry and Normal inc, have recently begun developing parsers and translators from CDL or CXF to their product lines. Furthermore, the authors have been working with KTC, a controls and energy optimization company, to incorporate ASHRAE Standard 231P into their design-build-operate workflow via a translation to a PLC controller using IEC 61131-10 XML. Notably, Meta has been using the Modelica Buildings Library and CDL to design and operate hyperscale data centers and optimize their operation using Modelica-based digital twins (Rivalin et al. 2023).

5 Outlook

We expect that in 2025, the ASHRAE Standards 231P and 223P undergo a formal vote for approval. Once accepted, this will provide a robust foundation for BAS and EMIS providers for the digitalization of control and energy information system delivery. Through the ESTCP project "DoD Building Controls Design Tool"[7] that is led by the US Army Construction Engineering Research Laboratory, the authors are working on adopting the ctrl-flow software to the needs of DoD who owns around 550,000 buildings and facilities and thus provides an opportunity for scaled

[6] Typically, one also has to set initial states. However, many BAS do not allow setting initial states or recording them. In this case, the verification should start once initial transients disappeared.

[7] See `https://serdp-estcp.mil/projects/details/a964da95-b45e-404a-b7e1-d8dd6fcc246f/dod-building-controls-design-tool`.

deployment. The authors are also working with DOE and DoD/ESTCP in exporting Modelica template models for combined heat pump and chiller plants for buildings and district energy systems, and including them in ctrl-flow as part of a design guide for the robust, scalable deployment of such systems. In addition the authors are working on a California Energy Commission project to implement new demand-flexible control sequences in four California campuses using CDL in collaboration with two BAS and three EMIS providers.

6 Conclusion

Our proof of concept translation and various follow on work showed that a small subset of Modelica that is simple to use and support suffices for many building control representation in support of a digital design-deploy-verify process, with a notable exception of certain complex equipment staging sequences that are much simpler to implement in finite state machines, for which CDL provides a means for including such encapsulated Modelica constructs. With CDL, which is a Modelica subset, and its CXF representation, which is in JSON-LD, languages were developed that allows controls design, closed loop performance assessment with HVAC and building models in the loop, creation of template libraries of HVAC and associated control logic, and digital deployment to control product lines.

The next challenge is to scale its use in the buildings industry to make workflows cheaper, more robust and repeatable based on a highly digitalized workflow that allows formal validation and verification at every step along the design, build, and operate process. With the inherent higher control complexity that we see for energy efficient, grid-responsive and resilient systems, we believe such a new process is essential to control costs and meet the technical performance goals.

7 Data Availability

The CDL reference implementation, the control sequence libraries and the HVAC and control templates are available in the Modelica Buildings Library (`https://github.com/lbl-srg/modelica-buildings`). The modelica-json translator is available at `https://github.com/lbl-srg/modelica-json`. The guide for how to implement Modelica templates for use with ctrl-flow is available at `https://lbl-srg.github.io/modelica-buildings-templates`. The ctrl-flow source code is at `https://github.com/lbl-srg/ctrl-flow-dev` and the online web version is at `https://ctrl-flow.lbl.gov/`. A specification of CDL and CXF, together with accompanying process descriptions and publications, is available at `https://obc.lbl.gov/`. The ASHRAE Standards 231 and 223, once approved, will be available at `https://www.ashrae.org/technical-resources/standards-and-guidelines` (access to draft versions is restricted to committee members) and an unofficial specification of CDL together with other information is available at `https://obc.lbl.gov`.

Abstract

This paper presents the CDL-PLC translator, a tool to convert control sequences for building heating, ventilation, and air conditioning (HVAC) systems expressed in a subset of Modelica called Control Description Language (CDL) which is undergoing standardization via the voluntary ASHRAE Standard 231P into the IEC 61131-10 XML format. Such a translation is a step in a model-based design workflow and contributes to digitalizing the control delivery process in the building sector. The translation into the IEC 61131-10 XML is the last step in the implementation of control logic developed in CDL on programmable logic controllers (PLCs) standardized in IEC 61131. The paper presents the details of the translator, an example for the validation of a CDL block vs. the corresponding IEC block, and a practical application example for the translation of a control sequence for a hybrid heat pump plant from a case study neighborhood in Belgium. Practical applications, use cases, and future developments are discussed in the context of building industry processes.

Keywords: HVAC systems, Control Description Language, PLCs, Model-based Design

1 Introduction

1.1 Motivation

The building sector is facing major challenges to improve energy efficiency and load flexibility. In order to increase the share of renewable and residual energy sources, new supply systems will be installed in new and existing buildings the next years. The integration of intermittent renewable energies raises the complexity of design and operation as modern installations often use multiple technologies, such as heat pumps, solar systems and storage in order to meet new requirements for buildings to shift supply and demand and to interact with electrical grid signals. Optimizing controls of air handling units and room-side emission systems is another strategy to increase the efficiency of new and existing HVAC systems in buildings. To perform these engineering tasks in building practice, the methods, tools, and procedures for the development of HVAC control sequences come into focus.

1.2 Industry practice and related problems

In the buildings industry, the initial development and the final implementation of HVAC system controls are separated between design engineers and installation contractors (see 'Building practice' in Figure 1). This is a structural difference to, for example, the manufacturing or automotive industry. The design and the execution phases are separated by the tendering and award procedure.

The design and the development of HVAC control sequences is largely based on static considerations in single operation modes, rules of thumb, and often based on previous projects. Control sequences are documented using graphical control schemes and textual so-called 'functional descriptions' or 'sequence specifications', for example based on VDI 3814-4.3:2022 (Verein Deutscher Ingenieure 2022). These analog documents are then manually interpreted by the control provider who develops control logic for the building automation system. This practice is highly susceptible to human error (Barwig et al. 2002; Torabi et al. 2022), and leads to several well-documented problems, such as inappropriately parameterized control sequences (Crowe et al. 2020; Raftery et al. 2024) and a gap between predicted and measured performance (Wilde 2014). An in-depth revision of the control sequences in the control code, which goes beyond parameter optimization, requires qualified engineers and is therefore costly.

1.3 Model-based HVAC control design

Model-based design is an approach to master the increasing complexity of future HVAC systems and their controls through an increased level of detail and increased quality in the design phase. Based on regulatory or user-defined requirements for the energy and comfort performance, a model-based and digitalized workflow generally includes three parts (see dashed boxes in Figure 1):

1. A Building Performance Simulation (BPS) environment for the integrated simulation of the building envelope, HVAC systems, and their controls, and the verification against performance requirements.

2. A digital exchange format for the lossless and unambiguous documentation and transfer of control sequences.

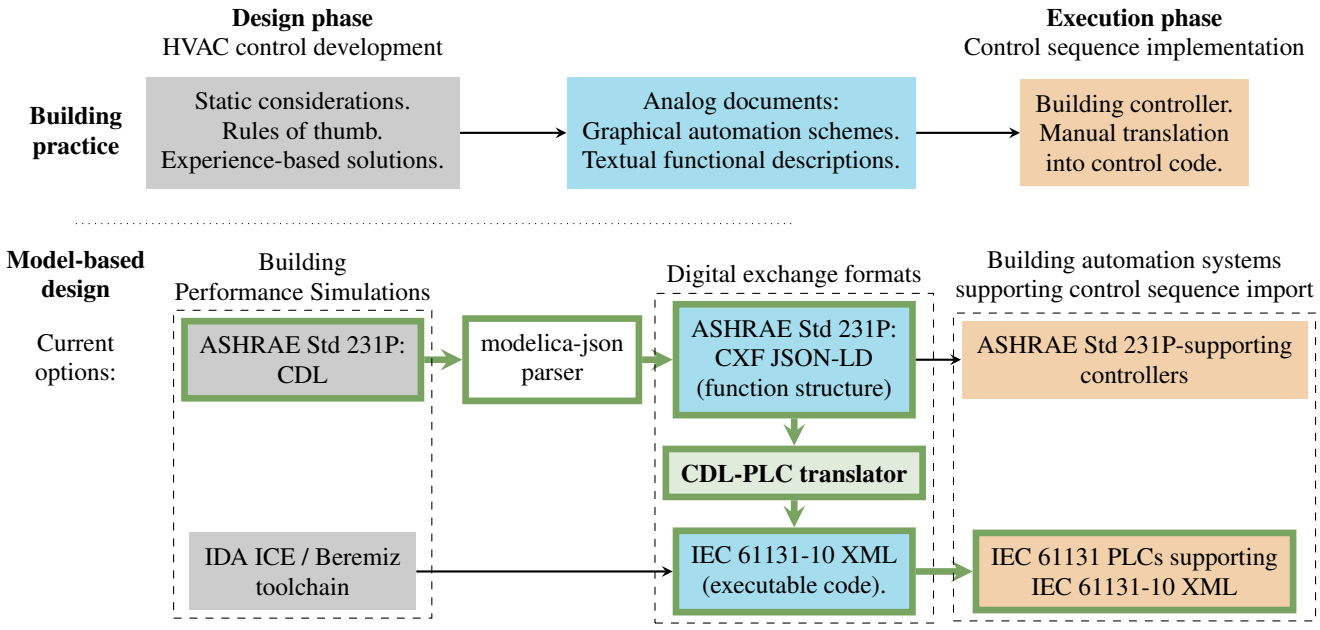

Figure 1. CDL-PLC translator in the context of development and implementation of HVAC controls in building practice, model-based design, and the workflow described in this study (green label). Note that from CDL to CXF, there is an alternate path via the ctrl-flow software[1] that does not require a building performance simulation. This path is not shown here as it does not include performance evaluation as is typical in model-based design.

3. For a seamless and efficient implementation, a building automation system (BAS) supporting the import of control sequences is needed.

Model-based design of HVAC controls is a new approach in the building industry, and generally applicable to all types of buildings. However, due to the effort required for model development, complex and individual HVAC systems in commercial buildings and supply systems in urban districts and neighborhoods would be typical applications. While model-based design is generally independent of the control approach, the toolchains discussed in this paper use conventional Rule-Based Controls (RBCs), which are still the standard in the building sector.

In the literature, two approaches can be distinguished that are presented in the following two sections.

IEC 61131-3 code simulation in IDA ICE The first option (see bottom row in Figure 1) uses the IEC 61131-3 code simulation in the commercial equation-based BPS software IDA ICE, the IEC 61131-10 XML standard as digital exchange format, and IEC 61131 PLCs as target system. The idea behind this toolchain is to simulate the behavior of real controllers in an equation-based simulation environment with a variable step size solver, such as IDA ICE (Sahlin, Bring, and Eriksson 2009). This toolchain was initially developed for Software-In-the-Loop (SIL) testing of PLC programs during the commissioning phase (Sahlin, Skogqvist, and Högberg 2018), however, it can also be used for the development of HVAC controls during the design phase, as demonstrated in a full-scale end-to-end application for air handling units (AHUs) in a factory building (Walther 2025).

IEC 61131-3 (International Electrotechnical Commission 2003) is a standard for the programming of controllers standardized in IEC 61131, called PLCs. IEC 61131 PLCs are commonly used for building automation in Europe. PLC programs are organized in program organization units (POUs) that can be a type or an instance of functions, function blocks, or programs. IEC 61131-3 defines 5 languages, two of which are textual (Structured Text (ST), Instruction List (IL)) and three of which are graphical (Function Block Diagram (FBD), ST, IL), which can be different for each POU. In chapter 2.5.1.5. of IEC 61131-3, standard functions for arithmetic, numerical, type conversion operations etc. are defined. For a technology overview and suggestions for future developments, e.g. to achieve deterministic behavior, we refer to Sehr et al. (2021).

In the IDA ICE toolchain, an XML file standardized in IEC 61131-10 is used for the digital delivery of control sequences from the design to the execution phase. The first version of this XML format was published in 2005 under the umbrella of the PLCopen organization (Marcos et al. 2009). IEC 61131-10 XML was originally designed to exchange control sequences between different PLC Integrated Development Environments (IDEs). Some PLC IDEs support the IEC 61131-10 XML import, for example Codesys, TwinCAT (Beckhoff), or e!cockpit (Wago). However, due to the above mentioned construction-specific workflow procedures (no code development in the design phase, normatively prescribed graphical and textual exchange formats), it is not used in

[1] See `https://ctrl-flow.lbl.gov`.

DOI 10.3384/ecp218515

the building sector today.

Modelica Control Description Language Within the OpenBuildingControl (OBC) project, a new process and supporting tools was developed to digitalize specification, implementation, and verification of HVAC control sequences (Wetter, Ehrlich, et al. 2022) (see middle row in Figure 1). The central part of CDL[2] is a library with standardized function blocks typically used for building applications, as a small subset of Modelica (Wetter, Grahovac, and Hu 2018a). This library alongside with rules for how to compose control logic in a hierarchical way was first presented in (Wetter, Grahovac, and Hu 2018b) and it is currently being standardized in ASHRAE Standard 231P.

To transfer HVAC control sequences defined in Modelica, multiple options are possible.[3] In principle, the (already existing) Functional Mock-up Interface (FMI) standard can be used, however, today's Building Automation Systems mostly do not support the direct execution of Functional Mock-up Units (FMUs) / C code, and they do not support editing Modelica models and regenerating FMUs if the control logic need to be changed after installation. To address this issue, the modelica-json translator[4] was developed to parse CDL sequences into an intermediate JSON file format, called Control Exchange Format (CXF) (Wetter, Hu, et al. 2021). With such an intermediate format, the translation of control sequences developed in CDL into product-line specific languages in general is performed in two steps:

1. *Parsing* control sequences in CDL into a JSON CXF using the open-source modelica-json translator. This step is fully covered by the CDL toolchain (open-source).

2. *Translation* of the CDL JSON into the product-line specific language. If the target system uses proprietary language, this step has to be performed by the controller manufacturer.

CDL vs. IEC 61131 The previously described options have introduced two standards, IEC 61131 and CDL (ASHRAE Standard 231P). Different areas of application are briefly contrasted below to underline that the two standards are not mutually exclusive.

IEC 61131, on the one hand, is a standard for controllers. It standardizes a computational model, programming languages, interfaces, exchange formats, etc. The IEC 61131 standard is only adopted by some manufacturers, while other manufacturers use proprietary control implementations. The crucial step that influences the actual building performance in operation most is, however, the early design phase when control sequences have to be designed in the building context, and when the actual control vendor might not yet be decided.[5] CDL, on the other hand, is specifically designed to allow simulation of control sequences together with HVAC systems in the building context, and subsequent translation to a Building Automation System. CDL is product-neutral and addresses all downstream controller types, including those that follow IEC 61131.

A further crucial aspect is that CDL provides a library of standardized function blocks. Such a library is missing in the PLC-domain where usually each vendor provides proprietary libraries. These vendor-specific libraries have several drawbacks: (a) they are typically proprietary and only documented textually, (b) they are not standardized and vary from vendor to vendor which locks customers into specific systems, and (c), most importantly, they only come into play during the programming of controllers during the execution phase and are therefore inevitably differ from what mechanical engineers have drafted during the design stage.

1.4 Research gap and contribution

In the context of CDL, current efforts focus on the standardization of control blocks and the exchange formats, such as the CXF JSON-LD, in ASHRAE Standard 231P (first step, 'parsing', described in 'Modelica-based Control Description Language' above).

This study presents the CDL-PLC translator to address the final step of transferring CDL sequences to building controllers following IEC 61131. The translator converts the CXF JSON into the IEC 61131-10 XML, and as such link CDL and the PLC-domain (see green path in Figure 1). The particular benefit maximizing the impact of such a translator is that CDL is linked to IEC 61131 which is followed by several automation manufacturers.

The translation of the CDL CXF into the IEC 61131-10 XML is associated with two main challenges:

1. The *translation of the structure* of the CXF JSON-LD into the target structure, here the IEC 61131-10 XML.

2. The *implementation of control functions* defined in CDL blocks into the language of the target system, here control code according to IEC 61131-3.

The remainder of this paper is organized as follows: First, the CDL-PLC translator is presented in section 2. In section 3, the translator is applied to a control sequence from a real project to demonstrate the functionality in a practical case. We conclude with a discussion on industry transformation and future work.

2 CDL-PLC translator

In this section, first, the general approach of the CDL-PLC translator is presented, then, source and target formats are

[2] https://obc.lbl.gov/specification/cdl.html

[3] https://obc.lbl.gov/specification/codeGeneration.html

[4] https://github.com/lbl-srg/modelica-json

[5] This applies for the case of new buildings. In existing buildings, the implemented BAS might or might not follow IEC 61131.

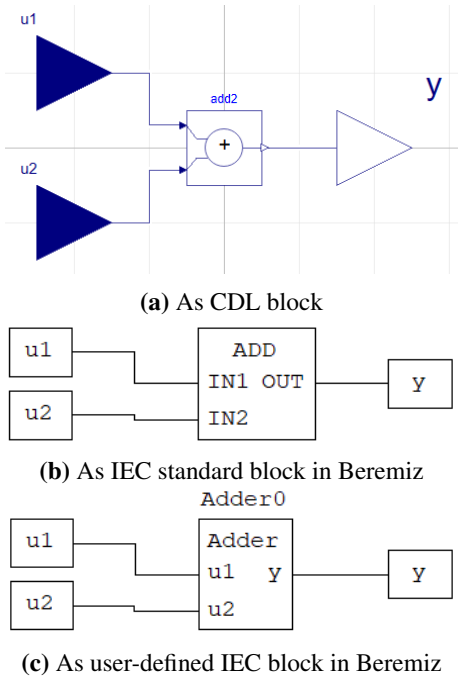
described, and, finally, the program architecture and the features are described.

2.1 Basics

General approach The general approach of the CDL-PLC translator is to convert the information from the CDL CXF JSON-LD format to the IEC 61131-10 XML format. The translator directly maps CDL blocks to IEC blocks, and the output IEC 61131-10 XML uses the graphical FBD language. This enables a direct and visual comparison of the graphical FBD representations in Modelica and IEC 61131-3. The translator is implemented in Python. For all PLC-related tasks within this study, the open-source PLC IDE Beremiz[6] was used.

Workflow and use cases The CDL-PLC translator is meant to be used either by design engineers or by executing contractors depending on how the control delivery is organized. During the execution phase, automation contractors tasked with the programming of IEC 61131 PLCs then import the IEC 61131-10 XML into the product-line specific PLC IDE.

The translator addresses two building-specific use cases:



1. The development of control sequences in *new buildings*. In this case, the option to import the IEC 61131-10 XML must be specified in the tender. If a BAS already supports the FMI standard, importing an FMU might be a more straightforward option.

2. The revision of control sequences in *existing buildings*, where the existing BAS is kept, and where an existing HVAC system is either kept or replaced within a renovation. Only BAS with PLCs following IEC 61131 and IDEs supporting the import of the IEC 61131-10 XML are discussed below. As new PLC product lines might directly support the FMI standard (see section 4), such a redesign of existing legacy PLC-based BAS is a likely application for the CDL-PLC translator.

Development status The CDL-PLC translator is currently at a prototypical stage as a proof of concept that CXF can be translated into IEC 61131-10 XML. The translator supports the necessary basic features such as mapping and connecting function blocks. The translator currently supports a small subset of CDL elementary blocks, mainly those needed for the application example presented in section 3. However, as the core features are covered, extending the translator to a fully-fledged software is straightforward.

In its current form, the translator works only in the CDL-to-PLC direction. The PLC-to-Modelica direction may be possible for some control logic and would be beneficial, for example, in case executing contractors have made changes to the PLC code that have to be verified in Modelica, or when operational problems are easier to be addressed using simulation. However, whether a translation from a Building Automation System to CDL is possible is case dependent, as Building Automation Systems allow for formulations that are outside of the allowed formulation of Modelica or its CDL subset. For example, Wetter, Chen, et al. (2023) shows some differences between how control logic is implemented in building automation systems and in Modelica.

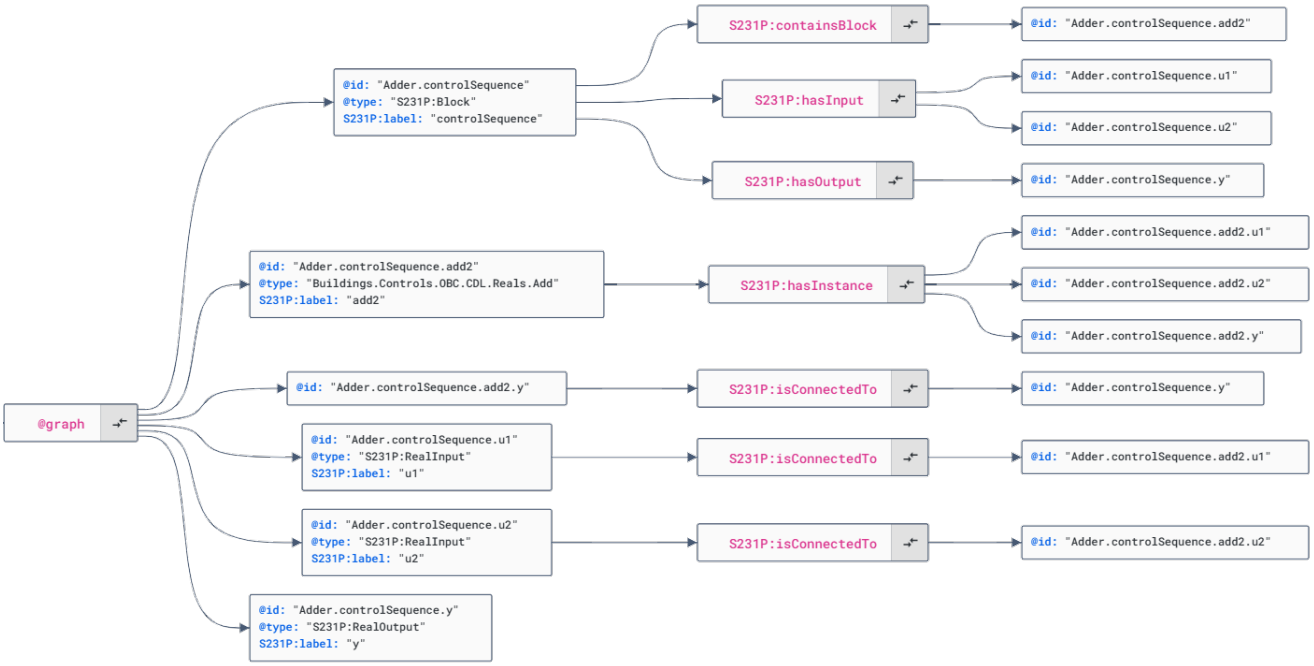
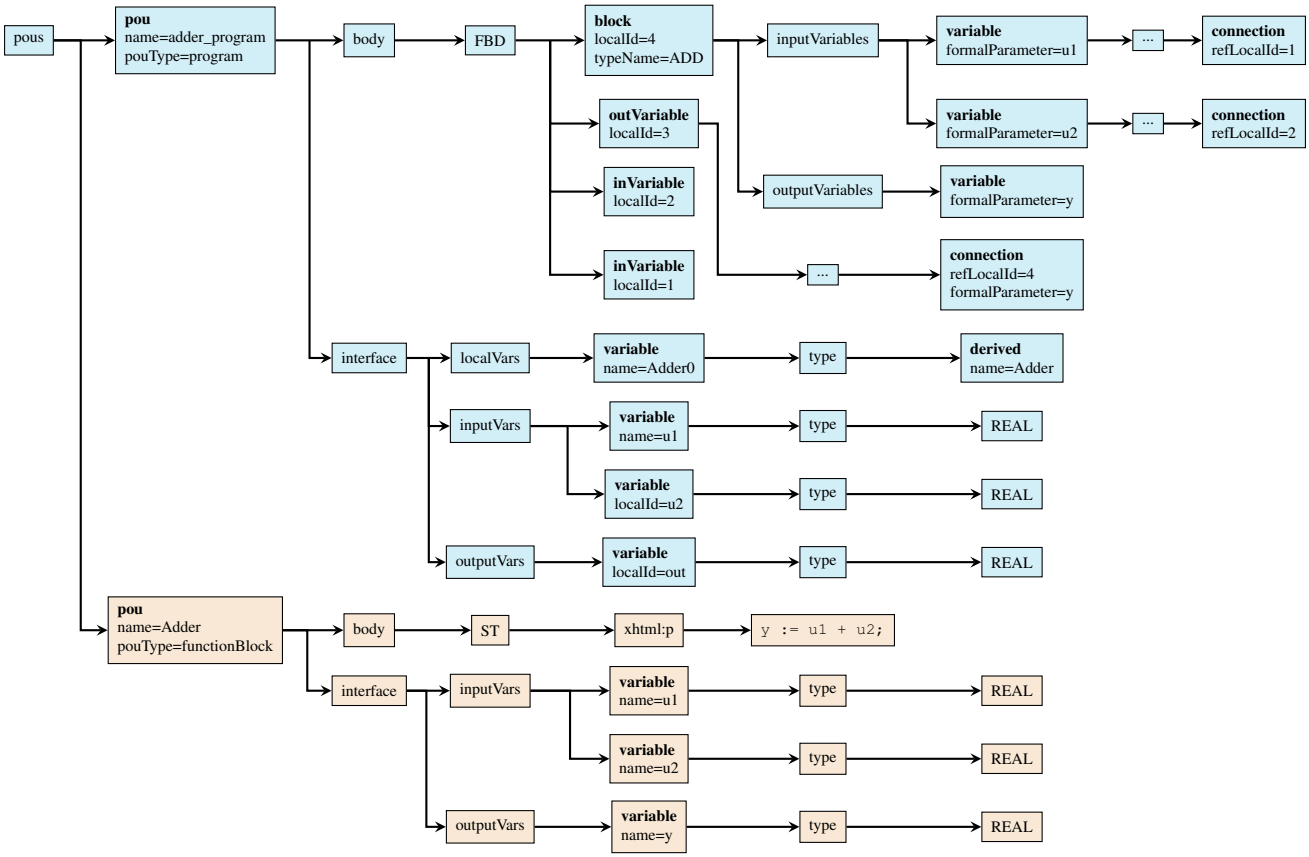
(c) As user-defined IEC block in Beremiz

Figure 2. Control sequence with an adder as FBD



2.2 Source and target formats

In the following two sections, the CXF JSON-LD source format and the IEC 61131-10 XML target format are described in order to outline differences and the functional prerequisites for the translator. The description is done for a simple control sequence with inputs `u1` and `u2`, an adder block, and output `y` as shown in Figure 2.



2.2.1 CXF JSON-LD

In CXF, nodes are separated depending on whether they represent composite or extended blocks, inputs (`Real`, `Integer`, or `Boolean`), outputs (`Real`, `Integer`, or `Boolean`), elementary blocks, parameter definitions, parameter assignments, or connections. Figure 2a depicts a simple control sequence with the instance `add1` of `Buildings.Controls.OBC.CDL.Reals.Add`. The visualization in Figure 3a shows the graph objects: the control sequence itself (`@id: "Adder.controlSequence"`), inputs, outputs, the adder block instance, and the output `y` of `add1`.

Figure 3. Visualized graphs of the example from Figure 2 (in both visualizations, information, such as for the graphical rendering, is removed to improve readability).

2.2.2 IEC 61131-10 XML

Figure 2b depicts the control sequence as FBD in Beremiz, Figure 3b depicts the structure of the corresponding IEC 61131-10 XML. In Figure 3b, for example, the instance `adder_program` is of `pouType=program` and the instance `Adder` is of `pouType=functionBlock`. While the instance `program` uses the `FBD` language (IEC Function Block Diagram), the instance `adder` is expressed in `ST` (IEC Structured Text). Figure 2b and Figure 2c also illustrate the difference between an IEC 61131-3 standard adder (see Figure 2b) and a user-defined function blocks (see Figure 2c, where the output in the `Adder` class is defined as `y := u1 + u2;`). Connections between block instances and inputs and outputs (IOs) are described in an *input-is-linked-to-output* form. IDs assigned to each block instance, each input variable, and each output variable (see `localId` attribute), are used as identifiers for connections.

2.3 Program flow

The translation is executed in two steps that are explained in the following two sections.

2.3.1 Information extraction and conversion

In a first step, the information included in the CXF JSON-LD is extracted and converted into Python objects. According to the structure of the IEC XML, the objects are grouped as follows:

- Inputs
- Outputs
- Parameters (see next paragraph)
- Blocks (with/without direct CDL-IEC equivalent separated, see next paragraph)
- Composite blocks

Handling of parameters IEC 61131-3 does not support the concept of parameters editable per function block instance as in Modelica or its CDL subset. As a workaround, CDL parameters are converted into program inputs assigned to the corresponding function block instance (see application example in subsection 3.3). The translator also supports global parameters that can be propagated to one or more block instances. An option to avoid additional program inputs would be using IEC 61131-3 *local variables*. However, such *local variables* are fixed per class declaration rather than class instance, which would require creating different class declarations for each set of parameters.

Mapping of CDL elementary blocks and validation CDL blocks are mapped to the equivalent blocks in PLC code as follows:

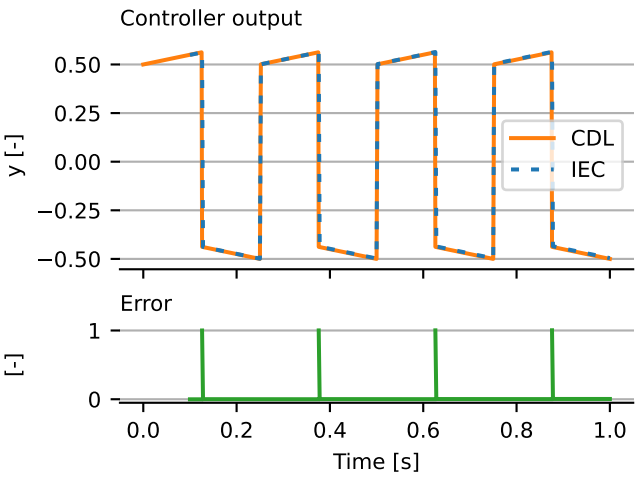

Figure 4. Validation of the `Reals.PID` CDL block vs. the corresponding block translated into IEC 61131-3 code.

- If possible, CDL blocks are directly mapped to the corresponding *IEC standard blocks* (see subsubsection 2.2.2). For example, `Logical.And` (CDL) is mapped to `AND` (IEC 61131-3).
- If a direct mapping is not possible, CDL function blocks are *individually translated* into IEC code and stored as XML snippets (see for example `Adder` function block class in Figure 3b).

An approach to facilitate the translation of each block individually would be using PLC function blocks from the open-source OSCAT library[7]. However, OSCAT blocks often do not fit exactly to the CDL definitions. OSCAT blocks are, however, used to process the PLC time (see section 'Different implementations of IEC 61131-3'), and for the integration block within the PID block.

To check whether the CDL elementary blocks have been correctly translated into the target language, the CDL toolchain offers validation packages. Figure 4 shows the result of such a validation for the `Reals.PID` block with a simulation time of 1 s. For the validation, a pulse input for the setpoint with a period time of 250 ms is prescribed on the PI controller setpoint u_s (fixed measurement input $u_m = 0.5$, proportional gain $k = 1$, time constant of the integrator block $T_i = 1$. The controller output of the IEC block matches with the CDL trajectory with a constant error of $e = 0.004$. The peaks occur because the IEC controller (cycle time 2 ms) switches one tick later than the CDL controller.

Translation of topology While connections are an attribute of output connectors in the CXF, they are an attribute of inputs in the IEC XML. The translator performs the necessary reassignment.

Listing 1. XML template for a function block instance

```
<block localId="{{ values.localId }}"
    typeName="{{ values.ClassName}}"
    instanceName="{{ key }}"
    executionOrderId="0" width="{{ values.
    width }}" height="{{ values.height }}">
        <position x="{{ values.x_absolute
            }}" y="{{ values.y_absolute }}"
            />
        <inputVariables>
                {% for key, value in values
                    .inputs.items() %}{%
                    include "xml_templates/
                    structure/
                    FbdBlockInstanceInVar.
                    xml" %}{% endfor %}
        </inputVariables>
        <inOutVariables/>
        <outputVariables>
                {% for key, value in values
                    .outputs.items() %}{%
                    include "xml_templates/
                    structure/
                    FbdBlockInstanceOutVar.
                    xml" %}{% endfor %}
        </outputVariables>
</block>
```

Different implementations of IEC 61131-3 Despite the standardization in IEC 61131, there are differences in the implementation of the standard between the control manufacturers, e.g., in the way the control time is updated, e.g. for the integrator in PID controllers. This requires that different functions / function blocks have to be mapped depending on the specific IEC 61131 target system. The CDL-PLC translator is currently outputting an IEC XML that is tested in the open-source PLC IDE Beremiz. Further adaptations to the XML might be required depending on the target IDE (not investigated in this study). In the application described in Walther (2025) an XML created with Beremiz is imported into the commercial PLC IDE e!cockpit.

2.3.2 Rendering

In a second step, the information collected in the Python objects is rendered in a IEC 61131-10 XML. For this rendering, the translator iterates over each level of the XML tree, and fills the information included in the corresponding Python objects in predefined XML templates. As an example, Listing 1 shows the template for the function block instance level of a `program` POU (cf. Figure 3b). For the rendering, the Python package 'Jinja2'[8] is used.

3 Application example

In this section, an application example is presented to highlight the currently developed features of the translator.

[8] `https://pypi.org/project/Jinja2/`

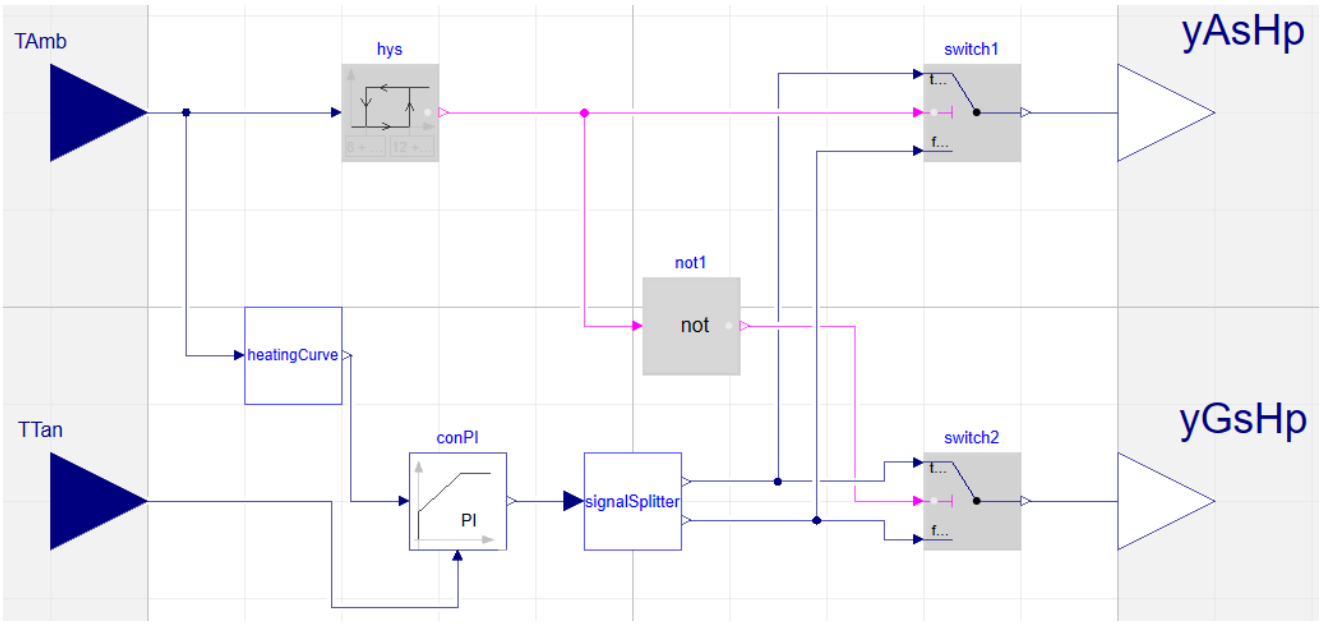
3.1 Demonstration building and HVAC system

CDL-PLC is used to translate a control sequence of a heat pump-based supply system for the renewable and residual energy sources (R^2ES)-based renovation of the 'Stijn Streuvelstraat' neighborhood in Bruges, Belgium. The project details are described in Walther et al. (2025).

3.2 Description of the control sequence

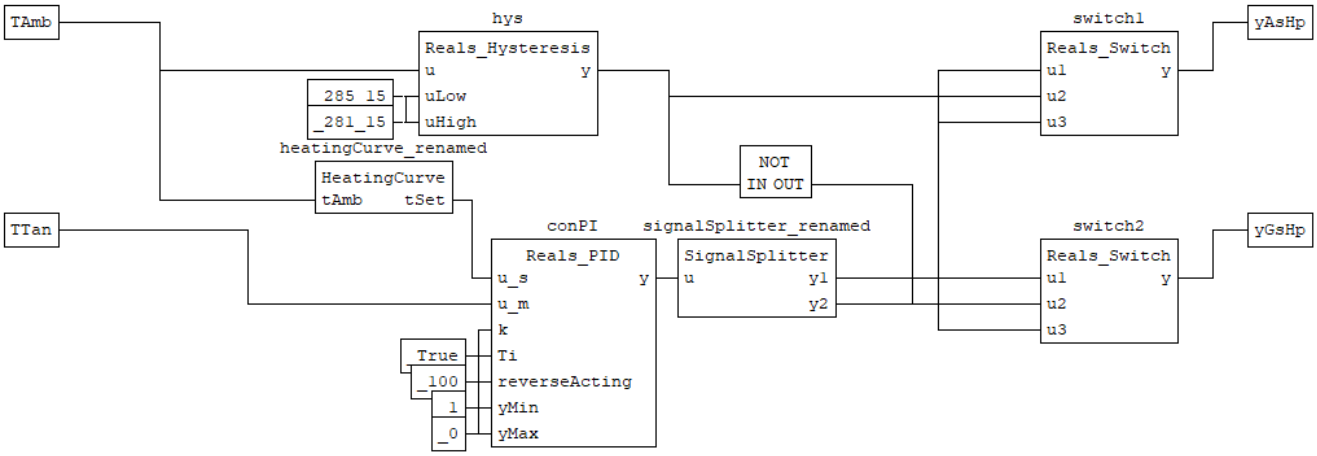
The control sequence is used to regulate a hybrid heating supply system with an air-source heat pump (ASHP) and a ground-source heat pump (GSHP). The FBD representation in Modelica is depicted in Figure 5. The control sequence has two inputs (the outdoor temperature `TAmb` and the tank temperature `TTan`) and two outputs (the two control signals `yAsHp` and `yGsHp` for the modulation of the two heat pumps, assuming that the compressor speed can be directly controlled). A so-called 'sequence controller' with a PI controller and a signal splitter is used to initially modulate only one heat pump, and to add the second heat pump if required. The `signalSplitter` block splits the input signal between `0` and `1` into two sequential output signals such that the first output increases from `0` to `1` when the input is between `0` and `0.5`, and the second output increases accordingly from `0` to `1` for inputs between `0.5` and `1`.

The hysteresis instance `hys` is used to switch the priority depending on the outdoor temperature: at lower outdoor temperatures the GSHP is the first generator in the sequence, and at higher outdoor temperatures the ASHP.



3.3 Comparison of CXF JSON-LD and IEC 61131-10 XML

The CDL source sequence and the translated IEC 61131-3 sequence are depicted in Figure 5 and Figure 5b.



Mapping of inputs, outputs, function blocks, and connections Figure 5b shows that the two inputs (`TAmb` and `TTan`) and the two outputs (`yAsHp` and `yGsHp`) have been transferred accordingly from the CDL representation (Figure 5). This illustrates that the definition of identifiers for inputs and outputs is already done during the design phase in Modelica, and not, as is current practice in construction, only during the commissioning phase.

As described in subsubsection 2.3.1, two cases can be distinguished: (1) CDL blocks that have a direct equivalent in IEC 61131-3 standard functions are mapped to those: the CDL elementary block `not1` (type `Logical.Not`) is mapped to the IEC 61131-3 standard block `NOT`. (2) CDL blocks without a direct equivalent in IEC 61131-3 standard functions, such as `Reals.Hysteresis` or `Reals.PID`, are mapped to the individually translated IEC 61131-3 blocks.

Note that for `Reals.PID`, which is an elementary block, we translated it as if it were a composite block because the CDL implementation is in fact done using only constructs as allowed for composite blocks. In this example, `conPI` is configured as PI controller, which can

(a) Graphical view of CDL, as rendered by Dymola

(b) Translation in PLC code (Beremiz)

Figure 5. Comparison of function block diagrams for a heat pump control sequence

be defined via the `controllerType` parameter. The two user-defined composite blocks `heatingCurve` and `signalSplitter` are translated recursively by iterating through the hierarchical instance tree.

Figure 5b also shows that connections are correctly translated.

Parameter propagation Figure 5b illustrates how parameters of the `hys` and the `conPI` CDL blocks are transformed into IEC program inputs that are connected to the corresponding block inputs. The parameter value with a leading underscore is used as name for the input object.

Graphical representation The comparison of Figure 5 and Figure 5b reveals differences in the graphical rendering of the FBD representation. To take into account the variable size of function blocks in IEC FBDs and avoid overlapping blocks, the IEC FBD layout is stretched in x and y directions. This is, however, a particular issue of Beremiz, where blocks can be positioned freely. Other (commercial) IDEs, such as Codesys or TwinCAT, ignore the x-y-coordinate information and re-position the blocks depending on the relation on inputs and outputs.

4 Conclusion and future work

This study has presented the CDL-PLC translator for the conversion of Rule-Based Control sequences from the Modelica-based CDL (Control Description Language) into the IEC 61131-10 XML for PLCs. The CDL-PLC translator is an example for the translation of CXF to a controller specific language, and the last step for the implementation of HVAC control sequences expressed in CDL on IEC 61131 building controllers. We presented an example for the validation of an IEC block against its

CDL equivalent, and an example for the translation of a real HVAC control sequence.

Implementing model-based design poses several challenges along the building life cycle. First and foremost, developing BPS software that enables the simulation of HVAC systems and controls for buildings with up to several hundreds of zones fast enough to be usable by practitioners remains challenging (Sahlin, Skogqvist, Lebedev, et al. 2019; Wetter, Benne, et al. 2023). In the meantime, simplifying load models such as by adding multiple rooms to one representative room is a recommended work-around.[9] For mechanical / HVAC and control engineers, this transformation can be done in two ways: Either by performing detailed HVAC control sequence development, for example using Modelica editors, during the pre-award design phase, which is not done today. Alternatively, ready-to-configure control and HVAC templates can be developed by library developers as shown in Gautier et al. (2023) and distributed with Modelica libraries, possibly integrated in configuration tools such as ctrl-flow.[10] The challenge for PLC vendors is to provide control sequence import functionality, either, if not already available, for the IEC 61131-10 XML or directly for the FMI standard. A noteworthy development is that a first PLC vendor starts to support the FMI standard[11].

To further develop and establish CDL-based model-based design of HVAC systems, joint efforts of academia and industry partners are required. Joint efforts need to focus not only on software toolchains and interfaces, but also - and perhaps even more importantly - on business models and best practice workflows to show various stakeholders the path to and benefit of adopting such model-based, digitalized processes.

The CDL-PLC translator is currently at a prototypical stage supporting a few CDL blocks as a proof of concept that such a translation is feasible. For a fully-fledged software, all CDL blocks have to be mapped and translated, systematically validated against their CDL counterparts, lacking features, such as the support of arrays[12], have to be added, and the import in different, particularly commercial, PLC IDEs has to be tested. Another challenge is the implementation of state machines in the translator. In CDL, a state machine can be implemented through so-called 'extension blocks' that are translated into FMUs.[13] The implementation of FMUs on the target automation system requires, however, that the target system is FMI-compatible, while the presented translator primarily targets legacy PLC-based automation systems that do not yet support the FMI standard (see '1' in 'Workflow and use cases'). One possible workaround would be a custom translator that converts the state machine code in the extension block to equivalent PLC code.

An important aspect for automated workflows is a complementary semantic model. CDL and its CXF translation supports such a semantic model based on ASHRAE Standard 223P, however, this information is lost when translating from CXF to IEC 61131-10 XML. To link the IEC 61131-10 XML with a semantic model, Ihlenburg et al. (2024) have proposed the PLCont methodology, however, further efforts towards a full integration or an extension of the XML schema are required.

[9] The simulation time for the control sequence used for the application example in section 3 with 61 thermal zones is around 24 h (Walther et al. 2025)

Abstract

Innovation in residential energy systems drives research efforts towards novel building and district control strategies. Development and testing of such strategies requires advanced, interactive building and district simulators. This paper presents *yards*, an interactive simulator that combines the modelling capabilities of Modelica with a language-agnostic and cross-platform interface for controller development. *yards* offers modelling flexibility beyond that of existing tools, as any custom, user-provided building or district model can be implemented easily. A case study demonstrates how *yards* can be used to simulate a tiny cluster of buildings.

Keywords: BOPTEST, Control Benchmarking, Functional Mock-Up Interface, Residential Energy Systems, yards

1 Introduction

Driven by climate targets, energy systems in the residential built environment are transforming. Fossil fuel-based technologies are being replaced by a combination of distributed renewable energy-based technologies e.g. photovoltaics (PV), heat pumps, batteries, thermal storage… To ensure an affordable, reliable and secure energy supply, hybrid configurations including different energy technologies at community level, rather than individual building level, have been gaining interest. Additionally, several energy services, such as heating, cooling and transport, are electrified, leading to the interconnection of the entire energy system via the electrical energy carrier. The increase in degrees of freedom, the interactions between the energy vectors and the wide range in time constants (sub-second-scale for electricity, minute-scale for thermal systems, daily-scale for short-term storage and seasonal-scale for long-term storage) lead to increasingly complex, but simultaneously increasingly flexible energy systems. Hence, to operate such energy systems and to use the full flexibility potential, advanced control strategies, customised to the specific energy system design, are necessary. Software-based emulators are essential for prototyping and validating such control strategies, as real-world experiments are often costly and time-consuming.

Emulators and controllers differ fundamentally in how they model and interact with physical systems, and as such tooling requirements for both are incompatible. Emulators describe acausal relationships between physical quantities in the form of equations. As emulators do not have fixed input-output relationships, they benefit from a declarative programming style that mimics the equation-based format. Since correctness is of major importance, emulators benefit from features such as static type and unit checking. In contrast, controllers inherently represent an input/output relation between sensor measurements and control signals sent to actuators. These relationships are more conveniently described through algorithms, in an imperative style, as opposed to equations. A focus on rapid prototyping and performance metrics rather than correctness favours dynamically typed programming languages for controller development, especially in research contexts where robustness and real-time requirements are typically less emphasised. For these reasons, software tools which focus on emulator development, such as Modelica, tend to be a poor fit for implementing some types of advanced controllers, such as data-driven model predictive control (MPC) or reinforcement learning. Indeed, while Modelica can be used to, for example, describe the system model within an MPC implementation, it is ill-suited to tasks such as training a neural network or tuning a gray-box model, which are essential in data-driven control strategies. Likewise, high-level programming languages that are suitable for controller development, such as Python or Julia, are often not ideal for creating an emulator. In these languages, tools for emulator development do exist, e.g. ModelingToolkit (Ma et al. 2021), but their syntax often bears little resemblance to that of the programming language they are used with. As such, control research for the residential built environment benefits from a multiple-tool approach: on the one hand, a declarative and statically typed programming language for the emulator; on the other hand, an imperative, dynamically typed programming language for the controller.

Various frameworks have been previously developed to interface building and district emulator models with controllers. The BOPTEST (Blum et al. 2021) and related

DOPTEST (Arroyo et al. 2023) frameworks have emerged as benchmarks for building and district controllers, respectively. Whereas the emulators in these frameworks have been implemented in Modelica, the simulation[1] interface is web-based and, as such, is controller-agnostic. This simulator-as-a-server approach allows complete freedom for control development. Both BOPTEST and DOPTEST support a curated set of emulators which serve as a global benchmark for advanced control strategies.

In contrast, CityLearn provides an efficient framework for benchmarking control algorithms, including rule-based control, MPC, and multi-agent reinforcement learning, at the urban scale, but it presents several limitations compared to more comprehensive platforms such as BOPTEST and DOPTEST (Vázquez-Canteli et al. 2019). First, its modelling approach consolidates district energy systems, heat pump behaviour, and building thermal dynamics into simplified representations, limiting the fidelity of simulations, especially for multi-zone or commercial applications (Nweye et al. 2025). Thus, while CityLearn is well-suited for rapid comparative analyses, high-fidelity studies may benefit from alternative, more detailed modelling environments. Second, the CityLearn framework is not language-agnostic: the framework is Python-based and requires controllers to be implemented as such.

Furthermore, TACO (Toolchain for Automated Control and Optimisation) (Jorissen, Boydens, and Helsen 2019) is a Modelica-based framework to develop white-box nonlinear MPC strategies for any energy system. However, TACO only implements and solves white-box MPC for detailed emulator models. Hence, energy system configurations can be compared, but no control strategies.

In this context, the field lacks a customisable, high-fidelity emulation tool for buildings and districts, which could further support the development of novel control strategies and the deployment of sustainable energy systems. BOPTEST and DOPTEST implement high-fidelity benchmark models, but these frameworks are not intended for simulating custom user models, yet alternatives such as CityLearn are not suitable for studies requiring high fidelity, while tools such as TACO support detailed emulator models but don't offer controller freedom. Therefore, this paper presents **y**et **a**nother **r**esidential **d**istrict **s**imulator, *yards*.[2,3] *yards* targets interactive, high-fidelity simulations of buildings and districts with support for custom, user-defined, energy system models and Key Performance Indicators (KPIs). *yards* bridges the gap between emulator designers who use Modelica to create emulators, and controller developers, who may interact with the *yards* simulator through a web Application Programming Interface (API). The *yards* simulator takes inspiration from the BOPTEST and DOPTEST frameworks and adopts the same interface, retaining near-compatibility with BOPTEST and DOPTEST from the perspective of the controller developer. *yards* is open source, cross-platform, and supports multiple (open source and proprietary) Modelica compilers.

The rest of the paper is structured as follows: Section 2 discusses *yards* design and implementation, and compares its design with that of the BOPTEST framework. Section 3 showcases *yards* from both emulator designer and controller developer perspective. The case study repackages and simulates a residential district model using the *yards* framework. Section 4 concludes the paper.

2 Design and Implementation

yards (Fig. 1) is consists of two components: the build pipeline and the simulator server. The build pipeline transforms the user[4]-provided model into a *yards*-compatible Functional Mock-up Unit (FMU) (Modelica Association 2022), and generates additional metadata files for the simulator based on the model and user-provided metadata files. The simulator defines a high-level web API to run the simulation, log the results, provide forecasts and calculate KPIs. This section first presents the build pipeline, followed by a discussion on the simulator.

2.1 Build Pipeline

The build pipeline generates all files required to run the simulator, i.e. the FMU and the files managed by the data manager in Fig. 1. To this end, *yards* generates a model description in XML format using OpenModelica and requires the user to specify any remaining metadata. As such, the user provides not only a Modelica model, but also several configuration files in JSON format (left side of Fig. 1): the `forecastables.json` file provides a description of all forecasts and how to calculate them; `libraries.json` is a list of Modelica dependencies of the model; `build_config.json` and `config.json` configure the build pipeline and simulator.

2.1.1 Model and Metadata

The emulator designer must provide *yards* with a simulatable Modelica model without inputs or outputs at the top level. Instead, the model includes read and overwrite blocks at arbitrary depth, indicating variables to be exposed or overwritten, respectively (Fig. 2). *yards* searches the generated XML description of the model for these read and overwrite blocks, and generates a wrapper model that contains the original model and exposes the inputs and outputs of these read and overwrite blocks at the top level. Subsequently, a *wrapped* FMU of this model can be generated using either OpenModelica or Dymola. The latter option requires the user to manually compile the wrapper model and provide *yards* with the compiled FMUs.

[1] This paper makes a distinction between emulators and simulators: emulators are models to test/benchmark a controller against; simulators are software that simulates a model.

[2] *yards* is intentionally all lower case.

[3] Available at `https://gitlab.kuleuven.be/positive-energy-districts/yards`

[4] User refers to the emulator designer

DOI 10.3384/ecp218525

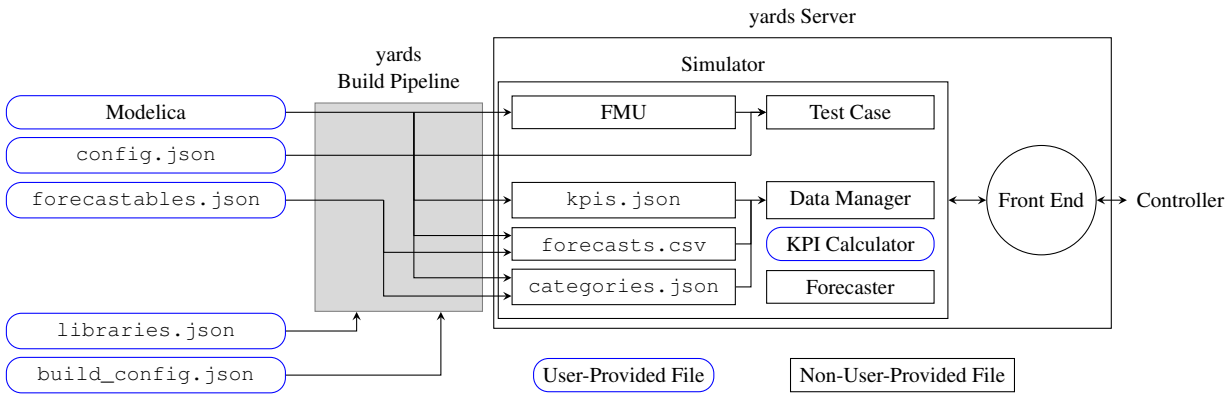

Figure 1. *yards* design overview: the emulator designer provides a Modelica model, corresponding metadata, a KPI calculator and a list of Modelica dependencies and how to install them. *yards* uses these inputs to build an FMU of the model, which is managed by the *yards* server and exposed to the controller via a web interface. The controller is not part of *yards*.

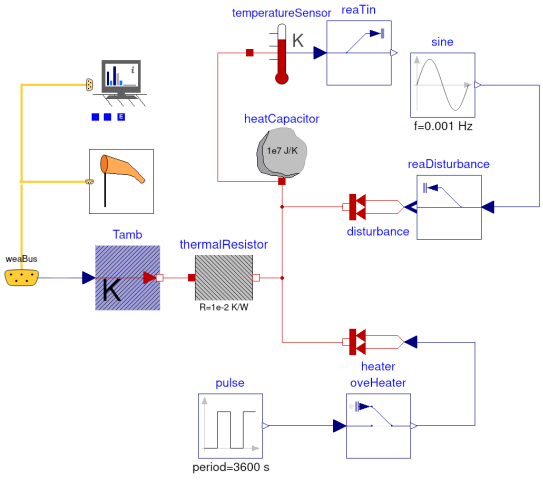

Figure 2. Example of a thermal RC model with read and overwrite blocks. The `reaDisturbance` and `reaTin` read blocks, and the `oveHeater` overwrite block indicate that these quantities should be exposed at the top level.

The read and overwrite blocks indicate which quantities are measurable or controllable, but they do not provide any information about their forecastability. *yards* relies on the emulator designer to specify which quantities have available forecasts, as defined in the `forecastables.json` file. Quantities should only be indicated as forecastable if there is no causal relationship between the quantity and any control input. For example, weather conditions are forecastable, but the building's indoor temperature depends on the control actions of the heating system and, as such, is not forecastable. The forecastables file takes the format of Listing 1: at the first level, the forecast interpolation method is specified (linear or zero-order hold); at the second level, forecast names are specified as keys, and their corresponding values indicate how the forecast is to be calculated and provide additional properties when necessary. In Listing 1, *forecast1* corresponds directly to a variable in the model. *yards* will search the XML description for metadata and replicate that metadata for this forecast. *forecast2* is an expression of multiple variables. In this case, *yards* is unable to determine the correct unit and description from the XML description. Hence, the emulator designer must provide this information.

Listing 1. Forecast metadata example

```
{ "linear": {
    "forecast1": "model.reaVar1.y",
}, "zoh": {
    "forecast2": {
        "expression": "model.reaVar2.y +
            model.reaVar3.y",
        "unit": "A unit",
        "description": "Var2 + Var3"
    }
  }
}
```

2.1.2 Implementation

The *yards* build pipeline (Fig. 3) uses a combination of Bash, Python and OpenModelica. To organise the build process, recipes are noted in a Makefile that can be parametrised via a simple configuration file (`build_config.json`). The pipeline runs in a containerised environment.

The build pipeline (Fig. 3) works as follows: First, the Modelica dependencies are downloaded to the container, and the OpenModelica path is populated with the model dependencies. Second, a prelude script to load all model dependencies is generated and combined with predefined templates to generate Modelica scripts. The script generation also involves filling in arguments such as model names, since custom command line arguments cannot be provided to `.mos` scripts. Third, the generated `dump_xml` script is used to obtain the XML description of the model. Fourth, the wrapped model is generated, and the user-provided metadata is combined with the XML description to generate the forecast data and metadata files for the simulator. Generating the forecast data involves simulating the original model for a user-specified time frame and resolution. Since this step can be costly, *yards* provides

options to accelerate this step using a simplified model. Fifth, the wrapped model is compiled into an FMU. Sixth, the generated forecast and metadata files are bundled with the wrapped FMU, and the pipeline is finished.

Whereas the FMU compilation step by default uses OpenModelica, *yards* allows compiling FMUs with other tools, such as Dymola.[5] In that case, the build pipeline stops after generating the wrapped Modelica model (step four above). The user should then compile the FMU manually. *yards* checks (and repairs) the model description of the manually compiled FMU for deficiencies against the OpenModelica XML description. The repaired FMU is bundled with the generated metadata files, after which the pipeline is finished.

2.1.3 Comparison with BOPTEST

The *yards* and BOPTEST build pipelines differ in three aspects: design approach, tooling, and model description generation. *yards* presents a configurable monolithic build pipeline aimed at non-expert emulator designers who require only minimal knowledge of the build process. In contrast, BOPTEST implements and maintains a separate build pipeline for each model but reuses some common utility functions across test cases. The declarative configuration required by *yards* including model metadata, is arguably easier to use compared to manually writing build scripts. BOPTEST uses the JModelica compiler (Åkesson, Gäfvert, and Tummescheit 2009), the Optimica Compiler Toolkit (OCT) and Dymola (Dempsey 2006) to build its test cases. OCT and Dymola are proprietary software, whereas the open source development of JModelica has been discontinued (Modelon 2019). *yards* depends on the open source OpenModelica compiler (Fritzson et al. 2020) but also supports other compilers such as Dymola (Dempsey 2006). The choice of tooling leads to differences in model generation as well. Whereas BOPTEST extracts model metadata from an FMU of the original model, *yards* uses OpenModelica to generate an easily parseable model description directly from the Modelica model using OpenModelica's `dumpXMLDAE` function. The approach of *yards* avoids compiling an intermediate FMU, which is typically an expensive step in the build process.

2.2 Simulator and API

2.2.1 Simulator

The *yards* simulator contains four core components (see Fig. 1): the forecaster, the KPI calculator, the data manager, and the test case. The forecaster provides predictions for forecastable quantities. The KPI calculator computes model-specific key performance indicators. The default *yards* KPI calculator returns an empty dictionary when KPIs are queried, but emulator designers may provide a custom implementation (in Python) instead. KPI calculators may implement arbitrary KPIs based on the exposed measurements, overwrites and forecasts. *yards* provides a base class to simplify the implementation of custom KPI calculators. The data manager tracks control signals and measurements, providing a convenient interface for other components to access simulation data. The test case handles the FMU simulation and processes incoming requests from the front end.

yards reuses a substantial part of the BOPTEST codebase. The simulator is implemented in Python and uses the PyFMI package (Andersson, Åkesson, and Führer 2016) to interact with the FMU.

[5] Our approach could hypothetically work with any tool that compiles FMUs from Modelica models, but we have only tested it with Dymola and OpenModelica

Table 1. Types of requests that *yards* accepts and their behaviour

Type	Behaviour
GET	Obtain model/simulator metadata
PUT	Obtain data/set simulator parameter/initialise
Identical sequential PUT requests → same result	
POST	Advance simulation
Identical sequential POST requests → different results	

Table 2. *yards* API and compatibility with BOPTEST (v0.5.0). Additions to the API after BOPTEST v0.5.0 are unimplemented.

Command	BOPTEST compatibility
GET forecast_points	Compatible
GET inputs	Compatible
GET kpi	Model-specific return
GET kpi_absolute	Model-specific return, superset
GET measurements	Compatible
GET name	Compatible
GET scenario	Compatible
GET step	Compatible
GET version	Compatible
POST advance	Compatible
POST submit	Silent or loud failure
PUT forecast	Compatible
PUT initialize	Compatible
PUT results	Compatible
PUT scenario	Model-specific input and return
PUT step	Compatible

2.2.2 API

The *yards* simulator provides a REST API for interactively simulating the model, obtaining measurements and forecasts, and for calculating KPIs. The API is available through HTTP, such that *yards* is not restricted to controllers implemented in any specific programming language. Commands are grouped into HTTP GET, PUT and POST requests by intended behaviour (Table 1). Responses are JSON strings and always take the format of Listing 2. The front end implementation uses the Flask framework (Pallets Projects 2010).

DOI 10.3384/ecp218525

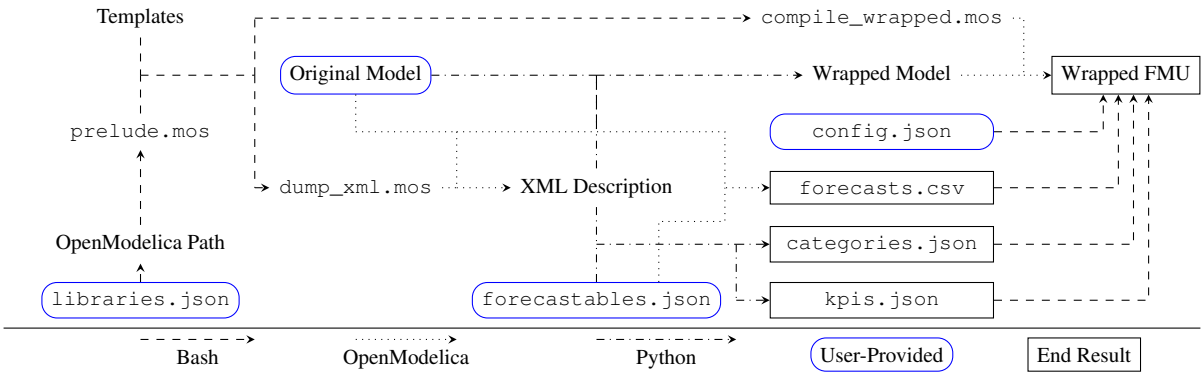

Figure 3. *yards* build pipeline. This diagram represents the case where OpenModelica is chosen as the compiler and the entire pipeline can be run in the container. Additional steps are needed if external compilers are used.

Listing 2. *yards* API response. The status value is 200, 400 or 500, indicating success, invalid request or internal errors, respectively.

```

}
```

The *yards* API is fully compatible with that of DOPTEST, which is in turn a superset of the BOPTEST (v0.5.0) API, in terms of request format. Responses and behaviour are, however, not identical for the complete API. Differences are listed in Table 2. Commands related to BOPTEST dashboard submission fail either silently or loudly (depending on configuration). As the KPIs and scenario are defined by the emulator designer, related commands and their return values may take arbitrary formats.

3 Case Study

This case study[6] showcases the *yards* framework, from both an emulator designer standpoint and a controller developer perspective. The section starts with the model description, followed by an overview of the KPIs. Next, the implementation of the model and KPIs in the *yards* framework is described, comprising the emulator designer's tasks. Afterwards, three controllers and their implementation are treated. The section ends with a discussion of the results.

3.1 Model Description

This case study uses the `MoPED.Districts.Layout4` model from the open source MoPED library (Verleyen et al. 2022). This model is similar to the `MoPED.Districts.Layout3` model, which is used in the DOPTEST framework (Arroyo et al. 2023). The district model is implemented using component models from the Modelica Standard Library (Modelica Association 2020), the Modelica Buildings library (Wetter et al. 2014), and the IDEAS library (Jorissen, Reynders, et al. 2018). For detailed information on the model equations, refer to (Arroyo et al. 2023) and the respective library documentation.

The model `MoPED.Districts.Layout4` represents a tiny cluster consisting of three residential, detached, single-family buildings. Each house is modelled as a single-zone building, relying on the detailed, white-box IDEAS (Jorissen, Reynders, et al. 2018) *RectangularZoneTemplate*. This building model template models each building envelope component as a construction consisting of several material layers and includes one-dimensional conduction, internal and external convection, and long-wave and short-wave radiation, allowing for dynamic heat transfer simulations. Occupancy behaviour is included to account for the internal heat gains of the occupants. More information on the building geometry and occupancy can be found in (Arroyo et al. 2023).

Each building of the tiny cluster is equipped with an individual energy system to provide heat for space heating and domestic hot water, cold for space cooling, and electricity for appliances. The only interconnection between the buildings is via the electrical distribution grid. Each building has an individual air-to-water heat pump connected to a simple parallel throttling circuit with an embedded floor heating system for space heating and a domestic hot water storage tank. Domestic hot water is drawn from the tank via a tap, resulting in the inflow of cold city water into the tank. Space cooling is provided by a separate air-to-air heat pump. The electrical load of each house is a combination of an inflexible demand profile for plug loads and flexible loads consisting of the air-to-water heat pump and the air-to-air heat pump. Each house has a PV installation with an inverter that curtails power generation when the grid voltage deviates by more than 10% from the nominal voltage.

To obtain realistic results, the use case is subject to consistent boundary condition data of 2021 linked to Leuven (Belgium). Weather data has been measured by the Build-

[6] Available at `https://gitlab.kuleuven.be/positive-energy-districts/yards-case-study`

ing Physics Section of the KU Leuven on campus. Occupancy profiles, including plug loads, have been generated using StROBe (Baetens and Saelens 2016). Hourly emission profiles have been derived from the Belgian generation mix (ENTSO-E 2025) and emission factors published by ElectricityMaps (ElectricityMaps 2025). Hourly electricity prices correspond to the hourly day-ahead price (Elexys 2024) without additional taxes.

3.2 Key Performance Indicators

The emulator designer can customise the KPI calculation according to their needs. This case study implements the KPIs below. All KPIs are calculated over the full simulation horizon, spanning from the start time t_s to the final time t_f. KPIs can be calculated on a per-house basis (κ^i, $i \in \{1,2,3\}$) or on a district level (κ^{tot}).

3.2.1 Thermal Discomfort

For space heating and space cooling, the thermal discomfort, $\kappa_{tdis,shc}$, in $[Kh]$, is calculated as the cumulative deviation of the operative zone temperature $T_o(t)$ from its lower $\underline{T}_o$ and upper $\overline{T}_o$ comfort limits for each house i (Eq. (1)).

$$\kappa^i_{tdis,shc} = \int_{t_s}^{t_f} \delta_{T_{o,i}}(t)\,dt \qquad i \in \{1,2,3\} \tag{1a}$$

$$\delta_{T_{o,i}}(t) = \begin{cases} \underline{T}_{o,i} - T_{o,i}(t) & \text{if } T_{o,i}(t) < \underline{T}_{o,i} \\ 0 & \text{if } T_{o,i}(t) \in [\underline{T}_{o,i}, \overline{T}_{o,i}] \\ T_{o,i}(t) - \overline{T}_{o,i} & \text{if } T_{o,i}(t) > \overline{T}_{o,i} \end{cases} \tag{1b}$$

The comfort limits are determined according to the EN16798-1:2019 standard (Eq. (2), where $n_{occ,i}$ is the amount of building occupants present in house i).

$$\underline{T}_{o,i} = \begin{cases} 20°\text{C} & \text{if } n_{occ,i} > 0 \\ 15°\text{C} & \text{otherwise} \end{cases} \qquad i \in \{1,2,3\} \tag{2a}$$

$$\overline{T}_{o,i} = \begin{cases} 26°\text{C} & \text{if } n_{occ,i} > 0 \\ 30°\text{C} & \text{otherwise} \end{cases} \qquad i \in \{1,2,3\} \tag{2b}$$

For domestic hot water, the thermal discomfort, $\kappa_{tdis,dhw}$, also in $[Kh]$, is calculated as the cumulative deviation of the tank temperature $T_{tan}(t)$ from its lower limit $\underline{T}_{tan} = 45°\text{C}$ for each house i (Eq. (3)).

$$\kappa^i_{tdis,dhw} = \int_{t_s}^{t_f} \delta_{T_{tan,i}}(t)\,dt \qquad i \in \{1,2,3\} \tag{3a}$$

$$\delta_{T_{tan,i}}(t) = \begin{cases} \underline{T}_{tan,i} - T_{tan,i}(t) & \text{if } T_{tan,i}(t) < \underline{T}_{tan,i} \\ 0 & \text{if } T_{tan,i}(t) \geq \underline{T}_{tan,i} \end{cases} \tag{3b}$$

Thermal discomfort is aggregated at the district level as in Eq. (4).

$$\kappa^{tot}_{tdis,shc} = \sum_{i=1}^{3} \kappa^i_{tdis,shc} \tag{4a}$$

$$\kappa^{tot}_{tdis,dhw} = \sum_{i=1}^{3} \kappa^i_{tdis,dhw} \tag{4b}$$

3.2.2 Electric Energy Use

Electric power is aggregated at the building and district levels. For an individual building i, electric power exchange at the building's grid connection point P_i comprises the PV installation, plug loads, the air-to-water heat pump for heating and the air-to-air heat pump for cooling. Injection and offtake electric power of individual buildings is defined in Eq. (5).

$$P_{inj,i}(t) = \max\{0, P_i(t)\} \qquad i \in \{1,2,3\} \tag{5a}$$

$$P_{off,i}(t) = \max\{0, -P_i(t)\} \qquad i \in \{1,2,3\} \tag{5b}$$

At the district level, energy exchange between individual houses is taken into account, resulting in the district injection and offtake electric power (Eq. (6)).

$$P_{inj,tot}(t) = \max\{0, \sum_{i=1}^{3} P_i(t)\} \tag{6a}$$

$$P_{off,tot}(t) = \max\{0, -\sum_{i=1}^{3} P_i(t)\} \tag{6b}$$

The electric energy use KPIs, κ^{inj}_{ener} and κ^{off}_{ener}, aggregate electric power injection and offtake over the simulated time period, resulting in Eq. (7) (with abuse of notation).

$$\kappa^{inj,i}_{ener} = \int_{t_s}^{t_f} P_{inj,i}(t)\,dt \qquad i \in \{1,2,3,tot\} \tag{7a}$$

$$\kappa^{off,i}_{ener} = \int_{t_s}^{t_f} P_{off,i}(t)\,dt \qquad i \in \{1,2,3,tot\} \tag{7b}$$

3.2.3 Operational CO_2 Emissions

Since all energy services are electrified, the operational CO_2 emissions only originate from the offtake of electricity $P_{off}(t)$ from the grid.

$$\kappa^{off,i}_{emis} = \int_{t_s}^{t_f} \varepsilon(t)\,P_{off,i}(t)\,dt \qquad i \in \{1,2,3,tot\} \tag{8}$$

$\varepsilon(t)$ is the hourly CO_2 emission factor. The houses are rewarded for injecting emission-free electricity generated by their PV installation, $P_{inj}(t)$. Sharing energy between buildings within the district is considered emission-free, but when injecting energy into the grid, an injection compensation equal to 50% of the emission intensity is assumed.

$$\kappa^{inj,i}_{emis} = \int_{t_s}^{t_f} 0.5\,\varepsilon(t)\,P_{inj,i}(t)\,dt \qquad i \in \{1,2,3,tot\} \tag{9}$$

A clear distinction between the emissions due to offtake, κ^{off}_{emis}, and the emission compensation due to injection, κ^{inj}_{emis}, is made to have a better understanding of the system's behaviour.

3.2.4 Operational Costs

Since all energy services are electrified, the operational costs only originate from the offtake of electricity, $P_{off}(t)$, from the grid.

$$\kappa_{cost}^{off,i} = \int_{t_s}^{t_f} c(t)\, P_{off,i}(t)\, dt \qquad i \in \{1,2,3\} \qquad (10)$$

$c(t)$ is the hourly electricity price. The houses are rewarded for injecting electricity generated by their PV installation, $P_{inj}(t)$. An injection tariff equal to 50% of the offtake price is assumed.

$$\kappa_{cost}^{inj,i} = \int_{t_s}^{t_f} 0.5\, c(t)\, P_{inj,i}(t)\, dt \qquad i \in \{1,2,3\} \qquad (11)$$

The case study does not consider any financial agreements at the district level. As such, the district injection revenue and offtake cost are simply the sum of the individual revenues and costs (Eq. (12)).

$$\kappa_{cost}^{inj,tot} = \sum_{i=1}^{3} \kappa_{cost}^{inj,i} \qquad (12a)$$

$$\kappa_{cost}^{off,tot} = \sum_{i=1}^{3} \kappa_{cost}^{off,i} \qquad (12b)$$

3.3 Implementation

To prepare the model for the *yards* build pipeline, metadata, dependencies, and the builder configuration must be provided.

3.3.1 Modelica and Model Metadata

The `MoPED.Districts.Layout4` model is obtained from the MoPED repository (Verleyen et al. 2022). This model has been expressly built for DOPTEST and as such, the necessary read/overwrite blocks are already present. The Modelica dependencies of MoPED are specified in the `libraries.json` file. These dependencies can be either installed directly through OpenModelica or downloaded using Git. Alternatively, the user may mount a local version of the dependencies in the builder container and provide an empty `libraries.json` file. Forecast metadata is provided in the format of Listing 1.

The configuration of the build pipeline (Listing 3) specifies various technicalities such as the name of the models to compile, the path to the model package and metadata files, but also includes instructions for generating the forecast data. Since the district model is quite computationally expensive, the simplified `MoPED.Districts.Layout4RC` model is used to generate the forecasts for weather and occupancy instead. This model uses linear second-order RC models for the building envelope instead of the more complex IDEAS *RectangularZoneTemplate*. The `MoPED.Districts.Layout4RC` model is simulated with the provided arguments, and the simulation results are used as forecasts.

Listing 3. Build pipeline configuration for the case study

```
{
  "models": ["MoPED.Districts.Layout4"],
  "modelicafile": "MoPED/package.mo",
  "metadata": "metadata",
  "compiler": "omc",
  "forecast": {
        "forecast_model": "MoPED.Districts.
            Layout4RC",
        "start_time": 0.0,
        "stop_time": 691200.0,
        "number_of_intervals": 768
  }
}
```

3.3.2 KPI Calculator

The KPI calculator (Listing 4) implements each KPI as a separate method. The *yards*-provided base class is used for easy access to model variables at simulation runtime. Some KPIs, such as those related to operational emissions take extra parameters, which can be passed by setting the scenario, either in the `config.json` or during the simulation through a request (Table 2). The structure and contents of the scenario can be fully customised by the emulator designer.

Listing 4. KPI calculator for the use case. The code is simplified and abbreviated. Class methods have been de-indented one extra level for readability.

```
from .baseclass import BaseKPICalculator
class KPICalculator(object):
# mandatory methods
def __init__(self, testcase):
  self.base = BaseKPICalculator(testcase)
  self.house_prefixes = ["house1", "house2"
      , "house3"]
def initialize(self):
  self.base.initialize()
def get_kpis_absolute(self, scenario=None):
def get_core_kpis(self, scenario=None):
# helper methods
def emissions(self, prefix,
    injection_scaling_factor=0.5):
def thermal_discomfort(self, prefix):
...
def get_house_kpis(self, prefix, scenario):
def get_district_kpis(self, scenario):
```

3.3.3 Building the Model

To build the FMU, the *yards* builder image must be started as a container with local development files mounted (Listing 5). The `buildcache` and `target` volumes cache intermediate build steps and store the build result. Using this approach, changes in model, metadata and KPI calculator files are available immediately and build results can be accessed by inspecting the `buildcache` volume.

Listing 5. Run the *yards* build pipeline

```
$ docker run \
    -v buildcache:/yards/build \
    -v target:/yards/target \
    -v ./MoPED:/yards/MoPED \
```

```
    -v ./metadata:/yards/metadata \
    -v ./build_config.json:/yards/
        build_config.json \
    yards/builder
```

To run the simulator after finishing the build, a different container based on the *yards* simulator image must be started. When starting this container (Listing 6), the `target` volume and custom KPI calculator must be mounted and the network must be configured.

Listing 6. Run the *yards* simulator. After running this command the simulator can be accessed via `http://localhost:5001`.

```
$ docker run -p 5001:5000 \
    -v target:/home/user/target \
    -v ./kpis/kpi_calculator.py:/home/user/
        kpis/kpi_calculator.py \
    yards/simulator
```

Above approach is suitable for active development of the simulator, but requires that model files are available on the host machine. To simplify distribution of the packaged model, one may create a new image that includes the built FMU and custom KPI calculator (Listing 7) and distribute this image.

Listing 7. Package the model by running the *yards* build pipeline as an intermediate stage in a multi-stage image build resulting in a self-contained simulator image with the custom model and KPIs.

```
FROM yards/builder:latest AS build
# copy model and metadata config files from
    host to image
COPY . /yards/
RUN ./entrypoint.sh make target
FROM yards/simulator:latest
COPY --chown=user --from=build /yards/
    target/models/wrapped.fmu target/models
    /wrapped.fmu
COPY --chown=user kpis/kpi_calculator.py ./
    kpis/kpi_calculator.py
```

3.4 Controller Development

This section introduces and compares three controllers for space heating. The three controllers are the baseline (C0), the price-based controller (C1) and the price-difference-based controller (C2). Controller C0 reduces the temperature setpoint when no occupants are present, to reduce energy usage. The price-based controller C1 preheats the building when the electricity price is low, to avoid energy use when the price is high. Controller C2 forecasts the electricity price and preheats the building only before a significant price increase. All three controllers aim to balance thermal comfort with energy use and cost.

3.4.1 Controller Design

In the district model, the control logic for space heating contains two control loops. The outer loop determines the temperature setpoint $T_{o,\mathrm{set}}(t)$ for the zone. The inner hysteresis-based loop operates the heat pump to drive the zone temperature towards this setpoint. The hysteresis band has a width of 1°C and is centred around the current setpoint $T_{o,\mathrm{set}}$. The heat pump is switched on or off to maintain the zone temperature within this band. All controllers in this section determine the temperature setpoint $T_{o,\mathrm{set}}$ and rely on the inner control loop to operate the heat pump.

First, controller C0 implements the rule in Eq. (13). Since comfort bounds are less strict when the building is empty (Eq. (2)), the temperature setpoint can be decreased significantly at this time. Second, the rule for C1 is given by Eq. (14): when the electricity price is low, temperature is increased. The thermal inertia of the building can be used to reduce energy consumption when prices rise above this threshold, reducing costs.

$$T^{\mathrm{C0}}_{o,\mathrm{set},i} = \begin{cases} T^{\mathrm{C0}}_{\mathrm{high}} = 21\,^{\circ}\mathrm{C} & \text{if } n_{occ,i} > 0 \\ T^{\mathrm{C0}}_{\mathrm{low}} = 15\,^{\circ}\mathrm{C} & \text{otherwise} \end{cases} \tag{13}$$

$$T^{\mathrm{C1}}_{o,\mathrm{set},i} = \begin{cases} T^{\mathrm{C1}}_{\mathrm{high}} = 24\,^{\circ}\mathrm{C} & \text{if } c(t) \leq c_{\mathrm{th}} \\ T^{\mathrm{C1}}_{\mathrm{low}} = 21\,^{\circ}\mathrm{C} & \text{otherwise} \end{cases} \tag{14}$$

Finally, controller C2 aims to anticipate large changes in electricity price. It modulates the temperature setpoint between upper and lower limits depending on the forecasted short-term change in price Δc (Eq. (15), where Δt is the timestep, $\alpha \in [0,1]$ the modulation factor, and $\Delta c_{scale} = 0.05$ €/kWh, a parameter to tune controller sensitivity).

$$\Delta c = \max\{c(t + j\Delta t) - c(t) | j = 0 \ldots 6\} \tag{15a}$$

$$\alpha = \min\{\Delta c / \Delta c_{scale}, 1\} \tag{15b}$$

$$\begin{aligned} T^{\mathrm{C2}}_{o,\mathrm{set},i} &= (1-\alpha) T^{\mathrm{C2}}_{\mathrm{low}} + \alpha T^{\mathrm{C2}}_{\mathrm{high}} \\ &= 21^{\circ}\mathrm{C} + \alpha \cdot 3^{\circ}\mathrm{C} \end{aligned} \tag{15c}$$

3.4.2 Implementation and Simulation

Controller C0 is implemented directly in the Modelica model and is part of the MoPED library; it can be simulated by calling the *POST advance* method of the *yards* API without arguments. Controllers C1 and C2 are implemented in Python (Listing 8). They first query the electricity price via a *PUT forecast* call, and use this information to compute the heating setpoint. The heating setpoint is then supplied as an argument to the *POST advance* call to *yards*.

Listing 8. Implementation of C1. Code altered for brevity.

```
def do_step(url, Tlow, Thigh, cth):
  price_key = '
      PriceElectricPowerHighlyDynamic'
  price = requests.put(f'{url}/forecast',
      json={'point_names': [price_key], '
      horizon': 0, 'interval': 1}).json()['
      payload'][price_key]
  Tset = Tlow if price[0] > cth else Thigh
  setpoints = {
    'house1_hva_oveTSetHeaDay_u': Tset,
```

DOI
10.3384/ecp218525

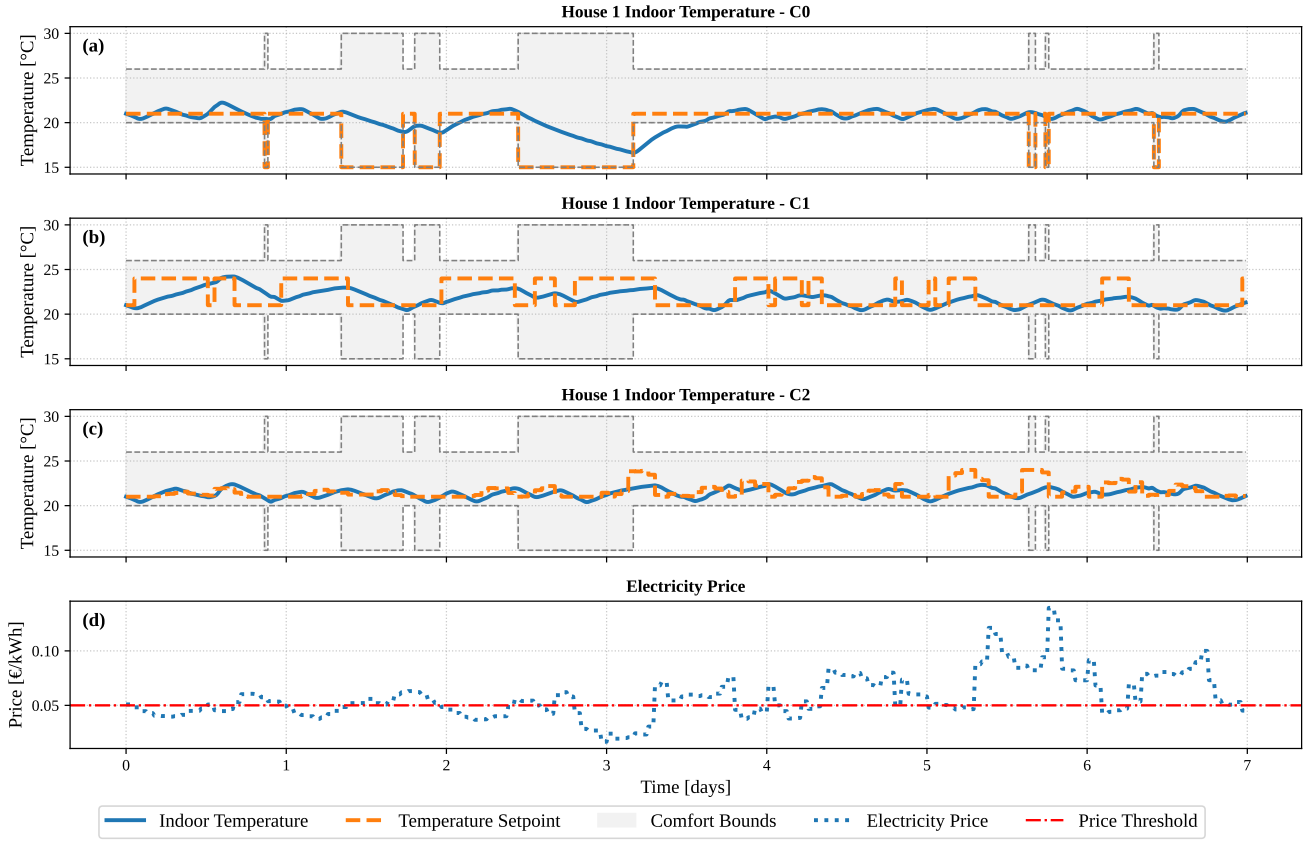

Figure 4. (a)-(c) Indoor temperature in house 1 (solid line) over a one week period under each of the three control strategies ((a) - C0, (b) - C1, (c) - C2). Dashed lines show the heating setpoints computed by the controllers, and the lightly shaded band represents the occupancy-dependent comfort bounds (Eq. (2)). (d) Dynamic electricity price (dotted) and C1 price threshold (dash-dotted).

```
    'house1_hva_oveTSetHeaDay_activate': 1,
    # set other houses...
}
requests.post(f'{url}/advance', json=
    setpoints).json()['payload']
```

All simulations are performed for one week, starting on the 1st of January, with a time step Δt of 1 hour. For each of the three simulations, the same controller was applied to all three houses of the tiny cluster simultaneously.

3.5 Results and Discussion

The KPI calculator allows to easily compare the implemented controllers (Table 3). For all three controllers, district electricity offtake is substantially larger than injection, which aligns with expectations for a winter month with limited PV production and consistent heating demand. The baseline C0 achieves the lowest energy use and operational emissions, but incurs higher costs and space heating-related thermal discomfort than the custom C1 and C2 controllers. Figure 4 clearly shows the cause of the thermal discomfort: C0 is unable to anticipate the sudden change in comfort bounds, resulting in thermal discomfort (around day 2 and 3.25 in Fig. 4a). In contrast, C1 and C2 (Figs. 4b and 4c) use more conservative temperature setpoints, and thus avoid this problem. Controller C1 achieves the lowest offtake cost (€43.00, -4.97% vs. C0) but also the highest offtake-related CO_2 emissions (44.10 $kgCO_2$, +2.8% vs. C0).

Table 3. District-level KPIs for all three controllers. These results were obtained through a *GET kpi* call to *yards* after finishing each simulation.

Metric		C0	C1	C2
Operational Costs [€]	$\kappa_{cost}^{inj,tot}$	0.49	0.24	0.36
	$\kappa_{cost}^{off,tot}$	45.25	43.00	43.31
Operational Emissions [$kgCO_2$]	$\kappa_{emis}^{inj,tot}$	0.32	0.15	0.26
	$\kappa_{emis}^{off,tot}$	42.90	44.10	43.93
Energy Use [kWh]	$\kappa_{ener}^{inj,tot}$	10.25	4.76	8.11
	$\kappa_{ener}^{off,tot}$	760.5	773.5	775.2
Thermal Discomfort [Kh]	$\kappa_{tdis,shc}^{tot}$	18.05	0.00	0.00
	$\kappa_{tdis,dhw}^{tot}$	0.00	0.00	0.00

A follow-up to this case study could be to develop a novel, more performant and more advanced controller. This may be done by another researcher, using a different programming language, on a different operating system. The flexibility of *yards* to package custom models with a consistent interface opens up a lot of possibilities for

collaborative and open research: emulator designers can independently and rapidly publish their models for controller developers to optimise. Where centralised, curated benchmarks like BOPTEST and DOPTEST allow comparisons between controllers across the globe on a curated set of models, *yards* is ideal for collaborations comparing a limited set of controllers for an arbitrary model or even for use in a one-person project. As such, the work presented in this paper can be seen as complementary to existing efforts, rather than competitive.

4 Conclusion

yards is a novel building and district simulator for developing and testing advanced control strategies with high-fidelity models. It allows emulator designers to package Modelica models as an interactive web-based simulator with which controllers can interact. Custom KPI calculators can optionally be embedded alongside the models.

The presented case study demonstrates *yards*' capabilities on a small residential district, showing how *yards* facilitates cross-language co-simulation of emulator and controller, and allows to easily compare controller performance using custom KPIs. *yards* provides a versatile environment for evaluating and testing advanced control concepts in residential energy systems.

Abstract

Physics-based simulations (PBS) are increasingly valuable for real-time applications in embedded systems, yet integrating them on resource-constrained devices remains challenging. This paper presents ufmu, a lightweight framework that enables execution of source-code FMI 2.0-compliant Functional Mock-up Units (FMUs) within the MicroPython environment, targeting platforms such as the ESP32. The proposed approach integrates into the MicroPython firmware the FMU source code and the FMU model description translated into C structures, and exposes a minimal Python API for simulation control, enabling model-based computations on-device without cloud dependencies. We evaluate the framework using a standard FMU model, comparing performance across ESP32, Unix, and plain C environments in terms of memory usage, execution time, and firmware size. Despite the ESP32's hardware limitations, the results demonstrate that meaningful simulations can be achieved efficiently, with minimal memory overhead. All code, documentation, and experiment instructions are freely available under an MIT license, supporting reproducibility and adoption in education, prototyping, and embedded research. This work also lays the foundation for future integration with eFMI and the FMI 3.0 standard.

Keywords: Physics-Based Simulation, FMI, FMU, eFMI, MicroPython

1 Introduction

The simulation software market is expected to reach 40.5 billion US dollars in 2030 according to a report (Zoting 2023). In recent years physics-based simulation (PBS) has become a very important tool in different domains of both science and industry. PBS support for the analysis and prediction of events, with applications ranging from breaking systems in vehicles (Magargle et al. 2017) to earthquake prediction (Saad et al. 2023), having the potential to save lives.

Embedded devices support physics-based simulation (PBS) by supplying data. In a cloud–edge architecture, they typically collect sensor data, such as temperature or humidity, and transmit it to the cloud for processing and storage. Still, performing real-time calculations in the cloud is costly, as it increases network traffic and latency, lowers energy efficiency, and can hinder scalability (Savaglio et al. 2019). Recent developments enable embedded devices to run simulations themselves, helping to address these issues while also simplifying the overall architecture (Lenord et al. 2021). However, the skill gap between simulation development and embedded system programming remains a barrier to broader adoption and integration of these capabilities, especially for hobbyists or DIY (Do-It-Yourself) enthusiasts.

The Functional Mockup Interface (FMI), developed by the Modelica Association, is an open standard for sharing and co-simulating dynamic models, supported by tools for monitoring, evaluation, and plotting (Blockwitz et al. 2012). Models are packaged as Functional Mock-up Units (FMUs), which encapsulate code, data, and metadata in a standardized format for easy integration across tools.

Developed as part of the EMPHYSIS project, the embedded Functional Mock-up Interface (eFMI) extends FMI to enable simulation execution on embedded devices (Lenord et al. 2021). eFMI introduces a dedicated programming language, GALEC, with the goal to ensure PBS execution stays within the resource constraints of embedded systems. GALEC guarantees static worst-case execution time and memory usage, and prevents illegal memory access. Additionally, eFMI's container architecture supports multiple model representations, including algorithmic, production, and binary code. These features make eFMI suitable for safety-critical applications and adaptable to various embedded software environments.

Optimized for microcontrollers, MicroPython (George and MicroPython community 2014) is a streamlined implementation of Python 3 designed to compile and execute code directly on microcontrollers, which are at the heart of most embedded devices. MicroPython is easier to learn and use than C (Fangohr 2004) and provides a rich set of libraries, making it well-suited for education and rapid prototyping in embedded systems (Tollervey 2017). To our knowledge, embedding FMI simulations directly within the MicroPython environment is unprecedented and complements the eFMI paradigm.

Therefore, this paper addresses the following research

question: *How can FMUs be integrated into MicroPython for execution on embedded devices ?* We propose the ufmu framework, which enables execution of FMI 2.0-compliant FMUs within MicroPython by:

1. translating the FMU model description into a C structure,
2. integrating it and the FMU source code into the MicroPython build, and
3. exposing the FMU via a lightweight Python API through the ufmu library, allowing simulations to run directly within MicroPython.

This paper makes the following key contributions:

- A framework for exporting and running one source-code FMI 2.0-compliant FMU embedded inside the MicroPython firmware;
- Performance evaluation of the proposed integration;
- Exploration of future perspectives, including the potential use of eFMI for further optimizations and adaptation to the FMI 3.0 standard.

The rest of this paper is structured as follows. Section 2 provides background information. Section 3 outlines the ufmu framework, detailing our methodology, associated challenges, and optimizations. It also validates the implementation through test cases, including running the bouncing ball simulation on an ESP32 microcontroller. Section 4 discusses related work. Finally, Section 5 concludes the paper by summarizing the contributions, discussing the implications of the work, and outlining future directions for research and development.

2 Background

2.1 The need for PBS in embedded devices

PBS are models that represent the physical behavior of a system. Applications include predictive maintenance, where a component's remaining life is estimated based on its current condition to enable timely intervention before failure (Magargle et al. 2017), and fault diagnosis, where the source of faults is identified from observed behavior to support corrective actions and improve system reliability (Aivaliotis et al. 2019).

The use of PBS directly inside embedded systems is an emerging field that holds great promise for improving the accuracy, efficiency, and performances of these systems (Tavella et al. 2016). Accuracy is improved by offering a more precise representation of the system's physical behavior, which is crucial for real-time operations in safety-critical systems, medical devices, and automobiles (Armugham et al. 2021). Efficiency is improved by enabling auto-calibrating scenarios, reducing the need for extensive testing and debugging (Liu and Negrut 2021; Gundermann et al. 2017). Performance is enhanced by optimizing the architecture and operation of the system, leading to a more efficient and responsive system (Vanommeslaeghe et al. 2018; Tavella et al. 2016). Additionally, performing the process on the embedded device itself boosts responsiveness and scalability.

However, several challenges remain. First, PBS can be computationally demanding, restricting their deployment on resource-constrained devices. Second, integration with existing embedded software can be complex and may require significant development effort and expertise. Finally, their sensitivity to input data quality makes them difficult to apply in real-world scenarios (Duraiswami and Zotkin 2016). Despite these challenges, the benefits of integrating physics-based simulations into embedded systems are evident. As technology advances, their adoption is likely to grow across a wide range of applications.

2.2 FMI and FMUs

The Functional Mockup Interface (FMI), developed by the Modelica Association, is an open standard for sharing and co-simulating Modelica models, which are typically exported as Functional Mock-up Units (FMUs). FMUs encapsulate code, data, and metadata in a uniform package, enhancing the credibility and usability of simulations in complex engineering processes (Gall et al. 2021).

FMI 2.0 is the most widely adopted and extensively supported version of FMI, with over 210 tools offering compatibility and ensuring seamless integration across industries such as automotive, aerospace, and energy.[1] While FMI 3.0 introduces advanced co-simulation features, richer data-type support, and scheduled-execution interfaces—such as 8-, 16-, 32-, and 64-bit integer types, single-precision floats, and opaque binary variables—its adoption remains nascent compared to 2.0. Given its proven stability, broad toolchain compatibility, and full backward-compatibility with existing FMUs, FMI 2.0 is the preferred choice for most engineering workflows today, and the one we will focus on in this paper.

The following outlines the sequence of FMI function calls that ensure accurate state propagation, event handling, and system updates within the simulation. All FMU function calls omit the `fmi2_` prefix for better readability. During initialization, the FMU is created with `instantiate`, and memory is allocated for state variables and event indicators. The experiment is configured using `setupExperiment`, followed by a transition into initialization mode with `enterInitializationMode`. Initial variable values are retrieved using `getReal` and `getInteger`. After exiting initialization mode with `exitInitializationMode`, an initial event iteration is performed using `newDiscreteStates`. The simulation loop starts by retrieving continuous states and derivatives via `getContinuousStates` and `getDerivatives`. Time advancement is handled with `setTime`, and the next simulation step is performed using `setContinuousStates`. The event handling mechanism is activated when necessary, transitioning into event mode with `enterEventMode` and resolving

[1] `https://fmi-standard.org/tools/`

DOI 10.3384/ecp218535

discrete state updates via `newDiscreteStates`. If required, the simulation re-enters continuous-time mode using `enterContinuousTimeMode`. Throughout the process, output variables are gathered by invoking `getReal` and `getInteger`.

2.3 MicroPython

MicroPython (George and MicroPython community 2014) is a lightweight implementation of Python designed for microcontrollers. Unlike CPython, which requires a full OS, MicroPython runs directly on bare-metal hardware, providing direct access to peripherals like GPIO, I2C, SPI, and UART, making it ideal for resource-constrained environments. Arduino has embraced MicroPython as a supported platform for programming microcontrollers, providing tools like the Arduino Lab for MicroPython to facilitate development. This integration allows developers to leverage the simplicity of Python while utilizing Arduino's extensive hardware ecosystem.

MicroPython leverages one of Python's key advantages: its ease of use, especially in comparison to C/C++, the dominant languages for embedded systems programming. According to (Fangohr 2004), Python-based development can significantly reduce the time needed for implementation and debugging.

Additionally, as discussed in (Tollervey 2017), MicroPython includes an extensive standard library and supports external modules, allowing developers to leverage a broad range of functionalities without needing to write low-level firmware from scratch. It also has built-in libraries to harness as much as its support can offer, like the for the ESP32, as shown in Figure 1

Despite its compact size, MicroPython remains highly extensible. Developers can integrate it with C/C++ code for performance-critical tasks, ensuring that time-sensitive operations are not compromised. Furthermore, the active community and robust documentation provide support, making MicroPython an attractive option for both hobbyists and professionals.

```
from machine import Pin
from onewire import OneWire
from ds18x20 import DS18X20
# Initialize DS18B20 sensor on GPIO pin 4
ds = DS18X20(OneWire(Pin(4)))
# Scan for connected devices
roms = ds.scan()
# Start temperature conversion
ds.convert_temp()
print("Temperature:", ds.read_temp(roms[0]),
↪  "°C")
```

3 The ufmu framework

3.1 Overview

Our approach integrates an FMU following the FMI 2.0 standard into a MicroPython-compatible C module, enabling users to interact with FMUs directly from MicroPython scripts. Figure 2 illustrates the process, which involves: (A) Exporting the simulation as FMU, (B) Decompressing the FMU, (C) Parsing and modifying the .c, .h, .xml files, (D) Building MicroPython with the ufmu library, (E) Flashing the device with the firmware.

The following subsections detail the process. Section 3.2 covers the extraction and preparation of the FMU archive for integration into the embedded environment. Section 3.3 discusses the process of adapting the FMU to work seamlessly with MicroPython, including wrapping simulation functions for compatibility. Several challenges had to be addressed, such as adapting FMU execution for a resource-constrained embedded environment, handling compilation differences between Unix and ESP32, and ensuring modularity and reusability of the functions. Section 3.4 discusses how these issues were tackled and the optimizations applied. Finally, Section 3.5 reports on the evaluation of the ufmu framework.

ufmu supports both the Unix and the ESP32 ports of MicroPython. All the code and necessary instructions to reproduce the experiments are openly available on Github under the open-source license of the MIT,[2] alongside the end-user documentation.[3]

3.2 FMU Preprocessing

The first step of the framework involves exporting the simulation as an FMU (Step A). FMUs are zip archives typically containing C source files, an XML model description file, and precompiled binaries for various platforms, as can be seen in States 2 and 3 of Figure 2. The framework then consists in preprocessing the FMU.

First, the FMU file is unzipped (Step B) using a Makefile, revealing its internal structure, including the `modelDescription.xml` file and source code (State 3). Then, the `modelDescription.xml` file is parsed to extract metadata about the FMU, such as variable definitions, simulation parameters, and function mappings (Step C). This parsing is performed using the `xmllint` software to dynamically configure the library.

Once the relevant information is extracted, the source files are modified to integrate with the MicroPython-compatible library. This includes wrapping core FMU functions to expose them as callable functions from MicroPython, adjusting variable storage and memory handling to fit the microcontroller's limitations, and adding required definitions to handle different prefixes for function names. Additionally, configuration headers are generated based on the extracted metadata, storing variable

[3] https://imaginus02.github.io/MicroFMU-library

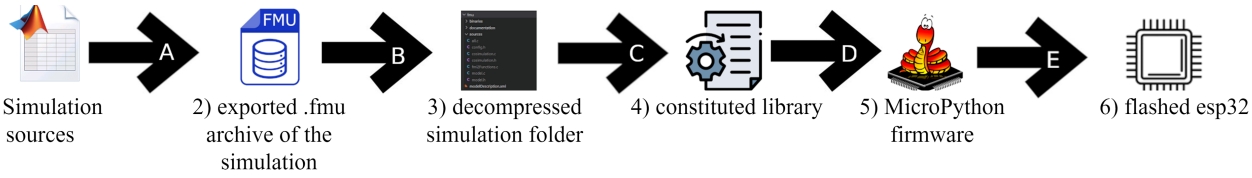

Figure 2. Flow diagram of the MicroPython firmware creation process, showing the integration of the FMU execution engine, preprocessing, and compilation steps.

definitions and simulation parameters efficiently (State 4).

This preprocessing ensures that each FMU is correctly configured before compilation, allowing it to run on the target environment with no manual intervention (either Unix or ESP32 in our case).

3.3 Library Integration into MicroPython

Once the FMU source code has been preprocessed, the next step involves integrating it into the MicroPython firmware (Step D), and flashing it on the device (Step E).

Integration is achieved using a C module that bridges the FMU execution engine and the MicroPython interpreter. This module exposes the core FMU functions via the minimal MicroPython-compatible ufmu API. As detailed in Annex A, the API includes a main class and utility functions to initialize a simulation instance with specified time parameters, access variable names and descriptions, read and modify variable values, and iterate through the simulation instance with output at each step.

The build process then differs by target: building for Unix uses a traditional Makefile workflow, while building for the ESP32 relies on CMake and the ESP-IDF framework, with different flags for function name overrides and linker configuration. Once the FMU execution engine is shipped into the MicroPython firmware, the end-developer only needs to define how the simulation is controlled and executed using this API.

Figure 3 illustrates the use of the ufmu API to control and execute the **BouncingBall.fmu** simulation. A simulation instance is created by calling the `setup_simulation` function with a start time, a stop time, and a step size. Once initialized, simulation variables can be accessed using `get_variable_names`, which returns an array containing the names of all FMU variables, and `get_variables_description`, which provides additional details on each variable's purpose and properties. The simulation instance is implemented as a Python *generator*, allowing users to step through it with a simple `for` loop. At each iteration, it yields an array of current variable values in a consistent order. Users can dynamically modify some of the variables during execution using `change_variable_value`, in line with the FMI 2.0 specification. This design ensures both simplicity and flexibility when interacting with the simulation.

```
>>> import ufmu as fmu
>>>
>>> # Print available variables and their
 ↪  descriptions
>>> for name in fmu.get_variables_names():
>>>     description =
 ↪  fmu.get_variables_description(name)
>>>     base_value =
 ↪  fmu.get_variables_base_values(name)
>>>     print(f"'{name}' (= {base_value} at
 ↪  t0): {description}")
'step' (= 0 at t0): Simulation step count
'time' (= 0.0 at t0): Simulation time
'h' (= 1.0 at t0): Position of the ball
'der(h)' (= 0.0 at t0): Derivative of h
'v' (= 0.0 at t0): Velocity of the ball
'der(v)' (= 0.0 at t0): Derivative of v
'g' (= -9.81 at t0): Gravity acting on the ball
'e' (= 0.7 at t0): Coefficient of restitution
>>>
>>> # Set up the simulation parameters
>>> startTime, stopTime, stepSize = 0, 3, 0.1
>>>
>>> # Initialize simulation instance
>>> sim = fmu.setup_simulation(startTime,
 ↪  stopTime, stepSize)
>>>
>>> # Change a variable (e.g., 'h' for height)
>>> fmu.change_variable_value(sim, 'h', 20)
>>>
>>> # Run the simulation and print time and
 ↪  height for each step
>>> for s, t, h, der_h, v, der_v, g, e in sim:
>>>     print(f"t: {t:.2f}s, h: {h:.2f}m")
t: 0.10s, h: 19.95m
t: 0.20s, h: 19.80m
...
```

3.4 Challenges and Optimizations

DOI 10.3384/ecp218535

Developing the ufmu framework to run FMUs from MicroPython on an ESP32 presented several challenges that required careful consideration and optimization to ensure the library's functionality and efficiency. Since microcontrollers in embedded systems are typically dedicated to a single task, the approach adopted was to embed a single FMU within the MicroPython environment and expose it through the fmu module.

One of the main challenges was the discrepancy between the compilation processes for Unix and ESP32 targets. The Unix port relies on Makefiles, while the ESP32 port uses CMake and the ESP-IDF framework. This difference necessitated adjustments in build configurations to ensure compatibility across both platforms. Specifically, the ESP32 compilation process required additional flags to override certain function name prefixes in the FMU source code, which were incompatible with the linker's expectations. By dynamically adjusting the build flags, we ensured proper linking of functions during compilation, resolving this issue effectively.

Memory management was another critical challenge, given the ESP32's limited RAM (approximately 4MB). To optimize memory usage, the library reuses the same variable to store the results of each simulation step. Instead of retaining historical data, each new step overwrites the previous values, ensuring minimal memory consumption. This approach allows the library to handle simulations with a large number of variables and steps without exceeding the microcontroller's memory limits. The end-developer decides whether to retain the values or not.

Function name prefix conflicts also posed a significant challenge. The FMU source code often included prefixes that conflicted with the linker's expectations during the ESP32 compilation process. To address this, the library dynamically modifies the function names during preprocessing, ensuring they align with the linker's requirements. This adjustment was crucial for enabling successful compilation and execution on the ESP32.

3.5 Evaluation

While the Unix port served as a reliable testing ground, the ESP32 port required additional debugging due to its unique constraints. The bouncing ball simulation, provided as a FMU test case, was instrumental in identifying and resolving issues related to memory management, function naming, and execution speed.

We assessed the ufmu framework by measuring the impact of shipping the **BouncingBall.fmu** on the firmware size, and measuring the execution time and peak memory usage for running this model from 0 to 10 with two distinct configurations: one with a step size of 0.01 and another with a step size of 0.0001.

Two ports were compared to a plain C simulator[4] developed alongside the ufmu library: MicroPython for the ESP32 target, and MicroPython for Unix. To ensure the reliability and accuracy of our performance measurements, each simulation was executed 10 times under identical conditions, with the same code as shown in Figure 4, and the mean value of the results was calculated. This approach minimizes the impact of any outliers or transient system behaviors that could skew the data. The Plain C simulator and the MicroPython Unix port were both executed within a WSL2 environment on a Windows 10 system, leveraging the computational power of an Intel(R) Core(TM) i7-10750H CPU @ 2.60GHz. The MicroPython ESP32 implementation, on the other hand, was run directly on the embedded hardware to evaluate its performance in a resource-constrained environment.

The results are summarized in Table 1. Integrating ufmu with the **BouncingBall.fmu** model increased the ESP32 MicroPython firmware by 220 KB (15 %), bumping it from 1.5 MB to roughly 1.72 MB. The Plain C simulator outperformed both Unix and MicroPython implementations in terms of execution speed (respectively 2 and 100 times faster). However, its memory usage, because of the fact that it keep all step result, is hardly comparable to the MicroPython one. The executable size is minimal, as it avoids the overhead associated with interpreted languages like MicroPython.

The MicroPython Unix port exhibited a bug when handling simulations with more than 5,000 steps, preventing it from completing the larger simulation (step size = 0.0001).[5] This issue is reflected in the results with an "X" in Table 1. Despite this limitation, the Unix port demonstrated competitive performance for smaller simulations.

The MicroPython ESP32 port, while significantly slower than the other two due to the hardware limitations of the ESP32, successfully completed both simulations. These results highlight the trade-offs between performance and resource efficiency when deploying simulations on embedded systems.

```
import ufmu as fmu
import time
import micropython
start_time = 0
end_time = 10
step_size = XX
start = time.ticks_ms()
simInstance = fmu.setup_simulation(start_time,
↪  end_time, step_size)
fmu.change_variable_value(simInstance, 'h', 20)
for i in simInstance:
        pass
print("Time taken: ",
↪  time.ticks_diff(time.ticks_ms(), start),
↪  "ms")
micropython.mem_info()
```

Figure 4. The code run by MicroPython to get the result presented in Table 1. The value replaced here by XX is respectively 0.01 and 0.00001

4 Related Work

4.1 Portable runtime environments for Python-based FMUs

The concept of portability extends beyond just MicroPython. In the field of FMUs, ensuring that Python-based FMUs can execute across various systems without dependency conflicts is crucial. One approach to achieving this portability is through containerization.

A notable effort in this direction is the addition of Docker support to UniFMU (Schranz et al. 2021), a tool designed for building and executing FMUs. By encapsulating all necessary runtime dependencies in a Docker container, this approach allows FMUs to be distributed and deployed seamlessly across different environments. This capability is particularly beneficial in scenarios requiring co-simulation, as demonstrated in the case of a robotic arm and its controller, where two Python-based FMUs were successfully executed within a Docker container. This method eliminates compatibility issues and simplifies the deployment process, aligning with the broader goal of making Python-based embedded applications more accessible and portable.

By combining the lightweight nature of MicroPython with advances in FMU portability, developers can leverage Python for a wider range of embedded and simulation applications. The ability to run MicroPython on constrained hardware while simultaneously supporting Python-based FMUs in containerized environments highlights the versatility and growing influence of Python in embedded systems and simulation workflows.

This approach becomes particularly valuable when deploying large-scale embedded systems for co-simulation scenarios, such as in (Jung, Shah, and Weyrich 2018), where a dynamic, multi-agent-based simulation framework was used to model a smart warehouse. In this scenario, various IoT components—such as storage racks, temperature sensors, forklifts, and incoming goods—communicate and make autonomous decisions in real time. Each component is represented as an independent simulation agent capable of dynamically joining an ongoing co-simulation, enabling a flexible "Plug-and-Simulate" behavior. By leveraging modular co-simulation techniques, the study demonstrates how distributed embedded systems can interact seamlessly, allowing for efficient and adaptive digital twin implementations. The ability to deploy Python-based FMUs within portable runtime environments, such as Docker, further enhances this flexibility, enabling scalable and reproducible simulations across heterogeneous IoT ecosystems.

4.2 FMI and eFMI in Embedded, Automotive, and Industrial Applications

Recent advancements have demonstrated the feasibility of using FMUs and their embedded counterpart, eFMU, for real-time simulation on microcontrollers. The increasing computational capabilities of embedded hardware, along with the standardization of the FMI, have unlocked new possibilities for Cyber-Physical Systems (CPS), industrial automation, and automotive systems.

In the context of CPS, (Hong et al. 2020) proposed a simulation framework leveraging FMI, incorporating a redundancy reduction algorithm to optimize performance for resource-constrained microcontrollers. Similarly, (Gundermann et al. 2017) validated embedded FMI for lifetime testing of electromechanical systems through a 60-day real-time study on a linear stepper motor, confirming its reliability in embedded environments.

The eFMI standard, developed under the EMPHYSIS project and detailed in (Lenord et al. 2021), is tailored to meet the constraints of embedded systems, including hard real-time requirements and limited memory. It enables seamless integration of high-fidelity, physics-based models into embedded control systems, making it particularly impactful in domains like automotive, aerospace, and industrial automation, where such models can enhance control strategies, diagnostics, and predictive maintenance.

In the automotive sector, FMI plays a pivotal role in software validation, virtual Electronic Control Unit (ECU) testing, and real-time simulation of vehicle dynamics. (Mikelsons and Samlaus 2017) demonstrated the integration of FMI-based models into ECU validation workflows, identifying software issues early in the development process and improving reliability.

To overcome the incompatibility of traditional Co-Simulation FMUs with embedded automotive applications—due to stringent real-time constraints, MISRA compliance, and AUTOSAR architecture—eFMI has been extended to AUTOSAR environments (Armugham et al. 2021). In a case study, a physics-based model was integrated into a Bosch ECU using an AUTOSAR toolchain, illustrating a compliant, efficient, and cost-effective approach that significantly reduced the manual coding effort typically required.

Beyond automotive use cases, FMI and eFMI are also advancing industrial automation by enabling embedded simulations for real-time failure detection and predictive diagnostics. As embedded FMI technology evolves alongside edge computing and optimized firmware, its role in real-time embedded systems is expected to grow substantially, driving innovation across various high-demand sectors.

Building upon these advancements, our MicroPython FMU implementation bridges a gap in the embedded systems landscape by making simulation capabilities accessible to Python programmers in resource-constrained environments. While existing work has demonstrated FMU viability on dedicated microcontrollers, our approach extends these benefits to the growing ecosystem of MicroPython-enabled devices, enabling rapid prototyping, interactive debugging, and simplified deployment without sacrificing real-time performance. This contributes to the democratization of complex simulation

capabilities, allowing domain experts without extensive embedded C programming knowledge to leverage FMI's standardized approach for applications ranging from educational settings to industrial IoT deployments where Python's flexibility and MicroPython's efficiency can significantly accelerate development cycles.

4.3 Cloud vs. Edge Deployment for FMI-Based Simulations

Several studies have investigated the trade-offs between cloud-based and edge-based IoT simulations. (Savaglio et al. 2019) assessed the performance, latency, scalability, and resource utilization of both deployment options. Their findings suggest that edge computing provides lower latency and better scalability for IoT applications, whereas cloud computing offers superior data handling and processing reliability. Recent advancements in edge deployment, such as those proposed by (Bu, Filipau, and Baklanov 2024), have further streamlined the process of deploying cyber-physical models at the edge or in the cloud. Their framework utilizes FMUs as executable binaries and JavaFMI as the simulation engine, encapsulating each model deployment within a microservice. This approach ensures flexibility and scalability, as demonstrated by their examples of a winch controller at the edge and a wireline logging unit simulator in the Azure DevOps pipeline.

For FMI-based simulations, the choice between cloud and edge computing depends on factors such as real-time constraints, network bandwidth, and security considerations. Many real-time embedded applications benefit from edge-based execution, as it allows FMUs to run with minimal latency directly on the device. The classification of hardware types, as outlined by (Bormann et al. 2025), provides further clarity on this decision. Table 2 summarizes the classification of common devices used in IoT simulations and deployments.

For instance, devices like the Raspberry Pi, classified as Class 15, are well-suited for fog computing, while microcontrollers such as the ESP32, classified as Class 10, are ideal for edge computing. This classification helps in aligning the hardware capabilities with the specific requirements of IoT simulations and deployments.

The work of (Jung, Shah, and Weyrich 2018) complements this discussion by proposing a dynamic co-simulation approach for IoT systems, where each component is simulated independently and can dynamically join the co-simulation during runtime. This "Plug-and-Simulate" behavior is particularly advantageous for edge deployments, where heterogeneous devices with varying computational capabilities must interact seamlessly. Their modular framework aligns with the microservice architecture proposed by (Bu, Filipau, and Baklanov 2024), highlighting the importance of flexibility in edge-based FMI deployments.

Table 2. Classification of devices for IoT simulations and deployments by (Bormann et al. 2025)

Device	**Classification**
Arduino Uno	Class 5 (Edge Computing)
ESP32	Class 10 (Edge Computing)
Raspberry Pi	Class 15 (Fog Computing)
Modern Smartphone	Class 16 (Edge/Cloud Computing)
Laptop	Class 17 (Cloud Computing)
High end Home Computer	Class 18 (Cloud Computing)

On the cloud side, (Stelzig and Rodenberg 2023) introduces the concept of Simulation Model as a Service (SMaaS), which leverages cloud infrastructure to deploy, execute, and track simulation models efficiently. While cloud-based solutions excel in handling large-scale simulations and complex data processing, they often face challenges related to latency and real-time responsiveness. This trade-off underscores the need for hybrid approaches, where computationally intensive tasks are offloaded to the cloud, while time-critical operations are handled at the edge.

The integration of these approaches is further supported by (Vanommeslaeghe et al. 2018), which explores the co-simulation of embedded platforms and physics-based models. Their work emphasizes the importance of optimizing hardware architectures to support FMI-based simulations, particularly in edge environments where resource constraints are a significant concern. By combining insights from these studies, it becomes clear that the choice between cloud and edge deployment is not binary but rather a spectrum, where the optimal solution depends on the specific requirements of the application, such as latency tolerance, computational complexity, and scalability

needs.

Building on these deployment insights, our MicroPython FMU implementation presents a good middle ground particularly well-suited for Class 10 devices like the ESP32. By embedding FMU capabilities directly into MicroPython, we enable sophisticated edge-based simulations without requiring cloud connectivity or fog computing resources. This approach addresses the latency concerns highlighted in edge computing research while maintaining the flexibility needed for dynamic co-simulation scenarios. The memory-optimized design of our module responds directly to the resource constraints emphasized in the literature, while its Python interface removes barriers to implementation that typically accompany embedded FMU deployments. This positions our work as a practical enhancement to the "Plug-and-Simulate" paradigm, extending FMI's benefits to resource-constrained IoT devices where traditional deployment methods would be prohibitively complex or performance-intensive.

4.4 Discussion

By combining insights from these studies, it becomes clear that hardware optimization for FMI execution involves a multi-faceted approach, encompassing efficient memory management, real-time scheduling, and hardware-specific optimizations. These advancements are paving the way for more sophisticated FMI-based simulations on resource-constrained devices, enabling their use in a wider range of applications, from industrial automation to autonomous systems. The state of the art in FMI-based simulations for embedded systems demonstrates significant progress across multiple fronts, from portable runtime environments to hardware optimization. The integration of Python-based FMUs with containerization technologies, such as Docker, has enhanced portability and reproducibility, enabling seamless deployment across diverse environments. This is particularly valuable for co-simulation scenarios, where modular and dynamic frameworks, as proposed by (Jung, Shah, and Weyrich 2018), allow heterogeneous systems to interact efficiently.

Despite these advances, there remain significant limitations to the adoption of MicroPython-based FMU implementations in industrial settings. Professional environments typically demand rigorous certification, long-term support, and deterministic performance guarantees that interpreted languages like Python may struggle to provide. While our implementation offers valuable prototyping capabilities, industry practitioners will likely continue favoring native C/C++ implementations for production systems where reliability and performance predictability are paramount.

The development of eFMI has further expanded the applicability of FMI in resource-constrained environments, enabling high-fidelity physics-based models to run on microcontrollers. This advancement is particularly transformative for automotive and industrial applications, where real-time execution and compliance with standards like AUTOSAR are critical. The successful integration of eFMI into automotive ECUs, as demonstrated by (Armugham et al. 2021), highlights its potential to bridge the gap between simulation and real-world execution. eFMI being compatible with FMI, we expect that our framework could be used to run FMUs optimized for resource-constrained environments thanks to GALEC.

Our current implementation focuses exclusively on FMI 2.0 standard compatibility, which presents both advantages and limitations. While FMI 2.0 offers widespread tool support and established functionality, it lacks newer features from FMI 3.0 such as binary co-simulation interfaces and enhanced array variable handling that could potentially improve performance on constrained devices. Future work could explore adapting our approach to leverage these newer standard capabilities as tool support matures.

The debate between cloud and edge deployment for FMI-based simulations underscores the importance of balancing computational power, latency, and scalability. While cloud-based solutions excel in handling large-scale simulations, edge computing offers the low latency and real-time responsiveness required for many embedded applications. Hybrid approaches, combining the strengths of both paradigms, are emerging as a promising solution for complex, distributed systems. Our choice of the ESP32 platform was strategically motivated by its unique combination of computational capability, memory resources, and wide adoption in the IoT ecosystem. With dual-core processing up to 240MHz and typically 4MB of flash memory, it represents an optimal middle ground between severely constrained Class 1-5 devices and more powerful Class 15+ systems. Furthermore, the ESP32's native support for both WiFi and Bluetooth positions it ideally for co-simulation scenarios where edge devices must communicate with other simulation components.

As the field continues to evolve, the convergence of these technologies—portable runtime environments, eFMI, cloud-edge hybrid architectures—will play a pivotal role in addressing the challenges of real-time execution, resource constraints, and system integration.

5 Conclusions

This paper introduced ufmu, a lightweight library that enables FMU simulations to run efficiently on resource-constrained microcontrollers. By integrating and executing FMU models within the MicroPython environment, ufmu provides an accessible and flexible FMU tool that may prove useful for education and rapid prototyping in embedded systems.

The library achieves this by translating FMU model descriptions into a C-based structure and embedding them within the MicroPython build process. This approach ensures seamless execution while exposing a minimal high-level Python API for user interaction. As a result, ufmu allows developers to run model-based simulations directly

DOI
10.3384/ecp218535

on microcontrollers without relying on a full desktop or cloud computing setup.

While the current implementation successfully enables FMU simulations to run on an ESP32 microcontroller, there are several areas for future improvement to enhance the library's functionality, usability, and performance.

As a natural progression of this work, adding support for the FMI 3.0 standard is a key objective. The current implementation supports basic simulation execution but supporting advanced states such as setup, pause, and resume modes, would be desirable. For example, users could pause a simulation to modify parameters and then resume execution without restarting the simulation.

Future development will also focus on expanding support to other microcontroller platforms, such as STM32 or Raspberry Pi Pico.

A ufmu class and methods description

`simulation_instance`
Class representing a configured simulation instance:

- Implements iterator protocol for step-by-step simulation
- Maintains internal simulation state

`simulate(tStart, tEnd, h)`
Executes a complete simulation in one call.

- *Parameters:* `tStart`, `tEnd`, `h` (float): start time, end time, step size
- *Returns:* list of output value tuples

`setup_simulation(tStart, tEnd, h)`
Creates a simulation instance for step-by-step execution.

- *Parameters:* same as above
- *Returns:* a `simulation_instance` object

`get_variable_count()`
Returns the number of variables in the model.

- *Returns:* integer count

`get_variables_names(...)`
Retrieves variable names.

- *Parameters:* optional indices/names
- *Returns:* tuple of variable name strings

`get_variables_base_values(...)`
Retrieves initial values of variables.

- *Parameters:* optional indices/names
- *Returns:* tuple of values (float/int)

`get_variables_description(...)`
Retrieves variable descriptions.

- *Parameters:* optional indices/names
- *Returns:* tuple of variable description strings

`change_variable_value(...)`
Modifies a variable's value during simulation.

- *Parameters:*
  - `sim_instance` (object)
  - `var_ref` (int or str)
  - `value` (float)
- *Returns:* boolean success indicator

FMI Meets SystemC: A Framework for Cross-Tool Virtual Prototyping

Abstract

As systems become more complex, the demand for thorough testing and virtual prototyping grows. To simulate whole systems, multiple tools are usually needed to cover different parts. These parts include the hardware of a system and the environment with which the system interacts. The Functional Mock-up Interface (FMI) standard for co-simulation can be used to connect these tools.

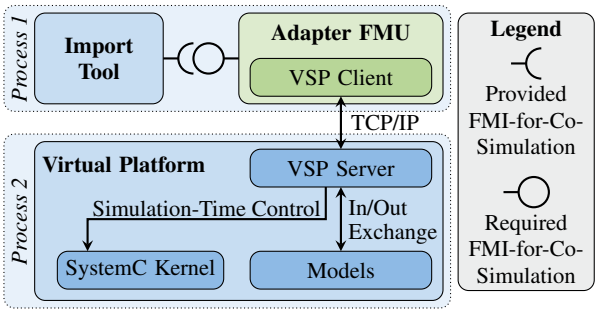
The control part of modern systems is usually a computing unit, such as a System-on-a-Chip (SoC) or Microcontroller Unit (MCU), which executes software from a connected memory and interacts with peripherals. To develop software without requiring access to physical hardware, full-system simulators, the so-called Virtual Platforms (VPs), are commonly used. The IEEE-standardized framework for VP development is SystemC TLM. SystemC provides interfaces and concepts that enable modular design and model exchange. However, SystemC lacks native FMI support, which limits the integration into broader co-simulation environments.

This paper presents a novel framework to control and interact with SystemC-based VPs using the FMI. We present a case study showing how a simulated temperature sensor in a SystemC simulation can obtain temperature values from an external tool via FMI. This approach allows the unmodified target software to run on the VP and receive realistic environmental input data such as temperature, velocity, or acceleration values from other tools. Thus, extensive software testing and verification is enabled. By having tests ready and the software pre-tested using a VP once the physical hardware is available, certifications like ISO 26262 can be done earlier.

Keywords: SystemC, TLM, FMI, Virtual Platform

1 Introduction

In today's rapidly evolving technology landscape, systems are becoming more complex, requiring advanced development cycles and rigorous testing methodologies. As industries, such as automotive, tend to solve more problems in software rather than hardware, early and intensive software testing is paramount (Ondrej Burkacky et al. 2018). To start software development and testing while the hardware is still under design, Virtual Platforms (VPs), also known as *Level 4 Virtual Electronic Control Units (L4 vECUs)*, can be used. It has been shown that the earlier bugs are found, the lower the cost of rectifying them. Fixing a bug during the development phase can be up to 100 times cheaper than fixing it while the product is already in use (Boehm 1976). VPs are the key enabler of early software testing. By simulating a System-on-a-Chip (SoC), the unmodified target[1] software can be developed and tested without requiring access to the physical hardware.



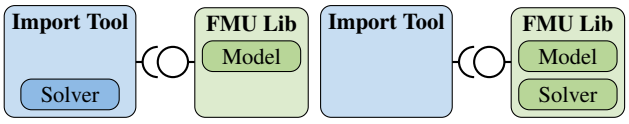


Figure 1. SystemC-FMU adapter approach.

The IEEE-standardized framework for VP design is SystemC with its Transaction-Level Modeling (TLM) extension (IEEE Standards Association and others 2023). While VPs are well-suited tools for software development and verification, they reach their limits when it comes to realistic testing of different scenarios. Because embedded systems, such as Electronic Control Units (ECUs), interact with their physical environment by reading sensor values and controlling devices, it is not enough to simulate only the system itself. In addition, environmental effects must also be considered and simulated.

To simulate physical systems and define complex test cases, there are many tools available. In this paper, we show how a SystemC-based simulation can be connected to those tools using the Functional Mock-up Interface (FMI) standard (Modelica Association 2024). The FMI co-simulation standard allows to synchronize the simulation time of multiple simulations and to exchange data.

Figure 1 shows the integration of our approach in a co-simulation. We developed an Functional Mock-up Unit (FMU) that can be imported by any FMI-compatible tool to control a VP. This FMU exposes the specified output of

[1]*target*: architecture that is simulated; *host*: architecture that runs the simulation

(a) Model Exchange. **(b)** Co-Simulation.

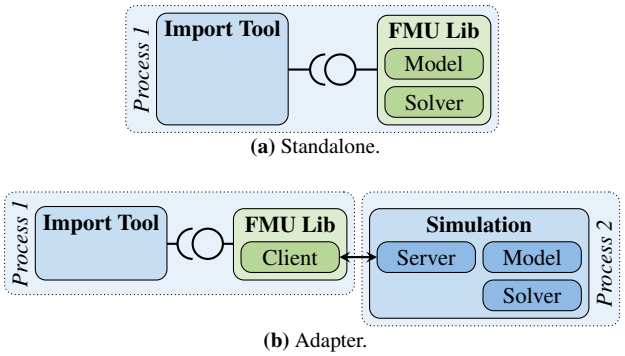
Figure 2. FMI types.

VP and accepts the inputs that are forwarded to VP. The VP runs in a second process, either on the same host as the FMI import tool, or on a different one. The connection between the FMU and the VP is TCP/IP based.

We present a case study where we show how an open-source VP can be connected to tracetronic's *ecu.test* tool using FMI. ecu.test allows defining complex test scenario where environmental data can be specified and responses of the tested system are compared against expectations.

In the end, we propose a software design flow that uses our integration for early testing and verification. This design flow helps to shorten the time to reach specifications like ISO 26262 (ISO/TC 22/SC 32 2018).

2 Background and Related Work



This section provides an overview of the related work that forms the foundation of this study. Section 2.1 explains the FMI standard and the features used in this work. Section 2.2 provides an overview of virtual prototyping, including background information on the industry-standard framework SystemC and the Virtual Components Modeling Library (VCML), which builds on top of SystemC. In Section 2.3, an overview of existing approaches to integrate SystemC modules into an FMI co-simulation is given.

2.1 Functional Mock-up Interface (FMI)

The Functional Mock-up Interface (FMI) is an open standard designed to enable seamless integration and interoperability of simulation models from various tools and vendors (Modelica Association and MODELISAR Consortium 2024). Initially introduced by the Modelica Association in 2010, FMI has become a widely adopted standard for modular and tool-agnostic simulation workflows and is supported by more than 200 tools.

Simulation models are encapsulated into so-called FMUs. This encapsulation process is performed by *export tools*, which are typically provided by simulation-software vendors. FMUs can then be imported and utilized by *import tools*, which coordinate the simulation and facilitate data exchange between multiple FMUs.

The original standard supports two interface types, *Model Exchange* (Modelica Association 2010b) and *Co-Simulation* (Modelica Association 2010a), as illustrated in Figure 2. As physical systems are often described by differential equations, a numerical solver is needed to solve and evaluate these equations. The difference between the FMU interface types is primarily in the placement of the numerical solver. In the Model-Exchange use-case, the solver is not part of the FMU and therefore needs to be implemented in the import tool.

(a) Standalone.

(b) Adapter.

Figure 3. FMI Co-Simulation scenarios.

With the introduction of FMI 3.0 (Modelica Association and MODELISAR Consortium 2024), a third interface type, *Scheduled Execution*, was added. For this work, we only use the Co-Simulation interface, so the other ones are not further discussed. We demonstrate how a full VP can be encapsulated into an FMU. Because VPs usually operate at a much higher level of abstraction than differential equations, we do not require a numerical solver. Consequently, Co-Simulation is the preferred approach.

When the Co-Simulation interface is used, two scenarios are possible, a *standalone* and an *adapter* scenario (Blochwitz et al. 2011). Both scenarios are visualized in Figure 3. The FMU contains a shared library (*FMU Lib*) that is loaded by the import tool. It implements standardized FMI functions, the import tool calls. In the standalone scenario, as shown in Figure 3a, the shared library contains the full simulation model. The simulation model can be directly executed in the process of the import tool.

In the adapter scenario, illustrated in Figure 3b, the shared library acts as an interface to another process that executes the simulation. This connection can, e.g., be established using network-based protocols, such as TCP/IP. One key advantage of this approach is the ability to run the import tool and simulation on different machines, which can offer potential performance benefits by distributing computational load. Additionally, this configuration allows the simulation and import tool to run on different Operating Systems (OSs) or even different hardware architectures, such as x86 and Arm.

2.2 Virtual Prototyping

Virtual prototyping is a technique in which electronic systems are modeled entirely in software. This work focuses on VPs, virtual prototypes designed for software development for the simulated target platform. VPs can simulate the execution of an unmodified target-software stack. In the automotive domain, they are referred to as *L4 vECUs*.

The industry-standard framework for VP development is SystemC with its TLM extension (IEEE Standards Association and others 2023). SystemC standardizes the interface and functionality of a C++ library that features interfaces, data types, and a Discrete Event Simulation

(DES)-based scheduler to simulate parallelism. A simulation usually contains multiple modules that can be connected via TLM sockets. TLM abstracts the underlying communication protocol and offers low-overhead data exchange. The standardized interfaces guarantee seamless integration of different models into a simulation.

On top of SystemC, modeling libraries provide additional functionalities. One open-source modeling library is VCML (MachineWare 2024). VCML extends SystemC with essential components, such as register models, prebuilt hardware components, and specialized TLM-based communication protocols. A key feature used in this work is the VCML Session Protocol (VSP). VSP is a remote-control protocol that is based on GDB's Remote Serial Protocol (RSP) protocol (Free Software Foundation, Inc. 2024). VCML includes a VSP server module, which allows clients to connect via TCP to control the simulation.

Another crucial VCML feature used in this work is *properties*, which encapsulate configuration variables within modules. These properties can be set at VP launch and accessed via the VSP protocol, facilitating dynamic reconfiguration.

2.3 Related Work

Previously, various publications have described methods for integrating SystemC-based simulations into FMI co-simulations. Most of these approaches are based on the FMI 2 standard and involve tight coupling between the FMI interface and the VP.

One approach integrates an FMI import tool directly into the VP to co-simulate SystemC models with FMUs that provide environmental models (Safar et al. 2018). This approach means that the VP cannot be used with other import tools, e.g., for setting up test scenarios, as described in Section 4. Furthermore, the VP is no longer standalone, so co-simulated FMUs are always required.

For detailed Register-Transfer Level (RTL)-like SystemC simulations, a different approach can be used to expose SystemC ports to FMI (Centomo, Deantoni, and De Simone 2016). This approach also requires modifications to the VP, which prevents a standalone simulation. In our work, we focus on SystemC-TLM-based VPs that use a higher abstraction level to achieve increased performance.

For SystemC Analog/Mixed-Signal (AMS) simulations, wrapper classes can be created to wrap models and connect the needed inputs and outputs to an FMI integration (Krammer et al. 2015). This kind of simulation also targets more detailed abstraction levels and requires modifications to the simulation.

In another approach, *FMI variables* are introduced, that can be bound to different protocols like CAN, or I^2C (Saidi et al. 2019). When a variable changes, different actions can be carried out. For example, a CAN frame carrying the updated variable as payload can be injected onto the bus. This approach is useful for simple sensors that use common protocols. An advantage is that the sensor itself does not need to be part of the VP but can be completely used from the FMI integration. This approach also does not allow for standalone use of the VP.

In our work, we present an approach that does not require VP modifications and therefore no source-code access. The requirement is that theVP is based on the used modeling library VCML and the VSP server is not disabled. The VP can then be used without the FMI integration when environmental input are not needed. When environmental inputs become important, the VP can be integrated into an FMI co-simulation without any changes by using our standalone FMI-adapter FMU.

3 Approach

In this section, we present our approach. First, Section 3.1 describes the application scenario. Then, Section 3.2 explains how we integrate a VCML-based VP into an FMU. In the end, Section 3.3 provides further details on the FMU

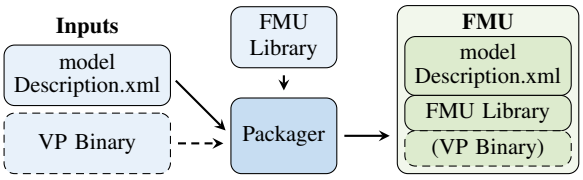

Figure 4. FMU creation.

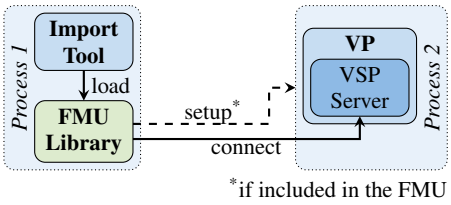

Figure 5. Working principle.

implementation and the integration process.

3.1 Application Scenario

Imagine a VP that models an ECU that consists of various peripherals including sensing devices for measuring environmental conditions. Such a VP is crucial for target software development and verification but traditionally lacks dynamic environmental modeling capabilities. For instance, a virtual model of a temperature sensor simulates all hardware interfaces other components can access but typically returns constant values during standalone VP execution, limiting its ability to test software responses to varying conditions. Directly integrating environmental simulations, such as temperature models, into device models like sensors would have multiple drawbacks:

- **Simplicity**: The model should be kept simple to have a high performance. Complex algorithms to model the environment would unnecessarily slow down the model and increase its complexity when the environmental simulation is not needed.
- **Genericity**: The model should only reflect the behavior of the hardware to use it in various scenarios. An environmental simulation model heavily depends on the scenario and not the component itself.
- **Specialization of Tools**: There are well-established tools to create environmental models, e.g., based on physical equations or test cases.

Because of those reasons, the returned temperature value from our model is read from a VCML property (see Section 2.2). This means that in a standalone simulation, the temperature value is set at startup and remains constant throughout execution. While this setup allows for full software stack execution including sensor interaction, it does not support testing of how the software reacts to changing environmental conditions.

To overcome this limitation, our FMI integration enables co-simulation of the VP together with external tools that dynamically provide environmental data. This approach allows for realistic scenario testing and a more comprehensive evaluation of the system's behavior using dedicated tools to solve various tasks.

3.2 FMU Creation

To create an FMU from a VCML-based VP, our *Packager* tool can be used. Figure 4 illustrates the creation process. The resulting FMU includes our VP-independent FMU library and a model-description file, which defines its properties. Section 3.3 explains the working principle of the FMU library in detail. A simplified example of a model-description file is shown in Listing 1.

The `ModelVariables` element lists the VP's inputs and outputs that are accessible via FMI. Each variable's name corresponds to the property name within the module hierarchy of the VP. For example, the `system.max31855.temp` property defines the property `temp` of the SPI temperature sensor `max31855`, which is a submodule of the `system` module. It is sufficient to list the hierarchical name of the property in the model-description file. There are no changes in the VP needed to expose the property. The VSP server can clearly identify and access the properties by their hierarchical names. Additionally, data types are specified, and it is indicated whether the property functions as an input or output. For inputs, a start value can be assigned. During simulation, FMI uses the `valueReference` numbers when updating the variables.

The `Annotations` element defines VP-specific properties using the available attributes listed in Table 1. The VP binary can be embedded within the FMU and launched by the FMU. In this case, the `executable` attribute points to the relative path of the VP binary within the FMU (e.g., `resources/my_vp`). Additionally, the `host` is set to *localhost*, and the `port` specifies the TCP port the VP's VSP server is listening.

If the VP is not embedded in the FMU, e.g., because it is manually launched on a separate machine, only the `host` and `port` attributes need to be configured. The `host` attribute defines the hostname of the machine that executes the VP. This machine needs to be reachable by the import tool via a TCP connection.

3.3 Working Principle

An exported FMU can be loaded by an FMI-3-compatible import tool. Figure 5 illustrates the workflow.

Table 1. Attributes of the VCML annotation node.

Attribute	Meaning
`executable`	Path of the VP executable
`args`	Args that are passed to the VP executable during startup
`host`	IP address or hostname of the machine that executes the VP
`port`	Listening port of the VP server

DOI
10.3384/ecp218545

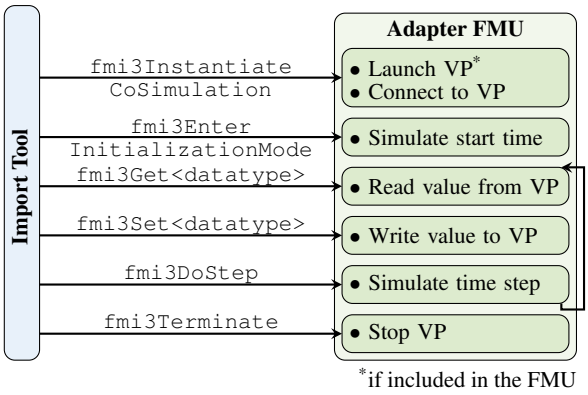

Figure 6. FMI functions implemented by our FMU.

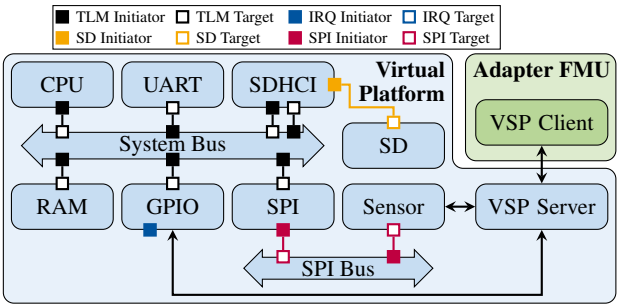

Figure 7. AVP64-based ECU with connected FMI adapter.

The import tool unpacks the FMU and reads the model-description file. It then loads the FMU library (*.dll* or *.so*). Afterward, the import tool can call the standardized FMI functions that are implemented by the FMU library. If the VP binary is packed into the FMU, the FMU library starts the VP in a second process. The library establishes a TCP-based connection to the VSP server of the VP and uses this connection to control the simulation.

Figure 6 shows the FMI functions our FMU implementation. The tasks that are executed by those functions are explained in the following in more detail.

First, the `fmi3InstantiateCoSimulation` function is usually called. If the VP is part of the FMU, a second process is started to run the VP. Parameters can be passed to the VP via command-line arguments. If the VP is not part of the FMU, it needs to be started manually. This can be done either on the same machine or on a different one that is located in the same network as the machine that runs the FMU. In this case, the corresponding hostname of the machine that runs the VP needs to be set in the `VCML` node of the model description's `Attribute` node. Once the VP is started, the VSP server listens on the TCP port for a connection and suspends the VP until the FMU is connected. The FMU connects the VSP server of the VP.

When the `fmi3EnterInitializationMode` function is called by the import tool, a command is sent to the VSP server to simulate until the virtual simulation time of the SystemC simulation reaches the specified `startTime`. The start time parameter of the FMU can be used to, e.g., skip the boot process of the OS running on the system. If the start time is set to 0, our FMU does nothing in this step. After the `fmi3EnterInitializationMode` function call, the VP is ready for simulation.

The import tool can read model variables that have been declared as *output* in the model description by calling the `fmi3Get<datatype>` functions. For example, `fmi3GetFloat64` is used when the variable is declared as *Float64* in the model description. The variable is referenced by its `valueReference` property. The FMU translates the `valueReference` into the `name` using the model description. This name corresponds to the hierarchical name of the property in the VP (see Section 3.2). This hierarchical name can be directly used by the VSP server to identify, read, and write the property value within the simulation. All available properties of the simulation can be used as FMU inputs and outputs by simply specifying their hierarchical name in model description.

To update an FMU input, the `fmi3Set<datatype>` function can be used in the same way. Again, the variables are referenced by their `valueReference` property. The updated input values are directly sent to the VP to update the corresponding model properties.

After variables have been updated, the `fmi3DoStep` function can be called to simulate a time step. The amount of simulation time that is simulated on a call is usually defined by the `stepSize` attribute in the model description (see Listing 1). Our FMU sends a command to the connected VP to simulate the step. The VP's SystemC scheduler simulates events until the virtual simulation time is increased by the specified step. This allows the virtual CPU model to execute target software, and interact with other simulated peripherals. The import tool repeatedly calls the `fmi3Get<datatype>`, `fmi3Set<datatype>`, and `fmi3DoStep` functions as long as the test or the simulation is running.

To end the simulation, the `fmi3Terminate` function is called, which stops the VP and shuts down the simulation.

4 Case Study

To demonstrate the effectiveness of our FMI integration approach for SystemC-based VPs, we present a case study of a software-based Schmitt trigger application with a temperature input. We show how the different components of the system can be efficiently modeled and integrated into an FMI-based co-simulation using our developed framework. The full system consists of three parts:

ECU: The ECU consists of an ARMv8 processor, memory, and peripherals. The components and their connections are shown in Figure 7. A *MAX31855* (Maxim Integrated 2015) temperature sensor (denoted as *Sensor* in Figure 7) can measure the ambient temperature. The sensor is connected via an SPI interface to the SPI controller, which is accessible by the CPU. Additionally, the system features a General Purpose Input/Output (GPIO) controller that allows the CPU to control external signals. To simulate the ECU hardware, the open-source, SystemC-TLM-based ARMv8 Virtual Platform (AVP64) (Jünger et

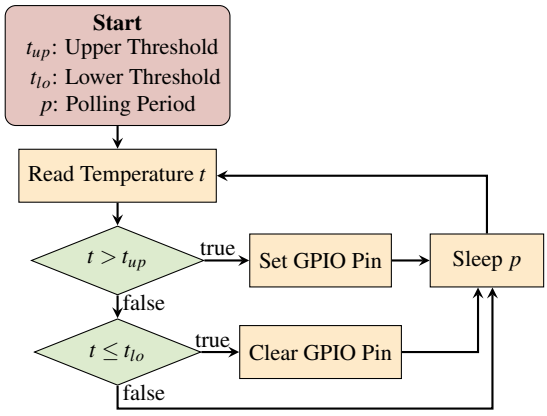

Figure 8. Schmitt-trigger algorithm executed by the VP.

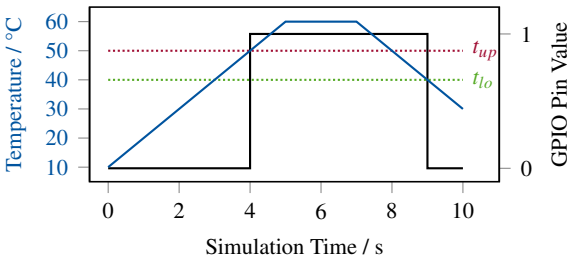

Figure 9. Temperature input and expected GPIO-pin output for $t_{lo} = 40\,°\text{C}$ and $t_{up} = 50\,°\text{C}$.

al. 2019; Jünger 2023) is used. The VP is capable of executing the full target-software stack.

Software Application: The ECU boots a *Buildroot*-based Linux OS (Buildroot 2024). Upon completion of the boot process, a simple Schmitt-trigger application is automatically launched. The Schmitt-trigger application implements the algorithm depicted in Figure 8. This algorithm monitors the temperature input of the sensor and sets or clears a GPIO pin based on the predefined threshold values t_{lo} and t_{up}. When the temperature exceeds t_{up}, the GPIO pin is set. When it falls below t_{lo}, the GPIO pin is cleared. The application periodically polls the temperature sensor at a configurable interval p. An example of a temperature curve and the expected output for $t_{lo} = 40\,°\text{C}$ and $t_{up} = 50\,°\text{C}$ is shown in Figure 9.

Environmental Impacts: The ECU interacts with its environment by measuring the ambient temperature and reacting to changes. To add the simulation of changing environmental conditions and enable comprehensive testing with dynamic environmental scenarios, we package the VP into an FMU using our FMI integration approach.

This allows for co-simulation with external tools that can provide varying temperature inputs. The FMU configuration for our scenario includes one input and one output as shown in Figure 10. The input is connected to the temperature property of the MAX31855 sensor model, and the output retrieves the GPIO pin value from the GPIO controller (see Figure 7). There are no changes in the VP required to be connected to the FMU. It is sufficient to specify the hierarchical names of the properties for the temperature value and the GPIO pins in the model description (see Section 3.2).

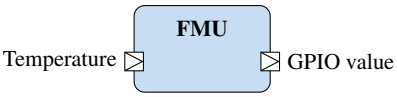

Figure 10. FMU with inputs and outputs.

4.1 Target-Software Verification

Software verification and testing play a crucial role during the design process of a system. The earlier a bug is found, the less effort and cost it will take to fix it. As described in Section 1, if a bug is first found during product operation, the cost of fixing it can be up to 100 times higher than if it is found during software development (Boehm 1976). By integrating the VP into an FMI co-simulation using our approach, complex scenarios can be tested to find bugs as early as possible. This leads to lower costs, a shorter time to market, and overall improved development efficiency.

A typical measure that is used to determine the percentage of tested code is code coverage (Ivanković et al. 2019). Traditional line coverage (Miller and Maloney 1963) describes the number of executed lines of code divided by the total number of lines of code. More advanced metrics like Modified Condition/Decision Coverage (MC/DC) (Kelly J. Hayhurst et al. 2001) are required for ISO-26262-based Automotive Safety Integrity Level (ASIL) D certification (ISO/TC 22/SC 32 2018). Besides counting the executed lines of code, MC/DC adds additional metrics like counting if Boolean expressions have been evaluated as both, true and false. The VP can directly extract coverage metrics of the target software after execution without requiring instrumentation of the target software (Bosbach et al. 2024).

For extensive testing and validation, we utilize *ecu.test* from *tracetronic GmbH* (tracetronic GmbH 2024). This tool allows defining complex test scenarios, specify environmental input data, and compare the system's responses against expected outcomes to test if the system fulfills its requirements. ecu.test is commonly used for ECU testing and verification. It has native support for FMI.

For easy setup and test configuration, ecu.test can be executed on Windows-based machines and controlled using a Graphical User Interface (GUI). The VP is executed on a Linux cloud server. ecu.test loads our adapter FMU on the Windows machine. The FMU connects via a TCP/IP connection to the VSP server that runs on a Linux machine in the same network. For scaled testing, the whole setup can be executed on a single Linux machine using tracetronic's Linux version of ecu.test. By combining our VP FMU with ecu.test, we can perform realistic and thorough testing of the Schmitt trigger application by simulating various temperature conditions. An example of a successful test run is illustrated in Figure 11.

Execution traces of the CPU model can be used to generate coverage reports. To showcase the usefulness of a coverage report, we turned on the code-coverage feature

(b) Temperature controlled by ecu.test.

Figure 12. Coverage results for different configurations.

of the VP to generate execution traces and converted them to a *lcov*-based coverage report (Linux Test Project 2023).

Figure 12 visualizes coverage results for the presented Schmitt-trigger application. Figure 12a shows the report for the standalone VP without the FMI integration and ecu.test. Since the temperature value is constant in this case, the algorithm never executes the path that sets the GPIO pin (see Figure 8). This leads to a line coverage of 86.1 %. When ecu.test is connected and test scenarios are executed, the line coverage is increased to 100 %.

This simple example shows that the consideration of environmental influences is necessary for extensive testing. The effectiveness of the applied testing is directly reflected by the increased code coverage.

A more realistic industrial-grade application is, e.g., the simulation of an engine control unit in a VP. The various sensor inputs (e.g., position, temperature, and veclocity sensors) can be read from FMI. Output-signal characteristics, such as the duty cycle and frequency of Pulse Width Modulation (PWM) signals to control actuators like fuel injectors, ignition coils, and idle speed control valves, are forwarded to the importing tool for further processing.

5 Design-Flow Integration

Based on our integration, we propose a design flow that can be used for early target software verification and creation of tests. An overview is shown in Figure 13. At the beginning of the design process, a VP can be created according to the specification of the system. The target software can be developed and tested using this VP. Once the target software development is done, our FMI integration can be used to integrate the VP into a co-simulation and develop test scenarios. Edge-cases can be tested to find bugs in the target software early. The extracted coverage metrics guide verification and test engineers to cover all parts of the target software.

To fulfill standards like ISO 26262 (ISO/TC 22/SC 32 2018), the satisfaction of the requirements needs to be tested. Our FMU can be used to design those tests using a VP. Once physical hardware is available, the hardware can directly be tested using the already developed tests.

In contrast to physical hardware, the virtual model can be scaled arbitrarily, distributed around the world within seconds, and easily integrated into Continuous Integration/Continuous Delivery (CI/CD) flows. CI/CD allows for continuous and automatic testing during the development process to reduce costs by finding bugs earlier.

Once the physical hardware is available, the same test can be executed on the real hardware by replacing the adapter FMU by an hardware-communication interface.

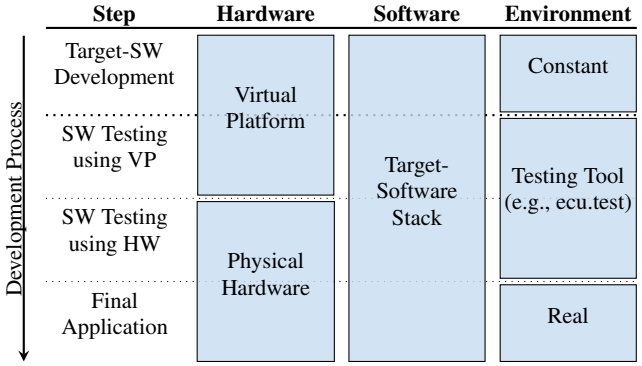

Figure 13. Incorporation of early target-software testing and validation in the design process.

Without our co-simulation integration, the test would have needed to be created directly for the physical hardware, making it possible only later in the development process.

When the target software stack passed all tests on the VP and the physical device, the application can be used in the real world application.

6 Conclusion and Future Work

In this paper, we have presented a novel approach to interface SystemC-based VPs with the FMI standard for co-simulation. By developing an adapter FMU that communicates with the VP via a TCP/IP-based connection, we enable the VP to exchange data with external tools in a co-simulation environment. Our method allows unmodified target software to run on the VP while interacting with realistic environmental inputs provided by other tools.

We demonstrated the effectiveness of our approach through a case study involving a Schmitt-trigger application running on the open-source AVP64. By connecting the VP to the FMI-compatible ecu.test tool, we supplied dynamic temperature inputs and observed the corresponding behavior of the software, achieving comprehensive testing and improved code coverage. This integration facilitates thorough software testing and verification by simulating environmental effects on the system, which is crucial for developing complex embedded systems.

While ecu.test is the leading testing tool in the automotive domain, and thereby a key candidate for evaluating our FMI integration, FMI opens the door to connect various other tools to VPs using our integration. Users have the possibility co-simulate VPs with models created by other tools, e.g., to add realistic physical environmental models to sensors of the VP. Tool providers that support FMI can directly benefit from our integration without the need of extending their tool. Moreover, VP developers can adopt a co-simulation approach to introduce physical environmental models when necessary, while retaining the flexibility to revert to a VP-only simulation if those models are not required.

Since our method only relies on VCML's VSP to establish the TCP/IP connection, it is not limited to a specific VP. There are no changes required for the VP to work with FMI, so other VPs can directly be integrated into an FMI co-simulation.

We showcased how the approach can be integrated into the target-software design process to enable early test development and testing. This speeds up the design process and reduces the number of errors in the product.

For future work, we plan to extend our approach to support more advanced communication between the VP and other FMUs by adding support for the new FMI Layered Standard for Network Communication (FMI-LS-BUS). This addition will allow connecting FMUs via virtual network interfaces like CAN or Ethernet.

Hybrid Simulation Models for Embedded Applications: A Modelica and eFMI approach

Tobias Kamp[1] Christoff Bürger[2] Johannes Rein[1] Jonathan Brembeck[1]

[1]Institute of Vehicle Concepts, German Aerospace Center, {tobias.kamp, johannes.rein, jonathan.brembeck}@dlr.de
[2]Dassault Systèmes AB, Sweden, christoff.buerger@3ds.com

Abstract

Hybrid simulation models combine physics equations with trainable components to improve simulation results and performance. Physics-enhanced neural ordinary differential equations (PeN-ODE) are a promising type of hybrid models that combine artificial neural networks (NN) with the differential equations of a dynamic system. Dynamic simulation models are often part of embedded control algorithms of cyber-physical systems (CPS); compliance with the safety and real-time requirements of such embedded environments is, however, challenging.

In this work, we propose a workflow to incorporate trained NNs in Modelica models to form hybrid simulation models that are PeN-ODEs. We thereby focus on the transformation steps from equation-based trained PeN-ODEs in Modelica towards causal solutions suited for the embedded domain – up to and including MISRA C:2023 compliance checks and final software-in-the-loop (SiL) tests of generated production code in the modeling environment – for which we leverage eFMI standard compliant tools (Dymola and Software Production Engineering). It is of particular interest how the trained NNs of the hybrid model are implemented. We present two approaches: (1) generation of C code using existing Open Neural Network Exchange (ONNX) tooling and (2) pure Modelica code with the tensor-flow represented as multi-dimensional equations. Both approaches are discussed, highlighting why (2) is, in the long run, a better option given the eFMI technology space.

Keywords: Hybrid modeling, neural network, machine learning, embedded system, Modelica, eFMI, Physics-enhanced Neural ODE, recalibration

1 Introduction

Two important objectives for system engineers that try to improve their simulation models are (1) minimizing the simulation-to-reality gap and (2) optimizing the model with respect to the simulation performance. In addition to traditional methods, machine learning (ML) methods offer varying data-driven approaches (Rai and Sahu 2020). Addressing the first objective in this context typically means using ML methods to learn (missing) dynamics from real-world measurements, thereby enhancing the predictive accuracy. To approach the second objective, surrogate models can be trained to replace computationally expensive components, using these very components to generate the necessary training data.

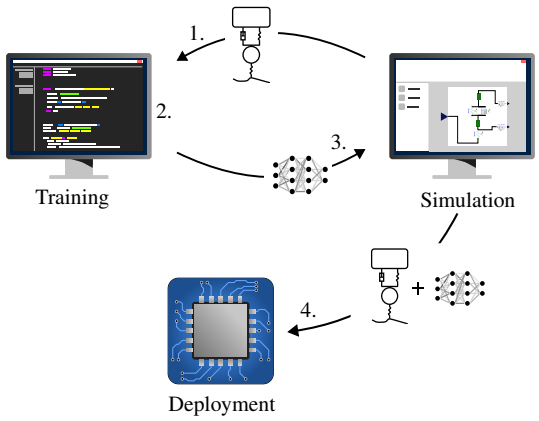

Figure 1. Development workflow of hybrid simulation models, including final deployment on the embedded target of a cyber-physical system.

It has been shown that dynamical systems can be thoroughly represented by recurrent neural networks (RNN) (Funahashi and Nakamura 1993), physics-informed neural networks (PINN) (Raissi, Perdikaris, and Karniadakis 2019; Cuomo et al. 2022), or neural ordinary differential equations (NODE) (Chen et al. 2018). Hybrid models (Willard et al. 2022) that directly combine trainable components with physics equations usually yield better stability, data efficiency and interpretability. In this study, we focus on a type of hybrid model known as physics-enhanced neural ordinary differential equation (PeN-ODE). PeN-ODEs combine ordinary differential equations (ODE) and artificial neural networks (NN) in a meaningful way (Kamp, Ultsch, and Brembeck 2023). The NNs are trained within the model-equations to capture missing non-linear effects or quantities to improve the predictive quality of the model. The implementation of PeN-ODEs is relatively straightforward, as it requires only the extension of the right-hand side of the ODE-system $\dot{x}(t) = f(x,u,t)$ with NNs. For the training and simulation of PeN-ODEs, well-established numerical integrator algorithms can be used.

Figure 1 sketches the general development workflow of hybrid models for system simulation, eventually deployed in a cyber-physical system (CPS). Assuming an equation-based model in a simulation environment, such as a Modelica[1] model in Dymola[2], is already available, the process is covered by Steps 1-4:

Step 1 (Export): The physics equations of the model are exported into an ML training environment (e.g., PyTorch[3] in Python[4] or Julia[5]).

Step 2 (Extension & training): The physics equations are extended with NNs to form a hybrid model (the PeN-ODE) that is typically trained using gradient-based optimization methods.

Step 3 (Re-import and simulation): The trained PeN-ODE or the NNs are re-imported into the simulation environment, enabling simulative validation and combination with other, non-hybrid model parts and/or control algorithms of the CPS.

Step 4 (Embedded application): The PeN-ODE is transformed into an implementation suited for deployment on an embedded target of the CPS.

In this study, we assume that the PeN-ODE is already trained – i.e., Steps 1-2 have been accomplished – for example using techniques presented by Thummerer et al. (2022). Thus, we present solutions for Steps 3-4, i.e., the incorporation of trained NNs in Modelica models with the ultimate goal to apply the whole PeN-ODE on an embedded system. The latter objective (Step 4) typically comprises compliance with complex, non-functional embedded domain requirements such as:

4a: MISRA:C 2023 compliance (The MISRA Consortium 2023).

4b: Restricted dependencies on libraries and frameworks.

4c: Worst execution-time and memory-consumption guarantees.

4d: Self-dependent implementation of the PeN-ODE, with its ODEs inline integrated to a level where only linear solver calls are required; such extensive inline integration is typically required to achieve (4b) and (4c), since non-linear solvers jeopardize (4b) and likely violate (4c).

4e: Strict error-handling concepts, especially in case of unexpected Positive or Negative Infinity and Not-a-Number (NaN) results of floating-point operations (IEEE 2019).

4f: Software-, processor- and hardware-in-the-loop (SiL, PiL & HiL) tests which are ideally derived from model-in-the-loop (MiL) tests defined in the simulation environment.

To comply with these requirements is of uttermost importance for CPS applications and especially relevant in control engineering, where Step 4 often is the ultimate objective for hybrid models. A typical use-case is to obtain a reduced order/surrogate model for unknown physics or to achieve acceptable performance in an embedded environment where computational resources are scarce.

An important question with respect to Step 4 is how the trained hybrid model – i.e., the PeN-ODE as the source for the embedded solution – looks like. The training and re-import of Steps 2-3 do not necessarily yield a model with the same abstraction level as the original equation-based model. For example, the approach of Thummerer et al. (2022) relies on the Functional Mock-up Interface[6] (FMI) for training and re-import. However, a Functional Mock-up Unit (FMU) is binary code or C source code. This means that the original physics equations are causalized and thus no longer explicitly available in the PeN-ODE. If only the NN parts of the PeN-ODE are re-imported as FMUs, manual integration with the original physics of the model is required. In any case, the tensor-flows of the NNs are hidden inside the FMU.

Thus, starting from an equation-based Modelica model, Steps 2-3 may yield a model with lower abstraction levels than the acausal equations. This holds also for approaches that use the Open Neural Network Exchange[7] (ONNX) format for trained NNs, or any low-level code implementation derived from that. Although re-importing such an implementation into an equation-based Modelica model for the sole purpose of simulation usually poses no issue, e.g., via FMI or the approach presented in Section 3, generating embedded code for the *whole* hybrid model is troublesome because the non-equation parts hamper compliance with requirements 4b-e. In particular, the ODE inline integration for the PeN-ODE (4d) is challenging, but also fulfilling requirement 4e is difficult without equation knowledge. If, on the other hand, Steps 2-3 yield a trained hybrid model whose physics and NNs are modeled as equations or ODEs, the simulation tool can leverage its existing numeric and symbolic manipulations and optimizations to find an algorithmic, causalized inline integration with only linear solver calls.

In the following, we investigate how the tensor-flow of trained PeN-ODEs can be preserved as equations in Step 3, such that Step 4 can leverage existing code generation facilities of the equation-based simulation tooling, which yields a toolchain from acausal physics equations with trained NNs down to safety-critical, hard real-time capable embedded code satisfying 4a-f. The key enabler for Step 4 is the Functional Mock-up Interface for em-

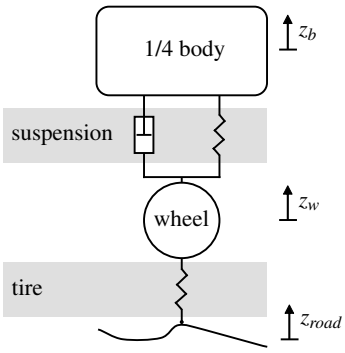

Figure 2. Scheme of the simple quarter vehicle model (QVM) comprising the body and wheel masses, a spring to represent the tire and a spring-damper pair for the suspension. The model input is the road height z_{road}; the vertical wheel and body positions z_w and z_b are the model outputs.

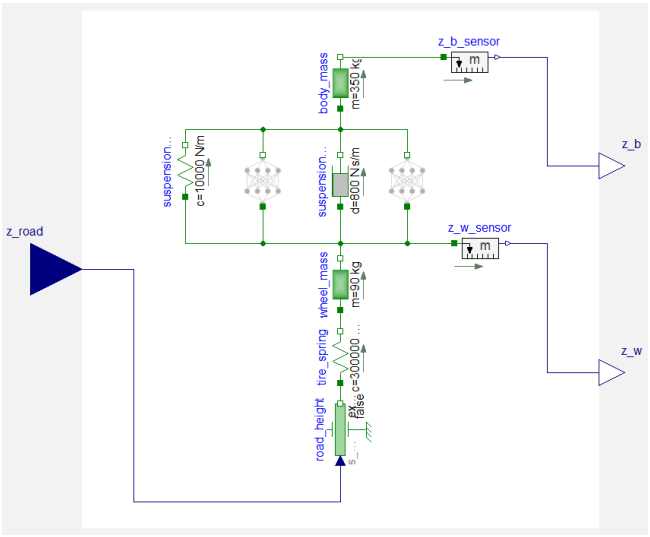

Figure 3. Modelica model of the neural QVM, i.e., the PeN-ODE. The two trained NNs capture non-linear effects of the suspension's spring and damper and are connected in parallel to the linear physics components. The NNs can be imported using generated C code from an ONNX representation (cf. Section 3) or as native Modelica equations obtained through a custom Python to Modelica generator (Section 4).

bedded systems[8] (eFMI). The final toolchain relies on the Dymola Modelica tool for equation-based physics modeling and simulation (Step 1), PyTorch for PeN-ODE training (Step 2), and the eFMI support of Dymola and Software Production Engineering[9] for embedded code generation (Step 4). In order to re-import the tensor-flows of trained PeN-ODEs as equations in Dymola (Step 3), we developed a simple Modelica code generator leveraging the open source NeuralNetwork[10] Modelica library.

The rest of the paper is organized as follows: Section 2 presents a motivating case-study which requires the deployment of a trained PeN-ODE on an embedded target and recalibration of NN parameters during runtime. Section 3 presents the C code generation from ONNX models via onnx2c[11] as a first approach for Steps 3-4. Sections 4 and 5 investigate our final solution for Steps 3-4, i.e., a Python to Modelica generator and eFMI with Dymola and Software Production Engineering. Section 6 presents future work, most importantly avoidance of scalarization of tensor-flows in embedded code, and Section 7 finally summarizes the related work regarding hybrid models and embedded code generation in Modelica.

2 Quarter vehicle model case-study

We showcase the suitability of the proposed toolchain for embedded code generation of PeN-ODEs (Step 4, a-f) by conducting a case-study for a quarter vehicle model (QVM) that represents the vertical driving dynamics of a road vehicle. QVMs are commonly used in the domain of vehicle dynamics to represent the dynamics of the suspension for controller synthesis and as prediction models (Fleps-Dezasse and Brembeck 2013; Ultsch, Ruggaber, et al. 2021). Typical applications of QVMs are fault detection of the suspension and the wheels or serving as part of a virtual sensor or as prediction model of controlled, semi-active suspensions that improve driving comfort or road-holding properties (Ultsch, Pfeiffer, et al. 2024). A QVM is limited to the one-dimensional (vertical) dynamics of one wheel and one quarter of the car-body, as depicted in Figure 2. Capturing the vertical dynamics of a road vehicle correctly is challenging, which is due to the influence of non-linear effects such as friction and elasticities (i.e., rubber bushings). To capture such effects, we use a PeN-ODE approach and integrate NNs into the physics equations to learn unknown non-linearities from measurement data, cf. (Kamp, Ultsch, and Brembeck 2023).

The starting point of the PeN-ODE development is a plain physics-based Modelica model which implements only the linear suspension dynamics. This linear QVM is exported as an FMU and imported into the training environment PyTorch. After extending the differential equations with two NNs – one amending the linear equations of the damper with its non-linear behavior and likewise another for the spring – a gradient-based optimization is conducted. After the training, the trained NNs have to be integrated into the (still linear) Modelica model (Step 3) to obtain a Modelica implementation of the PeN-ODE (cf. Figure 3). In Sections 3 and 4 we present two approaches to accomplish the transfer from the training environment back to the simulation environment. The neural QVM (nQVM) is then used for simulative validation, e.g., using Dymola, and shall further be deployed on an real-time target in the vehicle. There it serves as a prediction model

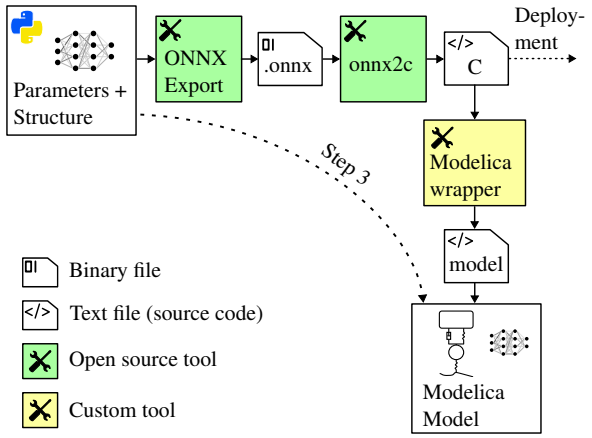

Figure 4. Scheme of the export toolchain using onnx2c to generate C code for ONNX models. Since many ML-frameworks already support ONNX export, we mark the ONNX export as openly available. Although the code onnx2c generates is suited for embedded application, there is no "ready-to-use" solution for embedded code generation of the *whole* PeN-ODE including its physics equations. The generated C code is imported into Modelica by using a Modelica external C function wrapped into a MSL MIMO block. Listings 1-2 show the wrapper code as generated by our custom tool.

for a control algorithm of the semi-active suspension. In addition, we want to enable the recalibration of the trained NNs during runtime on the embedded system, i.e., without recompilation. This is especially useful when multiple variants of the PeN-ODE are trained to consider changing circumstances, e.g., the current road type or suspension adjustments, as it is common practice in scheduled control algorithms. The application on the embedded target leverages the eFMI standard with tunable NN parameters, which is described in Section 5.

This work captures intermediate results of ongoing work, thus the scope of our case-study is up to the SiL validation of the embedded solution, including the recalibration. The SiL tests allow the comparison with the (continuous) simulation results and constitute the foundation for future HiL and driving tests under real world conditions.

3 NNs as external C code

In this section, we present a method to leverage ONNX as a model exchange standard and an open source ONNX to C compiler to incorporate trained NNs in Modelica models. The presented workflow can be automated to a high degree which we underline with generated code samples. However, the dependency on external C code hinders the application of the obtained PeN-ODE on embedded systems through eFMI, since integration with the embedded code generation for the physics part of the PeN-ODE is not obvious. Nevertheless, the method yields plain C code for the NNs that is generally suited for embedded application and is therefore relevant for cases without additional Modelica physics. We will outline how this approach can be used to deploy trained NNs in a CPS context, even if it is not the favorable approach to our use-case.

3.1 The ONNX format

"ONNX is an open format built to represent machine learning models. ONNX defines a common set of operators – the building blocks of machine learning and deep learning models ..."[7]. Once the model is defined using these operators, ONNX uses the (binary) Protocol Buffers format for serialization. Such ONNX files serve as exchange containers and can be compared to FMUs. The ONNX format is already widely established as an exchange standard for ML models and is supported e.g., by the Keras[12] and PyTorch frameworks, MATLAB®[13] and many more. The ONNX Runtime enables direct inference using an ONNX model.

3.2 ONNX to C compiler

In some applications, relying on the ONNX Runtime is not a valid option, especially when the model should be deployed on an embedded system. The open source onnx2c[11] compiler offers a remedy for users that can make use of plain C code. It is optimized for TinyML[14], i.e., running on microcontrollers. Provided with an ONNX model, onnx2c generates a single C file with all required functions that correspond to the atomic ONNX operators. The parameter arrays that hold the trainable parameters are likewise contained in the generated code. It has to be mentioned that onnx2c does not support all available operators and not all model typologies and is a privately maintained project. The C code contains a function `entry(const float x[1][M], float y[1][N])` with the input dimension M and output dimension N. This function is the only function that needs to be called in order to perform a forward pass through the model.

3.3 Integration in Modelica

Once the NN is exported as an ONNX model and compiled into C code, it can be used in Modelica using its external C interface (cf. Figure 4). Listing 1 presents an example implementation of the entry-function call that can be used as a template for generation. Further, it can be convenient to wrap the function into a Modelica Standard Library (MSL) MIMO block as shown in Listing 2.

Listing 1. Modelica function that calls the entry function from the generated C file (called nn.c). The dimensions M and N correspond with the number of in- and outputs of the NN (to be replaced with size_t values).

```
function call_entry "call_entry"
  input Real u[M];
  output Real y[N];
  external "C" call_nn(u, y)
    annotation(
    IncludeDirectory="<<nn.c dir>>",
```

[14] https://github.com/mit-han-lab/tinyml

DOI
10.3384/ecp218555

```
    Include="
#include \"nn.c\"
void call_nn(const double* u, double* y)
{
  float u_buf[1][M], y_buf[1][N];
  size_t i;

  for (i = 0; i < M; i++)
  {
    u_buf[0][i] = (float) u[i];
  }

  entry(u_buf, y_buf);

  for (i = 0; i < N; i++)
  {
    y[i] = (double) y_buf[0][i];
  }
}");
end call_entry;
```

Listing 2. MIMO wrapper for C-function call (cf. Listing 1); The dimensions M and N correspond with the number of in- and outputs of the NN (to be replaced with Integer values).

```
model MyNN
  extends Modelica.Blocks.Interfaces.MIMO(
    nin = M,
    nout = N);
equation
  y = call_entry(u);
end MyNN;
```

If a PeN-ODE contains multiple NNs, one must assure that variable- and function names in the C code are unique. When using onnx2c, this is generally not the case, since the C files are generated independently and at least the entry-function always has the same name. As of now, this can only be solved by editing the C code after its generation. Issues can also occur, when the ONNX model is composed in a way that the operator-nodes have ambiguous or repeating names. This can be avoided by giving a unique name to each node during the ONNX export of the ML model. The node names of an existing ONNX model can still be adapted, e.g., using the ONNX Python API.

3.4 Discussion

The presented approach uses the ONNX open standard and an open source ONNX to C compiler. The incorporation of the generated C code in Modelica (Step 3) is straightforward and can be effectively automated by generating corresponding Modelica wrappers. Furthermore, ONNX is a well established exchange standard for ML models and many ML frameworks already offer the export to ONNX. The onnx2c compiler is stable, maintained, and supports many of the existing ONNX operators. It generates C code which is suitable for the application on microcontrollers, which is important for CPSs. In comparison to solutions that use the ONNX Runtime, it has the advantage to be self-contained without any third party library or framework dependencies, which facilitates exchange and portability. Modelica tools can, for example, export PeN-ODE models as binary code FMUs without further dependencies.

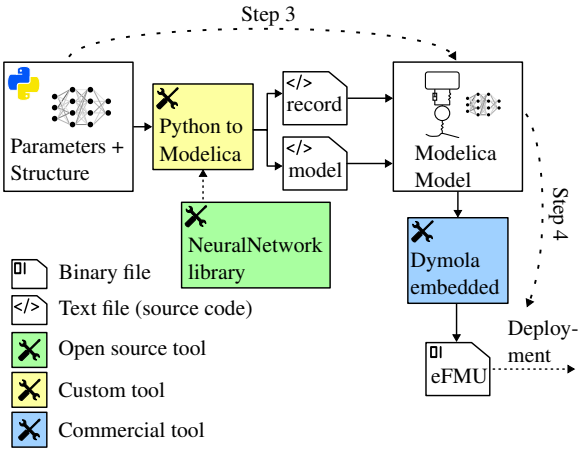

Figure 5. Scheme of the export toolchain employing the NeuralNetwork library. The Python to Modelica generator is a custom tool that allows direct Modelica code generation from Python. This approach leverages Dymola's existing symbolic facilities to find algorithmic solutions suited for embedded application and enable embedded code generation for the *whole* PeN-ODE using the open eFMI standard.

However, the onnx2c approach yields embedded code only for the NN parts of the PeN-ODE. Embedded code generation for the whole PeN-ODE (Step 4) is not straightforward because the production code for the physics equations must be generated and connected with the NNs. This is not a trivial system integration task, since knowledge about causalization, equation system properties and connectivity of the *whole* PeN-ODE must be properly incorporated. There might be, for example, algebraic loops between physics and NNs, or the physics equations and NNs form a mixed system of equations where Boolean conditions depending on NN outputs switch physics behavior fed into the NN. In such cases, the NN code has to be properly embedded into the iterations of the inline integrated ODE solver when generating embedded code for the physics parts of the Modelica model.

These embedded code generation issues for PeN-ODEs can be bypassed by handing the challenges over to the already existing, advanced symbolic facilities of Modelica compilers like Dymola. Section 4 presents an approach for Step 3 where the NN parts of the PeN-ODE are re-imported as pure Modelica equations such that the Modelica compiler can take care of proper integration.

4 NNs as native Modelica

In this section, we present an approach that implements trained NNs as Modelica models utilizing the NeuralNetwork Modelica library. This method allows seamless integration of the NNs with the physics equations and enables eFMI-based embedded code generation for the whole PeN-ODE. Figure 5 summarizes the tooling of this Modelica-centric workflow, where the trained NNs are

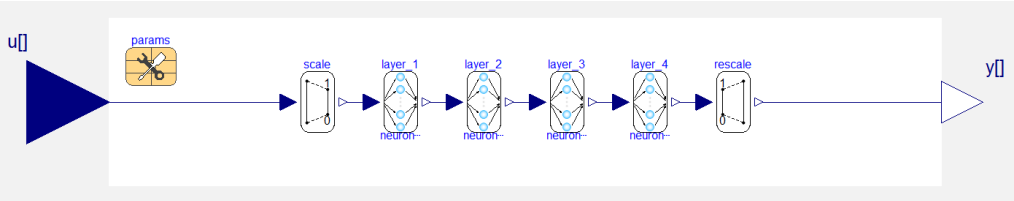

Figure 6. Generated, equation-based Modelica model of one of the trained NNs of the nQVM, showing its diagrammatic tensorflow using NeuralNetwork library components. The NN parameters (weights and biases) for each of the four dense layers (16×1 – 16×16 – 16×16 – 1×16) are contained in the parameter record that can be marked for exposure as tunable eFMI parameters.

transformed back to Modelica equations.

4.1 The NeuralNetwork library

The NeuralNetwork Modelica library was first published in 2006 (Codecà and Casella 2006). Since 2023, it is further developed by the University of Applied Sciences and Arts Bielefeld (HSBI) under open source 3-Clause BSD Licence[10]. As of version 2.1, it offers implementations to compose multi-layer perceptrons (MLP) including dense layers, scaling, standardizing, and principal component analysis (PCA) layers, and the activation functions rectified linear unit (ReLU), sigmoid, hyperbolic tangent (tanh), softplus and unit step.

Considering the vast variety of ML architectures, this is only a basic set. For PeN-ODEs however, simple MLPs suffice in many cases (Thummerer, Stoljar, and Mikelsons 2022; Kamp, Ultsch, and Brembeck 2023).

4.2 Generation of Modelica NNs

We implemented a custom Python to Modelica code generator to automate the implementation of trained NNs using the definitions of the NeuralNetwork library. Listing 3 presents an example of a simple MLP that was generated in this manner. We deem it best to generate a separate Modelica record alongside the NN that holds its parameters, i.e., NN weights and biases (cf. Listing 4). This record can be used to redeclare the parameters of the NN block and thus enables a fast exchange. This is useful when multiple variants of the NN are to be validated in simulation, given that the NN architecture (number of layers, number of neurons, and activation functions) is maintained. Figure 6 shows the composition of different layers of a typical MLP with the corresponding parameter record.

Listing 3. Sample of a generated Modelica NN. The NeuralNetwork library components are wrapped into a MIMO block comparable to the external C approach (cf. Listing 2).

```
block MyNN
  extends Modelica.Blocks.Interfaces.MIMO;
  import NN = NeuralNetwork;
  // NN parameter record
  parameter MyParametrization params;
  // NN layers
  NN.Layer.Dense layer_1(
    weights = params.layer_1_weights,
    bias = params.layer_1_bias,
    redeclare function f =
      NN.ActivationFunctions.ReLu);
  NN.Layer.Dense layer_2(
    weights = params.layer_2_weights,
    bias = params.layer_2_bias,
    redeclare function f =
      NN.ActivationFunctions.Id);

equation
  // NN composition
  connect(u, layer_1.u);
  connect(layer_1.y, layer_2.u);
  connect(layer_2.y, y);
end MyNN;
```

Listing 4. Generated parameter record defining default weights and biases for the NN of Listing 3, exposed as tunable eFMI parameters for the embedded code generation of Section 5.

```
record MyParametrization
  extends Modelica.Icons.Record;
  // Trained NN parameters
  parameter Real [16, 1] layer_1_weights =
    {{2.15}, {-0.713}, ...};
  parameter Real [16] layer_1_bias =
    {0.174, -0.0312, ...};
  parameter Real [1, 16] layer_2_weights =
    {{0.215, 1.342, ...}};
  parameter Real [1] layer_2_bias =
    {0.230};
  // Expose as tunable eFMI parameters
  annotation(
    __Dymola_eFMI_ExposeTunableParameters =
      true);
end MyParametrization;
```

4.3 Discussion

The pure Modelica approach offers a seamless integration of trained NNs with the physics part of the PeN-ODE in Modelica. The NN parameters can be encapsulated in records separated from the NN architecture, facilitating variation and training validation. A drawback compared to the usage of ONNX via onnx2c is the limited number of available architectures of the NeuralNetwork library. Further, a complete Python to Modelica generator leveraging the NeuralNetwork library is not (yet) freely available. Our implementation is, as of now, just a functional prototype and not published. The most important advantage of the native Modelica approach is the possibility to export the *whole* PeN-ODE via eFMI for embedded application as motivated and described in the following Section 5.

5 Embedded code via eFMI

In this section, we motivate the use of the eFMI standard for Modelica equation-based hybrid models in embedded applications. Our solution relies on the import of trained NNs as Modelica equations as presented in Section 4, meets requirements 4a-f of Section 1, and enables online recalibration of NN parameters.

5.1 The eFMI Standard

The Functional Mock-up Interface for embedded systems (eFMI) is "an open standard for the ... model-transformation-based development of advanced control functions suited for safety-critical and real time targets ... [, defining a] container architecture ... from high-level modeling and simulation – e.g., a-causal, equation-based physics in Modelica – down to actual embedded code"[8].

The key interface between the physics simulation and embedded application domains is the Guarded Algorithmic Language for Embedded Control (GALEC). To deploy an equation-based simulation model in a safety-critical, hard real-time environment, the simulation tool has to transform the model into a GALEC program (Algorithm Code container) and hand it over to any eFMI-aware production code generator for final embedded code generation (Production and Binary Code container). The idea is, that each tooling can be a domain expert on its abstraction-level without bothering about the other domains. A Modelica tool like Dymola knows a lot about discretization, symbolic optimization and inline integration – i.e., how to find a sampled algorithmic solution expressible in GALEC – whereas production code generators like Software Production Engineering are knowledgeable about satisfying embedded domain coding requirements but have no concept of modeling physics for equation-based simulation.

GALEC has some language characteristics making it a convenient intermediate representation between modeling and embedded software (Lenord et al. 2021). It is target independent, supports multi-dimensional arithmetic, and a rich set of built-in functions to abstract common math operations including interpolation and solving systems of linear equations. Most importantly, it is computational-safe, which means that a powerful static evaluation concept is used to guarantee all indexing is within bounds, all loops have an upper-bound, and all potential runtime errors like NaNs, singular linear equation systems or domain errors of built-in functions (like poles of trigonometric functions) are handled or explicitly exposed to the runtime environment. GALEC programs satisfy 4b-e of Step 4 by definition. Once a simulation tool finds a sampled solution for the simulation problem – which is not always possible for general equation systems – and expresses it as GALEC program, further tooling towards embedded C code "only" has to preserve these characteristics and can focus on code optimization (e.g., loop and multi-dimensional expression unrolling) and embedded target environment compliance (e.g., compliance with style guidelines, code analysers, interfaces or system integration requirements).

Besides Algorithm, Production and Binary Code containers, eFMI also defines Behavioral Model containers to define test-scenarios. Typically, Behavioral Models are derived from continuous MiL experiments in a physics simulation environment and shared for later SiL and HiL tests of production code.

5.2 eFMI support in Dymola

Dassault Systèmes provides several tools supporting eFMI: Dymola for generating eFMI Algorithm Code containers for synchronous Modelica models, Software Production Engineering for generating eFMI Production, and in turn, Binary Code containers and AUTOSAR Builder[15] to extend Production Code containers to become AUTOSAR[16] components.

It is noteworthy, that Software Production Engineering is also used as embedded code generation backend for No Magic Cameo Systems Modeler[17], a development environment for model-driven engineering, system architecture, system design, and software engineering based on SysML[18]. Generated production code therefore is of industry-level quality, for example MISRA C:2023 compliant. The integration with Dymola is seamless. Dymola provides facilities to configure 32 bit and 64 bit floating-point precision for production code generation, import production code for SiL simulation via generated Modelica wrappers, derive SiL tests from existing MiL experiments, check MISRA C:2023 compliance with Cppcheck Premium[19], import production code in MATLAB®/Simulink®[20] as C Function blocks, and export eFMUs with deployment-ready production code as FMUs.

5.3 QVM case-study with Dymola

Based on Dymola's eFMI support presented in the previous section, generating embedded code for the nQVM of Section 2, with its damper and spring NNs represented as NeuronalNetwork library models according to Section 4, has been straightforward. The two major challenges were, first, how to conveniently expose the NN weights and biases as tunable eFMI parameters, and second, how to model the respective recalibration SiL tests in Modelica.

For the first issue, we extended Dymola with a new annotation for Modelica records. Adding `__Dymola_eFMI_ExposeTunableParameters = true` to a record *class* marks the independent parameters of *instances* for exposure as tunable eFMI parameters, regardless how deeply nested within models they are. The Python to Modelica generator of Section 4 can hence automatically add the annotation to the NN parametrization record (cf. Listing 4).

[19] https://www.cppcheck.com
[20] https://www.mathworks.com/products/simulink.html

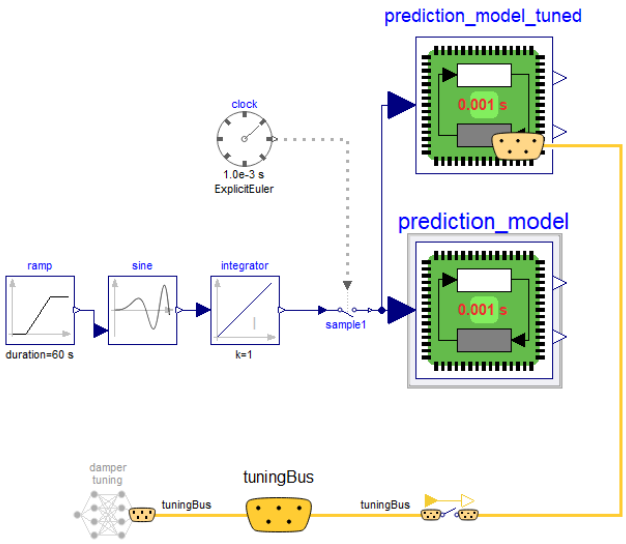

Figure 7. Recalibration SiL test in Dymola: The nQVM PeN-ODE is instantiated twice – once untuned and once tuned – via a generated Modelica wrapper backed by the eFMUs production code. The damper tuning component is manually implemented. It triggers recalibration at 2 s and applies updated NN parameters for the learned friction model on the generated tuning bus.

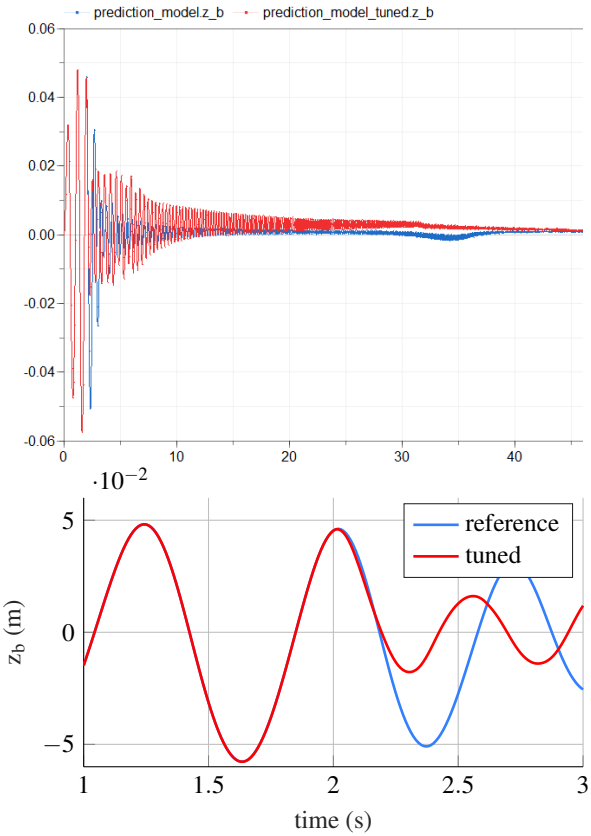

Figure 8. SiL simulation results of the body height z_b for the untuned (blue) and tuned (red) nQVM. At 2 s simulation time, the recalibration is triggered and leads to a new system behavior.

The second issue, how to model recalibration SiL tests, exposes a general Modelica shortcoming. From the eFMI perspective, recalibration test scenarios are well-supported in Behavioral Model containers; and Dymola supports the derivation of Behavioral Models from existing Modelica experiments by searching them for instances of the model that is subject to eFMI code generation. Each of those instances becomes a SiL test scenario, where the instance inputs are the stimuli and the outputs the reference trajectories. This concept works well to automatically derive SiL test suites from ordinary Modelica experiments. However, Modelica has no online recalibration concept. In Modelica, parameters can be only modified before, but not during the simulation. Hence, online recalibration must be modeled by runtime values encoding "parameters". Since this implies extensive model changes on the models to recalibrate, recalibration support for ordinary Modelica models is pointless. In our case however, we can provide recalibration facilities in the Modelica wrappers Dymola generates for SiL simulation of production code generated by Software Production Engineering. To this end, the wrappers provide an optional tuning bus, which can be enabled whenever recalibration shall be tested. Actual calibrations are simply connected to the bus, requiring manual modeling of a continuous time-based source provisioning the parameter sets to apply at each time point.

Figures 7 shows the recalibration scenario we used to validate the nQVM. In this experiment, we recalibrate the damper-NN with a slightly altered (learned) friction model after 2 s. The PeN-ODE is simulated with a chirp signal (sine-sweep) as input. In Figure 8, the simulation result of the body height z_b of the tuned and untuned PeN-ODE is plotted. Although the tuning clearly alters the dynamics of the system, the state of the PeN-ODE is not changed when recalibrating such that there are no discontinuities in the trajectory. If recalibration would take several sampling steps, which can be expected when using actual real-time hardware, the current state would be held – i.e., no samplings are conducted – until the recalibraion is terminated. Nevertheless, it is likely that observers or control algorithms using the PeN-ODE converge much faster when continuing sampling from the hold state compared to a full state reset. Although the nQVM is stable in the recalibration scenario of Figures 7 and 8, no such guarantee can be given for general equation systems; if, and under which constraints, an independent parameter indeed is suited for online tuning, is a domain specific characteristic.

6 Future work

This paper presents intermediate results of the ongoing research in the PeN-ODE-related work package (WP4) of the ITEA 4 Project OpenSCALING[21] (cf. Acknowledgements). The work scheduled for the second half of the project ending in October 2026 can be separated into three tasks, ranked from highest to lowest priority: (1) preserva-

[21] https://itea4.org/project/openscaling.html

DOI 10.3384/ecp218555

tion of the multi-dimensional arithmetic of the tensor-flow of NNs in production code, (2) actual system integration of the eFMU of the case-study presented in Section 2 with HiL and driving tests under real-world conditions including recalibration of NN parameters and (3) support of the System Structure & Parametrization[22] (SSP) standard for NN parametrization and recalibration.

6.1 Multi-dimensional embedded tensor-flows

Most Modelica tools, including Dymola, transform models into an index 1 differential algebraic equation (DAE) system, where each element of multi-dimensions is scalarized to individual variables; doing so, multi-dimensional arithmetic operations are flattened to a set of individual scalar operations (scalarization). Although this representation is essential for many advanced numeric and symbolic manipulations and optimizations, it also significantly increases code size when scalarizing the tensor-flows of the equation-based NNs presented in Section 4. For embedded applications, code size is critical. Hence, it is important to avoid the scalarization of tensor-flows. However, for the physics-parts of PeN-ODEs it still is beneficial to find symbolic solutions to avoid linear system solver calls.

In our case-study, the actual physics equations of the nQVM only result in ~4 KB of eFMI GALEC code including two symbolically solved size-1 linear equation systems, whereas the scalarized tensor-flows of the spring and damper NNs – each holding 593 parameters in the input layer (16×1, ReLu), two hidden layers (16×16, ReLu), and the output layer (1×16, Identity), each with bias (cf. Figure 6) – produce ~117 KB of code. This is a lot, considering that the tensor-flows of the NNs could be written as single-line multi-dimensional GALEC expressions. The ratios for derived C production and binary code are similar. The onnx2c solution of Section 3, which preserves the tensor-flows as for-loops, only yields ~5.5 KB of C code. All numbers are excluding the initialization of NN weights and biases, which contributes significantly to code size but cannot be avoided.

The prevention of scalarization is subject of work package 3 (WP3), large scale system (LSS) modeling, of the OpenSCALING project. Although the development focuses on physics based LSSs – like electric power grids with homogeneous components of huge quantities modeled as arrays of Modelica components – the planned solutions are likely also applicable in our use-case. If anything, tensor-flows are even simpler to handle because they are clean – i.e., not mixed with exceptions or zero crossing logic – arithmetic. Foundational research on how to preserve multi-dimensional operations for index 1 DAEs without sacrificing symbolic optimizations is already available (Otter and Elmqvist 2017; Abdelhak, Casella, and Bachmann 2023).

[22] https://ssp-standard.org

6.2 eFMU system integration and CPS tests

The presented toolchain has been validated up to, and including, SiL tests of the generated eFMU in Dymola. The actual system integration on a dedicated embedded target – for our case-study this involves the deployment of the nQVM as prediction model on the embedded control system of our experimental research platform (Ruggaber et al. 2023) – still must be conducted. We are confident, that our eFMI approach is well-suited for that eFMUs generated by Dymola and Software Production Engineering have been successfully system-integrated in the past, including final CPS tests under real-world conditions (Ultsch, Ruggaber, et al. 2021). A new challenge is the online recalibration for tuning the weights of the embedded NNs, which we deem non-critical, considering the successful SiL experiment of the recalibration facilities of the generated eFMU.

6.3 SSP standard support

Online recalibration of PeN-ODE NN-weights is related to ongoing SSP standardization efforts. SSP is supposed to be a universal standard for defining varying parameter sets for interconnected FMUs (Hällqvist et al. 2021). Modelica support, in particular SSP import and export in Dymola, is available (Brück 2023). Our tunable parameter record approach of Sections 4 and 5 for modeling NN-weights can be mapped directly using Dymola's existing SSP facilities. In FMI and eFMI however, recalibration of tunable parameters can be seen as a *timed sequence* of parameter changes; however, SSP has no notion of timing. Likewise, Modelica lacks the means to conveniently model online recalibration. In Modelica, parameters can only be changed by means of static modifications before simulation starts, which is why the SiL tests presented in Section 5 had to implement new calibrations via ordinary Modelica variables instead of parameters. This is troublesome and requires the definition of event-points for recalibration throughout the continuous simulation. To align SSP, Modelica, FMI and eFMI such that recalibration test-scenarios can be modeled as timed SSP parametrizations is an open issue, very much in the scope of OpenSCALING and its objective to harmonize the Modelica Association's[23] open standards ecosystem.

7 Related work

Our previous work provided an extended introduction to PeN-ODEs, including how to define and train them (Kamp, Ultsch, and Brembeck 2023). Requirements 4a-f, to enable embedded and CPS applications, were not considered however.

Thummerer et al. (2022) proposed a solution for export, training, and re-import of PeN-ODEs in simulation environments (Steps 1-3) using the FMI standard. Their approach is feasible even for complex systems, and especially in industrial applications where discretion is of importance. Thanks to the ubiquitous availability of

[23] https://modelica.org/association

FMI in the simulation domain, and increasing support also in training environments (e.g., FMPy[24] for Python or FMI.jl[25] for Julia), this approach is widely applicable. However, FMUs are implementation black-boxes, hiding the involved equations such that Step 4, preparing PeN-ODEs for embedded application, is not straightforward. The approach does not consider the embedded domain requirements 4a-f.

The open source SMArtInt library[26] offers a way to use ONNX models and TensorFlow[27] models exported as Lite Runtime[28] (LiteRT) in Modelica, supporting a huge range of NN types and architectures. However, its dependency on a plethora of heterogeneous third party frameworks and technologies severely impedes embedded application when compliance with 4b-e is required.

Hübel et al. (2022) trained a surrogate model that is benchmarked inside a Modelica model. Comparable to our approach, they used the NeuralNetwork Modelica library to transfer the trained NN to Modelica. They also mentioned the possibility to use generated C code as a future research topic, but did not elaborate on embedded applications.

In the ITEA EMPHYSIS project (EMPHYSIS International Consortium 2021), which bore the eFMI standard, multiple demonstrators used eFMUs to incorporate NNs into predictive model control applications targeting embedded systems. The starting point of embedded code generation were trained NNs however, not hybrid models. Hence, although 4a-c and 4e-f are supported by representing NNs as eFMI GALEC programs and leveraging the eFMI tooling as we do, the combination with physics equations – and therefore an ODE inline integration to a level where only linear solver calls are required (4d) – has not been investigated.

The work of Ultsch et al. (2021) within the EMPHYSIS project can be regarded as predecessor to our study. Similar to the QVM case-study of Section 2, they transformed a nonlinear prediction model in Modelica via eFMI into an embedded solution suited for the model-based control of the semi-active dampers of a car. An extended Kalman filter was used for the state estimation based on the prediction model. To this end, the eFMU of the prediction model was integrated into a dedicated Kalman filter library implemented in C. The state estimation algorithm of the Kalman filter thereby perturbates discretized continuous states of the prediction model by explicitly setting them before performing an integration step with the inline integrated solver. The eFMU was deployed on the ECU of a series-produced car and validated in driving tests under real-world conditions.

Kurzbach et al. (2023) proposed a low-level equation language for Modelica, in which the higher level object-oriented concepts like inheritance, modifications and nested components are flattened to simple equations. The motivation for such a "base Modelica" is to facilitate the integration of third party technology spaces with Modelica tooling. If such a representation becomes part of the Modelica standard and would be widely adopted, it could significantly ease bridging the simulation and ML domains (Step 1 and 3 of our approach); in particular, if it could be used as an actual *model* exchange format in FMI. Although the definition of a basic-equation language for Modelica has been a long time vision of the Modelica Association[23], it is much too early to judge if the proposal will be standardized and sufficiently widely adopted.

8 Conclusions

We presented a toolchain for the embedded application of PeN-ODE hybrid models derived from Modelica physics equations. In order to meet the non-functional requirements on embedded software, we relied on the Functional Mock-up Interface for embedded systems (eFMI) and its support in the Modelica tool Dymola. Dymola's existing symbolic optimization and inline-integration routines are prolific in finding causalized, algorithmic solutions for complex equation systems, in particular to avoid nonlinear solver calls as required in embedded applications. The export of algorithmic solutions as eFMI GALEC programs in turn enables further eFMI support to eventually derive high-quality production code.

A challenge of this approach is the correct integration of the trained NN-components of PeN-ODEs with the physics part, such that the integrated solvers of embedded solutions can properly handle the interactions between NNs and physics-equations, like event-handling and zero-crossings in mixed systems of equations, smoothness requirements, sampling and discretization, etc. We avoid this open research question by representing the tensor flow as such – i.e., as *multi-dimensional expression* – eventually yielding an equations-only representation of the whole PeN-ODE which can be processed by Dymola's existing symbolic facilities. For the required re-import of the trained NNs into the original physics-equations, we developed a Python to Modelica code generator targeting the NeuralNetwork Modelica library.

We validated our approach with the help of a neural quarter vehicle model (nQVM) case-study. SiL tests of the eFMI solution demonstrate its applicability, including recalibration tests for online changes of NN parameters. Left as future work is to extend Dymola's symbolic facilities such that they avoid scalarization of the tensor-flows of NNs and final system integration of the nQVM with HiL and driving tests under real world conditions.

A Study on Vehicle Suspension Loads Prediction Method Based on Hybrid Road Simulation using Modelica Library and FMI

Minsu Hyun[1]

[1]Hyundai Motor Company, South Korea, mshyun@hyundai.com

Abstract

This study presents a method for predicting vehicle suspension component loads at the early design stage. A hybrid road simulation combines road load data acquired from a reference vehicle with the Time Waveform Replication (TWR) technique to generate virtual equivalent road profiles. The TWR was implemented in Python, and a multibody dynamics vehicle model developed using Modelon's Vehicle Dynamics Library was used to simulate chassis response. Integration and iterative simulation between the TWR system and the vehicle model were conducted via Functional Mock-up Units using the Python FMI library, FMPy. These virtual inputs were applied to a virtual test rig. In this study, road load data from a reference vehicle were used to derive the input signals, which were then applied to simulate the suspension loads of a target vehicle. Simulation results were validated against measurement data to confirm the effectiveness of the proposed method.

Keywords: Suspension Component Loads, Hybrid Road Simulation, TWR(Time Waveform Replication), Four-Post Test Rig, Virtual Testing Lab, Virtual Proving Ground, FMI(Functional Mock-up Interface), FMPy, Modelica Library

1 Introduction

In the early stages of vehicle development, where physical test vehicles are not available, it is essential to predict the loads input into suspension components to evaluate the durability performance of the suspension system. The predicted suspension component loads are used not only for evaluating the severity and life expectancy of each suspension part, but also for the development of durability test modes at the vehicle level, as well as test methods at the system, module, and component levels. For this reason, accurate prediction of suspension component loads is critical, and technologies for such predictions have been actively researched for decades.

As shown in Figure 1, the technologies used to predict suspension component loads can be broadly categorized into two types.

The first is the Virtual Testing Lab (VTL) approach, where measured wheel loads are directly applied to the wheel center of a fixed body model to predict component loads. This method has the advantages of simple analysis and the ability to use realistic drive signals, but it cannot consider changes in wheel loads due to design modifications or interactions between front and rear suspensions.

In contrast, the Virtual Proving Ground (VPG) method predicts component loads without any measured data by utilizing highly accurate road, tire, driver, and vehicle models. Although it can be applied to any type of vehicle, its accuracy heavily depends on the fidelity of the tire, road, and driver models, and it is difficult to accurately replicate the driving path, speed, and steering of a real test driver, making the method complex to operate.

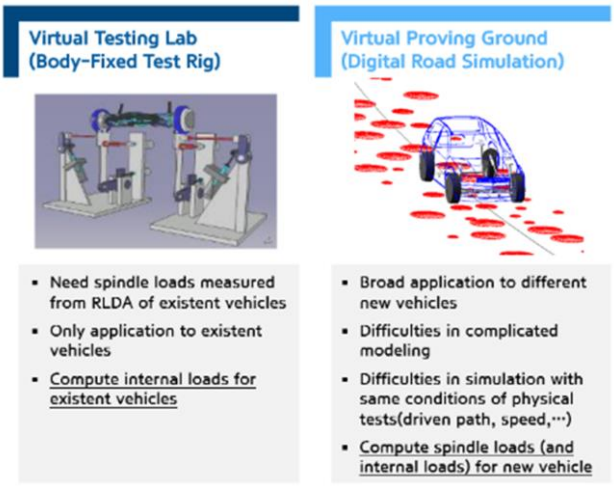

Figure 1. Types of component load prediction simulations.

This study proposes a hybrid road simulation-based suspension load prediction method that overcomes the limitations and leverages the strengths of both VTL and VPG. Section 2.1 introduces the fundamental concept of hybrid road simulation using FMI and Modelica Library. Section 2.2 explains the Time Waveform Replication (TWR) algorithm required for hybrid road simulation. Section 2.3 presents the virtual test rig and simulation method. Sections 2.4 and 2.5 present case studies using

RLDA (Road Load Data Acquisition) data from the reference vehicle and the target vehicle to validate the proposed methodology.

2 Methodology

2.1 Overview of Hybrid Road Simulation

Hybrid road simulation is a technique that utilizes both RLDA-measured data and a vehicle model. As shown in Figure 2, the core process of hybrid road simulation involves generating equivalent virtual road profiles or drive signal on a virtual test rig to replicate target signals from RLDA data using the simulation model of the reference vehicle. The inputs generated are then applied to the simulation model of the target vehicle to predict component loads. This approach should be applied to similar platforms to ensure accuracy, but it offers the advantages of simulating realistic responses without requiring separate road or driver models, thus reducing model dependency.

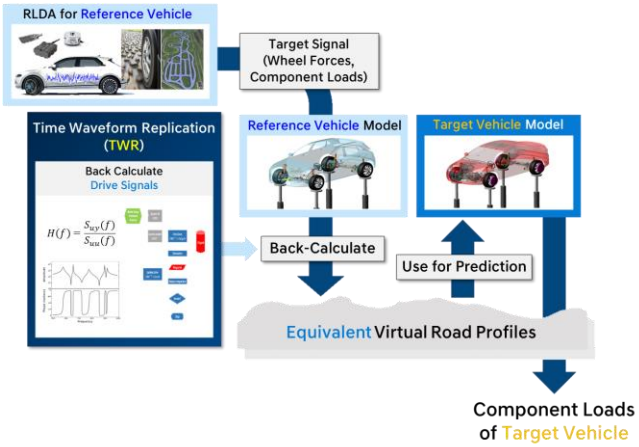

Figure 2. Hybrid road simulation process.

To perform hybrid road simulation, a TWR algorithm is required. The TWR methods include an iteration-based technique using Frequency Response Functions (FRF) and a control-based approach using PID or Iterative Learning Control (ILC). The FRF-based method requires more time due to its iterative nature but is easier to use and offers good reproducibility. The control-based method eliminates the need for iterations but requires optimization of the controller to improve tracking performance.

2.2 Time Waveform Replication (TWR)

In this study, the FRF-based iterative method among TWR techniques was employed to extract drive signals for the hybrid road simulation. Figure 3 illustrates the TWR process, which consists of four main steps: (1) FRF generation using white-pink noise, (2) initial drive signal creation, (3) iterative drive signal update, and (4) convergence check using RMSE thresholds. Each step is described in detail in the following subsections.

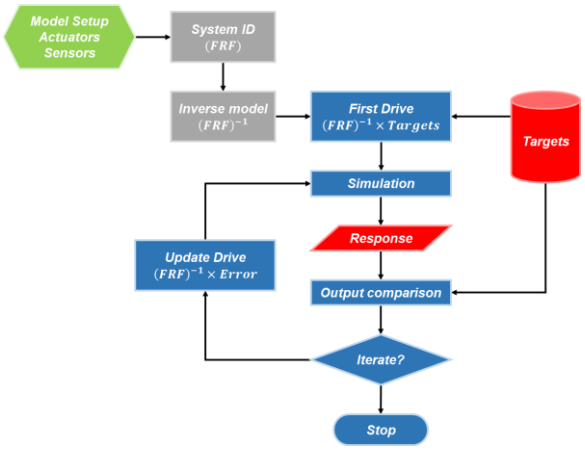

Figure 3. Time waveform replication (TWR) process.

2.2.1 FRF Generation Using White-Pink Noise

In the first step, white-pink noise is applied to the input channels of the vehicle model to extract responses from the output channels and generate an FRF model. The white-pink noise $WPN(f)$ has a constant magnitude from the start frequency (f_{st}) to the border frequency (f_b) and gradually decreases from f_b to the end frequency (f_{en}), as shown in Figure 4. Equation (1) defines WPN(f) across these segments, where the attenuation after f_b depends on the exponential parameter p.

$$WPN(f) = \begin{cases} \left(\frac{1}{f_b}\right)^{2p}, & f_{st} \le f < f_b \\ \left(\frac{1}{f}\right)^{2p}, & f \ge f_b \end{cases} \quad (1)$$

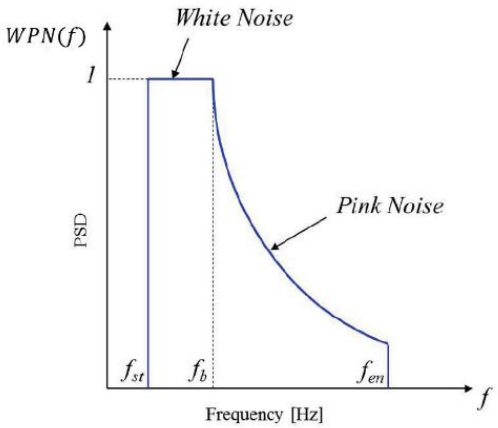

Figure 4. White-Pink Noise.

The process for FRF generation is shown in Figure 5.

DOI 10.3384/ecp218567

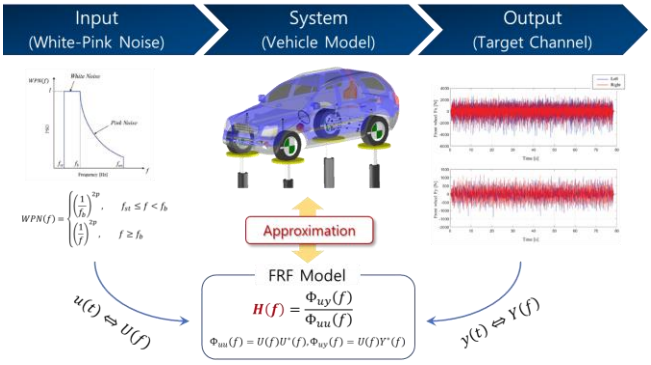

Figure 5. System identification (FRF generation) process.

In the FRF generation process, the auto-spectrum represents the frequency-domain power distribution of a signal, typically used to analyze the input characteristics. The cross-spectrum, on the other hand, quantifies the frequency-domain relationship between the input and output signals. These spectral components are used to compute the Frequency Response Function (FRF) by dividing the cross-spectrum by the auto-spectrum, enabling the identification of system dynamics. The cross-spectrum and auto-spectrum are obtained as shown in Equations (2) and (3):

$$\Phi_{uy}(f) = U(f)Y^*(f) \tag{2}$$

$$\Phi_{uu}(f) = U(f)U^*(f) \tag{3}$$

Here, $U(f)$ and $Y^*(f)$ are the Fourier transforms of $u(t)$ and $y(t)$, respectively, and * denotes the complex conjugate. The FRF $H(f)$ is then derived as:

$$H(f) = \frac{\Phi_{uy}(f)}{\Phi_{uu}(f)} \tag{4}$$

2.2.2 Initial Drive Signal Generation

The initial drive signal is generated using the inverse of the FRF and the inverse Fourier transform as shown in Equation (5):

$$u(t) = d \cdot \mathcal{F}^{-1}\left(H(f)^{-1}\mathcal{F}\left(S \cdot w(t)\right)\right) \tag{5}$$

Here, $H(f)^{-1}$ is the inverse FRF, $\mathcal{F}$ is the Fourier transform, $w(t)$ is the target signal, S and d are weights for the target and drive signals, respectively. The signal is valid within linear system regions, but nonlinear behavior introduces error, necessitating additional correction.

2.2.3 Drive Signal Update via Iteration

To correct errors between target and actual responses, an updated drive signal is computed iteratively. Equation (6) represents the iterative update of the drive signal in the TWR process. The initial drive signal is computed by applying the inverse FRF to the target signal. In subsequent iterations, the error between the simulated response and the target signal is calculated and passed through the inverse FRF to generate a correction signal. This correction is then added to the previous drive signal, progressively improving the match between the simulated and target responses. This approach is grounded in frequency-domain system identification and iterative learning control principles and has been widely used in road load replication studies for its convergence reliability and simplicity. The $k+1$-th drive signal is calculated as in Equation (6):

$$u_{k+1}(t) = u_k(t) + d \cdot \mathcal{F}^{-1}\left(H(f)^{-1}\mathcal{F}\left(E \cdot \left(y(t) - S \cdot w(t)\right)\right)\right) \tag{6}$$

Here, E is the error weighting parameter, and $y(t)$ is the output of the k-th iteration. The process continues until the RMSE (Root Mean Square Error) of each output channel is below the threshold.

2.3 Virtual Test Rig for Hybrid Road Simulation

The virtual test rig used in this study was constructed using a full vehicle model based on Modelon's Vehicle Dynamics Library (VDL), which supports high-fidelity multibody dynamics (MBD) simulation. This MBD-based model captures realistic vehicle responses and suspension loads by simulating the actual kinematics and compliance characteristics of suspension and chassis systems. The suspension architecture of the reference and target vehicles consists of a McPherson strut configuration at the front and a multi-link suspension at the rear, as illustrated in Figures 6 and 7. This combination was selected to reflect a typical modern passenger vehicle setup, where the front provides packaging efficiency and steering simplicity, while the rear enables better ride comfort and lateral stability.

Figure 6. Front suspension model (McPherson strut) in VDL.

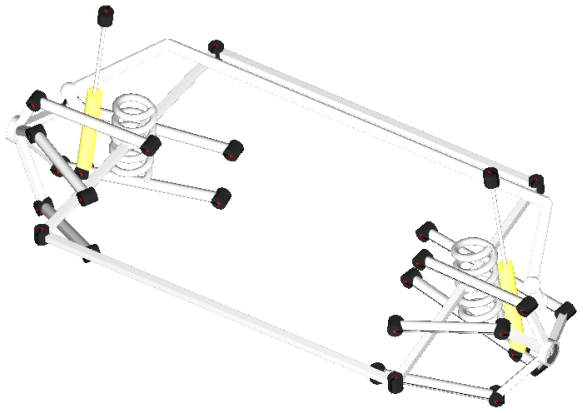

Figure 7. Rear suspension model (multi-link) in VDL.

While developing the suspension model, it was identified that the default bump stop element in Modelon's VDL lacks support for nonlinear force–displacement characteristics, which are critical for accurately capturing suspension component loads during durability simulations. To address this limitation, a custom bump stop model was implemented using Modelica. This component incorporates a user-defined nonlinear force–displacement curve using a lookup table and becomes active when the damper compression exceeds a predefined bump clearance. This modeling approach enables accurate replication of the sharp load increase that occurs during bottoming events, which significantly influences suspension component fatigue and durability assessment. To support this, two dedicated submodels were constructed and are illustrated in Figures 8 and 9.

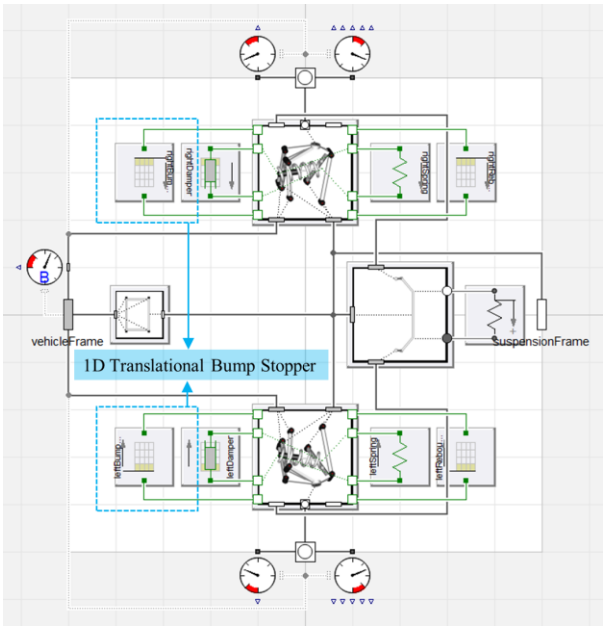

Figure 8. 1D translational bump stopper model.

Figure 8 shows the custom 1D translational bump stopper model used in the rear suspension system. The element accepts the force–displacement curve and is activated only when bump clearance is exceeded.

Figure 9 presents the kinematic model in the rear suspension linkage model that computes the bump stop compression displacement. In this configuration, the bump stop is mounted not on the shock absorber upper bushing but directly on the vehicle body. As such, the damper stroke alone does not reflect bump stop engagement. Therefore, an additional kinematic model was developed to calculate the relative displacement between the lower control arm and the chassis hardpoint. This value serves as the effective compression input to the bump stop force model.

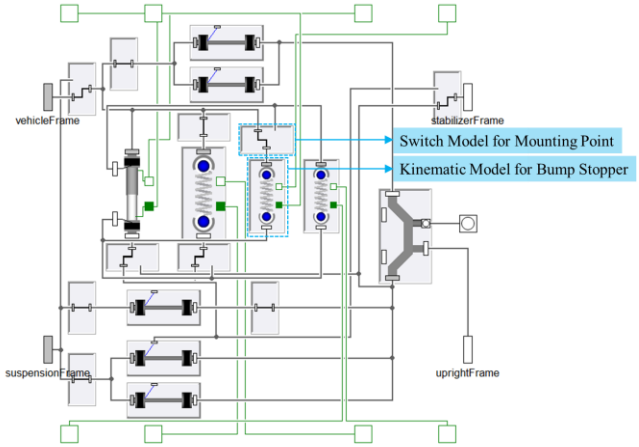

Figure 9. Kinematic model for bump stopper.

This approach ensures that the bump stop responds only under physically accurate conditions, enhancing the realism of load prediction and its influence on suspension durability performance.

The virtual test rig is configured as a 4-post setup, capable of applying vertical displacements at the tire contact patches through equivalent virtual road profiles. Additionally, actuators are installed at each wheel center to apply longitudinal and lateral forces, as well as moments. This configuration enables comprehensive reproduction of real-world wheel center load conditions and supports the simulation of both road-induced and control-induced excitations. Figure 10 shows the layout of this virtual durability test rig within the simulation environment.

DOI
10.3384/ecp218567

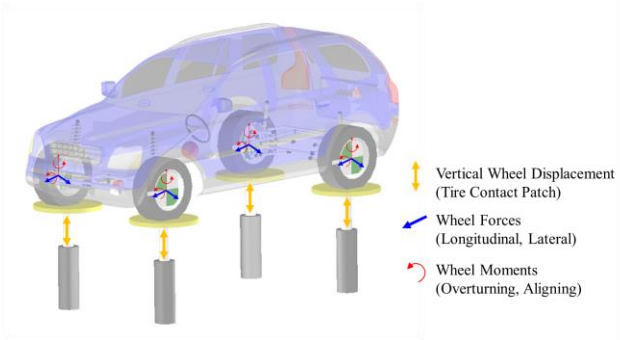

Figure 10. Configuration of virtual test rig.

To enable hybrid road simulation, the entire vehicle model and test rig were exported as Functional Mock-up Units (FMUs) using the FMI standard. These FMUs were integrated with a Python-based TWR algorithm, implemented using the FMPy library. This setup allows for automated iteration of drive signals to match target RLDA responses. The overall simulation framework and data flow between Python and the FMU-based vehicle model are depicted in Figure 11.

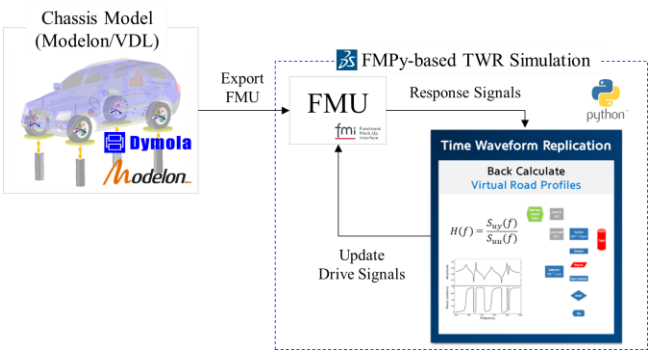

Figure 11. TWR simulation based on FMPy.

The TWR algorithm operates by comparing the actual response of the virtual vehicle to the target RLDA signals. It continuously updates the drive signals by feeding new input signals, stored in *.mat format, into the FMU simulation. These updates are computed using an FRF-based iterative optimization approach, which enhances tracking fidelity for complex time-domain signals. During each TWR iteration, the Python controller:

Step 1. Executes a simulation with the current drive signal.

Step 2. Evaluates the error between target and simulated output (e.g., wheel center forces).

Step 3. Updates the drive signal using the inverse FRF and re-simulates until convergence.

This tightly integrated Python-FMI workflow provides robust co-simulation performance while ensuring that realistic suspension dynamics are captured through the MBD-based virtual rig.

2.4 Application to Hybrid Road Simulation

2.4.1 Drive Signal Update via Iteration

For the reference vehicle, equivalent virtual road profiles and drive signals capable of reproducing 20 channels of wheel forces and moments were generated based on Belgian road RLDA data. Predicted and measured component and wheel loads were compared. Figures 12 and 13 show the improvement in front and rear vertical wheel force prediction accuracy across iterations. Figure 14 illustrates the RMSE convergence behavior across 10 iterations for 20 wheel load channels. All channels showed a consistent downward trend in RMSE, indicating stable convergence. While convergence patterns were similar overall, the final RMSE values for vertical loads remained slightly higher, stabilizing below 12%. This level of accuracy is considered reasonable for durability simulation purposes. In contrast, wheel center longitudinal and lateral loads, as well as aligning and overturning moments, achieved lower residual RMSE values, typically below 6%. These results confirm the robustness of the FRF-based iterative TWR algorithm in minimizing signal error across diverse load types.

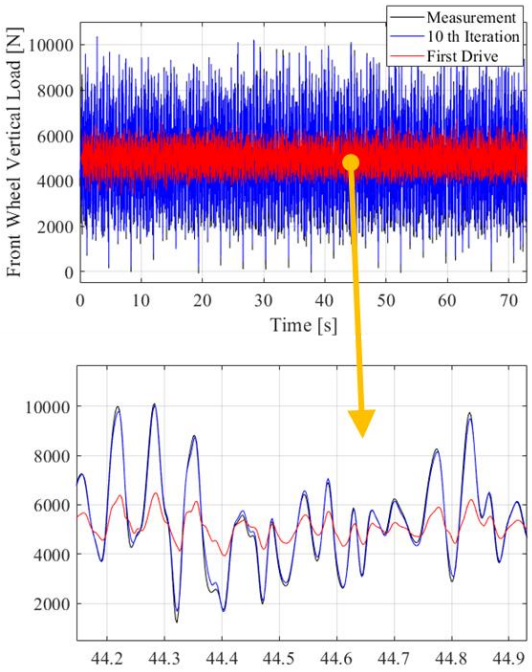

Figure 12. Predicted results of front wheel center vertical load.

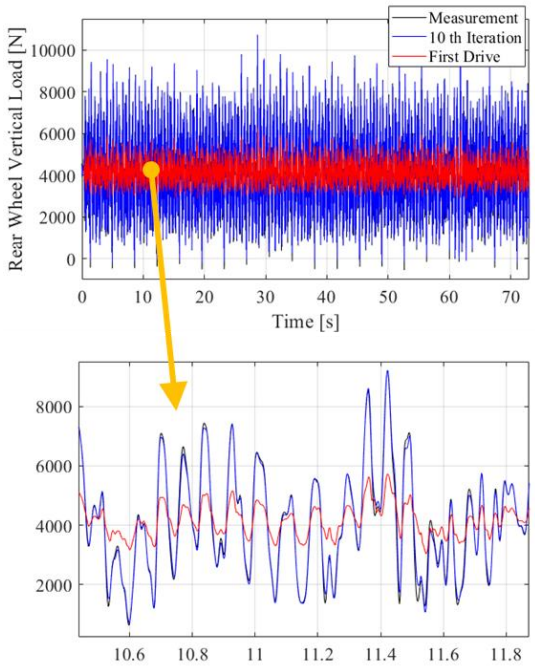

Figure 13. Predicted results of rear wheel center vertical load.

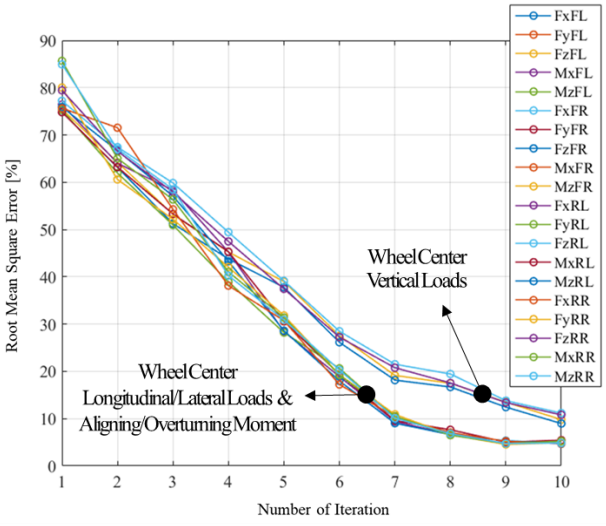

Figure 14. RMSE history of wheel loads and moments.

In this study, component damage was calculated as a normalized pseudo damage metric using rainflow cycle counting and Miner's rule. The damage values represent relative fatigue severity based on the simulated load time histories, allowing comparison between measured and predicted results without requiring material-specific S-N curves. Table 1 summarizes RMS and normalized pseudo damage values of measured and simulated component loads, confirming the high accuracy of the generated drive signal and road profile.

Table 1. TWR simulation results of reference vehicle.

Channel	*Index*	*Simulation*	*Target*	*Error*
Front Wheel Center Vertical Load	RMS	1729.62	1691.39	2.26 %
	Pseudo Damage	1.34	1.24	8.06 %
Rear Wheel Center Vertical Load	RMS	2074.84	2048.02	1.31 %
	Pseudo Damage	1.81	1.7	6.47 %
Front Lower Arm Boll Joint Fx Load	RMS	875.29	866.18	1.05 %
	Pseudo Damage	0.33	0.32	3.13 %
Real Assist Arm Axial Load	RMS	1634.37	1615.21	1.19 %
	Pseudo Damage	2.88	2.80	2.86 %
Rear Lower Arm Axial Load	RMS	1548.75	1571.01	1.42 %
	Pseudo Damage	2.80	2.96	5.40 %

2.4.2 Simulation for Target Vehicle

The extracted drive signals and road profiles were applied to the target vehicle model to predict component and wheel loads. Figures 15 to 19 present range pair graphs showing load distribution and cumulative damage. While vertical loads and front lower arm ball joint loads closely matched measured data, some discrepancies were observed in rear component loads, primarily due to sensitivity of damage metrics and reliance on reference vehicle measurements for lateral/longitudinal forces.

3 Conclusion

This study presented a hybrid road simulation method for predicting vehicle suspension component loads by integrating road load data and multibody vehicle models through FMI-based co-simulation. By employing an FRF-based iterative TWR algorithm, equivalent virtual road profiles were generated using RLDA data from a reference vehicle and applied to a target vehicle model exported as an FMU.

The proposed methodology offers several advantages relevant to the Modelica and FMI community:

- **FMI-based modular integration**: The approach demonstrates a practical application of the FMI standard using FMPy to couple a Python-based TWR algorithm with a Modelica-based full vehicle model, ensuring seamless interoperability in a simulation workflow.

- **Efficient virtual durability testing**: By leveraging existing RLDA data and applying it through a virtual test rig configuration, the method enables early-stage durability analysis without the need for physical prototypes or detailed driver models.

- **System-level fidelity with manageable complexity**: Compared to traditional Virtual Proving Ground (VPG) approaches, the hybrid method maintains accuracy in load prediction while reducing the dependency on high-fidelity subsystems like road or tire models.

Future work will focus on extending this FMI-based hybrid simulation framework to cover broader driving scenarios and enhancing prediction robustness, especially for design-dependent variables such as lateral and longitudinal load components. This research illustrates how the use of standardized model exchange formats like FMI can accelerate the development and validation of vehicle durability simulation methods in industrial applications.

Abstract

Testing real hardware and simulation models in combination in a software- or hardware-in-the-loop set-up is challenging. One of the key factors is the high demand for accuracy in the simulation model. If classical modeling based on physical principles is not sufficient to reach the desired level of accuracy, *hybrid modeling*, the combination of physical simulation models and machine learning can be applied. In this publication, we train a hybrid model for a controlled electric motor within the electro-hydraulic braking system of a car under the conditions and restrictions of a real engineering application in the field. We apply state-of-the-art modeling patterns for this, and further extend them with application specific methodological optimizations. Finally, we investigate and show the quantitative and qualitative advantages of the proposed approach for this specific application, resulting in a gain in accuracy by multiple factors.

Hybrid Modeling, Graybox Modeling, Scientific Machine Learning, Functional Mock-Up Unit, Functional Mock-up Interface, Braking System, Automotive

1 Introduction

Most simulation models in the automotive environment are built based on physical equations. This has the advantage that the model builder, as well as other engineers, have an intuitive understanding of the model and its parameters. As these physical equations also have very broad validity, most physical models can also generate correct results outside the required working range (extrapolation), making them robust in various application scenarios. When creating models, equations are chosen on the basis of assumptions, i.e. simplifying assumptions are made. This introduces a modeling error that leads to deviations between the simulation model and the real system. On the other hand, there are machine learning approaches that can theoretically generate arbitrarily accurate results depending on the selected model and model dimension if a sufficient amount of data is given. This flexibility comes at the cost of poor interpretability due to the black-box nature of most machine learning models like arifical neural networks (ANNs). The field of *hybrid modeling*, which is part of *scientific machine learning*, attempts to combine the advantages of both modeling and simulation approaches, e.g., to create more accurate, yet interpretable models.

1.1 Use Case: Bosch Integrated Power Brake

The Integrated Power Brake (IPB) is a vacuum-independent and electro-hydraulic brake control system that combines brake boosting and brake control functions in one piece of hardware. By applying the brake pedal, the control unit calculates the driver's brake request based on internal sensors. This brake request is implemented by activating a pressure build-up unit consisting of an electric motor, a gearbox, and a hydraulic piston. Finally, brake pressure is transferred to the wheel brakes via brake pipes to decelerate the vehicle. For more information on the system, see Robert Bosch GmbH (2025) and Robert Bosch GmbH (2024).

The developed control software is tested using software-in-the-loop simulation. This requires a model of the hardware that generates sufficient quality of results. A very detailed physical model only makes sense to a certain extent, as otherwise the required simulation performance cannot be achieved. Therefore, strict requirements are given for both simulation accuracy and performance. A hybrid modeling approach should be able to fulfill these requirements.

The model used for the use case contains the electric motor, including the mechanical parts of the pressure build-up unit. The physical model calculates the position, speed, torque, and current of the rotor. The motor is controlled by a motor controller that runs software that calculates control signals based on the position of the rotor. This motor controller is implemented in software for the use case considered.

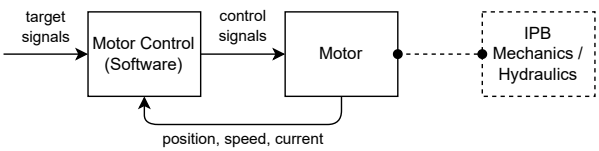

Figure 1. IPB motor control.

The model itself poses various challenges:

- The system is very sensitive with respect to the initial state of the rotor position, as the control signals are calculated based on this. Even small deviations make the motor run *out-of-sync*, as can be observed for the physical model during experiments (s. Sec. 4).
- The control signals are sampled with a frequency of $10^4\,Hz$, triggering time events at this frequency.
- The nonlinear physical model is marginally stable with real zero eigenvalues independent of the system state, so for the entire operation range of the motor.
- Special model conditions (such as reaching end-stop) cause additional state events.

The system consists of two mechanical and two electrical states. The mechanical states for the electric motor are the angular position and the angular speed of the motor rotor. In addition, the inputs to the electric motor are pulse-width modulation (PWM) signals for each motor phase, the motor supply voltage, and the time-varying mechanical load caused by the hydraulic subsystem.

The simulation model is given as functional mock-up unit (FMU), which is introduced in detail in the next section. The use of a FMU for the considered use case not only allows one to simulate the motor model but also to later extend it by a machine learning model without actually sharing the model equations and parameters. This is because the FMU contains only compiled machine code. In fact, the use case shown here was processed without knowing the physical model or its parameters. This demonstrates a significant advantage of the method, as models can be improved by hybrid modeling without disclosing the corresponding intellectual property.

1.2 Functional Mock-up Interface (FMI)

The Functional Mock-up Interface (FMI) is an open, tool-independent standard (container format) for exchanging and co-simulating dynamic models, usually in the form of ordinary differential equations (ODEs), across different simulation systems and tools. Developed initially in 2008-2011, FMI has become the de facto industry standard for model exchange and co-simulation, supported by more than 230 different simulation tools (Modelica Association 2020; Bertsch 2022; Modelica Association 2023). FMI supports two main types of FMUs: Co-simulation (CS) and Model-exchange (ME). The ME-FMU offers an interface similar to the right-hand side of a system of ODEs, for example providing the state derivative for a given state. This allows for the complementation of the ODE and its underlying physics with data-driven components from machine learning to improve, for example, the accuracy (Thummerer, Mikelsons, and Kircher 2021).
FMI 3.0 has introduced several features that enables one to integrate AI models in simulation, e.g. by updating parameters much more efficiently than in previous versions. For example, with the added support of adjoint derivatives, FMUs can be integrated in automatic differentiation frameworks, as demonstrated in *FMISensitivity.jl* [1].

1.3 Neural ODEs

In machine learning, using an ANN to learn for the right-hand side of an ODE is referred to as *neural ODE* (R. T. Q. Chen et al. 2018), compare Fig. 2. The gradient required for training neural ODEs is typically determined by back-propagation through the numerical solver (reverse mode automatic differentiation) or by applying adjoint methods. This concept was later extended to support event-ODEs as well (R. T. Chen, Amos, and Nickel 2020). Numerous publications show that neural (ordinary) differential equations are an excellent tool to learn dynamical system behavior (Ramadhan et al. 2023; Tac, Sahli Costabal, and Tepole 2022; Xie, Parlikad, and Puri 2019).

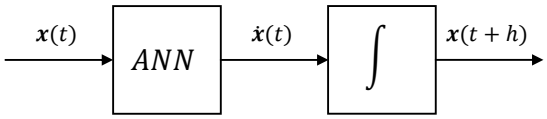

Figure 2. Within neural ODEs, the right-hand side of an ODE is expressed by an ANN and solved by a numerical integration algorithm (ODE solver). Based on a given state $\boldsymbol{x}(t)$, the ANN computes a state derivative $\dot{\boldsymbol{x}}(t)$, which is integrated to the next system state $\boldsymbol{x}(t+h)$ by performing a step of h. Figure adapted from (Thummerer, Kolesnikov, et al. 2023).

1.4 UODE / PeN-ODE

Compared to the concept of neural ODEs, one can conclude that, besides ANNs, other universal approximators are possible as well to approximate the right-hand side of an ODE. Further, the right-hand side can contain a priori knowledge in the form of equations. This concept was introduced as universal ordinary differential equation (UODE) (Rackauckas et al. 2021) together with a software framework. This framework serves as a software foundation for *FMIFlux.jl*[2], which is used within this application. Within the *OpenSCALING* research project (s. Sec. Funding), a special kind of UODE is introduced, combining explicitly ANNs and physical simulation models to be solved by an ODE solver, referred to as physics-enhanced neural ODE (PeN-ODE). Similar and related research was performed in Sorourifar et al. (2023) and Thummerer, Kolesnikov, et al. (2023), using the same terminology. A detailed discussion on PeN-ODEs can also be found in (Hofmann and Mikelsons 2025) and the model investigated in this paper can be interpreted as PeN-ODE.

[1] `https://github.com/ThummeTo/FMISensitivity.jl`
[2] `https://github.com/ThummeTo/FMIFlux.jl`

DOI 10.3384/ecp218575

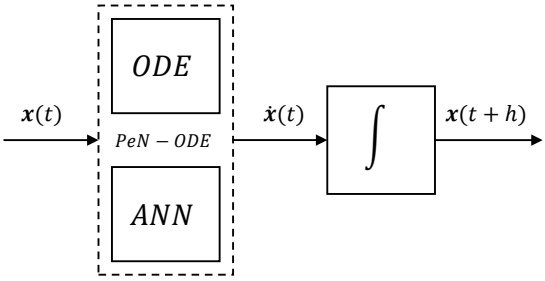

Figure 3. A physics-enhanced neural (PeN)-ODE, which consists of a ODE, an ANN and the ODE solver. Based on a given state $\boldsymbol{x}(t)$, the PeN-ODE computes a state derivative $\dot{\boldsymbol{x}}(t)$, which is integrated to the next state of the system $\boldsymbol{x}(t+h)$. There are no restrictions on how ODE is connected to the ANN.

1.5 Preliminary Work

ME-FMUs offer a similar interface compared to ODEs and can therefore be intuitively replaced with each other on a conceptual level. However, on the technical level, multiple adjustments are required. In Thummerer, Mikelsons, and Kircher (2021), *neural FMUs* were introduced as the combination of FMUs and ANNs. From the point of view of PeN-ODEs, a neural FMU can be constructed by replacing the ODE by a ME-FMU. In addition, neural FMUs can also be constructed based on CS-FMUs (Thummerer, Mikelsons, and Kircher 2021), but are not further investigated in this contribution.

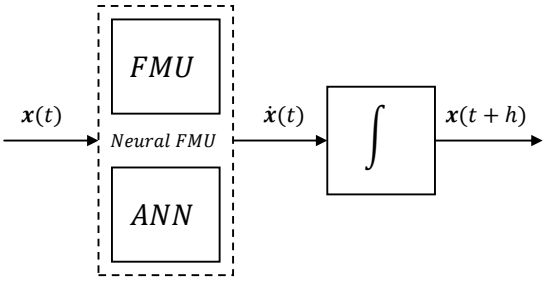

Figure 4. A neural FMU (ME), that consists of a ME-FMU, an ANN and the ODE solver. Based on a given state $\boldsymbol{x}(t)$, the neural FMU computes a state derivative $\dot{\boldsymbol{x}}(t)$, which is integrated into the next state of the system $\boldsymbol{x}(t+h)$. No assumptions on how the FMU is connected to the ANN are made. In addition, multiple FMUs and ANNs can be involved.

In Thummerer, Stoljar, and Mikelsons (2022), multiple training strategies for neural FMUs are investigated. In the following, we briefly explain the methodological foundation that we use as a starting point for the presented extensions. The following decisions are made:

Gates As a starting point for building a hybrid model architecture, the gates topology is used (Thummerer, Stoljar, and Mikelsons 2022), based on a parallel-serial layout (Thummerer and Mikelsons 2025). Here, two gates are applied that control how much of the (original) FMU motor dynamics and how much of the (newly) learned ANN motor dynamics contribute to the resulting hybrid model motor dynamics. The gates are parameterizable and are trained together with other optimization parameters, choosing proper initial parameters is part of hyperparameter optimization.

Pre- and Post-Processing To normalize the values between machine learning and the domain of the physical model, pre- and post-processing is applied online (Thummerer, Stoljar, and Mikelsons 2022). Here, pre- and post-processing corresponds to the introduction of two additional linear operations that shift and scale signals at the domain boundaries (between the physical and machine learning model and vice versa) in order to prevent suboptimal operation ranges for the nonlinearities inside the ANN. For example, if hyperbolic tangent activation is applied (as we used in the later experiment), small values close to zero lead to operation in (almost) linear ranges of this function and therefore neglection of the intended nonlinearity, whereas large values drastically saturate to 1 or -1, leading to a vanishing gradient. Both issues are major obstacles when training (nonlinear) hybrid models.

Interfaces In Thummerer and Mikelsons (2025), it is investigated how models can be combined, and learnable connections between physical and machine learning models are proposed. However, it is shown that this is not always efficient if only a limited amount of data is available. This motivates a clever selection of interface signals for the ANN. Because only little is known about the not modeled physical effect, it is decided to use the following signals as inputs for the ANN:

- The **system state** is used, to allow the ANN to learn its own representation of the right-hand side of the ODE. This corresponds to a parallel-like model architecture.
- The **system inputs**, to allow the learned right-hand side to further depend on the current input.
- The **state derivative** calculated by the FMU, which allows to *correct* the dynamical representation of the system calculated by the physical model. This corresponds to a serial-like model architecture.
- The time is explicitly not used as input to the ANN, because a time-invariant system is assumed, so without explicit time dependency.

The presented decisions result in the architecture visualized in Fig. 5, which is used as the foundation for the considered application.

2 Method

Although the architecture introduced in Fig. 5 was able to produce good results in a very similar form for different application scenarios from mechanical engineering (Thummerer, Stoljar, and Mikelsons 2022; Thummerer,

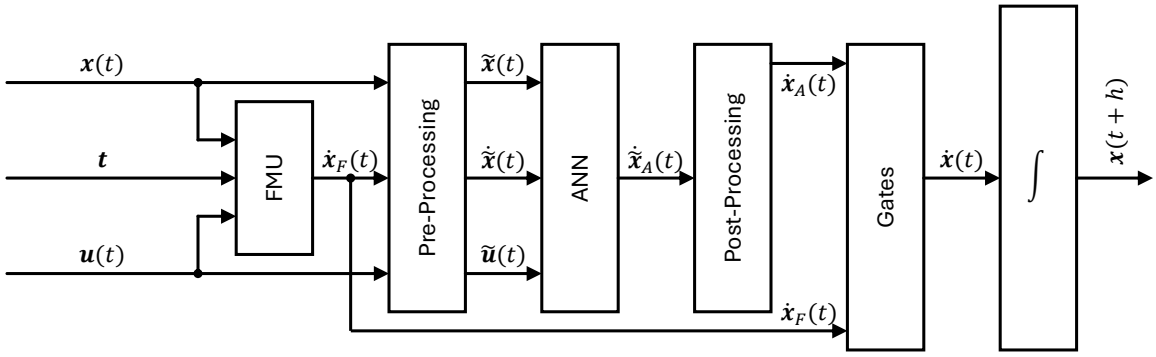

Figure 5. The starting point for derivation of the neural FMU (ME) used in this paper. It features pre- and post-processing layers as well as gates. First, the state $\boldsymbol{x}$, time t, and inputs $\boldsymbol{u}$ are fed into the FMU. The FMU computes a state derivative $\dot{\boldsymbol{x}}_F$, which is pre-processed together with the original state and input values. After pre-processing, the considered values are passed to an ANN, that computes its own state derivative vector $\tilde{\dot{\boldsymbol{x}}}_A$, which is further post-processed to $\dot{\boldsymbol{x}}_A$. The gates layer then controls how much of the ANN dynamics and the FMU dynamics contribute to the overall dynamics of the hybrid model $\dot{\boldsymbol{x}}$, which is finally integrated to the next system state $\boldsymbol{x}(t+h)$ by performing a step with size h in time.

Kolesnikov, et al. 2023) and medical technology (Thummerer, Tintenherr, and Mikelsons 2021), further methodological adjustments must be made for the particularly challenging application case at hand. These are introduced and discussed below.

2.1 Architecture: Learning Input Delay

The measurement data used is recorded at high frequency ($10^4\,Hz$). It is worth mentioning that this sampling frequency is not an excessive choice and is required to capture significant information, for example PWM signals to drive the electric motor. Due to the combination of several sensor signals in the data logger or errors in time synchronization between these sensors, time offsets may occur between the measurement signal of different sensors (see Fig. 6). In general, for small deviations, it is difficult to distinguish these temporal deviations from system dynamics. If the cause cannot be clearly identified (and explained), appropriate correction options can be provided in the architecture for both possible causes. This is achieved by integrating a block for introducing a constant-time offset for the input signal in addition to a neural network for correcting the system dynamics. Mathematically, this is defined simply as follows:

$$\boldsymbol{u}_{out}(\boldsymbol{u}(t),t) := \boldsymbol{u}(t+\Delta t), \tag{1}$$

where Δt is a trainable parameter and $\boldsymbol{u}_{out}$ is the output signal of the delay correction block. Since the time-offset block is parameterized and its parameter Δt can be differentiated, this parameter can be optimized together with the parameters of the neural network in a gradient-based training.

2.2 Architecture: Bypass Dynamics

For the presented application, we decide to only manipulate the *mechanical* part of the system state vector, so the mechanical subsystem, respectively. This is justified

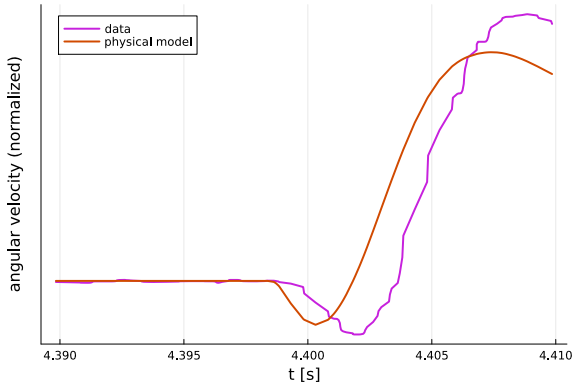

Figure 6. The plot shows the angular velocity data, as well as the output of the simulation model. There is a time shift in between that could be compensated by adding an offset in time to the input signals.

by the fact that the modeling and parameterization of the electrical subsystem are assumed to be accurate, while the mechanical subsystem has a higher level of uncertainty. As a consequence, the electrical part of the state derivative is forwarded to the ODE solver without any manipulation, which corresponds to leaving the right-hand side of the electrical subsystem untouched. To further preserve the second-order ODE structure for the mechanical subsystem, we only allow manipulation of the rotor acceleration (and not the rotor speed), which we achieve by forwarding the unmodified rotor speed to the ODE integrator as well.

Based on the preliminary work summarized in Fig. 5, the proposed input offset correction block and signal forwarding, a model architecture as in Fig. 7 can be deployed to address the presented use case.

2.3 Data Handling

As shown in Fig. 8, real measurement data is often very heterogeneous in terms of information content. For a

DOI
10.3384/ecp218575

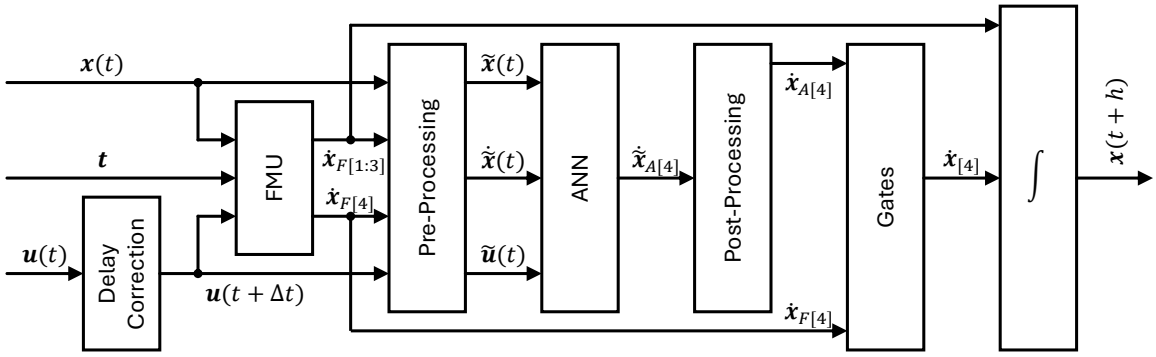

Figure 7. The architecture designed for the presented use case, based on the introduced architecture in Fig. 5 and extended by input delay correction. Not all state derivatives $\dot{x}$ are computed by the ANN and post-processing, only $\dot{x}_{A[4]}$ (the motor rotor acceleration). The others $\dot{x}_{F[1:3]}$ are cached and forwarded directly to the ODE solver.

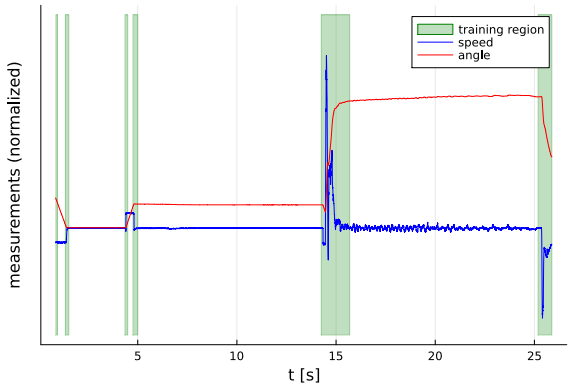

Figure 8. The training data. As data is *heterogneous* (varying information content), only the green regions (that offer information *variance*) are used for training.

large part of the time axis, the system is at rest (or almost at rest). This is due to a delay between the start and end of the recording and the execution of the actual test. In this application, we have decided to thin out the data manually, but we are working in parallel on robust approaches to automate this step. It is important to note that this step is more complex than, for example, filtering only for derivatives and has a significant influence on the quality of the results with such a small amount of training data.

3 Experiment

The presented method is validated in the challenging use case of the IPB introduced in Sec. 1.1. The experiment involves the training process, followed by the comparison of results against measurements of the real physical system (ground-truth data, baseline). To determine good hyperparameters, a hyperparameter optimization is performed.

3.1 Data

For intellectual property reasons, all data plots and error measures within this publication are normalized. The data used for training, validation, and testing was generated under typical development conditions:

- All measurements were performed on the real IPB hardware (prototype) and
- an ECU software measurement tool was used to measure the sensor and actor control quantities, so no additional sensor are required/used.

To show the ability of the presented method to provide good results on a very small data set under conditions of real development in the field, only three measurements with durations of $\approx 12-25\,s$ are used. One trajectory is used for training (gradient determination for optimization), one for validation (evaluating the success of hyperparameter optimization), and one for testing (completely unknown to the model and optimization processes).

3.2 Training

Because the experiment includes a real industrial simulation model that is part of active development, this model cannot be shared. However, the experiment setup is described in the following, to allow for reproduction within similar use cases:

Hyperparameter Optimization For hyperparameter optimization, the optimizer *Hyperband* (Li et al. 2018) is applied with parameters $R = 81$ and $\eta = 3$. The optimizer is paired with a simple random sampler as the inner sampling algorithm[3]. As resource for *Hyperband*, a time span is used for the processed training data, which is limited to a maximum of $100\,s$.

Optimizer For the actual training, the optimizer *Adam* (Kingma 2014) is applied, with step size $\eta \in [10^{-6}, 10^{-4}]$ (best: 3^{-6}), $\beta_1 \in \{0.99, 0.9\}$ (best: 0.99) and $\beta_2 \in \{0.9999, 0.999, 0.99\}$ (best: 0.9999). Stochastic mini-batching is applied as training strategy, with a batch element length of $[0.01\,s, 0.1\,s]$ (best: $0.02\,s$).

[3]Implementation available: `https://github.com/ThummeTo/DistributedHyperOpt.jl`.

Loss function The loss function consists of two separated errors, one for the motor angle and one for the speed. For error determination, mean squared error (MSE) as well as mean absolute error (MAE) (best) are used. To obtain a scalar loss, the loss terms are weighted by a percentage between 0 % and 100 % (best: 70 % speed, 30 % angle) and added together. This allows for loss functions that involve only the speed, only the angle, or a mixture of both.

ANN layout For the ANN, different widths $\{8, 16, 32\}$ (best: 8) and depths $\{2, 3, 4\}$ (best: 4) are tested. Only the *tanh* activation function is applied for all layers.

Gates The gates for the influence of the ANN are trained together with the ANN parameters, but feature different initial openings between $[0\,\%, 50\,\%]$ (best: 30 %).

4 Results & Discussion

After training, we find the following results that we want to discuss in detail in this section. It is important to note that training, validation, and testing are performed *open-loop*. This means that control signals are recorded from the closed-loop (controlled) system, but for training and validation, the motor is operated based on the pre-recorded control signals without involving the controller (remove feedback). This allows us to evaluate the actual accuracy of the hybrid model without controller influences positively distorting the results.

Training, validation, and test data vary w.r.t. different aspects, for example the maximum applied load or the maximum rotor velocity vary by at least 10 % between the individual datasets.

We deliberately decided against baselining against a pure ML model because under the given circumstances (very little data, very few training resources) no presentable ML model can be trained, even if more advanced approaches such as neural ODE are used for this purpose. Please note that training data only captures a part of the state space of the system, and therefore a pure ML approach is by design not able to recover the system behavior beyond the limited training data.

4.1 Validation

The best hyperparameter run values can be found in Sec. 3.2, leads to the following results for the motor angle (s. Fig. 9). The determined value for the time offset (input delay) is $\approx -1.995 \times 10^{-5} s$. Because the motor is very sensitive with respect to the inputs, this small offset has a significant positive influence on the simulation results.

Qualitatively, it can be stated that the neural FMU trajectory does not have any significant, obvious deviation compared to the data trajectory. This does not apply to the original FMU that has a large deviation, especially near the end of the trajectory. This can be seen in Fig. 10 starting at around $18.3\,s$, which shows the deviation in more detail.

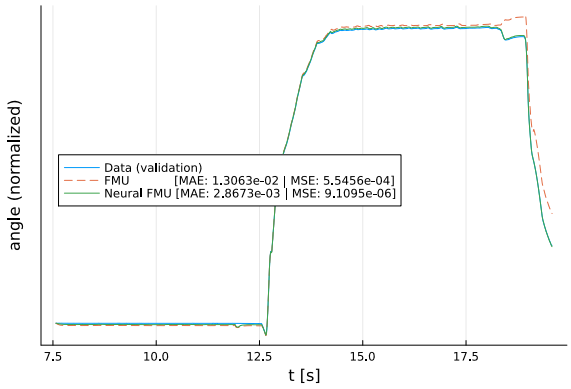

Figure 9. The motor angle on the validation data on the full trajectory. Loss values are given in square brackets.

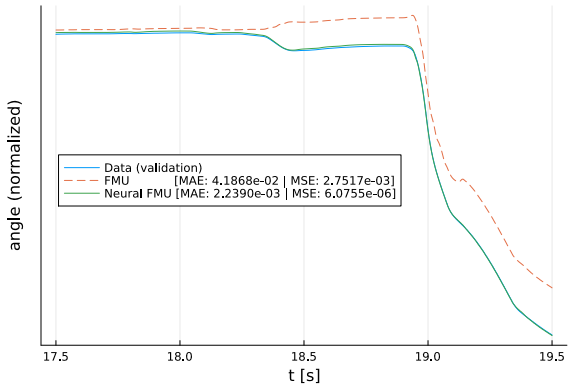

Figure 10. The motor angle on the validation data, zoomed in to the time interval from $17.5\,s$ to $19.5\,s$. The loss values for this interval are given in square brackets.

On a quantitative level, the deviation for the motor angle for the neural FMU is ≈ 4.6 times smaller compared to the FMU on MAE, and even around 61 times on MSE. At this point, we need to highlight that these factors are very impressive from an engineering point of view and deliver massive added value for the (hybrid) simulation model.

As expected from the good results for the motor angle, the neural FMU also provides a qualitatively good fit on the motor speed, see Fig. 11.

Again, we investigate a part of the speed trajectory in more detail. What is particularly striking are the deviating spikes of the FMU, which can be investigated in more detail in Fig. 12. The spikes result from the fact that the model is very sensitive with respect to the control signals and small deviations between the control signal and the position of the rotor lead to unstable behavior in the open-loop control system. Although the original simulation model (FMU) consistently shows these oscillations that even lead to overshoots in the event of rapid changes in speed (acceleration), the neural FMU is able to compensate for the unintended oscillations and provides a nice

DOI

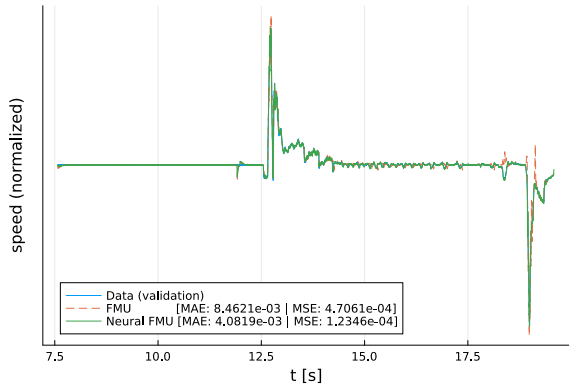

Figure 11. The motor speed on the validation data on the full trajectory. Loss values are given in square brackets.

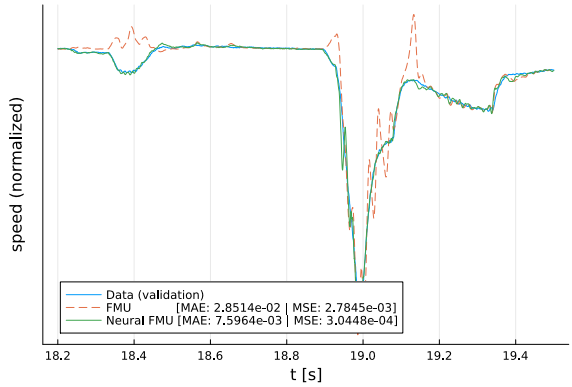

Figure 12. The motor speed on validation data, highlighting the interval between 18.2 s and 19.5 s. Loss values are given in square brackets.

and smooth fit without significant deviations.

4.2 Testing

For proper validation of the hybrid model, the neural FMU is further investigated under testing data, that is completely unknown from training as well as hyperparameter optimization. As for validation data, the neural FMU qualitatively performs very well on testing data (s. Fig. 13), and is even able to provide a little better increase in precision of the predicted rotor angle of factor ≈ 5.4 on MAE or factor ≈ 74 on MSE, respectively.

In contrast to the validation, we want to inspect a segment with raising edge for the motor angle in more detail, see Fig. 14. Within this segment, the original model (FMU) already performs very well, and we want to investigate if the neural FMU is able to retain the parts of the original model that already perform well. Even if the original model has high accuracy in the investigated time span, the neural FMU is able to outperform this performance by a factor of around 2.2 (MAE).

Finally, we also investigate the motor speed on testing data in the following. When investigating the rotor speed on testing data (s. 15), we find quantitative improvements similar to the validation scenario of factor > 2 (MAE).

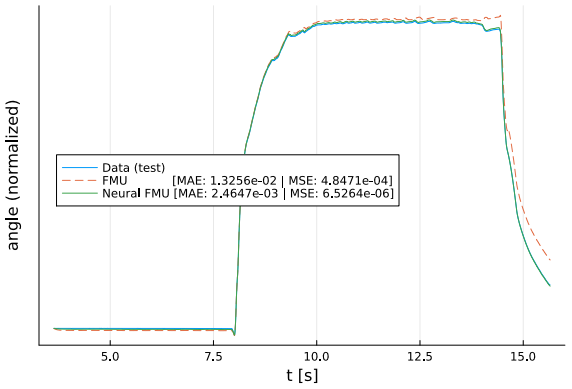

Figure 13. The motor angle on test data on the full trajectory.

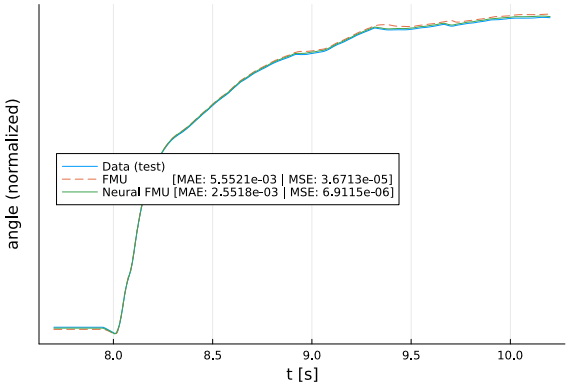

Figure 14. The motor angle on the test data, between 7.8 s and 10.2 s. Loss values are given in square brackets.

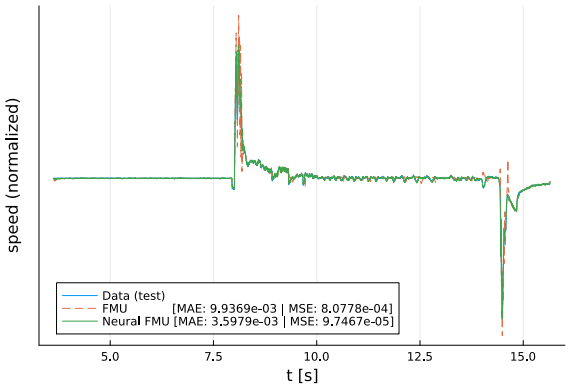

Figure 15. The motor speed on the test data on the full trajectory. Loss values are given in square brackets.

Again, more significantly, the qualitative fit has drastically improved in terms of reduced (wrong) oscillations in the open-loop simulated motor, see Fig. 16.

5 Conclusion

We can summarize that hybrid modeling has the potential to be used in challenging real industrial applications. In this particular use case of the automotive braking system, we were able to increase the accuracy by multiple factors, even though the physical model was based on a

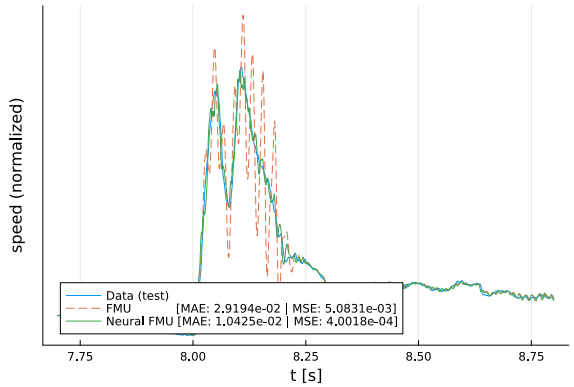

Figure 16. The motor speed on test data, highlighting the interval between 7.75 *s* and 8.75 *s*. Loss values are given in square brackets.

simulation model from real state-of-the-art engineering, built and parameterized by experts. Nevertheless, the successful results presented are still based on well-founded decisions by the development engineer, e.g. the choice of a model architecture that meets the requirements of the use case. We also see this as the task of the modern simulation engineer in the future. Although such decisions can in principle also be optimized by ML approaches, the approach presented here impresses with its very low computing power requirements compared to large-scale optimizations. In this use case, even the in general expensive hyperparameter optimization was executed on a standard desktop CPU with a runtime of only around 48 hours.

For the considered use case, we used data from the (partly) available real prototype to improve an existing simulation model. This approach is of course not applicable, e.g. during early phases of the development, when a real demonstrator is not available. However, the proposed method can also be applied based on synthetic data from another simulation model, e.g. to create a hybrid surrogate model with improved properties (e.g. computational performance or memory requirements) compared to the original model.

Future work will focus, for example, on training and testing based on a larger data set. In this application, in particular, a relatively small data set (one maneuver each for training, testing, and validation) was used to demonstrate the applicability of the method even with only small amounts of data, which is common for many industrial application fields — especially during protoyping. Further, we look at ways to further automate parts of development (e.g. training and batching strategies) to further reduce the development time of such hybrid models.

The authors thank all those involved for their support in making our research possible.

Availability of Software, Data and Model

The software used *FMIFlux.jl*[4] is open source on GitHub. However, the simulation model and the data presented are not available to the public due to intellectual property. All data shown was normalized. However, *FMIFlux.jl* offers demo applications that are similar to the workflow presented, and application-specific features, such as learning of time shifts, are available as part of the open source repository.

Abstract

The ability to systematically compare and evaluate diverse control strategies is essential for the development of effective control algorithms in autonomous driving. This contribution presents the VDCWorkbench Modelica Library, a unified platform designed to support the development, testing, validation and verification of vehicle dynamics controllers and energy management strategies. The presented library is an extension of the IEEE VTS Motor Vehicle Challenge 2023 models and offers multi-physical component modeling, including a hybrid energy storage system (fuel cell & hydrogen tank and battery with aging model), as well as vehicle dynamics control for autonomous driving research projects. Two path-following approaches are featured: an open-loop lateral controller with a static inversion of a single-track model, and a closed-loop state-dependent geometric path-following controller with static control allocation. The library may also serve as the foundation for development of vehicle control methods, such as two-degree-of-freedom control approaches concepts. One example is given for this combination of a feedforward controller with residual reinforcement learning, where a learned agent improves the performance of the open loop controller. The entire library will be released as open source on GitHub in September 2025.

1 Introduction

To accelerate the development of control algorithms in the field of vehicle dynamics, efficient modeling tool chains are required to capture key physical effects with reduced computational complexity. In this work, we present the Vehicle Dynamics Control Workbench Library (*VDCWorkbench*), a Modelica-based library that can be used as a workbench for the design, testing and validation of vehicle dynamics controllers and energy management algorithms of electric vehicles. This open-source library gives students, researchers and engineers the opportunity to familiarize themselves with vehicle dynamics modeling and control. The toolbox can be used, for example, for autonomous vehicle projects and assessment of different vehicle configurations.

Other Modelica-based simulation libraries for electric and autonomous vehicles are typically commercial libraries such as Modelon's Vehicle Dynamics, DLRs Powertrain and Alternative Vehicle Library and Claytex's VeSyMA offerings. Outside Modelica, open-source platforms like Gazebo (robotics simulation, can be adapted for vehicle control), CARLA (open-source simulator focusing on automated driving scenarios), Bullet Physics (general rigid and soft body physics, can be used for vehicle dynamics) provide multibody physics, sensor modeling, and scenario generation for vehicle dynamics and control [1]. Most of these previous simulation packages lack support for comprehensive multi-physics modeling of the entire vehicle system and do not allow exporting Functional Mock-up Units (FMUs) for training AI-based controllers—capabilities that are uniquely provided by our *VDCWorkbench* Library. Moreover, tools such as CARLA emphasize high-fidelity scenario visualization for generating synthetic perception data, rather than integrated vehicle-level control and energy management modeling, which are supported by the *VDCWorkbench* library. Note that advanced visualization capabilities can also be provided by the *VDCWorkbench* via the DLR Visualization Library.

A preliminary version of the *VDCWorkbench* library was used as the simulation engine for the IEEE VTS Motor Vehicle Challenge 2023 [2], a research competition for energy management strategies of hybrid electric vehicles.

This library has not yet been published and was only made available to the participants of the challenge as a black box FMU for the development of their energy management algorithms. The entire *VDCWorkbench* library is released as open-source software in the GITHUB repository of the Vehicle System Dynamics and Control department: DLR-VSDC/VDCWorkbench. The library is tested with Dymola 2025x Refresh 1 (64-bit Windows) and also works in OpenModelica v1.25.0 (64-bit Windows) to increase the potential user community for academic projects.

This publication is structured as follows. First, we will discuss the structure of the library with its control modules and the multi-physical modeling of the components. We then describe two concepts for the integration of vehicle dynamics control following a precomputed time-independent parametric path.

2 VDC Workbench Structure

This chapter presents the structure of the *VDCWorkbench* library. Figure 1 shows the schematic structure of the library which was derived and extended from the IEEE VTS Motor Vehicle Challenge 2023 [2]. The library has four types of components: i) vehicle dynamic and actuator models; ii) energy storage models; iii) vehicle control algorithms and iv) energy management algorithms (EMA).

The reference vehicle for the library is an adapted version of the DLR ROboMObil ([3] [4] [5] [6]), which is configured with an simplified drivetrain and a hybrid energy storage system (fuel cell & hydrogen tank and battery). The vehicle has two in-wheel electric motors installed in the rear axle (τ_{RL}, τ_{RR}), one central front motor (τ_F), and a front steer-by-wire actuation (δ). Within the vehicle control block different vehicle dynamics control algorithms are implemented as descripted later in Chapter 3. Some of these vehicle control algorithms can enhance energy efficiency of the vehicle by enabling energy recuperation in both front and rear axle [7] and also decreasing tire slip losses [8]. The in-wheel motors can improve motion control of the vehicle by extending the maximum lateral acceleration [9] and decreases response of inner (yaw-rate) control loops [2]. Additionally, the energy management algorithm (EMA), as developed in the IEEE VTS Motor Challange 2023 [2], sets the control variables for optimizing the energy consumption of the powertrain.

These normalized control variables of the EMA have the following meaning

- $\alpha_{AD} \in [0,1]$ the axle torque distribution ratio between front ($\alpha_{AD} = 0$) and rear axle ($\alpha_{AD} = 1$)
- $\alpha_{TV} \in [0,1]$ the torque vectoring ratio between rear left ($\alpha_{TV} = 0$) and rear right motors ($\alpha_{TV} = 1$)
- $\alpha_v \in [0,1]$ velocity derating factor,
- $\alpha_{FC} \in [0,1]$ the normalized fuel cell current,

For further details on the EMA, please refer to [2]. Several EMA strategies have been developed for this vehicle configuration, ranging from rule-based algorithms, machine learning and optimal energy management (see Ranking of the competition).

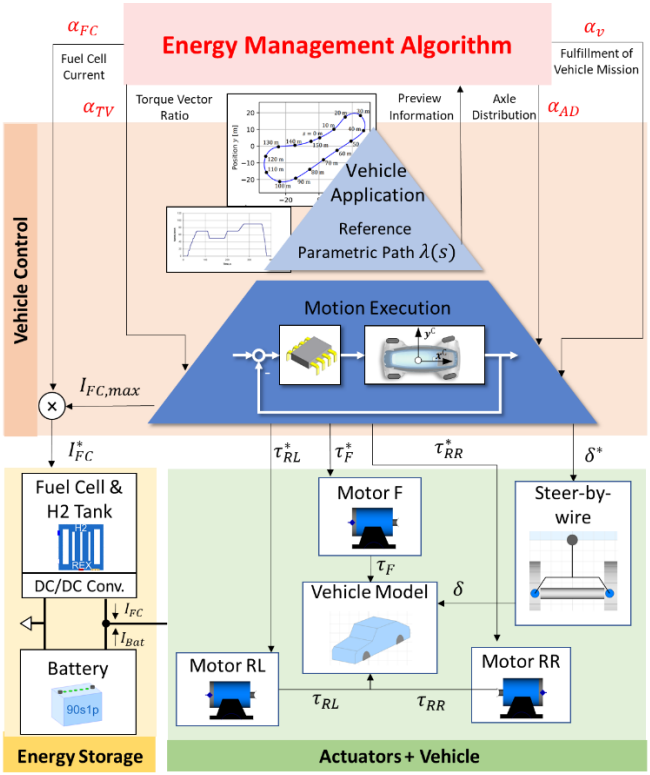

Figure 1. Schematic Structure of the VDCWorkbench Library

2.1 Overall Library Setup and Usage

Figure 2 provides an overview of the sub-packages available in the *VDCWorkbench*. In the `VehicleComponents` package, there is a sub-package for the mechanical structure of the `chassis` (Vehicle Model & Steer-by-Wire Model in Figure 1) based on the PlanarMechanics Library [10] [11].

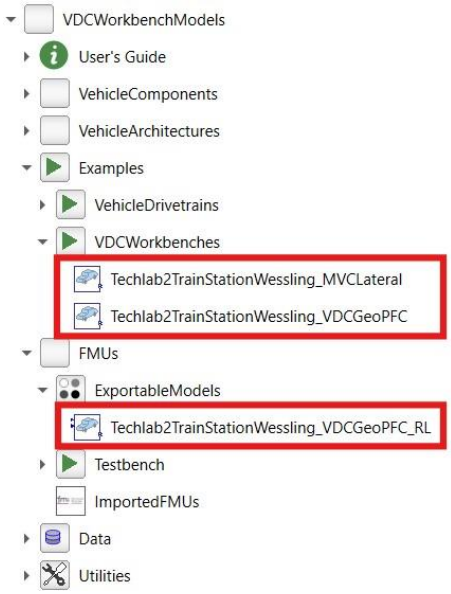

Figure 2. Architecture of the VDCWorkbench Library

The `Powertrain` sub-package contains firstly a model of a quasi-stationary Permanent Magnet Synchronous Machine (PMSM) with an approximated control in the d/q coordinate system. Secondly, a table-based first-order (RC) equivalent circuit battery model with a cell aging model that models the capacity loss over the cell lifetime as a function of the number of charging and discharging cycles, current load and temperature. The third component is a functional quasi-stationary model of a fuel cell with tank. In addition to the vehicle dynamic controllers, which are discussed in detail in Chapter 3, the last sub-package `Controllers` also contains a base class for energy management and the implementation of the baseline energy management strategy as described in Chapter IV.D in [2].

In the sub-package `Examples.VehicleDrivetrains` there are various test configurations to configure the component models with each other to create a multi-physical vehicle and thus build your own vehicle architecture. The examples contained here in `VariantsVehicleDrivetrains` range from a simple vehicle with only one centrally arranged PMSM with differential to a vehicle with four in-wheel hub motors. To test these vehicle configurations, various driving maneuvers are provided. The following two sub-packages `Examples.VDCWorkbenches` and `FMUs` contain complete vehicle models with the baseline energy management algorithm. In addition, there are driving dynamics controllers including test scenarios for experimental investigation or for export to AI training environments. The sub-package `Data` includes all the parameterizations used for the components and controllers of our simplified RObOMObil vehicle model [3]. This is intended to ensure that the models are consistently parameterized and represent a blueprint for your own vehicle configurations. In addition to the bus definitions, which are based on the VehicleInterfaces Library, the last sub-package `Utilities` contains various auxiliary models, such as a sensor model for determining the vehicle dynamics variables required for the controllers.

In order to use our library and simulate the examples, the user must clone the GIT repositories VehicleInterfaces (tested release V2.0.1) and PlanarMechanics (tested release V1.6.0) locally and load them in the Modelica simulator.

2.2 Vehicle Workbench Configuration

In this section, we provide more details about the main model of the *VDCWorkbench* library. The structure of the overall simulation model with the individual building blocks, as shown in Figure 1, is implemented in the model `VDCWorkbench2025_Model` of the sub-package `Examples.VDCWorkbenches` (see Figure 3). The color-coded boxes corresponding to the subcomponents in the schematic sketch. All data relevant for the simulation is stored in the record `data`. The controller block is implemented as replaceable, which we will instantiate, explain and examine in Chapter 3 with various vehicle controllers. The `vehicle`, `drivetrain`, `powerSource` and `baselineEMA` blocks are each taken from the parameterized models of the `VehicleComponent` sub-package.

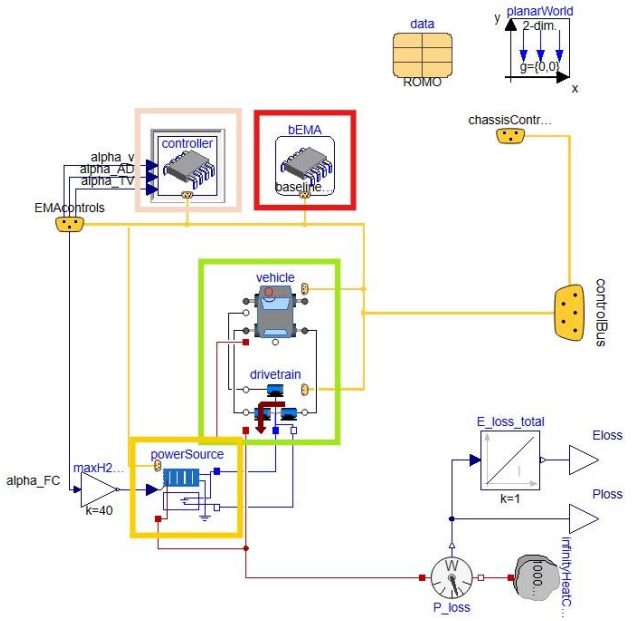

Figure 3. Structure of vehicle components and controllers

2.3 Test Scenario Generation

In order to be able to test our driving dynamics controllers in different scenarios, it is necessary to provide the `controller` block with a parametric path description of the test scenarios. This is defined as a time-independent vehicle movement request along a flat geometric path. For this purpose, we have developed an interactive path planning tool with which parametric paths, subject to constraints, can be generated. This is not planned to be part of the *VDCWorkbench* repository but we are open for inquiries, both for commercial and academic use. Based on an interface to Google Maps (expendable to other map systems such as Here MAPS or Open Street Maps), the reference vehicle path can be created via point-and-click and numerically optimized within the lane boundaries. An example of this is shown here for a section of a path around a roundabout on the route from the DLR site in Oberpfaffenhofen to the next railroad station in Wessling.

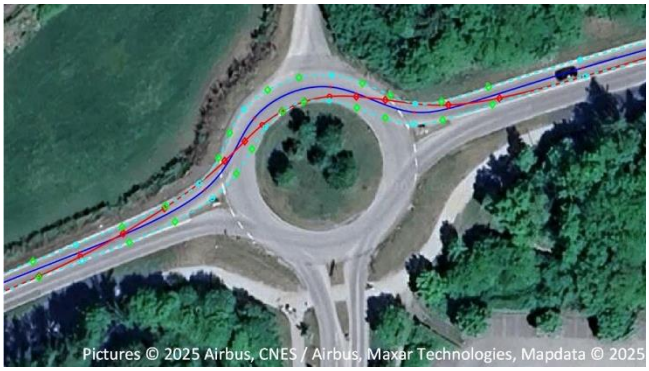

Figure 4. Interactive path planning GUI with boarders (green), unoptimized path (blue) and optimized path (red)

As can be seen in Figure 4, the geometric path is described as a two-dimensional polynomial (blue) with its interpolation points (small red dots), that are calculated under boundary conditions for the start and end points. Additionally, an optimization of the path (red) based on energy-optimal criteria with constraints, such as compliance with the road boundary (green), is given [12]. All variables are stored in the path description function $\boldsymbol{\lambda}(s) \in \mathbb{R}^5$, which depends on the path arc length s.

3 Vehicle Dynamics Control

The library also includes two baseline vehicle dynamics controllers designed to regulate both the lateral path and longitudinal velocity of a vehicle. These controllers serve as reference implementations that can be used out of the box or extended with more advanced control strategies, including machine learning methods.

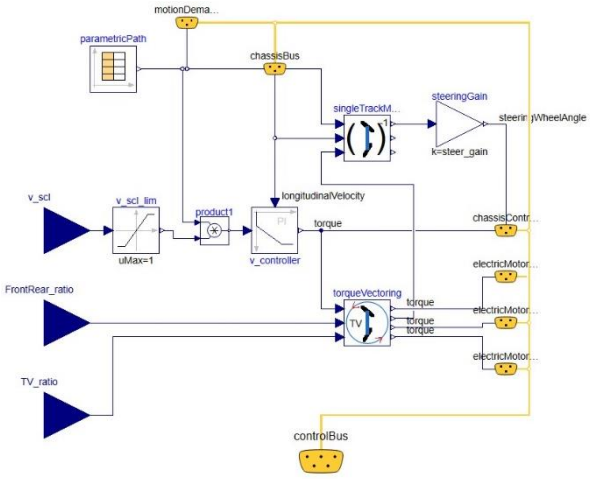

Figure 5. Baseline lateral and speed controller

The first controller is an open-loop lateral controller based on the static inversion of a single-track vehicle model (cf. Figure 5). It calculates the required steering angle to follow a predefined path using the kinematic properties of the vehicle. This is combined with a PI (Proportional-Integral) speed controller, referred to as `v_controller`, which regulates the longitudinal velocity of the vehicle. This modular structure allows the user to separately tune lateral tracking and velocity control loops. Further details can be found in [2].

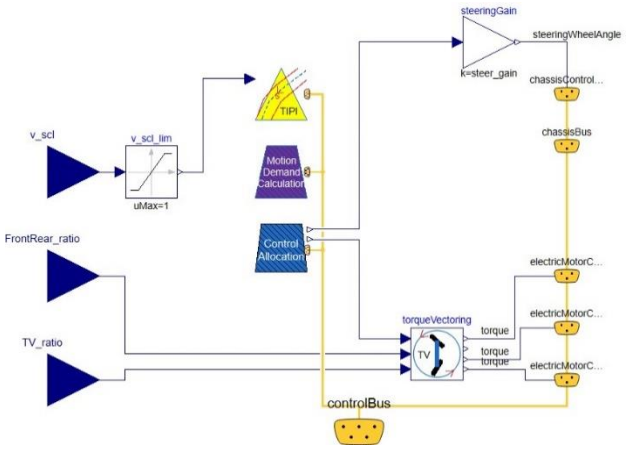

Figure 6. Geometric path following control

The second controller implements a closed-loop geometric path-following strategy (GeoPFC, cf. Figure 6). It relies on a state-dependent computation of the control input, which is then mapped to physical actuator commands through an optimization-based control allocation procedure. This approach allows the controller to adjust the vehicle's motion, depending on its current state with respect to a reference path (e.g., lateral deviation, heading error). For more information, refer to [5] [13].

Example: In Figure 7 we show the lateral and longitudinal deviation of the close-loop controller for our test scenario from Chapter 2.3. While the longitudinal error is minimized very well, particularly in dynamic maneuvers such as the roundabout in the section $s = [900 - 1200]$m there are larger deviations in the lateral error. These can be explained by the very simple control allocation approach, which does not take vehicle and actuator dynamics into account, and the pure front axle steering.

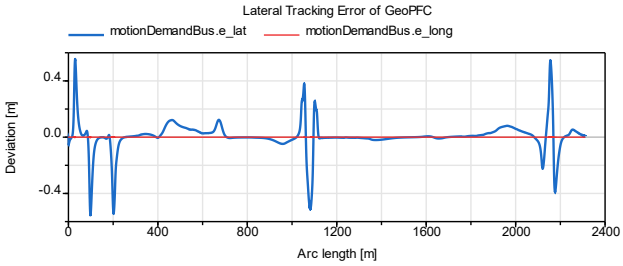

Figure 7. Deviation of controller tracking error

Figure 8 shows the results of the `Control Allocation` and `TorqueVectoring`, including the torque allocated to the traction motors and the steering angle.

DOI 10.3384/ecp218585

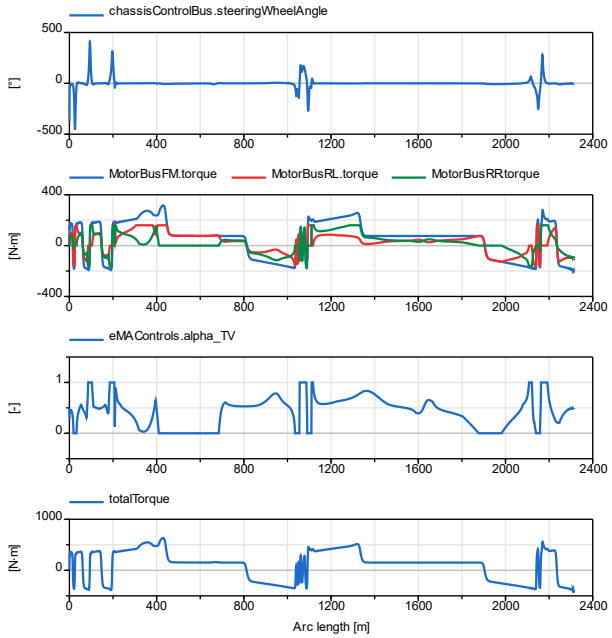

Figure 8. GeoPFC controller actuator demand values

These baseline controllers are designed to be compatible with residual reinforcement learning (rRL) frameworks. In this paradigm, the baseline controller is augmented with a learned agent that contributes an additional control input (red boxes in Figure 9). This residual term allows for performance improvement while preserving the interpretability and domain knowledge of the model-based controller [14] [15].

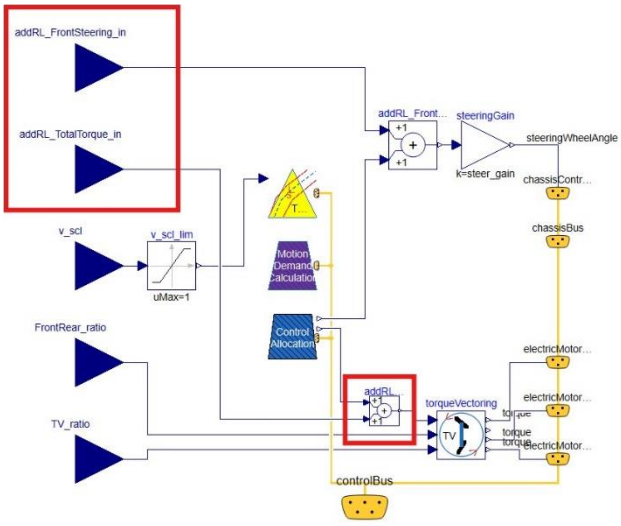

Figure 9. GeoPFC with additional RL agent inputs

4 Summary & Outlook

This work introduces a new Modelica library (*VDCWorkbench*) for simulation of vehicle dynamics and control. It supports developing, testing, and validating control algorithms in hybrid electric vehicles based on the DLR ROboMObil prototype vehicle. The library offers both open-loop and closed-loop vehicle dynamics controllers along a parametric path,. Energy management functions that make use of the multi-physical modeling approach can enhance the control strategy and optimize vehicle energy efficiency. A baseline policy EMA is included, and more sophisticated strategies can be added. *VDCWorkbench* library will be released open source in the DLR VSDC GitHub repository by September 2025, making it broadly accessible for all kind of research applications. It is planned to add further controllers, both for vehicle dynamics and energy management, as well as vehicle models to the library and thus provide the community with further application examples.

Abstract

This paper proposes a new paradigm of the Embodied Cyber-Physical System (Embodied CPS, ECPS) to address the issues of the disconnection between physical laws and intelligent decision-making and the insufficient interaction with dynamic environments in the modeling and simulation of traditional CPS. ECPS achieves unified modeling of physical laws and autonomous decision-making through the "perception-decision-action" closed loop. To verify ECPS, an embodied space framework based on Modelica/MWorks is designed. Through three major technological innovations: constructing an embodied domain modeling specification and embedding the Navier-Stokes equations into the training of the policy network; expanding the syntax and semantics of Modelica, encapsulating physical constraint reinforcement learning components, and establishing a gradient interaction protocol between the Physics-Informed Neural Network (PINN) and Modelica equations; building a digital twin-hardware-in-the-loop co-simulation platform based on the FMI/SSP protocol to establish a collaborative verification link between high-precision physical simulation and real-time decision-making. Taking the Unmanned Surface Vehicle (USV) as the carrier, the full-process method from dynamic modeling, reinforcement learning strategy training to virtual-real environment co-simulation is demonstrated. Experiments verify the effectiveness of this framework in achieving the closed-loop coupling of physical simulation and intelligent decision-making under complex sea conditions, providing a methodological foundation for interpretable modeling and verifiable simulation in the development of embodied intelligence.

Keywords: embodied intelligence, embodied domain, embodied spatial, physical information neural network

1 Introduction

1.1 Background

With the increasing demand for the adaptability of autonomous systems in dynamic physical environments, Cyber-Physical Systems (CPS) [1] are gradually evolving towards Embodied Cyber-Physical Systems (Embodied CPS, ECPS). Its core feature lies in that intelligent agents need to conduct real-time interactions with the physical environment through the "perception-decision-action" closed loop [2]. In the traditional CPS framework, physical models and intelligent algorithms are often designed in a segmented way, resulting in bottlenecks such as the lack of compliance with physical laws and insufficient dynamic interaction modeling when intelligent agents are deployed in real environments. For example, in scenarios where dynamic physical constraints (such as the torque limitations of robotic arm joints and the dynamic boundaries of mobile robots) coexist with high-dimensional environmental uncertainties (such as the random distribution of obstacles and multimodal disturbances), existing methods find it difficult to achieve the deep integration of physical laws, environmental interactions, and autonomous decision-making. How to construct a simulation system with the ternary coupling of "physics-information-environment" [3], and organically unify the strong constraints of physical laws with the data-driven environmental adaptability has become the core challenge in the development of embodied intelligence systems.

1.2 Related Work

In terms of ECPS simulation methods, current research presents two typical paths: One is based on the Modelica multi-domain modeling tool (such as MWORKS), which accurately describes the constitutive relations of physical

systems through acausal equations. However, in terms of the deep integration of the intelligent decision-making layer and the deep learning framework, it is still limited by the difficult problem of collaborative solving of discrete-continuous systems. The other is to adopt the Physics-Informed Neural Network (PINN) [4]. By embedding physical laws such as the Navier-Stokes equations into the neural network training process through the residual constraints of differential equations, it demonstrates the advantage of following physical constraints in embodied intelligence scenarios such as fluid mechanics prediction and robotic motion control. It is worth noting that recent research attempts to integrate PINN with Modelica [5], and realizes the co-simulation of the neural network model and the multi-domain physical model through the Functional Mock-up Interface (FMI) standard. However, there is still a lack of standardized protocols in key technical aspects such as the gradient backpropagation mechanism and the alignment of spatio-temporal scales between the two. Overall, the development of current ECPS simulation tools is still in the exploratory stage. Existing research generally faces three major bottlenecks: the lack of a semantic-level integration mechanism between physical equations and data-driven models; the insufficient standardization of the protocol stack for real-time interaction between heterogeneous simulation platforms; and the contradiction between the efficiency and interpretability of the representation of the embodied space in a high-dimensional dynamic environment.

1.3 Challenges

The core challenges of ECPS simulation are as follows:
It is difficult to couple multi domain models: the traditional Modelica standard library lacks a specific agent interface, and cannot uniformly describe the real-time interaction between physical equations (such as ship dynamics) and intelligent algorithms (such as DRL) [6];
Physical constraints are separated from intelligent decision-making: data-driven methods are easy to generate actions that violate physical laws (such as exceeding the safety threshold of roll angle), while traditional control theory is difficult to deal with high-dimensional environmental uncertainty; Lack of virtual and real collaborative verification system: the existing tool chain (such as Gazebo+ROS) [7] has a gap between the physical simulation accuracy (microsecond step size) and the efficiency of intelligent algorithm (millisecond response), and lacks standardized interface protocol.

1.4 Proposed Approach

In response to the above challenges, this paper proposes an ECPS simulation framework based on the embodied space, and achieves methodological breakthroughs through a three-level technical path. With the modeling specification of the embodied domain as the technical foundation, this framework expands the Modelica language to define standardized interaction interfaces (such as sensors/actuators) and physical constraint description grammars, and supports the semantic-level integration of complex physical models such as the six-degree-of-freedom dynamics of ships and reinforcement learning strategies. Relying on the embodied space architecture, a collaborative simulation link of "physical domain (high-precision fluid mechanics equations) - information domain (DRL decision-making) - embodied domain (PINN gradient interaction)" is constructed. The constraints of the Navier-Stokes equations are embedded in the strategy training through the PINN-Modelica protocol to ensure that intelligent decisions strictly follow the physical boundaries. Based on the FMI/SSP protocol, multi-time scale scheduling (1ms-level physical simulation/10ms-level decision-making) is realized. In combination with ROS/Unity, the co-verification of virtual and real environments is achieved, providing a methodological paradigm for the engineering of ECPS in dynamic environments.

2 Methodology

2.1 Modelica Modeling Specification for the Embodied Domain

To meet the needs of intelligent design for modern autonomous systems and address the issues of insufficient intelligence in traditional cyber-physical integration systems and weak theoretical constraints of intelligent algorithms, this paper constructs a three-tier technical system for the Modelica modeling specification of the embodied domain: forming the embodied domain specification based on the extensible syntax and semantics of Modelica; constructing a verification protocol stack for virtual and real systems based on API interfaces, the FMI standard, and the SSP protocol; and building a physical-intelligence integration engine based on the PINN-Modelica gradient interaction protocol. This specification incorporates intelligent considerations on the basis of the physical domain and the information domain to achieve the unification of physical laws and autonomous decision-making. On the one hand, by utilizing the extensible syntax and semantics of Modelica, a general modeling specification and architecture for embodied entities are formed. The model components of different objects are standardized, and generalized models of general autonomous systems such as autonomous vehicles and unmanned surface vehicles are constructed. This provides theoretical constraint boundaries for the embodied data training of various unmanned systems and scenario working conditions, and is verified in real time through the physics-informed neural network, breaking through the collaborative bottleneck between semantic ambiguity and physical compliance. On the other hand, based on the PINN-DRL architecture, physical laws such as the Navier-Stokes equations are embedded in the neural network training.

DOI 10.3384/ecp218591

Through the regularization constraints of physical equations, the model not only fits the data but also follows physical laws, thereby improving generalization ability, data efficiency, and interpretability of time decision-making in dynamic environment.

2.2 Extension Specification for Modelica Embodied Domains

Traditional engineering often faces problems such as poor compatibility of heterogeneous interface protocols, discretization of physical constraint description, and difficulty in cross domain simulation coupling, resulting in low efficiency of agent modeling and limited simulation credibility. Although the Modelica standard library can solve the unified modeling and simulation problems in many fields, such as Electromechanical, hydraulic and thermal control, it lacks standardized support for perception action closed-loop, real-time physical constraints and intelligent strategy fusion, and cannot realize the deep coupling between the agent and the physical environment. It is difficult to cope with the rapid development of embodied intelligence in the fields of robots, unmanned systems and so on.

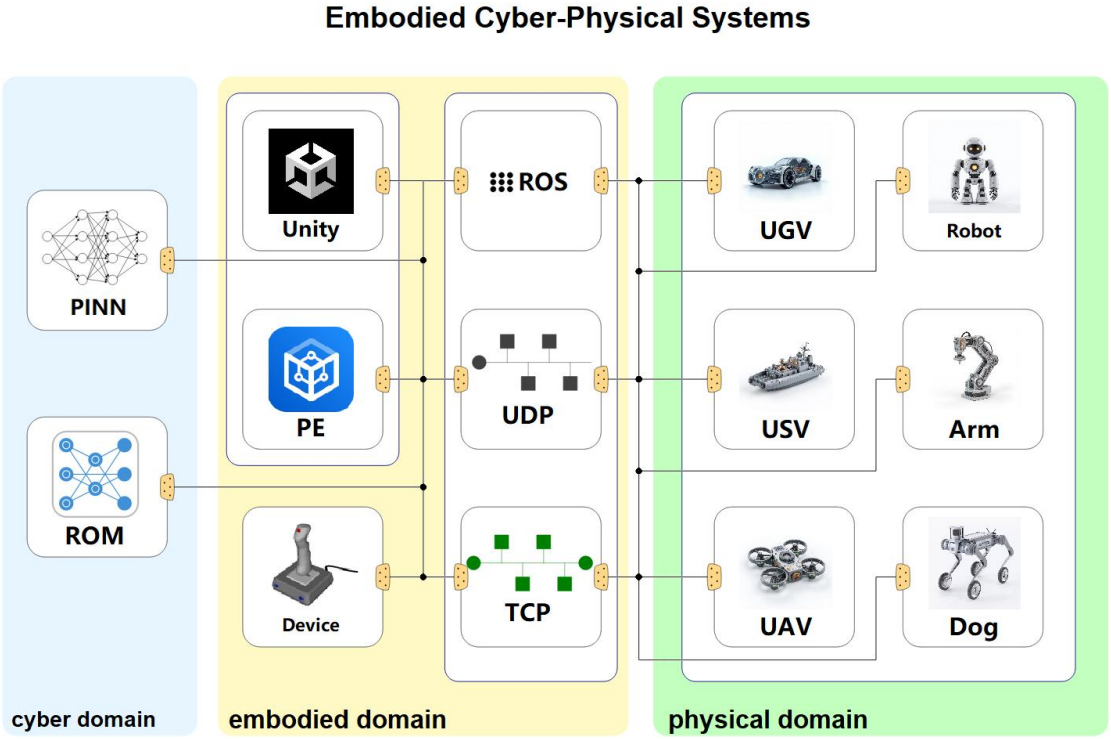

Figure 1. Embodied Cyber-Physical Systems.

The embodied cyber-physical system consists of three parts: the physical domain, the information domain, and the embodied domain. The physical domain includes various embodied intelligent agents, such as autonomous vehicles, unmanned ships, drones, robots, robotic arms, robotic dogs, and so on. Embodied intelligent agents satisfy the concept of Modelica replaceable classes and can switch autonomously according to demand. The information domain includes reinforcement learning strategies and neural network reductions, achieving closed-loop optimization of physical laws and autonomous decision-making. The embodied domain is responsible for the environmental interaction capabilities of the entire embodied space, including communication, 3D visual scenes, external devices, etc. The various parts are connected through the embodiment domain language extension, achieving a technical closed loop of "perception-decision-action".

Therefore, in order to support the formal modeling of embodied agents and improve the modeling ability of complex systems, it has three core functional modules: standardized interaction framework: defining the base class and open interface of embodied agents, unifying the sensor actuator communication standard and reducing the amount of hardware adaptation code. Integration of physical intelligence: innovative introduction of PINN hybrid modeling syntax and physical constraint reinforcement learning library to optimize AI strategy in strict accordance with dynamic laws. Multi domain collaborative support: define Modelica general standard interface based on API interface or communication protocol to realize the coupling simulation of control logic, physical model and environmental factors under a unified time base.

Specifically, this specification extends the following syntax for Modelica language:

- add the embodied keyword to support the declaration of embodied agents.

The traditional Modelica modeling is centered on physical entities and lacks the explicit expression of the cognitive behavioral characteristics of agents. The embodied keyword is realized through the reconstruction of the syntax layer:

1. Ontology mapping: forcibly declare the interfaces of perceptual input and action output, so that the code structure is strictly isomorphic with the perceptual action cycle of embodied intelligence.
2. Quantification of cognitive delay: by using cognitivedelay and other built-in parameters, the biologically inspired nerve conduction delay (about 50-200ms) is incorporated into the dynamic equation to avoid the distortion problem that the control delay is simplified to the ideal zero delay in the traditional modeling.
3. Constraint prefix declaration: physical constraints are required to be declared through constraint blocks at the agent definition stage to ensure that subsequent control strategy development naturally meets the physical feasibility.

The extension syntax is as follows:

Listing 1. Embodied keyword

```
embodied <AgentName>
  extends <BaseClassName>;
  parameter <Type> <paramName> =
<value> "Description";
  input <Type> <sensorName>[N] ";
  output <Type> <actuatorName>[M];
  replaceable
<PolicyPackage>.<Algorithm> policy
    constrainedby EmbodiedPolicyInterface;
  constraint <ConstraintType>
<constraintName>
equation
  <equation>;
end <AgentName>;
```

- physical constraint fusion modeling, introducing the physical constraint description equation, allowing the PINN prediction results to be embedded in the Modelica model.

Traditional physical modeling and data-driven modeling have been separated for a long time, mainly in the following aspects:

1. White box model dilemma: pure physical equations are difficult to accurately describe complex nonlinear phenomena (such as turbulence and material fatigue), and the error of traditional Navier Stokes equations in a ship motion case is significant.
2. Black box model risk: the pure neural network prediction may violate the law of conservation of physics, and the non-conservation of energy in the trajectory prediction of a manipulator leads to simulation collapse.

The differential equation level fusion of physical equations and neural networks is realized through the PINN_interface syntax. The extended syntax includes:

Listing 2. PINN_interface

```
equation
 <OutputVariable> = PINN_Interface(
   inputs = {<InputVariable1>,
<InputVariable2>, ...},
   modelFile = "pinn_model.onnx")
  <PhysicalVariable> = <PhysicsEquation>
+ PINN_CorrectionTerm ;
```

- physical constraint Reinforcement Learning Library. Develop physical component library and provide DRL algorithm with physical residual regularization (such as PPO Physics). Its loss function is defined as:

$$L = \alpha \cdot L_{DRL} + \beta \cdot \|N(u) - PDE(U)\|^2 \quad (1)$$

Define DRL algorithm class with physical constraints. Take PPO physics algorithm as an example:

Listing 3. PPO physics

```
package PhysicsRL
model PPO_Physics
   extends DRL.BasePPO;
   parameter Real lambda_physics = 0.5 ;
  protected
   function compute_loss
     input Real[:,:] trajectories;
     input PhysicalModel physics_model;
     output Real total_loss;
   algorithm
     Real policy_loss :=
compute_policy_loss(trajectories);
     Real value_loss :=
compute_value_loss(trajectories);
     Real physics_residual :=
physics_model.evaluate_residual(
       states = trajectories[:,1:state_dim],
       actions =
trajectories[:,state_dim+1:end]);
     total_loss := policy_loss + value_loss +
       lambda_physics * physics_residual^2;
   end compute_loss;
  end PPO_Physics;
end PhysicsRL;
```

The specification provides the underlying support for industrial 4.0 core scenarios such as digital twins and agent group collaboration, and promotes the leap of embodied intelligence from theoretical verification to engineering implementation.

The embodied space architecture based on Modelica mainly includes four core modules:

- Physical domain modeling layer: build a 6-DOF ship dynamics model based on Modelica/MultiBody, integrate wave disturbance

DOI 10.3384/ecp218591

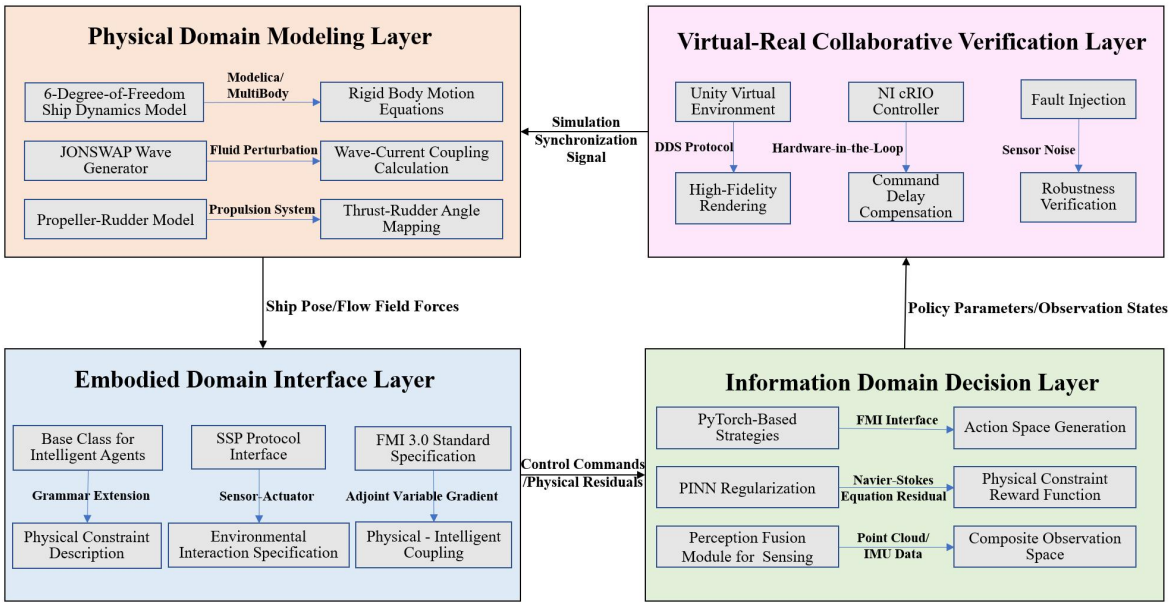

Figure 2. Embodied space architecture diagram based on Modelica.

(JONSWAP spectrum generator) and propulsion system (propeller actuator joint model);

- Embodied domain interface layer: extend Modelica language to define the embodied agent base class, support sensor actuator interface (SSP protocol) and physical constraint description syntax;
- Information domain decision-making layer: call the DRL policy network implemented by PyTorch through Python Modelica bidirectional interface (FMI standard) to dynamically generate control instructions;
- Virtual and real collaborative verification layer: build a high fidelity marine virtual environment based on unity engine, and realize millisecond data synchronization with Modelica simulation through DDS (data distribution service).

2.3 Modelica Embodied Space Architecture

2.3.1 Technical route

Traditional engineering often faces problems such as The main design idea of the embodied space based on Modelica is to achieve the two-way cognitive coupling between intelligent agents and the dynamic environment through the physical-information fusion mechanism, forming a three-layer architecture of "physical entity-digital twin-embodied intelligence". For different physical entities of autonomous systems, a system model and control algorithm are constructed based on the multi-disciplinary unified modeling software MWORKS.Sysplorer to achieve a control closed loop between the system model and the control algorithm. A visualization environment for the autonomous system is built based on the Unity 3D virtual engine to form a digital prototype of the autonomous system. Based on the virtual-real collaborative verification protocol stack of API interfaces, the SSP protocol, and the FMI standard, a unified solution architecture for physical models and autonomous decision-making algorithms is realized, breaking down the barriers between the virtual world and the physical world, expanding the boundary conditions of the digital prototype, and enhancing the ability of the physical entities of the autonomous system to learn independently and adapt to complex environments, thus forming a digital twin in the embodied space. Based on the PINN-Modelica gradient interaction protocol, an embodied intelligence training environment is added on the basis of the digital twin of the autonomous system, integrating key technologies such as perception fusion and decision-making reasoning to improve the intelligent characteristics of the embodied entity. The overall technical roadmap and framework diagram of the embodied space are as shown in the figure 2.

2.3.2 Implementation framework

The embodied space architecture based on Modelica mainly includes four core modules, as shown in the figure 3:

- Physical domain modeling layer: build a 6-DOF ship dynamics model based on Modelica/MultiBody, integrate wave disturbance (JONSWAP spectrum generator) and propulsion system (propeller actuator joint model);
- Embodied domain interface layer: extend Modelica language to define the embodied agent base class, support sensor actuator interface (SSP protocol) and physical constraint description syntax;

- Information domain decision-making layer: call the DRL policy network implemented by PyTorch through Python Modelica bidirectional interface (FMI standard) to dynamically generate control instructions;
- Virtual and real collaborative verification layer: build a high fidelity marine virtual environment based on unity engine, and realize millisecond data synchronization with Modelica simulation through DDS (data distribution service).

environment and physical deployment environment. For the Modelica model of the unmanned ship, a general theoretical model of the unmanned ship is formed based on the physical modeling system platform, and a physical simulation interface is formed based on the standard API interface or communication protocol to interact with the three-dimensional visual environment; For the intelligent algorithm construction and data training scenario, based on the virtual training environment and the universal model of unmanned ship,

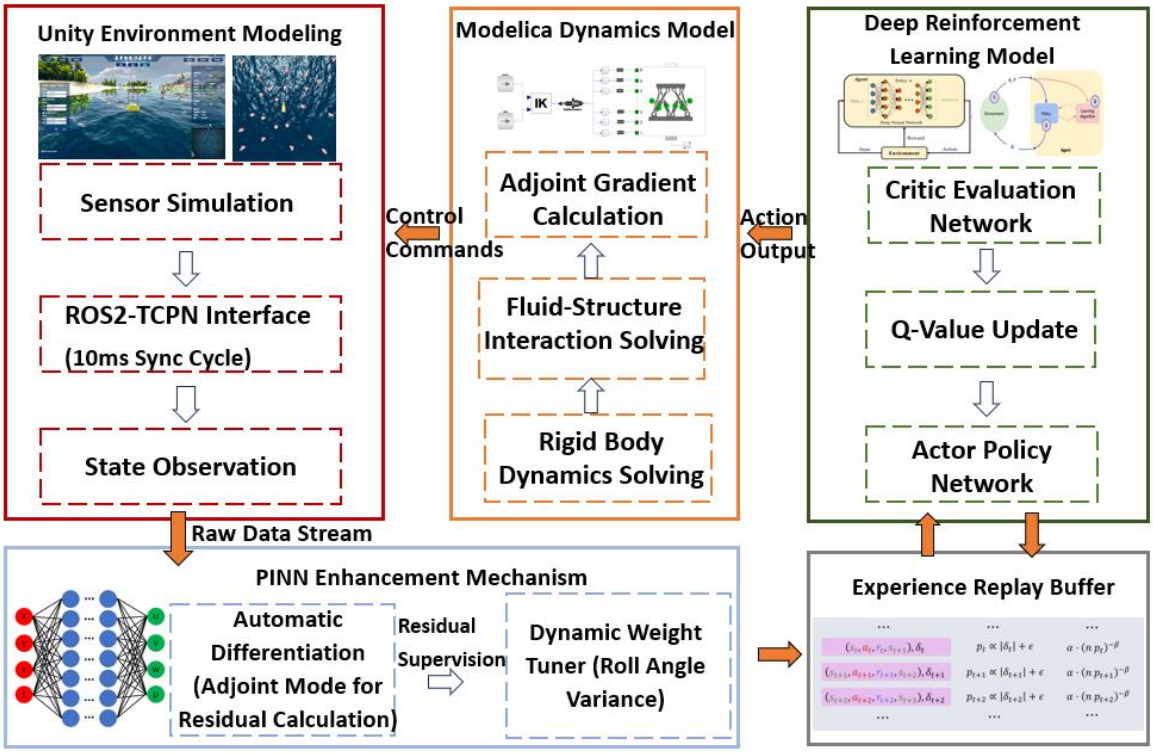

Figure 3. PINN enhanced DRL framework.

2.3.3 Virtual-Physical Co-Simulation Protocol Stack

The virtual real collaborative verification protocol stack of embodied space is the core module to realize the system integration and co-simulation of embodied information physical system. On the one hand, the virtual real collaborative verification protocol stack can organically integrate the digital sample ship and intelligent algorithm to form an intelligent ship model for virtual simulation verification; On the other hand, the virtual and real collaborative verification protocol can complete the data interaction between the virtual model and the physical ship, forming the virtual and real collaborative verification of unmanned ship.

1. Cross-Platform Interface Design.

The interface design of embodied information physical system needs to consider three levels of platform data interaction: physical modeling system, virtual training

the virtual environment interface is formed for the physical simulation interface, and the theoretical calculation is introduced as the constraint boundary in the three-dimensional visual environment and the large data sample training environment, so as to form a decision-making strategy model suitable for the actual unmanned ship. For the physical deployment environment of unmanned ship, the strategy deployment interface is constructed, and the algorithm model of rapid deployment training is completed, so as to realize the virtual real combination of unmanned ship and build a complete unmanned ship body space.

Physical simulation interface: a collaborative simulation interface for building physical models based on the MWORKS platform API interface or the general communication protocol standard. By analyzing the differential algebraic equation (DAE) generated by Modelica multi domain unified modeling language, the 6-DOF model of the unmanned ship can realize data

DOI 10.3384/ecp218591

interaction on different platforms, and finally realize the decoupling deployment of the physical simulation unit. Through the topology description file based on the physical simulation interface, the port connection relationship and parameter metadata are automatically maintained, which significantly reduces the repeated modeling cost of data collaboration.

Virtual environment interface: Based on the ROS2 distributed communication framework, develop customized TCPN (timed colored Petri net) plug-in to build a deterministic data channel. The high fidelity 3D visualization model is embedded in unity virtual environment, and the status synchronization with Physical model of unmanned ship is realized through ROS2-TCPN middleware. A 10ms fixed cycle hard real-time communication link is established.

Policy deployment interface: build AI policy deployment interface based on ONNX (Open Neural Network Exchange) open format. After compatibility check and optimization, the deep reinforcement learning strategy network trained by PyTorch/TensorFlow is transformed into a lightweight ONNX model. By integrating the ONNX algorithm engine, the end-to-end reasoning strategy deployment is realized on embedded controllers (such as NVIDIA Jetson AgX Xavier), which meets the real-time control requirements of edge devices under complex conditions.

2. Multi-Temporal Scheduling Mechanism.

The interface design of embodied information physical system under different platform levels and scenarios, the interface scheduling frequency is different, so it is necessary to add multi time scale scheduling module to the virtual and real collaborative verification protocol stack, including hard real-time layer, soft real-time layer and asynchronous event layer.

Hard real-time layer (1ms level): the hard real-time layer refers to building a real-time unmanned ship system model based on Modelica in the physical modeling system platform, and using the DAE (Differential Algebraic Equation) implicit solution algorithm to deal with the coupling effect between the six degree of freedom motion of the unmanned ship rigid body and fluid viscosity. By introducing variable step size integration algorithm or fixed step size integration algorithm, the real-time simulation control is realized on FPGA hardware accelerator card, which provides the bottom constraint boundary for the UAV body space frame.

Soft real-time layer (10ms level): soft real-time layer refers to the realization of data interaction between virtual environment and unmanned ship digital model based on virtual environment interface when intelligent strategy algorithm reasoning and 3D Virtual Environment Rendering of unmanned ship are carried out in virtual environment platform. The soft real-time layer has no real-time requirements for the embodied space frame, and its overall delay is stably controlled within 10ms.

Asynchronous event layer: when unmanned ships handle discrete events such as obstacle generation and task reset, it is necessary to design event driven architecture (EDA) to design discrete event processing mechanism to realize decoupling scheduling of aperiodic operations such as obstacle generation and task reset.

3 Case Study: Intelligent USV

3.1 Case Architecture Design

The embodied domain, as an intermediary layer between the physical domain and the information domain, realizes the deep integration of physical laws and information algorithms through the dynamic perception and adaptive decision - making of embodied agents. The experimental case selects the Embodied Space Simulation Platform on MoHub (https://mohub.net/). This platform is built based on MWORKS and is a comprehensive artificial intelligence platform focusing on embodied space modeling, unmanned system modeling, and simulation testing. Through the integration of multiple spaces and the collaboration of modular engines, it achieves a full - link closed - loop of the physical domain - embodied domain - information domain.

In this case, the USV - 130 unmanned surface vehicle is taken as the research object. Aiming at its navigation and obstacle - avoidance problems during rescue and search operations under uncertain conditions, an embodied intelligence modeling and training framework based on the MWORKS platform and PINN is proposed. Through modeling, simulation, and experimental verification, PINN is used to provide kinematic and dynamic constraints that conform to physical laws for the obstacle - avoidance algorithm. The influence of three environmental factors, namely wind, waves, and currents, is considered, and the calculation of the corresponding disturbing forces and torques is added to the motion mathematical model to make the algorithm simulation more consistent with reality.

3.2 Implementation of Embodied Domain Modeling

In the modeling and simulation of unmanned surface vehicles, high - precision hydrodynamic modeling is a key challenge for achieving the "simulation - to - reality" transfer. Traditional fluid resistance prediction methods based on empirical formulas, due to simplified assumptions, struggle to accurately describe the nonlinear hydrodynamic behavior in complex environments. In this case, PINN (Physics - Informed Neural Network) is introduced. By integrating the Navier - Stokes equations with measured flow field data, a data - physics dual - driven fluid resistance prediction model is constructed. In the MoHub Embodied Space

Simulation Platform, this method has established a multi - scale hydrodynamic calculation framework. At the macroscopic level, the fluid motion control equations are embedded as soft constraints, and at the microscopic level, the data from the pressure sensors on the hull surface are used to optimize the network parameters. This hybrid modeling approach significantly improves the calculation accuracy of complex flow states, reduces the error in the hull resistance characteristics between the virtual and real environments. Moreover, by encoding the spatio - temporal coupling characteristics of the wind, wave, and current disturbance fields into the input dimensions of PINN, the real - time calculation of dynamic environmental disturbance forces is realized, providing a basis for the physically reliable training of motion control algorithms.

3.2.1 Physical Domain Modeling

USV130 is an intelligent unmanned surface vehicle specially designed for scientific research and education. It integrates multi-source sensing system and has intelligent control modules such as speed and heading locking cruise, autonomous return path planning and obstacle avoidance. The main structure of the equipment is made of glass fiber composite materials. The whole ship is 1.3m (L) × 0.64M (W). It is equipped with a dual water jet propulsion system to achieve mobile control. The technical parameters show that its navigation performance includes: 18 cm working draft, 4 m/s peak speed, and 5 m minimum radius of gyration. The propulsion system can support high-precision motion control in complex hydrological environment. As shown in the following figure 3.

Figure 3. Physical Image of USV130 Unmanned Submarine

USV130 is equipped with Ubuntu 20.04 operating system and ROS noetic robot framework, and the underlying motion control adopts PID algorithm. The driving system supports multimodal operation: it can be controlled by the physical remote-control device, the upper computer software and the handle linkage or executed by the autonomous command based on the algorithm. The communication system is equipped with a dedicated base station to achieve stable data transmission with an effective radius of 200 meters.

The physical parameters required to build the unmanned ship are as follows:

Table 1. USV130 partial physical parameter table.

physical parameter	
Hull mass	30kg
Total length	1.3m
Geometric center	0.45m
Total width	0.64m
Hull width	0.27m
Draft	0.18m

3.2.2 Physics-Information Modeling

In this case, a dynamic model based on MWORKS platform is constructed to describe the motion behavior of the unmanned ship under complex hydrodynamic conditions. The dynamic model framework is divided into three parts: dynamic modeling framework, dynamic formula framework and additional mass matrix Mv framework.

- Dynamic equation modeling: the three degree of freedom dynamic equation of the system includes longitudinal velocity, lateral velocity and yaw angular velocity. The specific expression is as follows.

$$Mv + C(v)\mathrm{v} + D(v)\mathrm{v} = \tau \quad (2)$$

Where, M is the mass matrix, $C(v)$ is the Coriolis force matrix, $D(v)$ is the resistance matrix, and τ is the control input generated by the water jet propulsion system.

- Adaptive backstepping controller:

1. Speed control: realize the stable control of longitudinal speed through feedback linearization, and introduce adaptive compensation term to eliminate the uncertainty of resistance.
2. Heading control: Lyapunov function is designed to ensure heading error convergence. The controller expression is as follows:

$$\tau_z = k_1 e_\psi + k_2 r \quad (3)$$

Where, e_ψ is heading error and r is yaw rate.

3. Adaptive parameter estimation.

The adaptive law is introduced to estimate the resistance coefficient and added mass online, and compensate the uncertain disturbance of the system in real time to ensure the robustness and stability of the control system.

4. Improvement of integrated PINN.

In order to further improve the ability of the model to follow the physical laws, the physical information neural network (PINN) can be combined with the unmanned ship dynamics model. The Navier Stokes equation is embedded into the neural network as a physical constraint, and the PINN interface is introduced into the Modelica model to modify the hydrodynamic term in the

DOI 10.3384/ecp218591

dynamic equation of the unmanned ship, so that the model can strictly follow the hydrodynamic law while learning the data.

The core of the modeling framework of the dynamic model is to integrate the physical parameters and dynamic characteristics of the unmanned ship. The dynamic equation takes the force and motion state of the hull as the core, and calculates the motion response of the unmanned ship through moment balance. The framework contains the following key inputs:

- physical parameters.

Mass: including the influence of load change on the inertial characteristics of the hull.

Geometric center (LCG): describes the longitudinal position of the center of gravity of the hull.

Drag coefficient (CD) and water density (ρ): affect the hydrodynamic characteristics of unmanned ships.

Hull size parameters: including length (L), draft (T), and hull width (Bhull).

- function and modeling of hydrodynamic coefficient.

Hydrodynamic coefficients (HC) are the key parameters connecting hydrodynamic characteristics and motion equations, and their accuracy directly affects the prediction ability of the simulation model. For the catamaran USV, the hydrodynamic coefficients are divided into linear and nonlinear categories: linear damping coefficient (such as) represents the viscous resistance at low speed; The nonlinear damping coefficient (such as) describes the resistance characteristics dominated by the square term of speed under high-speed conditions. In addition, the additional mass coefficient (such as) reflects the inertial effect of the surrounding fluid when the hull accelerates.

3.3 Embodied Domain Simulation Analysis

After constructing the physical model of the unmanned ship based on the MWORKS.Sysplorer platform and implementing the virtual-real collaborative verification protocol stack based on the ROS framework, by randomly setting routes and obstacles, multi-level and multi-scenario data simulation can be carried out within the embodied space. The simulation data can further improve the training samples, enabling the self-improvement and autonomous learning of the PINN algorithm.

Environmental factors are one of the main factors that separate the unmanned ship model from the actual unmanned ship. By setting dynamic environmental parameters in the virtual environment engine, the ROS framework can transform the perception of disturbance factors such as wind, waves, and currents, achieving the deep coupling between the additional disturbances of the dynamic environment and the physical model of the unmanned ship. This adds physical boundary constraints on the basis of the real embodied training environment. The figure 4 below shows the disturbances transmitted to the physical model of the unmanned ship through the ROS framework.

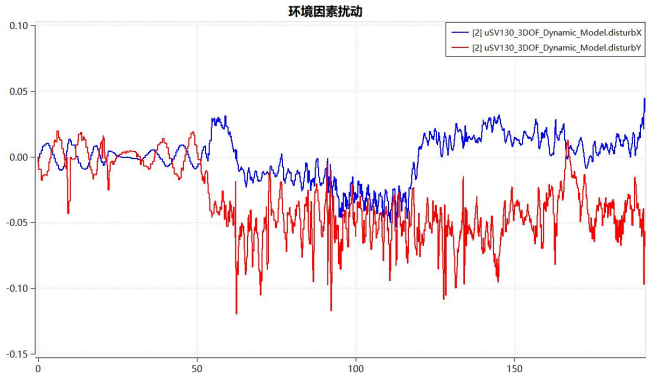

Figure 4. Dynamic Environmental Disturbances of the Unmanned Ship

After setting the route, the entire unmanned ship automatically locates its current position and the target route landmarks. It conducts navigation control by adopting the approach of global path planning and local obstacle avoidance, thus achieving the automatic navigation of the unmanned ship. After the simulation runs, the path changes of the unmanned ship in the dynamic environment can be observed, as shown in the figure 5 below.

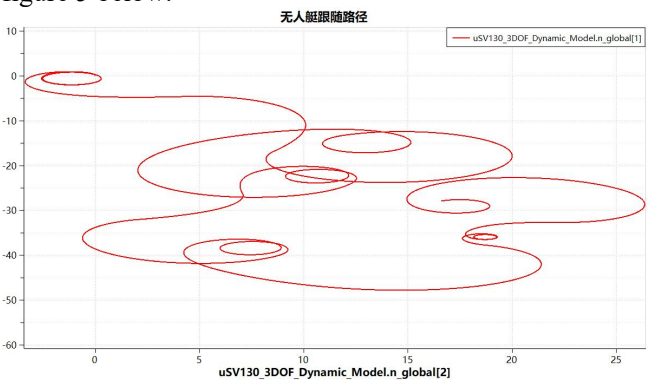

Figure 5. Response Path of the Unmanned Ship

3.4 Simulation Training in the Embodied Space

Traditional physical - based modeling methods have always been unable to clearly describe the hydrodynamic laws of the unmanned ship system. To achieve more accurate virtual - real collaborative verification, the Physics - Informed Neural Network (PINN) is introduced. It corrects the additional hydrodynamic effects in the unmanned ship system, further enhancing the model's ability to follow physical laws and adapt to dynamic environments, and ensuring the accuracy and reliability of the simulation results.

3.4.1 Hydrodynamic Laws

- Navier - Stokes Equation

The N-S equation, as the governing equation for describing the motion of viscous fluids, has its conservation form embedded in the loss function of the Physics - Informed Neural Network (PINN):

$$Residual = \frac{\partial u}{\partial t} + (u \cdot \nabla)u - v\nabla^2 u + \frac{1}{\rho}\nabla p \quad (4)$$

By forcing the prediction results of the neural network to minimize the equation residuals, it ensures that the flow field predictions (such as the flow velocity around the hull and the pressure distribution) conform to the principles of viscous fluid mechanics.

- Added Mass Effect

Based on potential flow theory, the inertial effect of the surrounding fluid when the hull accelerates is calculated as follows:

$$M_A = diag(X_{\dot{u}}, Y_{\dot{v}}, N_{\dot{r}}) \quad (5)$$

The added mass coefficients are determined by empirical formulas based on the hull's geometric parameters, reflecting the coupling characteristics of the hull shape on the fluid inertial response.

- Nonlinear Viscous Resistance Model

A resistance decomposition dominated by the velocity - squared term is adopted:

$$D_{(v)} = \begin{bmatrix} X_{u|u|}|u|u & 0 & 0 \\ 0 & Y_{v|v|}|v|v + Y_r r & N_v|v|v + N_r r \end{bmatrix} \quad (6)$$

The longitudinal resistance coefficient $(X\{u|u|\})$ is calibrated according to the wetted surface area of the hull and the Reynolds number, and the lateral/rotational damping coefficients $(Y\{v|v\}, N_r)$ are fitted from the ship model towing test data.

Coriolis - Centrifugal Force Coupling Effect

It is explicitly expressed in the hull motion equation as:

$$D_{(v)} = \begin{bmatrix} 0 & 0 & -m(y_g r + v) \\ 0 & 0 & m(x_g r - u) \\ m(y_g r + v) & -m(x_g r - u) & 0 \end{bmatrix} \quad (7)$$

where (x_g, y_g) is the position of the center of gravity, which directly affects the dynamic coupling of the roll - yaw motion.

3.4.2 Application of the PINN Algorithm

- PINN - corrected Resistance Prediction

Since the traditional resistance model has significant errors in turbulent flow conditions, for the calculation of the fluid resistance of the unmanned ship, the N - S equation is embedded as a soft constraint in the PINN algorithm for training, and a hybrid resistance model is constructed as follows:

$$\dot{D}(v) = D_{phys}(v) + PINN(v; \theta) \quad (8)$$

- Dynamic Compensation of Added Mass

Considering that the added mass coefficient of the unmanned ship changes with the draft (load fluctuations cause the draft to change by ±10 cm), a PINN surrogate model $M_A = f(T, nabla)$ is established for real - time online estimation:

- Fluid - Motion Coupling Decision - making

Traditional DRL strategies tend to generate actions beyond the feasible domain of fluid dynamics (for example, a sharp turn causing the lateral velocity to exceed the limit). Therefore, it is necessary to introduce a fluid - constraint reward term in the PPO algorithm:

$$r_{physics} = -||v_y|| \cdot \prod(|v_y| > v_y^{max}) - ||r|| \cdot \prod(|r| > r^{max}) \quad (9)$$

and calculate the gradient penalty of the Navier - Stokes equation on the policy parameters through automatic differentiation.

- Wave Disturbance Modeling

Considering the phase lag of the heave/pitch excitation force generated by the JONSWAP wave spectrum, a wave force transfer function is established based on potential flow theory:

$$F_{wave} = \int_{-\infty}^{\infty} H(\omega) \cdot S(\omega) e^{i\omega t} d\omega \quad (10)$$

Where ω is calculated by the hull strip theory, and $S(\omega)$ is the wave spectrum density.

3.4.3 Deployment and Operation of the Unmanned Ship System

In the deployment and operation phase, the preset water scene and the digital prototype of the ship are loaded based on the unity virtual simulation environment, and the sensor data stream (lidar, visual camera) and physical engine parameters are bound through the ROS-TCP communication protocol; Start the obstacle avoidance algorithm node within the ROS framework, load the pre trained PPO/TD3 reinforcement learning model and supervised learning strategy, and run MWORKS Sysplorer carries out ship dynamics calculation; The motion control module drives the digital sample ship model according to the real-time decision-making instructions (path planning, obstacle avoidance angular speed), and feeds back the ship position and attitude, environment interaction status to the simulation interface through ROS Topic; Finally, a real-time closed loop of "perceptual data acquisition - algorithm online reasoning - control instruction execution - physical state return" is formed. During operation, the system supports dynamic adjustment of environmental parameters (wind wave current intensity, obstacle distribution), and continuously optimizes the strategy network through PyTorch's online learning mechanism to ensure the autonomous navigation robustness and task adaptability of unmanned craft in complex scenes.

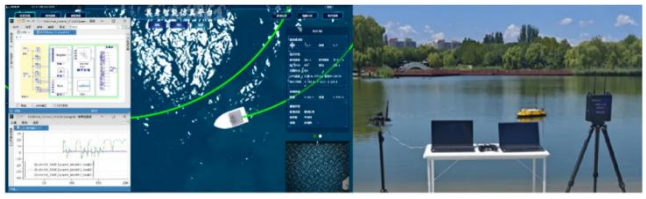

Figure 6. Digital prototype and physical prototype

DOI 10.3384/ecp218591

4 Conclusion

This study proposes an innovative framework of embodied information physical system (ECPS) based on Modelica/MWORKS, and constructs a "physical information embodied" ternary collaborative architecture through the extension of modeling language, which breaks through the separation limitations of physical laws and intelligent decision-making in traditional tools. The framework innovatively integrates the physical information neural network and multi domain modeling theory, and realizes the deep coupling of physical simulation and autonomous decision-making in the field of intelligent unmanned system. By constructing the reinforcement learning paradigm enhanced by PINN, the fluid dynamics equation constraint is embedded in the strategy network training, which significantly improves the ability of the agent to follow the physical laws; Relying on the FMI/SSP standardized protocol, a virtual and real collaborative verification system is built to effectively solve the timing conflict between high-precision simulation and real-time decision-making. The research results provide an integrated methodology of interpretable modeling, verifiable decision-making and scalable deployment for the upgrading of industrial intelligence, promote the leap of embodied intelligence from theoretical verification to engineering implementation, and establish a new benchmark for the development of independent systems in the era of digital transformation.

On the precise and efficient representation of industrial controllers in Modelica

Alberto Leva[1]

[1]DEIB, Politecnico di Milano, Italy alberto.leva@polimi.it

Abstract

This paper highlights some still-open issues in the Modelica representation of industrial controllers, particularly when simulation efficiency must balance with fidelity to their real-world implementation as digital components of cyber-physical systems. The treatise focuses on PID controllers due to their predominant role, though the ideas readily extend to virtually any other control structure. The aim is to stimulate discussion around this important yet often overlooked topic, while also suggesting directions for future development.

Keywords: Modelica, industrial controllers, PID controllers, digital control, digital twins, cyber-physical systems.

1 Introduction

Over the last decades, the Modelica ecosystem has grown to embrace a wide range of domains where control systems play a fundamental role. In many of those domains – process systems being a notable example – control blocks are combined to form articulated structures (Skogestad 2023). These structures are then deployed onto heterogeneous hardware/software architectures, resulting in complex cyber-physical systems. The *realistic* simulation of such systems is still a non completely solved open problem, as conventional "textbook" controller models fall short in terms of completeness, flexibility, and – if fidelity in the digital part matters – of computational efficiency (Cimino et al. 2023).

In the following we discuss the problem just evidenced, referring to the PID controller due to its generality and diffusion — though the underlying ideas are evidently general. After the brief motivating example in Section 2, Section 3 deals with completeness, illustrating the I/O structure required to manage a control block in a realistic application setting; Section 4 describes the various forms that a linear (PID) control law can take, while Section 5 addresses nonlinear functionalities like saturation management and shows how differently they can be realised.

The compound of the above should give the reader an idea of how flexible a controller model should be in order to put the analyst in the position of representing what will be really implemented, precisely enough and with an acceptable effort. Section 6 spends just a very few words on the important problem of simulating a control block accounting for its digital realisation, i.e., of balancing fidelity with computational efficiency. Finally, Section **??** draws some conclusions and sketches out the desired effects of the discussion we aim to trigger.

Throughout the paper, key design decisions are highlighted. While some recommendations are offered, no definitive solutions are proposed, as the complexity and criticality of the overall problem make it difficult to predict the long-term consequences of present choices. The aim of this work, as just said, is in fact primarily to foster informed discussion within the community, so as to promote thoughtful and effective decisions going forward.

2 A motivating example

First of all, before entering the problem, the reader might ask whether we really need to bother. The answer could take more than one paper, but suffice a toy example. Consider a control loop with a process and a PI controller, respectively described by

$$P(s) = \frac{\mu}{(1+sT_1)(1+sT_2)}, \quad C(s) = K\left(1+\frac{1}{sT_i}\right) \quad (1)$$

with $\mu = 2$, $T_1 = 2$, $T_2 = 0.25$, $K = 2$, $T_i = 2$. Build for it five simulation models, all fully continuous-time, with different antiwindup strategies: actuation error feedback, also known as integral recomputation, with tracking time T_t (denoted by `aerr1` for $T_t = 2.5$ and `aerr2` for $T_t = 0.5$); conditional integration (denoted by `cint`); clamping (`clamp`), internal feedback (`ifb`).

In the absence of saturation all models behave exactly the same, as expected; we omit plots for brevity. We conversely show in Figure 1 what happens of the controlled variable (`PV_`$\star$) vs. the set point (`ref`) and of the control signal (`CS_`$\star$) in the presence of [0,1] saturation. It is evident that realism requires the simulated antiwindup mechanism to match the implemented one.

Antiwindup aside, several PID functionalities are managed by industry-standard controllers in heterogeneous ways, often involving additional inputs and outputs, both modulating and logic, with respect to the minimal interface of a controller. And to top, all of the above intertwines with the form chosen for the PID control law, as well as with its realisation as digital algorithm.

Summing up, if industrial realism is required, there is no single "reference" controller model implementation —

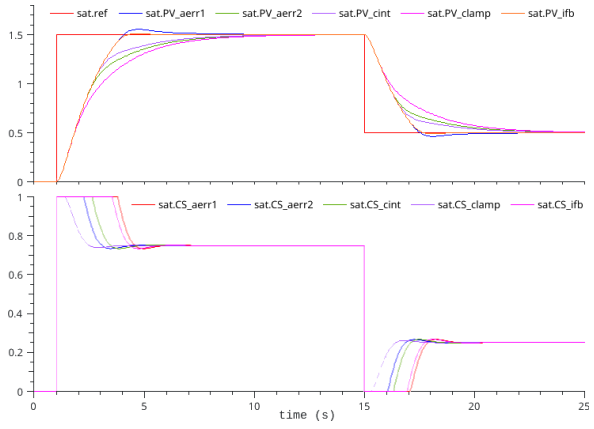

Figure 1. Motivating example: set point and controlled variable (top), control signal (bottom).

but at the same time, attempting to replicate the whole zoo of available products would not be practical. Indeed, a systematic design approach needs devising.

3 Interface and functionalities

Figure 2 illustrates a typical set of I/O signals for an industrial (PID) controller, adopting the Modelica colour coding, together with a brief description of their meaning. These signals refer to functionalities that are crucial for using PIDs in control structures; a few examples follow.

First, without a Bias input one cannot realise feedforward compensation, decoupling, or any structure where the output of a controller must receive an additive correction, as failure to account for that correction in the computation of the controller state may cause highly undesired behaviours. A notable case is backward decoupling, illustrated in Figure 3 by comparing the "textbook" model (top) and one in which the additive correction is duly introduced *upstream* saturation management (bottom).

Second, one cannot manage saturation in cascade controls without increment and decrement locks, as the saturation values for the inner controller come from the actuator, while those for the outer controller are substantially unknown. Assuming all gains positive for simplicity, one has to respectively connect the HI and LO saturation signals from the inner controller to the increment and decrement locks F+ and F- of the outer controller, so as to prevent it from pushing the inner one further into saturation if this occurs.

Third, and again about cascade controls, if the inner controller is set to tracking mode, the outer one must be forced into tracking as well. More in general, whenever a modulating control block is set to operate in any mode but automatic, all the blocks whose loops are consequently open cannot be in automatic mode (particularly if they are not asymptotically stable, as is the case when integral action is present). Enforcing this constraint requires logics to conveniently manipulate the TS and TR signals of the involved blocks. Figure 4, where the notation should be self-explanatory, provides an example of how the second and third point can be handled; variants are possible but discussing them is not our point here.

Fourth, TS and TR are necessary also to manage the switchover among two or more controllers: to avoid undesired bumps in the control signal applied to the rest of the system, all controllers must receive that signal as TR, the active one must be in automatic mode (TS=false) and all the others in tracking mode (TS=true). We omit a block diagram for this case given its simplicity.

More examples could be given – a longer discussion can be found in (Leva 2024) – but the point for this paper is that handling the above matter requires critical model design choices. Should we provide several PID blocks (from "basic" to "complete")? Or just one with flags (named for example hasTracking, has Locks and so forth) to enable/disable the required functionalities, plus the necessary conditional connectors? Or any combination thereof?

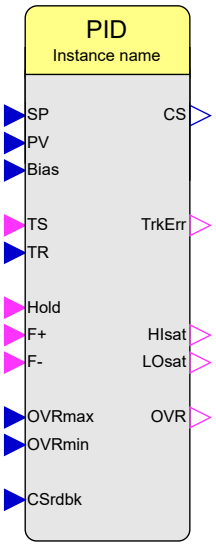
4 The LTI control law

The variety of forms or structures that the LTI (linear, time-invariant) control PID control law can take is large indeed (O'Dwyer 2009) but some "families" can be identified; with no exhaustiveness claim we could mention one degree of freedom (1-dof) forms, described as transfer functions $C(s)$ from the error $e := SP - PV$ to the control output CS, i.e.,

$$C(s) = K\left(1 + \frac{1}{sT_i}\right)\frac{1+sT_d}{1+sT_d/N}; \tag{2}$$

non-interacting (aka parallel), i.e.,

$$C(s) = K\left(1 + \frac{1}{sT_i} + \frac{sT_d}{1+sT_d/N}\right); \tag{3}$$



two degree of freedom (2-dof) forms characterised by different $SP \to CS$ and $PV \to CS$ signal paths, most notably the ISA one

$$CS(s) = K\Bigg(bSP(s) - PV(s) + \frac{1}{sT_i}(SP(s) - PV(s)) + \frac{sT_d}{1+sT_d/N}(cSP(s) - PV(s))\Bigg) \tag{4}$$

with the notable "output derivation" case ($c = 0$), as well as other analogous ones realised by pre-filtering the set point signal.

A source of confusion here comes from a certain tendency of the product literature to give different names to the same concept, but this is quite easy to cure with a proper documentation — and here too, a design equilibrium needs finding. More serious problems can arise from the different meanings of the PID parameters, as the reader can immediately guess from the small sample of possible structures in Figure 5.

DOI
10.3384/ecp218603

SP	Set point.
PV	Process (controlled) variable.
CS	Control signal.
Bias	Additive correction to CS (state consistency enforced).
TS	Track Switch: when true makes CS follow TR (state consistency enforced).
TR	Track Reference: followed by CS when TS is true.
TRkErr	Tracking Error: true if TS is true but for any reason (e.g., range) CS is not following TR.
HIsat	True when CS hits the high saturation value.
LOsat	True when CS hits the low saturation value.
Hold	When true causes CS to remain constant (state consistency enforced).
F+	Freeze plus: when true prevents CS from increasing (state consistency enforced).
F-	Freeze minus: when true prevents CS from decreasing (state consistency enforced).
OVRmax	Override max: takes over CS if greater than the computed value (state consistency enforced).
OVRmin	Override max: takes over CS if smaller than the computed value (state consistency enforced).
OVR	True if CS is overridden by OVRmax or OVRmin.
CSrdbk	Actuator readback for some antiwindup strategies (not discussed herein).

Figure 2. Typical I/O connections in an industrial (PID) controller.

In this case the problem will be finding a set of structures as small as possible but capable of accommodating for all the relevant LTI law variants. One structure cannot be enough because some have limitations and some do not (e.g., a series form like the topmost in Figure 5 cannot have complex zeroes), in some forms N modifies the zeroes with respect to the ideal PID form while in some others it does not, and there are other "system-theoretical" reasons to account for.

Furthermore, though in this paper there is not the space for addressing the subject with the required depth, the said set will need to encompass representations of biasing and direct/reverse action, as well as of velocity (as opposed to positional) forms; and moving toward non-LTI facts as we are going to do in the next section, of overriding and control signal rate limits.

5 Nonlinearities

The first item in this list is clearly saturation management or antiwindup, and here the author takes the occasion to suggest removing the adjective "integral" as for windup to occur a controller just needs to have a large enough gain and a slow enough mode with respect to the loop cutoff frequency. The point, in any case, is that here arbitrary choices are inevitable: denoting by $x_c(t)$ be the controller state and writing its output equation as

$$u(t) = c_c x_c(t) + d_c e(t); \tag{5}$$

when $u(t)$ is stuck into saturation, *any* x_c fulfilling (5) is I/O consistent and therefore fits — and notice that the same applies every time $u(t)$ is anyhow "altered" with respect to the value coming from the LTI law (whatever its form), that is with tracking, increment/decrement locks, holding, and so on.

There are other nonlinear functionalities in the list, and they interact with one another, and they could even *conflict* with one another: a few examples follow.

- Shall TR be allowed to violate saturation limits?
- Shall overrides prevail over tracking or *vice versa*?
- Shall increment/decrement locks be subject to tracking/holding or not?

Here too, different products make different choices, sometimes not immediate to figure out if not by thoroughly searching through their documentation. Further design problems are thus at the horizon, as we need to allow the analyst to take knowledgeable decisions because the behaviour of control structures is heavily impacted by facts like those just mentioned.

The author tends to prefer a solution in which the controller blocks do not contain any logic if not that entailed by the definition of I/O signals and their role as per Figure 2, while the coordination of the above functionalities (including the way possible conflicts are solved) is realised externally by means of logic blocks. Such a design approach is in the favour of flexibility and clarity, but on the other hand requires a certain level of user consciousness as well as modelling language knowledge: another point for the community to discuss.

6 Digital realisation

When modelling and simulating a digitally controlled process – or said in more recent terms, when creating and using a digital twin for a cyber-physical system (Lee 2008) – a precise representation of control algorithms is sometimes of relatively low importance but some other times extremely critical (Åström and Murray 2021; Cimino et al. 2024).

To effectively support a model-based design toolchain, especially for complex systems as discussed for exam-

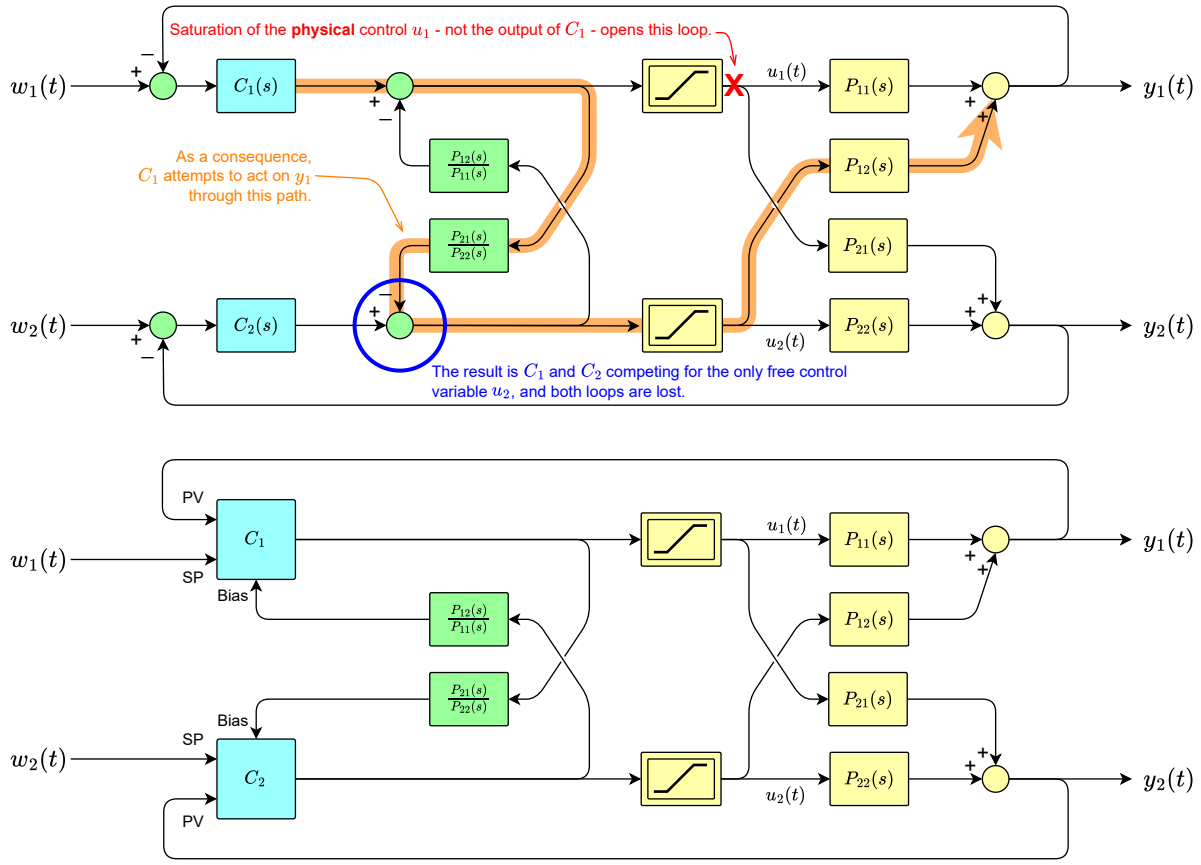


Figure 3. Decoupling control and the need for a Bias input.

ple in (Grieves and Vickers 2017), controller models must therefore be capable of operating sometimes in a time-driven manner, allowing for example for the use of variable-step solvers, and sometimes in an event-based manner, most typically (but not only) to represent the multi-clocked nature of industrial control architectures.

The Modelica language offers multiple means to address such needs, well known to the reader and not central to discuss in this paper. No matter what mix of the said means is adopted, however, the problem remains of structuring a controller model base in such a way that achieving and maintaining consistency between time- and event-driven (in a more industrial jargon, continuous- and discrete-time) models be as natural as possible.

To illustrate the ideas above, we report in Listing 1 a possible minimum set of base classes for Continuous-time (CT) and discrete-time (DT) PI models, and then in Listings 2 through 5 some elementary examples, referring to a 1-dof PI controller with antiwindup realised in the various ways mentioned in the motivating example in Section 2. Incidentally, these are the models used to produce the simulations reported in Figure 1; for the convenience of the reader willing to replicate he experiments and further investigate the matter, all the neces-

  end when;

end DTPI_AERR;
```

sary Modelica code is available under a 3-clause BSD licence at `https://github.com/looms-polimi/Modelica_PID_MWEs`.

Coming back to the our main subject, te challenge is to move from extremely simple blocks like those just shown, where most of the problems mentioned above are not addressed, to others capable of representing all the needed functionalities of which we gave a sample in the previous sections. To undertake this challenge we need a methodological and a technological framework, connected to one another as strictly and rigorously as possible. On the methodological side a choice could be switching (nonlinear) dynamic systems, written as

$$\begin{cases} CS(t) &= g_{\sigma(t)}\big(x_c(t), SP(t), PV(t), TS(t)\dots\big) \\ \dot{x}_c(t) &= f_{\sigma(t)}\big(x_c(t), SP(t), PV(t), TS(t)\dots\big) \\ \sigma(t^+) &= s\big(\sigma(t), x_c(t), SP(t), PV(t), TS(t)\dots\big) \end{cases} \tag{6}$$

in the continuous time (aka time-driven) context and as

$$\begin{cases} CS(t_k) &= g^*_{\sigma(t_k)}\big(x_c(t_k), SP(t_k), PV(t_k), TS(t_k)\dots\big) \\ CS(t_{k+1}) &= f^*_{\sigma(t_k)}\big(x_c(t_k), SP(t_k), PV(t_k), TS(t_k)\dots\big) \\ \sigma(t_{k+1}) &= s^*\big(\sigma(t_k), x_c(t_k), SP(t_k), PV(t_k), TS(t_k)\dots\big) \\ t_{k+1} &= t_k + q \end{cases} \tag{7}$$

in the discrete time (aka *periodic* event-driven) one.

In both (6) and (7) the σ subscript indicates that the state and the output equation can take a finite number of forms, for example to match the operating modes of a block in each of which the unique state vector x_c is managed in a different manner. In (6) t is the continuous time and the $^+$ superscript denotes values after a σ switching; in (7) q is a time quantum such that switching events can only occur at its multiples. The reader interested in more detail on these aspects can refer to (Miskowicz 2018) and the works quoted therein.

As for the technological side, a starting point could be the IEC 61499 standard (Lyu and Brennan 2020; Wies-

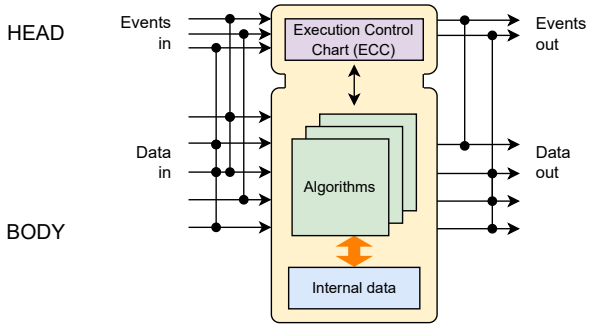

Figure 6. The concept of Function Block as per the IEC 61499 standard.

mayr, Mehlhop, and Zoitl 2023) and most notably its definition of Function Block (FB) exemplified in Figure 6. An FB is a modular, reusable component representing a functional unit in a distributed automation system. It offers data I/O to receive and produce information, and event I/O to execute and trigger actions.

Also, an FB is made of two main components, namely the Event-Condition-Action (ECA) automaton – or Execution Control Chart (ECC) – and the dynamic system. The ECA automaton governs the FB evolution based on events and conditions, triggering actions in response to specific events; the dynamic system is responsible for handling internal data, processing algorithms, and managing system state transitions over time.

The relationships between the two frameworks – methodological and technological – seem to the author quite evident and potentially capable of grounding the sought design and development process, yet they are not totally unambiguous, and in their application to the addressed domain decisions need taking. For example, continuous-time state/output equations naturally correspond to conditional DAEs, and discrete-time state/output

DOI
10.3384/ecp218603

equations to (branching) FB algorithms. Also, a sequential logic conceptually modelled as automaton naturally corresponds to an FB ECC in which one could talk about "mode σ" where σ takes values like AUTO, TRACKING, HIsat and so forth.

But coming back to our design-centric attitude, how could we *efficiently* implement this? By algorithm(s) with `when` clauses? With which event management policy? And most important, could we use the *same* automaton for time- and event-driven representations? Might we need (for the time-driven context) to represent as DAEs functionalities that were natively created as algorithms? Might we also need additional state variables for that purpose? Could this evidence numerical, solver-related issues/choices/precautions? As can be seen, we have a lot to discuss also on this front.

7 Conclusions and future work

Despite the numerous existing controller simulation models, also and particularly within the Modelica ecosystem, this paper has highlighted that substantial conceptual design choices remain to be made in the field. While many controller models – especially PID ones – are widely used, there is in fact a clear need for more flexibility to better reflect the complexities of real industrial systems, and most important, to allow an analyst to easily ensure that the simulated controls will match the particular implementation to consider. It is also important to stress that these choices are not merely technical; on the contrary, they involve a methodological shift that has yet to be fully realised.

In fact, at least to the best of the author's knowledge, no existing (Modelica) controller model has been entirely developed along the approach proposed here, and premising that the approach itself is still in its infancy and most likely contains several imperfections, nonetheless the observed *scenario* suggests that several critical design aspects are still unresolved. The challenge lies in synthesising the scattered and often fragmented knowledge available, alongside the need to adhere to industrial standards (the IEC ones being a paradigmatic but certainly not the unique example). Moreover, the development of such controller models requires careful and accurate planning, especially given the wide range of knowledge and expertise required. These conceptual and methodological gaps should be seen not just as challenges but also as opportunities for future research and innovation in the field of digital twinning for cyber-physical systems.

As an aside, though the matter could not find space in this paper, we have to notice that in addition to their relevance for industrial applications, flexible controller models also hold significant potential for educational purposes. These models could be particularly valuable in undergraduate and graduate programs, as well as in the context of continuing education, where they can bridge the gap between theoretical understanding and practical, real-world applications.

For the future, the hope is that this paper can stimulate a discussion on the problems here evidenced and (briefly) discussed, which he believes to be very relevant for the effective simulation of industrial (and particularly process) controls. Indeed, while the examples presented are intended – as said – to spark discussion, they could also mark a concrete first step toward a shared open-source initiative aimed at developing a structured, extensible library of industrial controllers, coordinating time- and event-based descriptions (here too, as exemplified above) to conjugate precision and efficiency. Yet, defining a coherent architecture and sustainable development – and particulary, maintenance – practices demands collective input, which is why the author warmly invites the community to engage in shaping both the technical direction and governance needed to realise such an initiative.

Master controller for offshore wind power and hybrid grids

Rüdiger Franke[1] Marcin Bartosz[2] Rasmus Nyström[3]
ABB, [1,3]{ruediger.franke,rasmus.nystroem}@de.abb.com, [2]marcin.bartosz@pl.abb.com

Abstract

Offshore power generation and transmission requires long subsea cables. When using AC, the inductance of the cables results in reactive power that contributes to the load of the cables and increases the voltage at busbars. At the same time, offshore power systems are becoming increasingly complex. They are evolving from dedicated collector grids and transmission cables for wind farms through shared use of transmission cables by multiple wind farms to hybrid offshore grids that connect wind farms to multiple countries.

This paper discusses operational challenges of offshore grids and how they are solved with model-based master control solving state estimation and optimal power flow problems in real-time.

The optimization model is built with Modelica using the PowerSystems library and FMI for its deployment in the control system. The optimization solver runs model evaluations and sensitivity analyses over different time intervals in parallel.

The Kriegers Flak Combined Grid Solution (KF CGS) serves as example. It is one of the world's first hybrid offshore grids. The methods have been implemented as Master Controller for Interconnected Operations (MIO). After extensive tests with a digital twin prototype, MIO has been deployed in a geo-redundant system with ABB Ability™ OPTIMAX® and System 800xA.

Keywords: Offshore grids, Hybrid Interconnectors, Optimal Power Flow, Modelica, PowerSystems, state estimation, optimal control.

1 Introduction

Offshore power and intercontinental power transmission are playing an important role for establishing climate neutral energy systems. The European Wind Power Action Plan sets ambitious goals for new installations. The North Sea Energy Consortium alone heads for at least 260 GW of offshore wind energy by 2050, with intermediate targets of at least 193 GW by 2040 and 76 GW by 2030, starting from 33 GW in 2023 (European Commission, 2023).

In December 2020, the Kriegers Flak Combined Grid Solution (KF CGS) was inaugurated by the transmission system operators 50Hertz, Energinet, the German Federal Minister of Economics and the Danish Minister for Climate, Energy and Utilities. It transports wind power from the four offshore wind farms (Baltic 1 and 2, Kriegers Flak A and B) with a total capacity of 950 MW to shore. Additionally, it promotes energy trade between Germany and Denmark. At the heart of the connection of these two energy grids through the Baltic Sea there is a Master Controller for Interconnected Operations (MIO).

This paper discusses the methods and technologies employed in the first of its kind master controller for interconnected operation (Marten et al, 2018).

2 Kriegers Flak Combined Grid Solution

The KF CGS connects the transmission cables of the German wind farms Baltic 1 and Baltic 2 with the transmission cables of the Danish wind farms Kriegers Flak A and B. This creates a hybrid offshore grid for the collection of wind power and the exchange of power between the northern and the continental European transmission grids, see Figure 1.

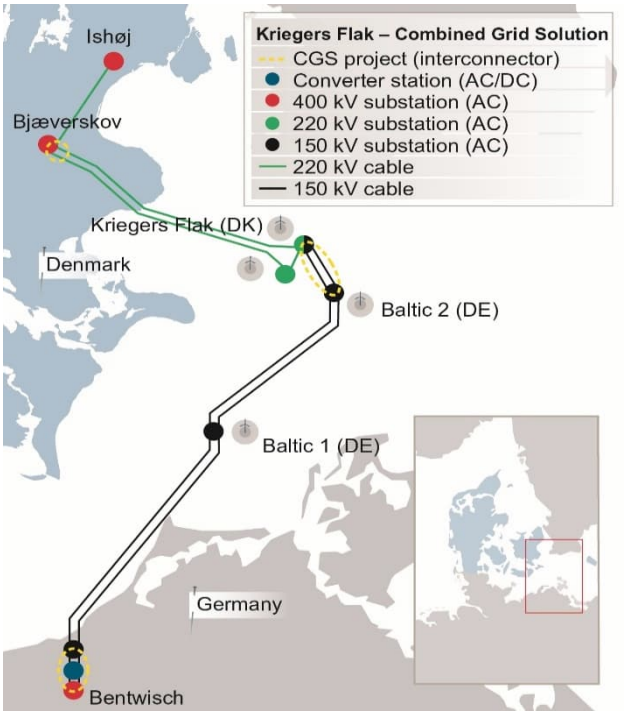

Figure 1: Overview of Kriegers Flak Combined Grid Solution (KF CGS) encircled in yellow. Source: 50Hertz

The KF CGS imposes several operational challenges. A Back-to-Back (BtB) HVDC converter station in Bentwisch enables the connection of the two unsynchronized AC transmission grids. It controls the power exchange at the interconnector in the Baltic Sea by manipulating power flow and voltage from the German coast. The meshed submarine grid interconnection is (n - 0) secure, meaning that a single failure can result in a system outage. Figure 2 shows a single line diagram.

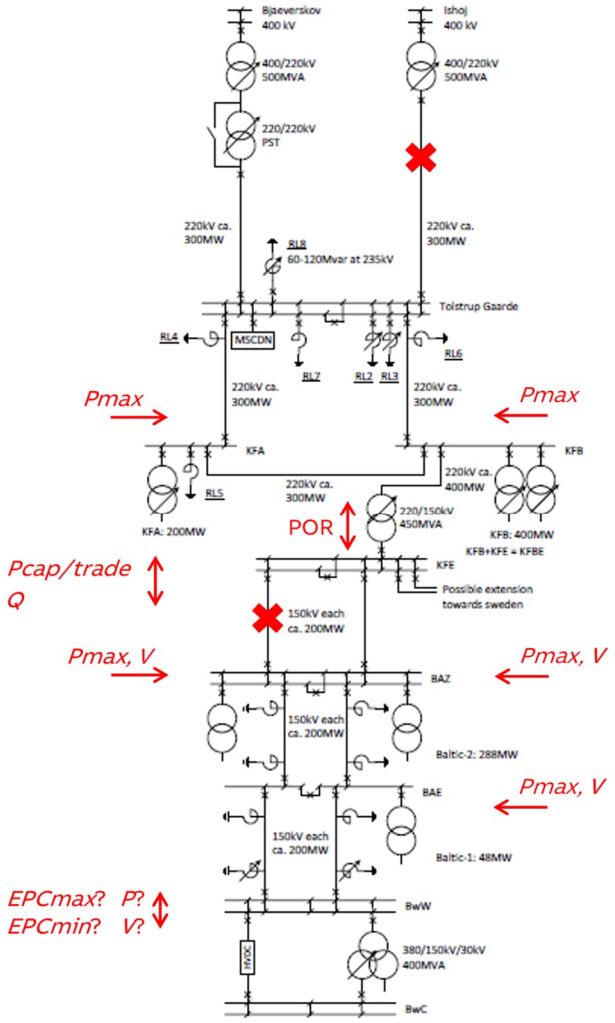

Figure 2: Single line diagram of KF CGS outlining operational challenges. Source: 50Hertz

This results in several tasks for the master controller. First, it provides forecasts for available transfer capacity *Pcap* at the point of reference (POR) using wind forecasts as input. Second, it controls the traded power *Ptrade* and reactive power *Q* in real time, thereby accounting for cable load limits, forecast errors, contingencies and other disturbances in the system. Primarily, the master controller manipulates active power and voltage at the BtB converter. Additionally, it may limit the maximum power Pmax of wind farms. Finally, it provides limits for emergency power control (EPC) in real time.

3 Model-based control with Modelica

Modelica has been widely used for model-based control for many years. Applications range from the treatment of optimal control problems (Franke, 2002) to the creation of inverse models and the generation of embedded controller code (Otter et al, 2012).

Modelica is also used for the modeling and simulation of power systems ranging from microgrids (Fachini et al 2023) to transmission systems (Feghali et al, 2023).

This section outlines the technologies used to implement the master controller for KF CGS.

3.1 PowerSystems library

The Modelica PowerSystems library (R. Franke, H. Wiesmann, 2014) provides a flexible way to model electric power systems at different levels of detail, up to advanced modeling of electromagnetic transients (B. Bachmann, H. Wiesmann, 2000).

This is achieved by different phase systems as shown in the library structure in Figure 3.

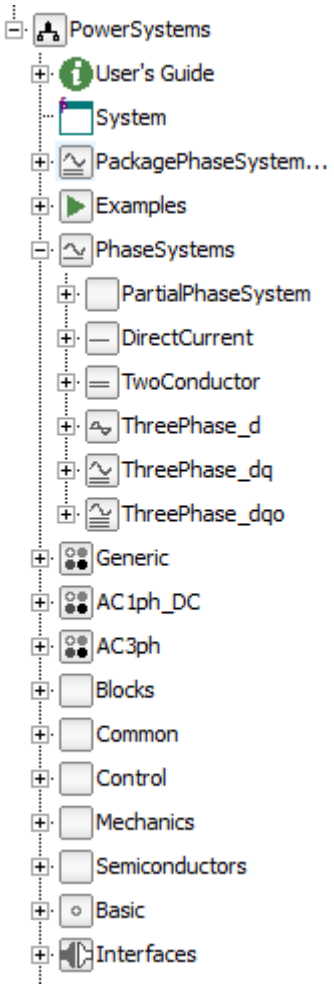

Figure 3: PowerSystems library structure.

DOI 10.3384/ecp218611

Each phase system defines the number `n` of independent current and voltage components, the number `m` of reference angles and appropriate supporting functions like the `j` "operator".

The interfaces define a general power terminal.

```
connector Terminal
  replaceable package PhaseSystem;
  PhaseSystem.Voltage
    v[PhaseSystem.n];
  flow PhaseSystem.Current
    i[PhaseSystem.n];
  PhaseSystem.ReferenceAngle
    theta[PhaseSystem.m]
      if PhaseSystem.m > 0;
end Terminal;
```

Table 1 summarizes the PhaseSystems that are predefined in the PowerSystems library.

Table 1: Phase systems by PowerSystems library.

PhaseSystem	n	m	Description
DirectCurrent	1	0	One voltage and one current component in natural coordinates
TwoConductor	2	0	Two voltage and two current components for Spot AC1ph_DC components
ThreePhase_d	1	0	One modal component for active power — like DirectCurrent, but converting voltage values to three phase
ThreePhase_dq	2	1	Two modal components for active and reactive power; one reference angle for frequency — cf. complex phasors with variable frequency
ThreePhase_dq0	3	2	Three modal components for active, reactive and dc power; two reference angles for transient dq0 components

Note the use of the function j that generalizes complex calculations known from quasi-static AC models to arbitrary phase systems. ThreePhase_dq, with two model components for active and reactive power defines a multiplication with the complex *j*:

```
function j
  input Real x[n];
  output Real y[n];
algorithm
  y := {-x[2], x[1]};
end j;
```

The simpler ThreePhase_d neglecting reactive power defines:

```
function j
  input Real x[n];
  output Real y[n];
algorithm
  y := zeros(n);
end j;
```

The more detailed PhaseSystem_dq0 (direct-quadrature-zero) also considers a component for dc power in asymmetric systems, besides active and reactive power. It defines:

```
function j
  input Real x[n];
  output Real y[n];
algorithm
  y := cat(1, {-x[2], x[1]},
           zeros(size(x,1)-2));
end j;
```

A general base model with two terminals reads

```
partial model PartialTwoTerminal
  replaceable package PhaseSystem =
    PackagePhaseSystem;
  package PS = PhaseSystem;
  function j = PhaseSystem.j;
  Terminal term_p(
    redeclare package PhaseSystem = PS);
  Terminal term_n(
    redeclare package PhaseSystem = PS);
  SI.AngularFrequency omegaRef;
equation
  v = term_p.v - term_n.v;
  i = term_p.i;
  if PS.m > 0 then
    omegaRef =
      der(PS.thetaRef(term_p.theta));
  else
    omegaRef = 0;
  end if;
  Connections.branch(term_p.theta,
    term_n.theta);
end PartialTwoTerminal;
```

A generic steady-state impedance can now be formulated as

```
model Impedance
  extends PartialTwoTerminal;
  parameter SI.Resistance R;
  parameter SI.Inductance L;
equation
  v = R*i + omegaRef*L*j(i);
  zeros(PS.n) = term_p.i + term_n.i;
```

```
  term_p.theta = term_n.theta;
end Impedance;
```

Accordingly, a generic steady-state admittance reads

```
model Admittance
  extends PartialTwoTerminal;
  parameter SI.Conductance G;
  parameter SI.Capacitance C;
equation
  i = G*v + omegaRef*C*j(v);
  zeros(PS.n) = term_p.i + term_n.i;
  term_p.theta = term_n.theta;
end Admittance;
```

A forced switch can be modeled with curve parameter `s`

```
model Switch
  extends PartialTwoTerminal;
  Modelica.Blocks.Interfaces.RealInput
    closed(min=0, max=1);
protected
  Real[PS.n] s;
equation
  {v, i} = {(1-closed)*PS.v_nominal*s,
            closed*PS.i_nominal*s};
end Switch;
```

The package AC3ph provides many relevant component models like Lines, Nodes, Breakers, Shunts and Transformers for the application at hand, see Figure 4.

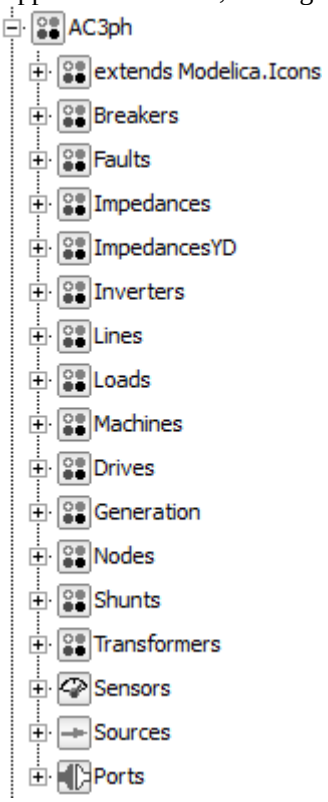

Figure 4: PowerSystems AC3ph component models.

3.2 Dynamic Optimization

Modelica distinguishes between equation-based models and executable simulation code. A model translator generates executable code. Beyond simulation runs in the Modelica tool at hand, the executable code can also be exported to other tools. It has been used for dynamic optimization in several industrial applications, e.g. (Franke, 2002). The introduction of the Functional Model Interface (FMI) and synchronous language features standardized the interface of executable discrete-time models (Franke et al, 2017).

Alternatively, (Åkesson et al, 2010) proposed a syntactical extension of the equation-based Modelica language to Optimica for optimization. Recent work couples Modelica with Matlab to implement model predictive control (Alizadeh et al, 2023).

Numerical solution as large-scale nonlinear program
The nonlinear solver HQP used by ABB OPTIMAX® treats discrete-time optimal control problems as large-scale mathematical programs. Discrete-time states and controls are collected in the state vector x and the control vector u, respectively. This gives the discrete-time optimal control problem:

$$J = f_0(x^K) + \sum_{k=0}^{K-1} f_0(x^k, u^k) \quad \rightarrow \quad \min_{x^0,\, u^k}$$

with the discrete-time state equations

$$x^{k+1} = f^k(x^k, u^k),$$
$$y^k = g^k(x^k, u^k), \quad k = 0, \dots, K-1$$

and the constraints

$$c^k(x^k, u^k) \geq 0, \quad k = 0, \dots, K-1$$
$$c^K(x^K) \geq 0$$

(1)

The executable model imported as Functional Model Unit (FMU) for model exchange implements the state equations f^k. It is important to note that the explicit relationship between f^k and x^{k+1} results in linear optimization constraints that can be exploited for efficient parallel optimization. The model can be evaluated in parallel in each time step. Additionally, the FMU provides optimization objective functions f_0 and the constraints c^k as outputs.

The states and the control inputs of all time intervals are collected into one large vector of optimization variables

$$v = (x^0, u^0, x^1, u^1, \dots, x^{K-1}, u^{K-1}, x^K).$$

(2)

DOI 10.3384/ecp218611

This results in the mathematical program

$$\begin{aligned} J(v) &\underset{v}{\rightarrow} min & J&: \mathbb{R}^{n_v} \rightarrow \mathbb{R}^1 \\ h(v) &= 0 & h&: \mathbb{R}^{n_v} \rightarrow \mathbb{R}^{m_e} \\ g(v) &\geq 0 & g&: \mathbb{R}^{n_v} \rightarrow \mathbb{R}^{m_i} \end{aligned} \tag{3}$$

HQP treats large-scale nonlinear optimization with Sequential Quadratic Programming (SQP).

Basing on the Lagrangian

$$\begin{aligned} L(v,\lambda,\mu) &= J(v) - \lambda^T h(v) - \mu^T g(v) \\ L&: \mathbb{R}^{n_v} \times \mathbb{R}^{m_e} \times \mathbb{R}^{m_i} \rightarrow \mathbb{R}^1 \end{aligned} \tag{4}$$

the solution must fulfill the Karush Kuhn Tucker (KKT) conditions

$$\begin{aligned} \nabla_v L(v,\lambda,\mu) &= \nabla J(v) - \nabla h(v)^T \lambda - \nabla g(v)^T \mu = 0 \\ \nabla_\lambda L(v,\lambda,\mu) &= -h(v) = 0 \\ g(v) &\geq 0 \\ \mu &\geq 0 \\ g(v)^T \mu &= 0 \end{aligned} \tag{5}$$

HQP applies Lagrange Newton iterations

$$\begin{aligned} \nabla^2 L(v,\lambda) \begin{pmatrix} \Delta v \\ \Delta\lambda \end{pmatrix} &= -\nabla L(v,\lambda) \\ \begin{pmatrix} v^+ \\ \lambda^+ \end{pmatrix} &:= \begin{pmatrix} v + \Delta v \\ \lambda + \Delta\lambda \end{pmatrix} \end{aligned} \tag{6}$$

to find the solution. The Lagrange Newton iteration is given here for the case $m_i=0$. HQP augments the Lagrangian to treat inequality constraints with an Interior Point method. The Jacobian $\nabla J(v)$ and the Jacobian matrices $\nabla h(v)$ and $\nabla g(v)$ are formed analytically exploiting directional derivatives provided by the FMU per time interval. The Jacobians of each time step are collected into large sparse matrices for the overall dynamic optimization problem giving

$$\nabla h(v) = \begin{pmatrix} \frac{\partial f^0}{\partial x^0}\frac{\partial f^0}{\partial u^0} & -I & & \\ & \ddots & & \\ & & \frac{\partial f^{K-1}}{\partial x^{K-1}}\frac{\partial f^{K-1}}{\partial u^{K-1}} & -I \end{pmatrix} \tag{7}$$

and

$$\nabla g(v) = \begin{pmatrix} \frac{\partial \bar{c}^0}{\partial x^0}\frac{\partial \bar{c}^0}{\partial u^0} & & & \\ & \ddots & & \\ & & \frac{\partial \bar{c}^{K-1}}{\partial x^{K-1}}\frac{\partial \bar{c}^{K-1}}{\partial u^{K-1}} & \\ & & & \frac{\partial \bar{c}^K}{\partial x^K} \end{pmatrix} \tag{8}$$

The Hessian of the Lagrangian $\nabla^2 L(v,\lambda,\mu)$ is formed numerically applying a rank 2 update in each time interval based on the progress over subsequent iterations. As the linear coupling between subsequent time intervals plays no role for second order derivatives in the Hessian, the large-scale nonlinear program is partial separable. This allows an efficient multi-rank update of the large Hessian of the Lagrangian. This is also why no analytical second order derivatives are required.

4 Application to KF CGS

A model of the Kriegers Flak Combined Grid Solution was implemented in OpenModelica using the PowerSystems library. For the operational optimization considered here, we assume symmetric load of the three phases and quasi-stationary behavior. This is achieved with the phase system ThreePhase_dq. Once selected globally, the connectors and most components adjust to it automatically, for insance cables, shunts and breakers. Some components, such as inverters, have multiple implementations in the PowerSystems library. The simplified InverterAverage uses time-averaged variables, whereas the rigorous Inverter model implements fast switching in the time domain. The phase system ThreePhase_dq0 would cover transient scenarios and unsymmetric loads at the cost of larger models involving fast dynamics.

The model is then exported as FMU for model exchange with the C++ runtime. Several activities are configured for state estimation, predictive planning optimization and real-time optimization.

Figure 5 shows a screenshot of the model. To keep the size of the model diagram better manageable, some details were encapsulated into sub models. Particularly a generic AC transmission line was formed from a π-line combined with an optional shunt and an optional switch at each end, see Figure 6.

The KF CGS model was tested in OpenModelica. It consists of 4722 variables and equations. Many of them are trivial equalities going back to connections between component models.

The translator identifies 788 non-trivial equations, 144 model inputs and 335 model outputs. For dynamic optimization, these numbers multiply with the number of time steps K, such as K=288 for three days with a step size of 15 minutes.

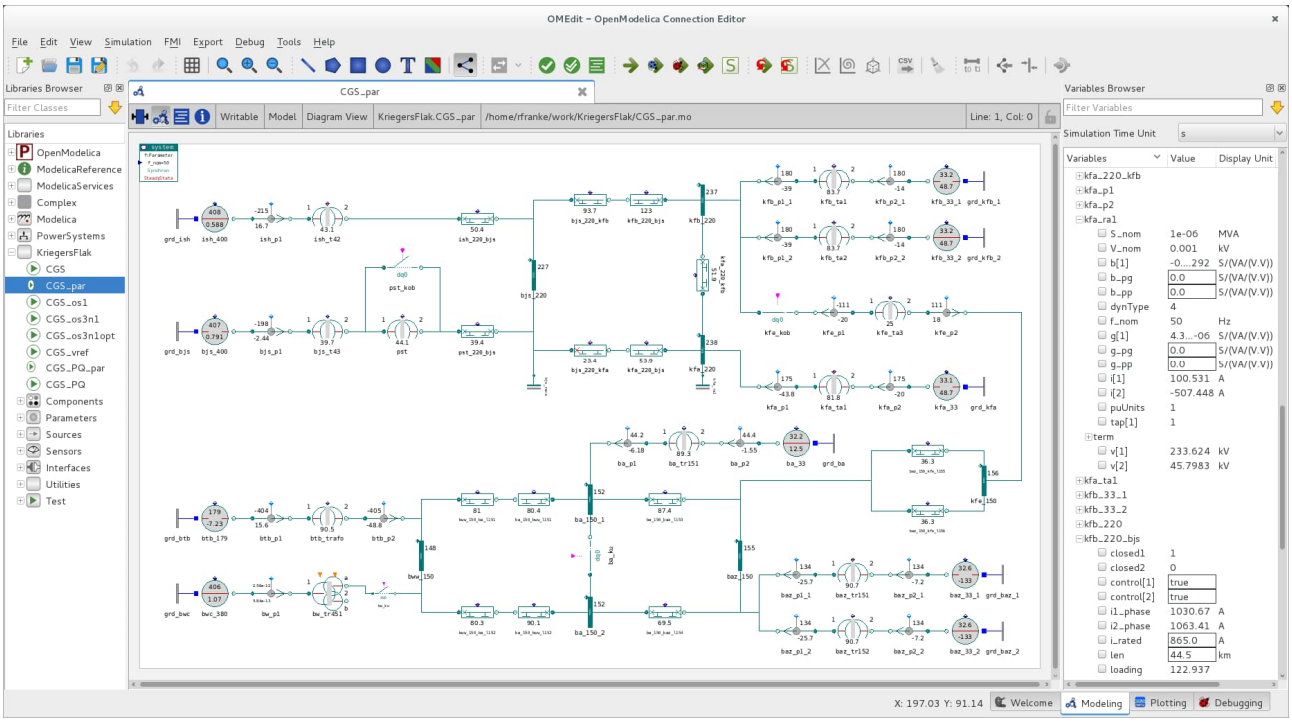

Figure 5: Screenshot of OpenModelica with KF CGS model.

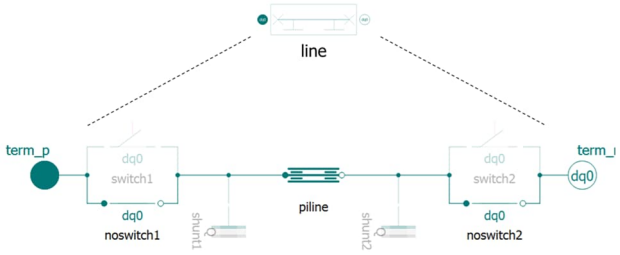

Figure 6: Generic sub model of an AC line with optional shunts and switches. Model icon at the top, model diagram at the bottom.

The variables relevant for optimization objective and constraints are quadratic functions of the internal voltage and current phasors. This gives active power and reactive power

$$P = v \cdot i$$
$$Q = -j(v) \cdot i \qquad (9)$$

along with absolute voltages, e.g. measured at busbars, and absolute currents, e.g. determining cable loads

$$V = \sqrt{v \cdot v}$$
$$I = \sqrt{i \cdot i} \qquad (10)$$

The steady-state system model depicted in Figure 5 leads to algebraic loops. Tearing reduces mutual dependencies to one linear equation system of dimension 81. The variables of this equation system are curve parameters `s` of switches at the lines, besides currents i and voltages v of transformers, see Section 3.1. The system is linear thanks to the use of rectangular dq coordinates.

Overall, this gives a quadratically constrained quadratic optimization problem that allows a fast and robust numerical solution.

Figure 7 shows the principle of the closed loop control. Measurements are absolute voltages, currents and power flows. Tuned model inputs u are voltage phasors in dq coordinates. Optimized variables y are set points for the BtB converter and wind farms.

The translated model is deployed with ABB OPTIMAX® in a geo-redundant setup. Several optimization activities are running using multiple instances of the same model.

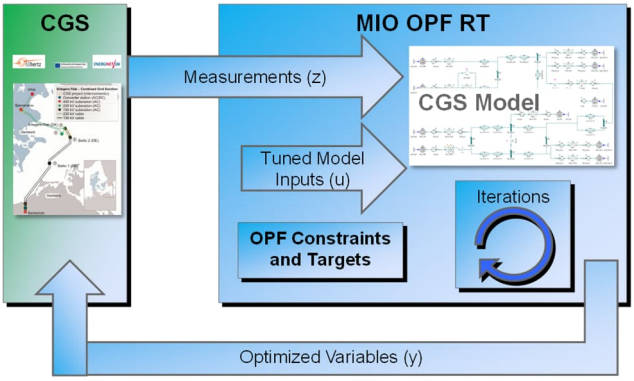

Figure 7: Principle of closed loop control with optimal power flow (OPF).

DOI 10.3384/ecp218611

Table 2: Speedup obtained with parallel optimization and different solver configurations.

Speedup for different solver configurations	Finite Differences	AD with refactoring	AD with factor reuse
Sequential shooting, Dense model blocks, no AD, 1 CPU	1.0		
Sequential shooting, Sparse model blocks, 1 CPU	1.9	1.3	3.9
Parallel multiple shooting, Sparse model blocks, 2 CPUs	2.8	2.2	4.6
Parallel multiple shooting, Sparse model blocks, 5 CPUs	4.6	3.7	6.3
Parallel multiple shooting, Sparse model blocks, 20 CPUs	7.0	6.5	7.6

4.1 Planning Optimization

Based on given wind power forecasts and maintenance schedules, the maximum remaining power transfer capacities from Denmark to Germany and from Germany to Denmark are obtained, maximizing the power flow through the system subject to utilization of wind, constraints on cable loadings and limits on busbar voltages.

The planning optimization turns out to be the most time critical task as the coverage of a time horizon of up to three days with a resolution of 15 minutes results in a large-scale dynamic optimization problem. The formulation as discrete-time optimal control problem (1) with the large vector of variables (2) allows the separation of the time horizon and the evaluation of the model in parallel for each time step. The method is known as Multiple Parallel Shooting.

Table 2 summarizes results obtained on a 20-core high performance server. A speedup of 1.9 is achieved by not only exploiting sparsity from the time staggered structure of the discrete-time optimal control problem, but also sparsity of Jacobian matrices at each time step as given in the modelDescription.xml file of the FMU. Coloring in particular leads to a reduction of the number of directional derivatives required to obtain the whole Jacobian matrix. Interestingly, Automatic Differentiation (AD) turned out slower than Finite Differences initially. A speedup to 3.9 is achieved when re-using factors of the 82-dimensional linear equation system for subsequent determinations of directional derivatives.

The solution time can be further reduced and a speedup of up to 7.6 is achieved by increasing the number of CPU cores to 20. The speedup of 7.0 for Finite Differences is almost as high with 20 CPU cores. This is achieved by higher utilization of parallel cores for repeated factorizations of the linear equation system.

Automatic Differentiation with re-use of factors achieves a high speedup of 6.3 already with 5 CPU cores. This leaves the remaining cores for other tasks, like the solution of two capacity planning problems towards Denmark and towards Germany at the same time.

4.2 Real-time Optimal Control

Uncertainties of wind forecasts, the intermittent nature of wind as well as possible disturbances are addressed by re-optimizing set points in closed loop control during the actual operation. Additionally, optimization is employed to determine limits for the underlying control during a possible emergency. Limits for power transfer change dynamically with the infeed of wind as well as with the switching structure of cables, shunts and transformers.

State estimation: existing measurements of absolute voltages and currents are used to estimate system wide voltages and currents in dq coordinates. This is achieved by minimizing the residuals between measurements of absolute quantities and respective model outputs. From a control point of view, the electrical system is in steady-state. Dynamic states arise from rate-of-change bounds of controlled electrical assets.

Real-time optimization: starting from the estimated state, optimal power and voltage set points for the BtB converter and possibly required curtailments of wind farms are determined every 5 seconds. The underlying optimal power flow problem maintains the given target value *Ptrade* at the point of reference while minimizing losses in the system subject to constraints on cable loadings and busbar voltages.

Emergency Power Control (EPC): starting from the estimated state, the maximum power transfer capacities towards Denmark and towards Germany are determined subject to constraints on cable loadings and busbar voltages in real-time and communicated as EPC limit to the BtB converter.

4.3 Digital Twin Prototype

A digital twin was employed during the engineering of MIO. It comprised the FMI model, the OPTIMAX® runtime and the communication protocol along with existing grid simulation software of 50Hertz and Energinet. This made it possible to test a vast number of operational scenarios with simulation prior to the commissioning of the actual system. It was key to shortening the commissioning time and for ensuring the reliable operation of this complex offshore grid.

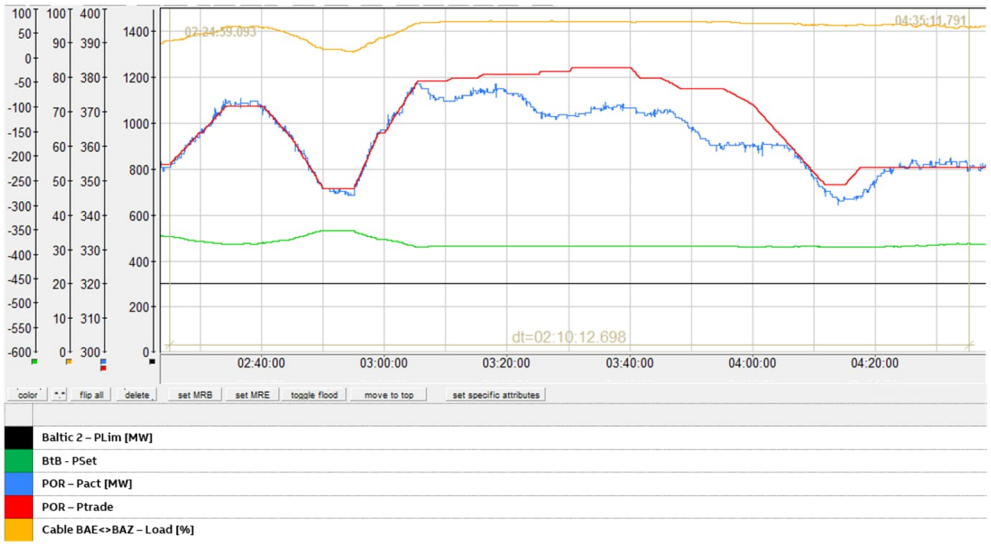

Figure 8: Real-time optimization: Overseeing planned energy transfer, respectful of network constraints.

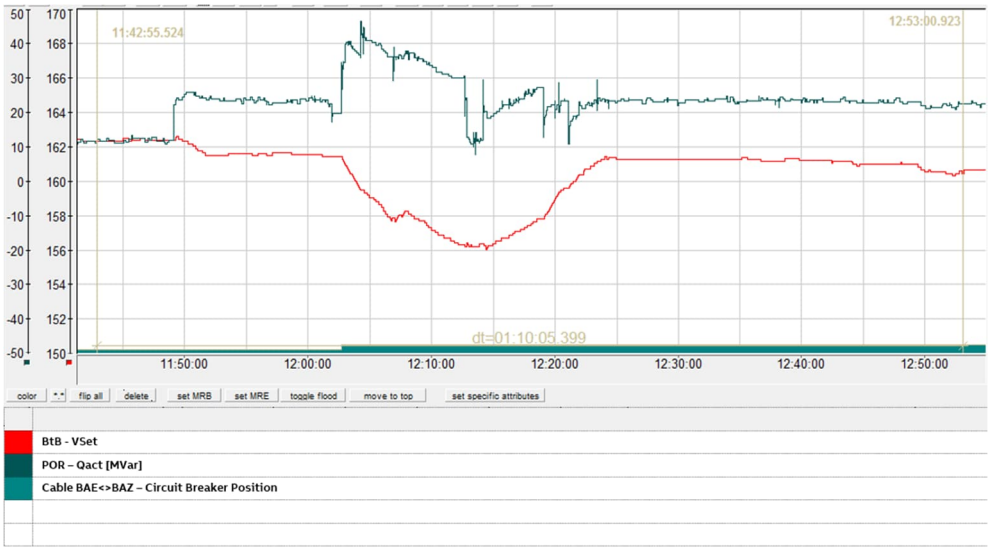

Figure 9: Real-time optimization: BtB voltage control and POR reactive power constraints.

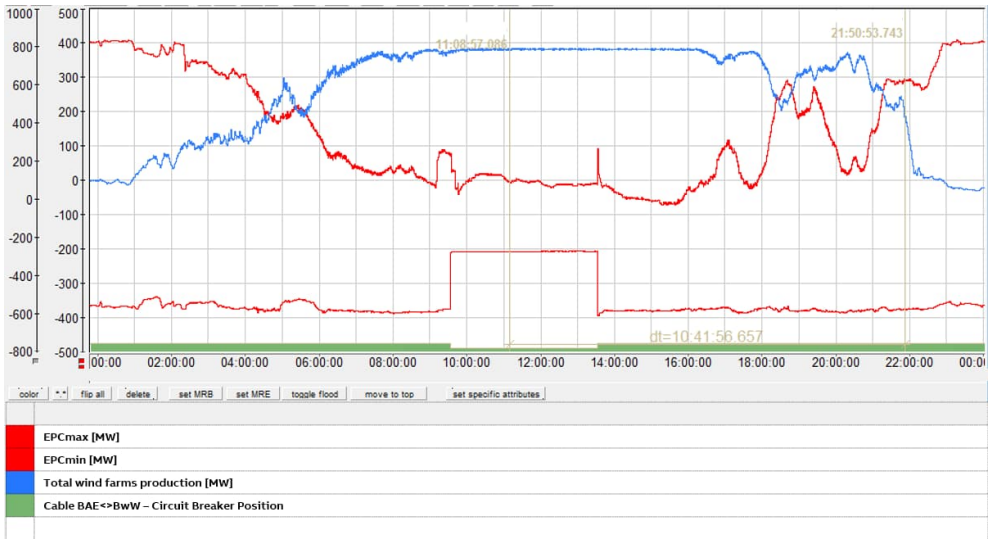

Figure 10: Emergency Power Control: Adjustment of the safe operating limit considering operational conditions.

DOI
10.3384/ecp218611

5 Operational Examples

This section discusses several examples of the actual operation of the Kriegers Flak hybrid offshore grid with real-time optimal power flow, maintaining planned power transfers while prioritizing wind power and considering limits on cable loadings. See also the single line diagram in Figure 2 for relating acronyms used in this section to the overall system.

The plots show active power in MW, reactive power in Mvar, voltage in kV, line loading in % and switch position as 0 (off) or 1 (on).

Real-time optimization: Figure 8 shows an example, where power transfer is optimized. MIO manipulates the BtB such that the actual power transfer via POR follows the planned transfer until 03:05. Then the load on cable BAE—BAZ reaches its limit as the actual wind power is higher than expected during the planning. The wind farm Baltic 2 is not curtailed. Instead, MIO manipulates the BtB to maintain the cable load limit, resulting in lower than planned power transfer until 4:20.

Figure 9 illustrates BtB voltage control during the connection of the BAE—BAZ cable at 12:03. MIO manipulates the BtB to limit the reactive power flow through POR by reducing the voltage. Simultaneously, the underlying control system adjusts transformer tap positions and reactive power compensators. This is why the BtB can return to a higher voltage until 12:24.

Emergency Power Control: Figure 10 illustrates the adaptive EPC limits responding to dynamic variations in wind power and contingencies. Starting from 01:00, MIO reduces *EPCmax* gradually to accommodate for increasing wind power. Additionally, unforeseen contingencies are directly impacting power transmission capabilities. This is seen as example by the loss of the BAE—BwB cable at 09:35. Consequently, MIO reduces *EPCmin* until 13:30

6 Conclusions

The increasing installation of offshore wind power results in more demanding power collection and transmission tasks. Multiple wind farms get connected to offshore grids. Hybrid offshore grids connect the wind farms to multiple countries and thus serve for power transmission between those countries as well. This increases the operational complexity.

This paper shows how hybrid offshore grids can be operated with model-based nonlinear control, solving optimal power flow problems in real-time. The methods were implemented in the Master Controller for Interconnector Operation (MIO) for the Kriegers Flak Combined Grid Solution (KF CGS). KF CGS connects multiple wind farms in the Baltic Sea to the northern and continental European transmission grids. MIO was tested extensively with simulations using a digital twin prototype and has been in successful operation in the real system since December 2020.

As a result, the transmission of power through offshore grids is maximized, complex flexibilities arising from connections to multiple wind farms and multiple countries are exploited and the reliability is improved.

The formulation of the electrical models in dq coordinates results in linear equation systems for voltage and current phasors with quadratic output relationships for absolute voltages, e.g. as measured at busbars, and currents, e.g. determining cable loads. The absolute quantities are constrained in the optimal power flow problem. This results in a quadratically constrained quadratic optimization problem, allowing a reliable and fast numerical solution for the application in closed loop real-time control.

Significant speedups are achieved with parallel multiple shooting in dynamic optimization problems for the planning of the operation. Parallel automatic differentiation and optimization had been addressed in the PARADOM project.

Current research investigates the extension of future offshore installations with the production of green hydrogen and the use of gas pipelines complementing electric cables. The OpenSCALING project addresses the treatment of large-scale green hydrogen production with Modelica.

The FlightControl library for aircraft control design applications

Reiko Müller[1]

[1]DLR Institute of Flight Systems, Oberpfaffenhofen, Germany
reiko.mueller@dlr.de

Abstract

Controller development of aerial vehicles is a long-standing task during aircraft design and has a large impact on the resulting systems performance. In today's integrated design loops, ideally all components of the aircraft must be considered in simulation and testing in order to develop complex system architectures and meet performance requirements. One of the tools that are suited for modeling and simulation of a multidisciplinary aircraft and systems assembly is DLR's FLIGHTDYNAMICS Library, which takes advantage of the capabilities of the MODELICA modeling language. In this work, a new augmentation to the library is discussed, which implements a range of common aircraft control concepts which can be used for design of new controllers, closed-loop simulation and experimental testing via code-export. The library is set up in a modular way, so that flight guidance and flight control systems can be developed for multiple aerial platforms, including manned/unmanned fixed- and rotary-wing aircraft. For this paper, a simulation example is provided by means of an autoland controller that shall be designed for a high-fidelity 6-DoF fixed-wing aircraft model in MODELICA. The combination of aircraft and controller models is subjected to a three step synthesis process, which yields a controller that is robust against external and internal disturbances.

Keywords: *Flight control, flight dynamics, design optimization*

1 Introduction

As was laid out in previous publications (Looye 2008; Looye et al. 2014), the DLR FLIGHTDYNAMICS library is a well established tool for aircraft system design and simulation in the language MODELICA. It can be employed in a multitude of applications, spanning from systems design / Multidisciplinary Design Optimization (MDO) (Liersch and Hepperle 2011), trajectory optimization (Müller 2021), mission simulation as well as reliability and validation studies. Many of these setups require some sort of flight controller and / or flight guidance functions in order to adhere to the respective simulation scenarios. Therefore, an effort was made to bring flight controllers and flight guidance functionality to the library / to MODELICA, where previous approaches relied upon model export (i.e., via Functional Mockup Interface (FMI)) and usage of other tools for the controller design. Hence, this paper exemplifies the usage of the flight controller sub-library to relevant aerospace applications.

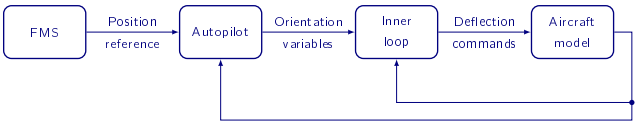

Figure 2. Standard cascaded flight controller layout: with flight guidance/trajectory generation (FMS) → Trajectory tracking (autopilot) → Tracking of aircraft orientation (Inner loop control).

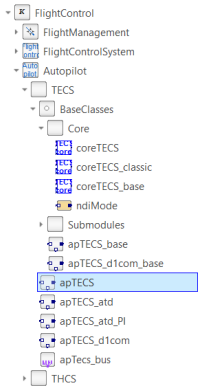
In Section 2, the overall structure of the sub-library is laid out. Section 3 covers the flight guidance functions (e.g. Flight Management System (FMS)). The actual flight controllers are discussed in Section 4, separated by the respective control task and design methodology. The application example covers the robust design of an autolanding controller and is laid out in Section 5.

2 Library structure

The FLIGHTCONTROL library was structured according to the classical perceiption of fixed-wing aircraft flight control where the control variables are associated with cascaded layers of tasks. This is possible due to the time-scale separation principle: the inner layer has the fastest dynamics, which allows to assume constant command inputs from the outer layer, where in turn, from the outer layer perspective, the reaction of the inner layer to commands are assumed to be instantaneous, see Figure 2. This separation is reflected in the library with subpackages for guidance (FMS), autopilot (shown in Figure 1) and inner loop controllers. Another distinction is made between classical flight control concepts relying on linear PID control and approaches containing more model information (like Nonlinear Dynamic Inversion (NDI) controllers) which are both collected in separate subpackages. The examples shown in the paper are of the first type, as they are better explainable with regards to flight physics as some of the more elaborated counterparts.



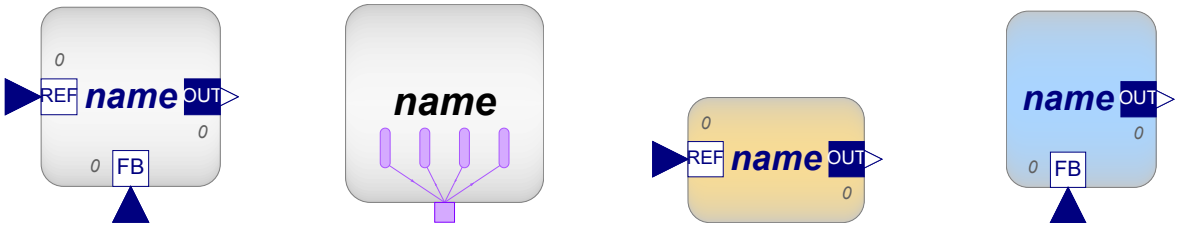


Figure 1. Opened autopilot package.

(a) The partial controller class. **(b)** The partial controller class using expandable bus inputs/outputs. **(c)** Partial guidance base class. **(d)** The partial computation base class.

Figure 3. Partial models that are used to discern between blocks with/without reference/feedback inputs, all blocks have an optional boolean input for integrator reset (not shown).

2.1 Interconnection with other libraries

As mentioned before, the FLIGHTCONTROL library lends itself to be combined with the DLR FLIGHTDYNAMICS library for easy integration with aircraft models or derivation of model-based controllers. With a clear I/O concept based on standard connectors and buses and a variable naming based on common standards (e.g. LN 9300, ISO 1151-1), it is also easy to integrate the flight controller library with other MODELICA based libraries for aircraft simulation. The base class models for controller blocks are shown in Figure 3. In addition, usage in form of exported models is possible, for example as Functional Mockup Unit (FMU) that can nowadays be integrated in a multitude of tools and languages (for example MATLAB®/SIMULINK®, PYTHON, etc.).

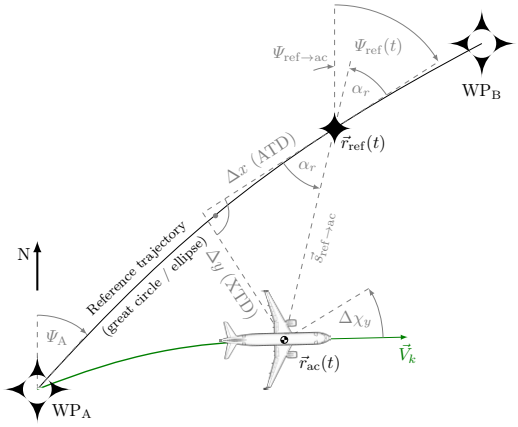

Figure 4. Variables for lateral tracking of a 4-D trajectory.

3 Guidance functions

The guidance module or often called FMS provides reference values for the downstream Flight Control System (FCS). While not being dependent on feedback in the sense of a controller, the FMS still needs information from the aircraft, for example to calculate a trajectory based on the current aircraft state or to provide switching of controller / autopilot modes. This is also reflected in the library, where models exist for 4-D continuous trajectory generation, and also a mode-based FMS relying on a state machine formulation with MODELICA STATEGRAPH2. Apart from this, the guidance focuses on the system kinematics, which are model - independent. For example the reference velocity $\vec{V}_k$ can be calculated from a trajectory given in ellipsoidal coordinates (φ, λ, h) by:

$$\vec{V}_k = [v_N, v_E, v_D]^\text{T} = \begin{bmatrix} (R_n + h)\cdot\dot{\varphi} \\ (R_e + h)\cdot\dot{\lambda}\cos\varphi \\ -\dot{h} \end{bmatrix}, \qquad (1)$$

with R_e, R_n as Earths radii of curvature. From this the usual reference variables V_k (total inertial speed), γ_k (trajectory pitch angle) and χ_k (course angle) can be calculated. If there is feedback from the aircraft, the inputs to e.g., 4-D trajectory tracking can also be provided, which would be the Along Track Distance (ATD) (for controlling time), as well as Cross-Track Distance (XTD) and altitude (for control of lateral / vertical offset), see Figure 4. The FMS can also be a part of a larger block involving an optimization to provide optimal trajectory guidance. In this case, the trajectory is parameterized (for example by polynomials/splines) and models a position (and time) trajectory that can be adjusted by an optimization algorithm to fulfill constraints and / or minimize objective functions (for details see (Müller 2020; Müller 2021)).

4 Flight control system

As mentioned in the introduction, for a cascaded flight controller, a separation can be made with regards to the time-scales of the control variables, and to the degrees of freedom of the aircraft.

4.1 Autopilot

As the outer loop controller, the autopilot keeps the aircraft on the desired trajectory specified by the FMS, usually in the variables altitude h, velocity V, heading angle Ψ as well as track length or time reference (sometimes sideslip angle β is also directly controlled, e.g. to facilitate cross-wind landings.). A well known and widely adopted autopilot controller for the longitudinal motion of the aircraft is the Total Energy Control System (TECS), see (Lambregts 2013a) for details. Considering the equilibrium of potential and kinetic energy of the aircraft,

DOI 10.3384/ecp218621

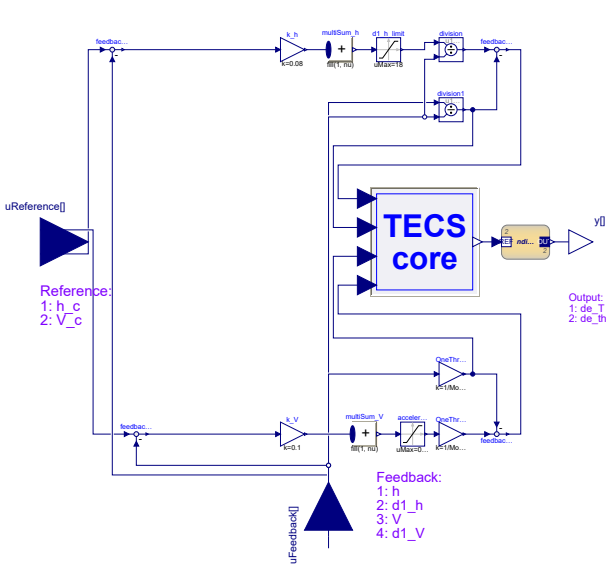

Figure 5. Realization of the Total Energy Control System (TECS). For 4-D trajectory tracking this controller serves as base class and is augmented with control of the ATD. By keeping ATD to zero, it is ensured that the aircraft will not fly ahead or behind the reference time-wise.

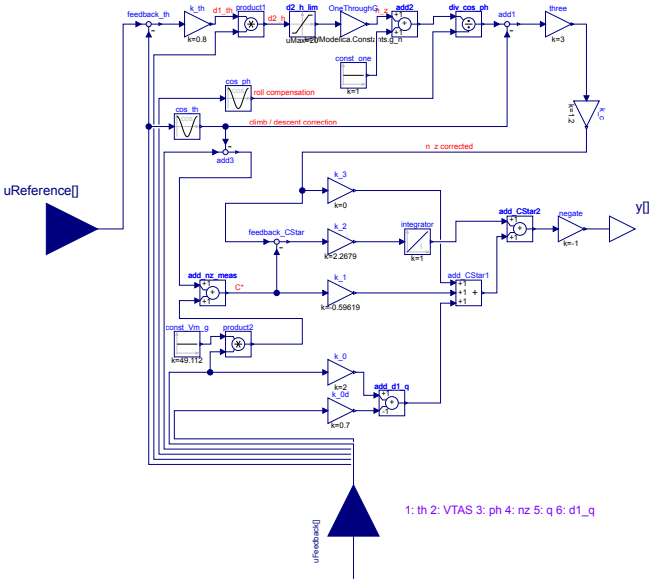

Figure 6. Aircraft pitch controller implementing the $C*$ - criterion for control performance and passenger comfort.

it builds upon the longitudinal force equation of a mass point:

$$m\dot{V}_k = T - D - mg \cdot \sin\gamma_k. \tag{2}$$

When assuming trimmed horizontal flight, errors in $\dot{V}_k$ and γ_k are cancelled with thrust and pitch commands δT and $\Delta\Theta$, working as energy generating and energy distributing control respectively. This coupling hence allows to control both channels in one block. An implementation using the FLIGHTCONTROL library is shown in Figure 5. A similar concept for the lateral aircraft motion was devised in the form of Total Heading Control System (THCS) (Lambregts 2013b), which is also implemented in the library but not shown here.

4.2 Inner loop

For the inner loop controller (sometimes denoted as Stability and Control Augmentation (SCA)), a separation into the roll/pitch/yaw channels (and thrust) can be made for fixed wing aircraft, as their longitudinal and lateral movement are usually not tightly coupled. The task of an inner loop controller is to increase mode damping and stabilization by generating appropriate control surface deflection commands (aileron, elevator, rudder) out of the reference inputs (e.g., commanded roll-, pitch- and yaw rates p_c, q_c, r_c) received from the autopilot. A number of controller architectures are possible here, implementing for example classical linear PID controllers (see e.g., (Brockhaus, Alles, and Luckner 2011; Stevens, Lewis, and Johnson 2015)) and model-based (e.g., dynamic inversion) approaches.

As a concrete example for an inner loop controller implemented in the library, see Figure 6. It represents a pitch controller, implementing the well-known C^* - criterion, where:

$$C^* = \frac{1}{g}\left(-\ddot{z} + x_{\text{pilot}}\dot{q} + V_m q\right) \tag{3}$$

is a weighting between vertical acceleration at the pilot position ($-\ddot{z} + x_{\text{pilot}}\dot{q}$) and pitch rate q. Since pilots judge aircraft reaction at high speeds depending on the former and at low speeds on the latter, this variable is well suited as pitch control variable throughout the flight envelope. The upper part converts pitch- to vertical load factor commands (also corrected for turning flight), which is then compared with the measured acceleration. Adaptation to an aircraft model can then be achieved by adjusting the five gains aligned in the middle, e.g. via pole placement and using aircraft derivatives obtained from linearization (which usually has to be done for a multitude of operating points in the flight envelope). An alternative to this for robust controller synthesis is an iterative process consisting of worst-case search across the envelope, multi-case optimization and Monte-Carlo analysis, which is shown in Section 5.

In addition to these structured flight control concepts, Multiple-Input Multiple-Output (MIMO) controllers can also be easily integrated, for example by using appropriate classes from the LINEARSYSTEMS2 library. Owing to the acausal modeling feature of MODELICA, a long tradition of using inverse models within the FLIGHTDYNAMICS library is preserved here in several controller implementations using concepts like NDI (Enns et al. 1994). All of the mentioned approaches however require model information, which is not included in the FLIGHTCONTROL library and has to be provided separately.

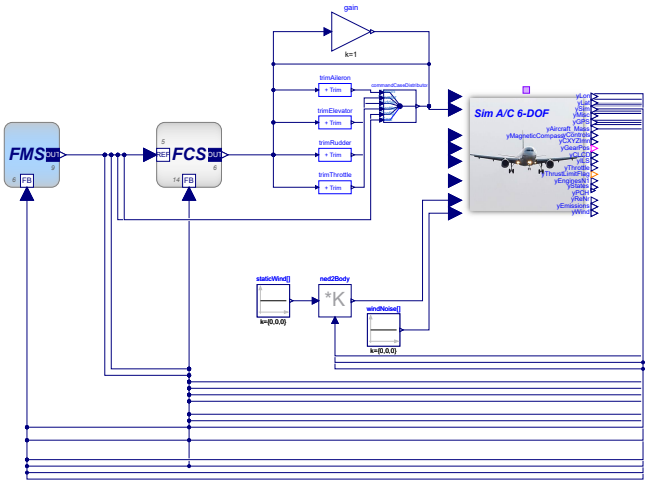

Figure 7. Assembly of FMS and Flight Control System (FCS) with aircraft model.

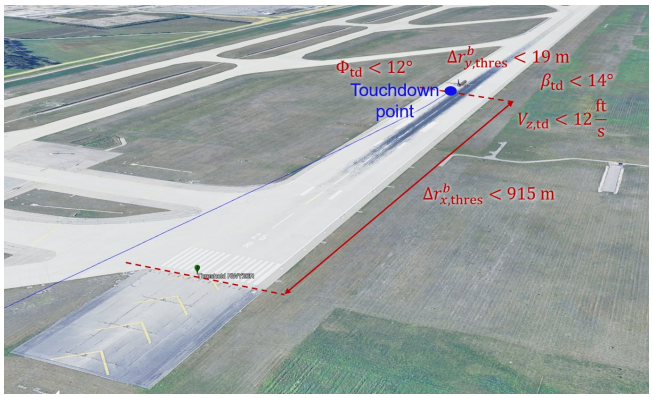

Figure 8. Touchdown criteria as specified by the CALC document.

4.3 Special control functions

The library also contains functions that are not part of primary flight control. This includes for example controllers for lateral and vertical gust load alleviation, which were deployed in (Müller and Ritter 2017). Controllers implementing Pseudo Control Hedging are for example important in trajectory optimization where non-feasible/flyable trajectories must be hedged with respect to different variables (mostly thrust). This is also crucial for simulation of High Altitude Pseudo Satellite (HAPS) aircraft with their very narrow velocity envelope, as was shown in (Müller, Kiam, and Mothes 2018). Related to landing, there are controllers for high-lift systems, which are based on various available specifications by manufacturers. Regarding autolanding, the library also contains controllers to follow the glideslope and glidepath, for manageing flare, groundroll and taxi. In the following example scenario, a respective autoland controller is designed.

5 Simulation example

An application of the FlightController library in conjunction with the FLIGHTDYNAMICS library as well as an optimization tool is shown in this section. The goal of this scenario is to investigate effects of sensor malfunction and disturbances on safe landing performance of an aircraft using GPS- and ILS-aided autolanding systems. The scenario is based on the description given in the Civil Aircraft Landing Challenge (CALC) proposed by Airbus and Onera in 2016 (AIRBUS 2016).

5.1 Modeling and scenario description

The 6-Degree of Freedom (DoF) aircraft and systems model is provided by the FLIGHTDYNAMICS library, as is shown in Figure 7. The GPS-, glideslope- and localizer sensors are the relevant systems in this setup and are subjected to distubances listed further below. The trajectory is part of the NAMUG 26R RNAV approach to Munich airport, starting from waypoint DM428 and landing on RWY26R, where the aircraft has to conduct a right turn. For this scenario, the 4-D FMS was not activated, since the focus was not to model aircraft scheduling but instead the adherence to the autoland criteria specified by the CACS challenge. The main objectives the aircraft has to fulfill when touching down are:

1. Absolute bank angle Φ_{td} lower than 12°,
2. Absolute sideslip angle β_{td} lower than 14°,
3. Lateral distance from the centerline $\Delta r^b_{y,thres}$ smaller than 19 m,
4. Longitudinal distance from the threshold $\Delta r^b_{x,thres}$ smaller than 915 m and
5. Vertical velocity $V_{z,td}$ at touchdown smaller than 12 $\frac{ft}{s}$.

The geometry of the constraints can also be seen in Figure 8. Disturbances are considered in the following systems and inputs:

1. A maximum of 100 ms in each of the roll/pitch/yaw and throttle channels of the controller, modeling worst-case cumulative time-delays in the whole controller.
2. Sensor noise in the GPS receiver with a maximum angle error corresponding to 5 m of position deviation.
3. Sensor noise in the glideslope and localizer sensors with a maximum signal boundary deviation of ± 10 % from the reference.
4. Winds with maximum values of 25/10/15 kts for head-/tail-/crosswinds. These values are translated in the model to wind strength and direction.

In order perform the autolanding, a combined FMS and FCS controller was used which either tracks the 3-D GPS

trajectory or controls lateral/vertical deviations from the localizer and glideslope signals to zero. For the flare and touchdown, a variable-τ law controller was implemented (for details see e.g. (Looye 2007)). In accordance to the CALC challenge specifications, the simulation is stopped after all three gears have weight on the wheels and commence braking, therefore excluding ground roll and taxi from the scenario. According controllers are however available in the library, for simulation examples (rejected takeoff, mission simulation) see (May, Müller, and Looye 2021).

5.2 Simulation and optimization

One way of obtaining a robust controller is an iterative process where in a first step, a worst-case search / anti-optimization was conducted in order to find the cases where criteria assume their worst value. This was realized in this scenario using a genetic algorithm optimizer (either e.g. from the OPTIMIZATION library (Pfeiffer 2012) or the DLR tool Multi Objective Parameter Synthesis (MOPS) (Joos 2016; Ossmann and Joos 2019)) with a population of 20 individuals and 100 generations. The parameters for the antioptimization are the controller time delays, the sensor noises and boundary devation as well as the wind disturbance mentioned in the last section. This yields the results shown in Figure 9, which represents 2-D cuts (one for each combination of the five criteria) through the 5-dimensional solution space generated by the optimization, along with histograms of occurrence. All the feasible, pareto-optimal solutions of the 100 consecutive generations are plotted (the colormap does not represent a value but shows which solutions belong together), and allows insight to possible criterion dependencies (for example, longitudinal deviation seems to decrease for higher touchdown speeds). It was found that only $V_{z,td}$ (marked with black triangles) generated critical results that are close or higher than 1 (value is normalized with maximum). In the second step, the controller gains and time constants for path tracking / glideslope capturing and the flare law are optimized for worst-cases in a common optimization setup. This is achieved by consecutive evaluation of each cases and min-max weighting of the resulting criterion values (the optimizer tries to minimize the current highest normalized criterion value) until all constraints are satisfied or the optimizer cannot find any better solution. Due to the non-convex nature and complexity of the model and setup, a gradient-free optimization algorithm (pattern-search, (Hooke and Jeeves 1961)) was employed. Also since only $V_{z,td}$ exceeded its admissible value (larger than one), the other criteria were considered active during the optimization, but were not as critical as the velocity in the min-max sense. The results of this optimization is shown in Figure 10, with the optimal solution colored in magenta.

(a) CDFs and PDFs for β_{td}.

(b) CDFs and PDFs for $\Delta r^b_{x,\text{thres}}$.

(d) CDFs and PDFs for Φ_{td}.

(e) CDFs and PDFs for $V_{\text{z,td}}$.

Figure 11. Monte-Carlo analysis of the found optimal controller subjected to random disturbances as specified in Section 5.1.

In the kinematics- (Figure 10a) and orientation (Figure 10c) plots, it can be seen that initial solutions touch down at slower speeds and higher incidence , which also leads to oscillations in the pitch axis due to the landing gear getting airborne again. Also cross-wind has a high effect during touchdown as the aircraft has not much control authority left to counter it. This leads to larger roll angles, which can also exceed the tolerances there. Furthermore there is a lateral deviation also caused through controller time delay and wind disturbance, creating an offset to the touchdown point and increasing deviation in the following roll phase (a roll controller is not implemented here). The ILS sensor noise however does not contribute to increased oscillations in the state variables which is probably due to its low magnitude and the damping of the controller. The final magenta controller however manages to fulfill all the requirements of the CALC including the longitudinal threshold deviation, which can be seen in the trajectory plot in Figure 10b.

In the third step, the obtained controller must be verified with respect to uncertainties and disturbances that might not have been present during the synthesis process. This is achieved in this case by a Monte-Carlo analysis taking into account the uncertain parameters listed in Section 5.1. The results of this process is shown in Figure 11, where 5000 simulations were conducted in an initial investigation. The failure probabilities postulated by CALC are shown as light red squares in the plots and may not be exceeded if the controller shall be considered verified[1]. For the criteria histograms, respective Probability Density Functions (PDFs) were fitted, leading to Cumulative Distribution Functions (CDFs) that mostly fit the obtained samples very well. One exception is the vertical velocity where small secondary occurrences are present around 7 $\frac{\text{ft}}{\text{s}}$ which are not covered by the unbounded Johnson PDF. This would make a sample-based analysis necessary in order to state the risk. Apart from this, all samples stay clear of the risk area with good margins, which allows the preliminary statement that the controller is safe in this exemplary simulation scenario. If that would not be the case, the three step process would have to be repeated iteratively, until the third verification step is successful.

6 Conclusion and outlook

In this paper, an overview of the FLIGHTCONTROL library was given, which was developed as an addon to the well-established DLR FLIGHTDYNAMICS library. The layout of the library and the main contents were described, along with examples of the main building blocks of an aircraft flight controller. Although these examples are mainly related to fixed-wing aircraft control, the FLIGHT-

[1] However, due to the small probabilities involved, the sample size should be much higher to ensure this with a certain confidence level. As this was considered out of scope for this exemplary simulation study and due to the long expected computation time, such a study was not performed here.

DOI
10.3384/ecp218621

CONTROL library also allows to integrate rotary wing, drone and other aircraft concepts, due to its modularity and straightforward application with other libraries (like the LINEARSYSTEMS2 and MSL).

A high-fidelity simulation study of an autoland approach trajectory was selected to showcase the controller synthesis capabilities of the library. For this scenario, an autoland controller was developed and tuned which behaves robustly under a wide range of external and internal disturbances. This was verified by an anti-optimization with subsequent multi-case optimization for controller gain tuning and finally a Monte-Carlo analysis to determine the safety of the found controller.

In the future, the FLIGHTCONTROL library will be further extended with means to automatically determine a controller's performance (e.g. via optimization and integration of common performance and handling quality measures). Furthermore, the support for model-based design approaches shall be extended and possibly concepts from optimal control (e.g. Model Predictive Control (MPC)) be included.

Quasi-Periodic Feedforward Control Based on Inverse Model Tabled FFT

Tilman Bünte[1] Jakub Tobolář[2]

[1,2]Institute of Vehicle Concepts, German Aerospace Center (DLR), {Tilman.Buente, Jakub Tobolar}@dlr.de

Abstract

Mitigating periodic oscillations (e.g. in rotating systems) is a common control engineering problem. Fast Fourier Transform (FFT)-based methods are well-suited for respective analysis. While FFT algorithms inherently assume signal periodicity, rotating systems often exhibit true periodic behavior (e.g., shaft rotation frequencies). Using angle-sampled data rather than time-sampled data allows direct analysis of oscillations relative to rotational cycles, which is particularly useful for tracking unbalance or periodic external excitation in rotating assemblies.
Modelica provides several built-in resources to address these challenges. First of all, inverse models have the potential to derive an ideal control signal in time domain. For periodic disturbances, this ideal control is likely to be approximated well by a periodic, i.e. Fourier-transformable signal. Modelica is an appropriate model environment to store and retrieve tabled FFT data depending on operating conditions such as rotational speed. In a real-time application, synthesizing control signals from precomputed Fourier tables offers a practical alternative to executing potentially complex inverse models online, reducing computational effort and system complexity. The paper demonstrates this approach using the example of mitigating oscillations induced by an internal combustion engine in a hybrid automotive power train.
Keywords: Model Inversion, Fast Fourier Transform, Fourier Synthesis, Vehicle Power Train, Torsional Vibration Suppression, Disturbance Cancelling

1 Introduction

This paper addresses mitigation or cancellation of periodic or quasi-periodic oscillations in technical systems caused by external or self-excitation mechanisms. To ensure clarity and simplicity, the presentation here focusses on mechanical 1D-rotational systems. However, the results can analogously be applied to other technical fields, for instance electric circuits or acoustic systems. The presence of a suitable actuator such as an electric motor is assumed which can be used as a torque source for control action. Considerations are here restricted to feedforward control without denying the potential of feedback control. More precisely, the approach presented here could well be combined with additional feedback control or other advanced methods like iterative control, invariant manifold tracking, and hybrid testing.

The novelty and main contribution of this paper is the Modelica based combination of the techniques

a) of model inversion for the synthesis of a theoretically perfect feedforward control,

b) the Short-Time Fourier Transform (STFT) of the quasi-periodic control signal and

c) model reduction of the control by approximating it with a correspondingly Fourier synthesized signal.

Moreover, a Modelica package is introduced and a practical application is demonstrated. To sum up the corresponding state of the art:

a) Model inversion in Modelica is a well established technique (Thümmel et al. 2005).

b) STFT is primarily used for analysing non-stationary signals whose frequency spectrum changes over time. In (Bünte 2011) it is used to determine describing functions of Modelica models. In (Kuhn 2017) it is used for stationary periodic steady state identification of AC electrical systems.

c) FFT for model reduction is applied for instance in the fields of material science (Gierden 2024) and Finite Element Method (FEM) based product design (Hülsebrock 2023).

In addressing the issue of quasi-periodic disturbances impacting a rotational system, we consider that the primary period of any given oscillation maintains a constant ratio relative to a single revolution of a reference shaft. For instance, an internal combustion engine (ICE) generates a periodic torque and hence torsional oscillations in the drivetrain due to the sequential firing of its cylinders. The harmonic structure of the crankshaft torque oscillations is typically influenced by factors like ICE speed, load torque, and throttle position. Given the known period of the oscillation, for a specific operational case (ICE speed, throttle position etc.) a STFT of the periodic crankshaft torque can be performed over the time window of one period. The resulting Fourier coefficients for a limited number of harmonics approach the dynamic torque characteristic of the ICE for this operational case. Thus, the complex thermodynamic process plus piston and rod related

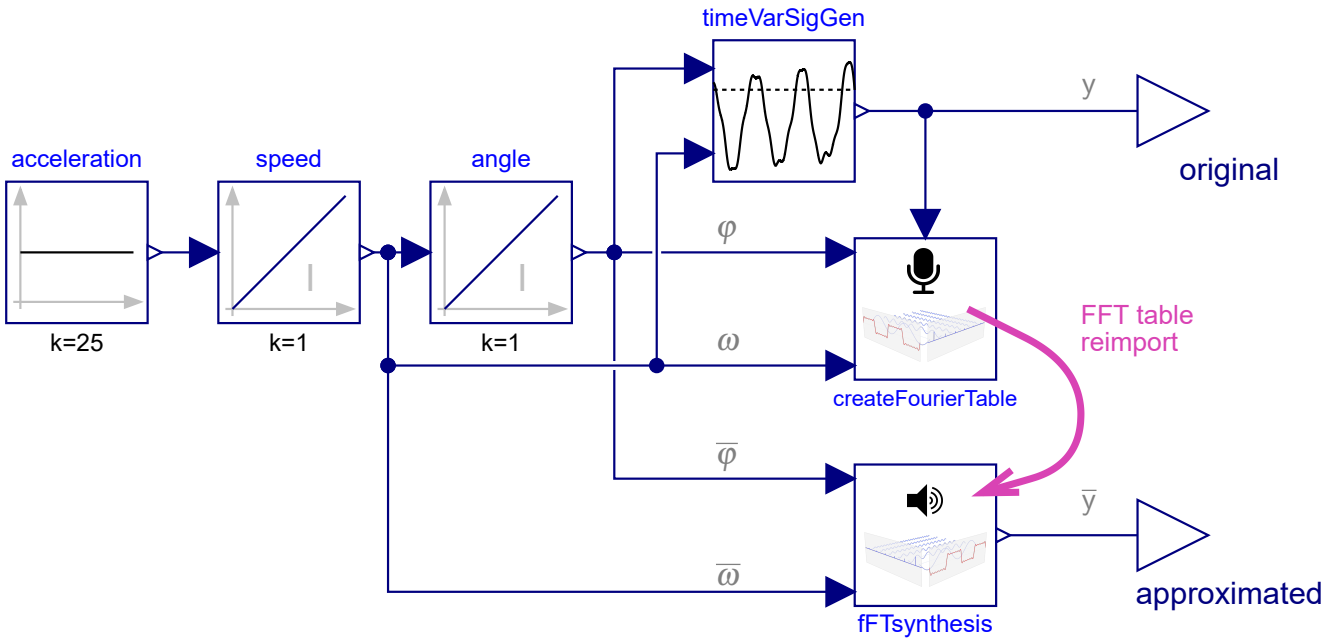

Figure 1. Demo Modelica model combining instances of the blocks `CreateFourierTable` and `FFTsynthesis`.

inertia dynamics in an ICE could be approximated and represented by a set of Fourier coefficients for the torque on the crankshaft (Chauvin et al. 2004), stored in a (multidimensional) table depending on operational parameters while using appropriate gridding. Obviously, a Modelica model of an ICE can be easily built as a Fourier synthesis-based signal generator acting as torque source and using the above-mentioned table for parameterization.

The paper is organized as follows. Section 2 presents a concise Modelica package which comprises classes for a) the repeated determination of STFT coefficients for a signal of a time varying oscillating system and b) a signal synthesizer as an effective approximative representation of the previously decomposed system and c) a demo model combining a) and b). A complex quasi-periodic nonlinear system which may be difficult to be solved numerically can thus potentially be replaced by interpolation from a lookup table. For some cases this can serve as a model reduction technique e.g. in view of real time capability. Section 3 considers the cancellation of quasi-periodic disturbances on a system by means of model inversion (well familiar to Modelicans (Thümmel et al. 2005)). Section 4 integrates the features of Sections 2 and Section 3 and thus, represents the main contribution of this work: A feedforward control scheme is presented which is based on the STFT decomposed ideal control signal from the inverse model. In Section 5, a hybrid automotive power train model with ICE and integrated starter generator (ISG) is used to demonstrate the practical applicability and relevance of the feedforward control scheme. Finally, Section 6 provides a conclusion and an outlook.

2 A Modelica Package for Fourier Decomposition and Playback of Quasi-Periodic signals

A Modelica package `FourierTable` was designed which provides

- a recording block `CreateFourierTable` using repeated STFT of a quasi-periodic signal y occurring in a Modelica model and
- a counterpart block `FFTsynthesis` for playback of a signal $\bar{y}$ using Fourier synthesis.

See Fig. 1 for an example which combines both classes in one Modelica model. A reference y ("original") is generated by a time varying signal generator `TimeVarSigGen`. The simulation of this demo model allows for direct comparison of y and its approximation $\bar{y}$. To do this, it is necessary to simulate twice. In the first run, the Fourier coefficient table is generated by `CreateFourierTable` and saved to a mat-file. During initialisation of the second run, this table is loaded as parameterization of `FFTsynthesis` which facilitates a meaningful comparison.

For the recording using `CreateFourierTable` it is assumed that the total Modelica model has the following features:

- There is a signal ω and its integral φ (e.g. with the physical meaning of angular speed and position, respectively, of a rotating shaft). It is further assumed that ω is varying slowly enough, such that "quasi-periodicity" of a considered signal y is always sufficiently well maintained. The reader is referred to Section 2.4 for deeper considerations.

DOI 10.3384/ecp218629

- The actual fundamental period of the signal y corresponds to an increase of φ by 2π (one revolution of the shaft). Consequently, periodicity of y relates to φ, not time.
- The composition of the signal y in terms of harmonics depends only on one single time varying parameter q. The latter could be but not necessarily is $q = \omega$. For the sake of simplicity, this case is assumed in the following.

During a simulation of the considered system while typically ω is monotonously increasing, events are triggered when ω reaches predefined threshold values. After each event, a STFT analysis of y is performed over the window of a complete period of φ (i.e. one revolution). Hereafter, the Fourier coefficients are stored into a new row of a table with the actual ω value in the first column, cf. Table 1 for illustration.

For playback (normally in another Modelica model), the previously collected tabled data is used as parameterization for an instance of `FFTsynthesis`. Using $\overline{\varphi}$ and $\overline{\omega}$ as inputs to the playback block, Fourier coefficients are interpolated from the table and a quasi-periodic signal $\overline{y}$ is generated which approaches y of the original system for $\overline{\omega} = \omega$ and $\overline{\varphi} \pmod{2\pi} = \varphi \pmod{2\pi}$.

The record and playback blocks are now described in more detail.

2.1 Data Sampling and Repeated STFT of the Quasi-Periodic Signal

The block `CreateFourierTable` has the following parameters:

```
parameter Integer n = 9 "Exponent; Number
 of angle samples per period is np = 2^n";
parameter Modelica.Units.SI.AngularVelocity
  wnodes[:] = linspace(10,100,5) "List of
 frequency nodes where data acquisition for
 STFT evaluation is triggered";
parameter Integer nh = 2 "Number of
 harmonics";
```

The block mainly consists of a single algorithm section. It is activated each time when the monotonously increasing signal ω surpasses one of the scheduled `wnodes` values. Now, sampled data for y is being collected during the newly started period in order to prepare for later STFT. The current φ period is divided into an equidistant grid of 2^n samples according to the model parameter `n` and data collection is triggered at each φ grid point. After the period is complete, the block is put to sleep til the next ω-induced activation in order to save non-essential events and thus to reduce computational effort.

As soon as data collection over the period is completed, an STFT is performed using the function `Math.FastFourierTransform.realFFT()` (Cooley and Tukey 1965) from Modelica Standard Library. A second input to the function is the number of frequencies specified by the model parameter `nfi` $= 1 +$ `nh` equalling the DC part plus the desired number of harmonics to be considered. The resulting amplitudes a_i and phases ϕ_i of the harmonics are stored into a new row of a table whose first column holds the mean value of ω during the collected period, cf. Table 1. Hence, the ω node differs a bit from the actual `wnodes` value. In most cases the exact values of the table interpolation nodes does not matter; the parameterization of `wnodes` can be used for an approximate scheduling. The table is filled during the simulation of the total model while ω is monotonously increasing and sweeps over the range of scheduled `wnodes` values. Section 2.4 will provide comments on selecting `wnodes` and appropriately scheduling the rate of change for ω.

Upon end of simulation, the resulting table is stored as a matrix which represents the set of Fourier coefficients for the quasi-periodic signal y at the given ω nodes. The sampled data collection of quasi-periodic signals and Fourier decomposition was reused from (Bünte 2011).

2.2 Signal Approximation by Fourier Synthesis

A set of Fourier coefficients (compliant with the format of the table generated from `CreateFourierTable` as described before) is the only parameter of the block `FFTsynthesis`:

```
parameter Real table[:,:] "FFT table as
 function of angular velocity (w rev/s (col.
  1), amplitudes (col. 2:nfi+1), phases (
 col. nfi+2:end))";
```

For the given input value of $\overline{\omega}$ (cf. Fig. 1), the corresponding set of Fourier coefficients is interpolated from the table. The synthesis of the signal $\overline{y}$ is straightforwardly computed by superposition of the `nfi` frequencies (DC part plus `nh` harmonics) with the (real or virtual shaft angle) input $\overline{\varphi}$ as independent variable:

$$\overline{y}(\overline{\varphi},\overline{\omega}) = \sum_{i=0}^{nh} a_i(\overline{\omega}) \cos\left(i\,\overline{\varphi} + \phi_i(\overline{\omega})\right) \qquad (1)$$

For a constant $\overline{\omega}$ the resulting signal $\overline{y}$ is strictly periodic. If $\overline{\omega}$ is slowly varying compared to the periodicity 2π of the cosine function argument, then $\overline{y}$ renders *quasi*-periodic.

2.3 Demo Model Simulations

Fig. 2 presents the results of two successive simulations of the demo model introduced with Fig. 1. The *original* output from the signal generator `TimeVarSigGen` consists of a DC part plus a stationary first harmonic plus a second harmonic whose amplitude changes with ω. Finally, there is a stationary fifth harmonic with a small amplitude:

```
y = -2.212
    +3.346*cos(1*phi + 0.526)
    +1.233*cos(2*phi + 0.745)*(0.3+1*cos
     ((w-10)/5))
    +0.300*cos(5*phi - 0.745);
```

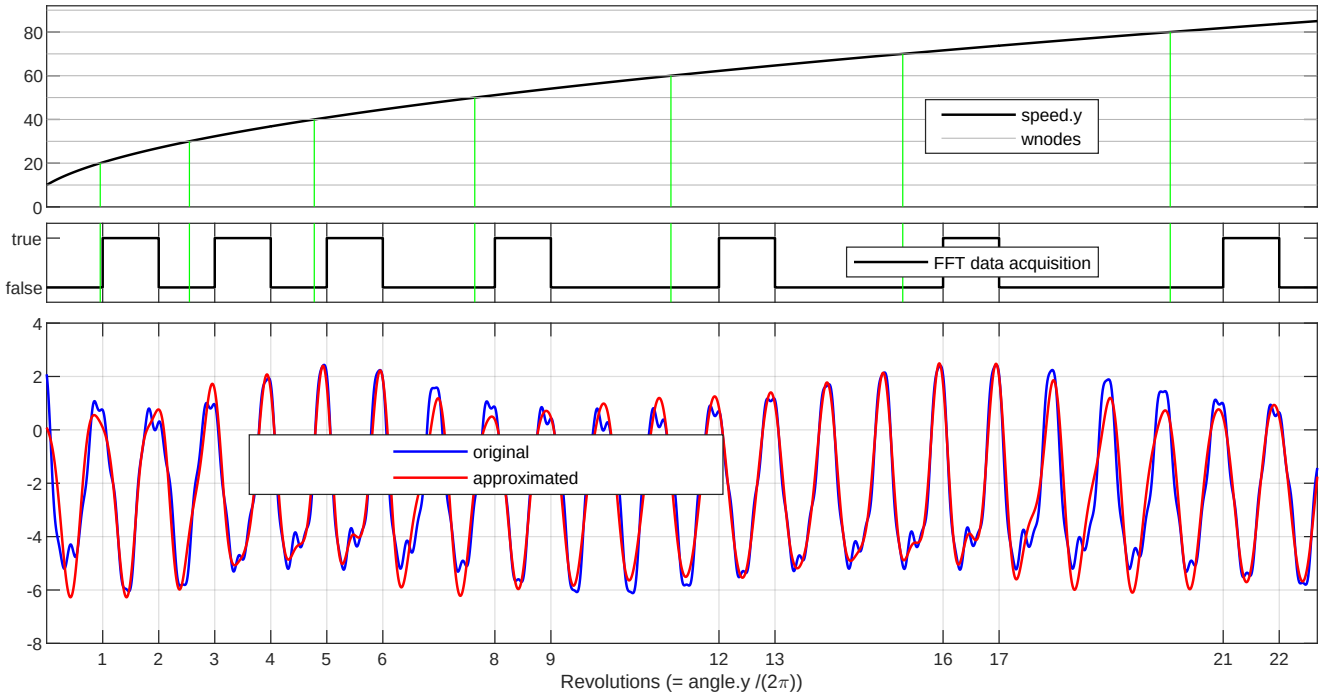

Figure 2. Simulation results from the demo Modelica model shown in Fig. 1. Top: Rotational speed and thresholds; Middle: Indication of data acquisition phases; Bottom: Comparison of original signal y with its approximation $\bar{y}$.

A first run of the model is made here with `CreateFourierTable.nh` $= 2$, i.e. only two harmonics are to be considered for the STFT. The table generated by `CreateFourierTable` is automatically saved to a file and then used as parameterization for the block `FFTsynthesis` in a second simulation. (Additional simulations with the model would deliver the same results as from the second run.) The upper plot in Fig. 2 shows the rising of $\omega =$ `speed.y` and the constant `wnodes` thresholds. Green vertical lines indicate the instants where the thresholds are surpassed. The FFT data acquisition phases, each covering the complete subsequent revolution, can be seen from the middle plot. Rather than time, in all plots the number of revolutions equalling $\varphi/(2\pi)$ is used as abscissa. The lower plot compares the *original* signal `TimeVarSigGen.y` with the *approximated* signal `FFTsynthesis.y`. Table 1 exhibits the example's numerical values for the Fourier coefficients interpolation table, compliant with the notation used in eq. (1). Where $\overline{\omega}$ is close to interpolation nodes, the lower plot shows good agreement of the approximated signal $\bar{y}$ (red) with the original reference y (blue). Understandably, here the interpolation of the Fourier coefficients for signal reconstruction matches best the recorded characteristics.

2.4 Parameters Influencing Approximation Quality

Obviously, the accuracy of the approximated signal depends on some parameters during data acquisition. Some skill and experience is required for their choice. In practice, the parameters of `CreateFourierTable` (see Section 2.1) and the total model can be adapted such that sufficient precision of the approximated signal is attained:

1. If denser gridding of `wnodes` is used, then the agreement of $\bar{y}$ with y is correspondingly better in-between

Table 1. Interpolation table for Fourier coefficients, compliant with the notation used in eq. (1), resulting from the demo model simulations.

$\overline{\omega}$	a_0	a_1	a_2	$\phi_0[^\circ]$	$\phi_1[^\circ]$	$\phi_2[^\circ]$
23.827	−2.2350	3.3433	0.71776	0.0000	31.639	−136.93

DOI
10.3384/ecp218629

the interpolation points.

2. The same applies to the rate of change of ω during data acquisition. If ω or any other operating conditions q are not changing slowly enough, periodicity is not sufficiently satisfied and the result may be spoiled. Generic statements about reasonable limits on the rate of change are difficult to derive and exceed the objective of this publication. A heuristic approach will serve well in most applications and the rise of ω should be controlled to be sufficiently moderate in the simulation such that the results are satisfactory.

3. The number `nh` of harmonics considered in the recording affects the achievable accuracy and should be chosen accordingly.

4. A large value of the parameter `n` contributes to good results. The Nyquist–Shannon sampling theorem (Franklin et al. 1990) should be regarded in the context of the considered harmonics. On the other hand, more data sampling events are triggered in the block `CreateFourierTable` during the FFT data acquisition phases and the analysis simulation takes more effort.

Note that in the example shown in Fig. 2 some of the above enumerated recommendations are violated for the sake of illustrating their effect: Due to the rapid rise of ω the periodicity assumption was not held. As a side effect, the resulting set of interpolation nodes for ω (cf. Table1) is coarse. The STFT only considered two harmonics, therefore the fifth harmonic oscillation of the original signal is not captured.

3 Inverse Model Based Disturbance Cancellation

Here, we use the term *disturbance* to mean an undesired effect on a specific system signal induced by (quasi-)periodic external or self-excited quantities.
Inverse linear and nonlinear models are of significant meaning as building blocks for the design of control systems, both for feedforward and feedback control. One of the outstanding features of Modelica is that nonlinear inverse models may under circumstances be automatically generated from the plant model (Thümmel et al. 2005).
Particularly, when addressing the problem class considered in this paper, the ideal control signal for cancelling disturbance can be derived using an inverted model, provided that the conditions for model inversion are fulfilled such as uniqueness and stable zero dynamics. Details on this can be found in (Thümmel et al. 2005; Thümmel 2007). To accomplish model inversion, the equation defining the control signal (i.e. the actuator input) is removed. Hence the total model equations will be solved for this quantity to be an output. The number of equations needs to remain balanced with the number of unknowns such that the model equations can be solved and the model can be translated and simulated. Therefore, replacing the removed control signal, an equation is added to the Modelica model which represents a desired behaviour of a specific model's quantity. In our case, this is an adequate disturbance cancelling condition, e.g. with the meaning that a desired target signal is set to zero or follows perfectly a certain reference.

In the case that the inverse model is lean and real-time capable, it can be used to generate the control signal for a given (periodic) disturbance and that control signal can be applied feedforward to a real system. If the basic model matches well enough the real system, then the control signal has the potential to significantly mitigate the disturbance. However, in general, solving the inverse model in real time may be unfeasible or computationally expensive. Moreover, the approach presupposes that the inverse model stays in tune with the real system in terms of system states and/or operating conditions. These challenges suggest to use an abstraction of the inverse model which combines the approaches from Section 2 and this one, to be introduced in the next section.

4 Feedforward Disturbance Cancellation Using Fourier Synthesized Approximation of the Ideal Control Signal

As this section is the core, the key idea of the paper is presented in four subsequent steps while using the Modelica implementation of the recording and playback blocks presented in Section 2:

1. As outlined in the previous section, an inverse model can be employed to generate an ideal, theoretic control signal for a given objective such as cancelling a target signal. In case of constant operating conditions including a perfectly periodic disturbance and the system model being in steady state oscillation this approach yields a periodic solution for the control variable.

2. The *pattern* of this periodic signal in terms of its harmonics can be expressed as Fourier coefficients and be considered as an eligible blueprint for periodic feedforward control action (to be applied with appropriate phase) for the given system model at steady operating conditions.

3. The blueprint can be applied to a real system by means of a Fourier synthesizer if

   - the periodic trigger for the disturbance can be measured or estimated and
   - the system matches the operating conditions of the underlying model which was used to generate the pattern.

4. If the operating conditions of the real system do vary and it is not in perfect steady state, then modified patterns are applied, each fitting the prevailing operating conditions.

    - For a manifold of operating conditions, the patterns are Fourier synthesized based on interpolated Fourier coefficient datasets which were generated each via STFT using a sufficiently dense node gridding to achieve good approximation.
    - For practical application of the approach, the recording of the patterns with the inverse system model should be done while the operating conditions are varying sufficiently slowly such that the inverse system model is always in quasi steady state.
    - The same applies to the playback of the patterns on the real system. The results will be best if the operating conditions vary only slowly such that the real system model is in quasi steady state oscillation.

5 Automotive Application Example: Hybrid Power Train

The application example used here is based on a simplified automotive mild hybrid power train consisting of a four-stroke four-cylinder internal combustion engine (ICE) plus integrated starter generator (ISG) mounted on the extension of the crankshaft.

5.1 Modelica Power Train Uncontrolled Base Model

The total Modelica model of the power train, depicted in Fig. 4, is completed by an abstracted drive train including rotational spring and damper plus an inertia representing the total load including the translated mass of the vehicle body. To facilitate a perfectly common scenario for various variants to be compared later, the model features a signal source (`speedScheduler`) which imposes a predesigned rotational speed profile to the inertia.
The ICE produces a quasi-periodic dynamic torque that varies with rotational speed. This torque consists of two main components:

- The forces generated by the pressure in the four cylinders, which follow the firing order and occur every second crankshaft revolution, influenced by the geometric arrangement like in boxer or V engines (Laschet 1988).
- The asymmetric inertial forces of the pistons and connecting rods.

Fig. 3 illustrates the resulting periodic torque pattern at full throttle for the ICE model used with a set of curves representing different crankshaft speeds.

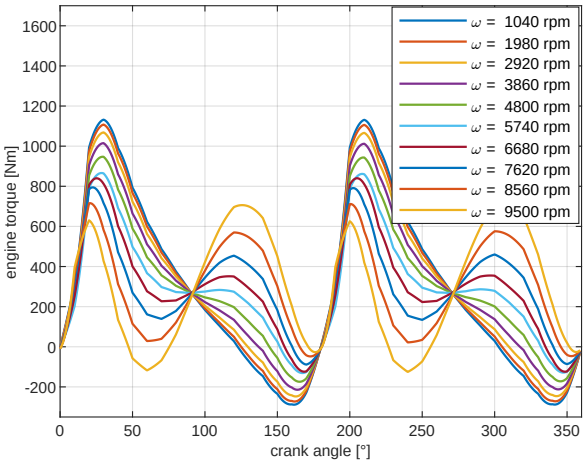

Figure 3. Full throttle periodic output torque of the four-stroke four-cylinder ICE depending on crank shaft speed ω.

The objective of the feedforward control derived in the next two subsections is to compensate for the quasi-periodic ICE torque variations around the DC torque component of the ICE such that torsional oscillations in the drive train are minimized.

5.2 Fourier Coefficient Recording of Ideal Control Using Inverse Model

Following the concept introduced in Section 2.1, a Fourier coefficient table is generated using the inverted model shown in Fig. 5. Therefore, starting from the model of the uncontrolled base model (Fig. 4), a `CreateFourierTable` block is added to the system. The block `Math.InverseBlockConstraints` from the Modelica Standard Library is used to invert the model such that the combined output torque of ICE plus ISG equals a constant torque (set to 280 Nm here to reflect the approximate mean torque of the ICE). In return, the equation defining the input torque of the ISG is dropped. By effect of the model inversion this quantity is calculated during the simulation and, repetitively, the STFT is performed after discrete rotational speed values are surpassed.

5.3 Power Train Feedforward Control for Approximative Disturbance Cancellation

Feedforward control of the hybrid power train using the Fourier synthesis introduced in Section 2.2 is applied here. The model shown in Fig. 6 uses the ISG torque as control variable. An instantiation of the block `FFTsynthesis` contains the FFT approximated and tabled information of the perfect disturbance cancellation control previously acquired using Fig. 5 as described above.

5.4 Comparative Simulation Results

For the plots shown in Fig. 7, results are compiled from simulations with the three models described in Sections 5.1-5.3 and Figures 4-6, respectively.

The scenario for all three simulations is the same: The drive train is accelerated constantly according to a given

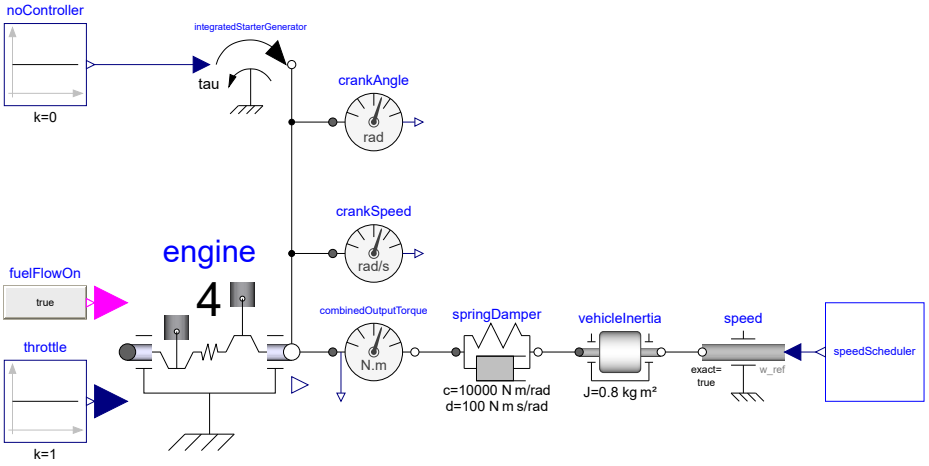

Figure 4. Uncontrolled power train model with imposed speed.

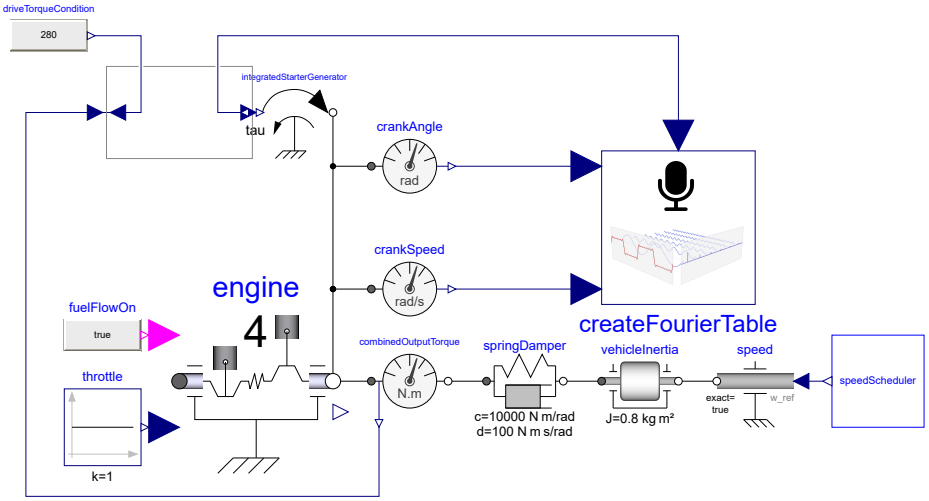

Figure 5. Inverse power train model for repetitive STFT recording of ideal control action.

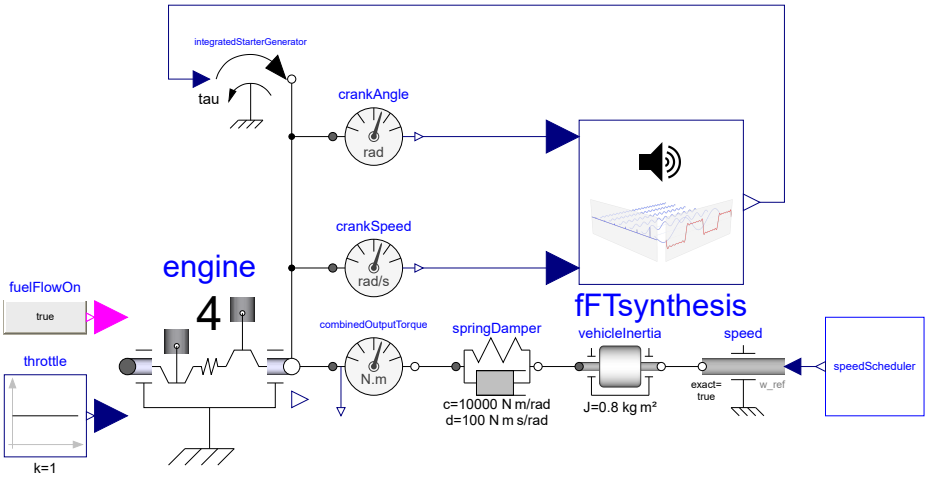

Figure 6. Feedforward controlled power train.

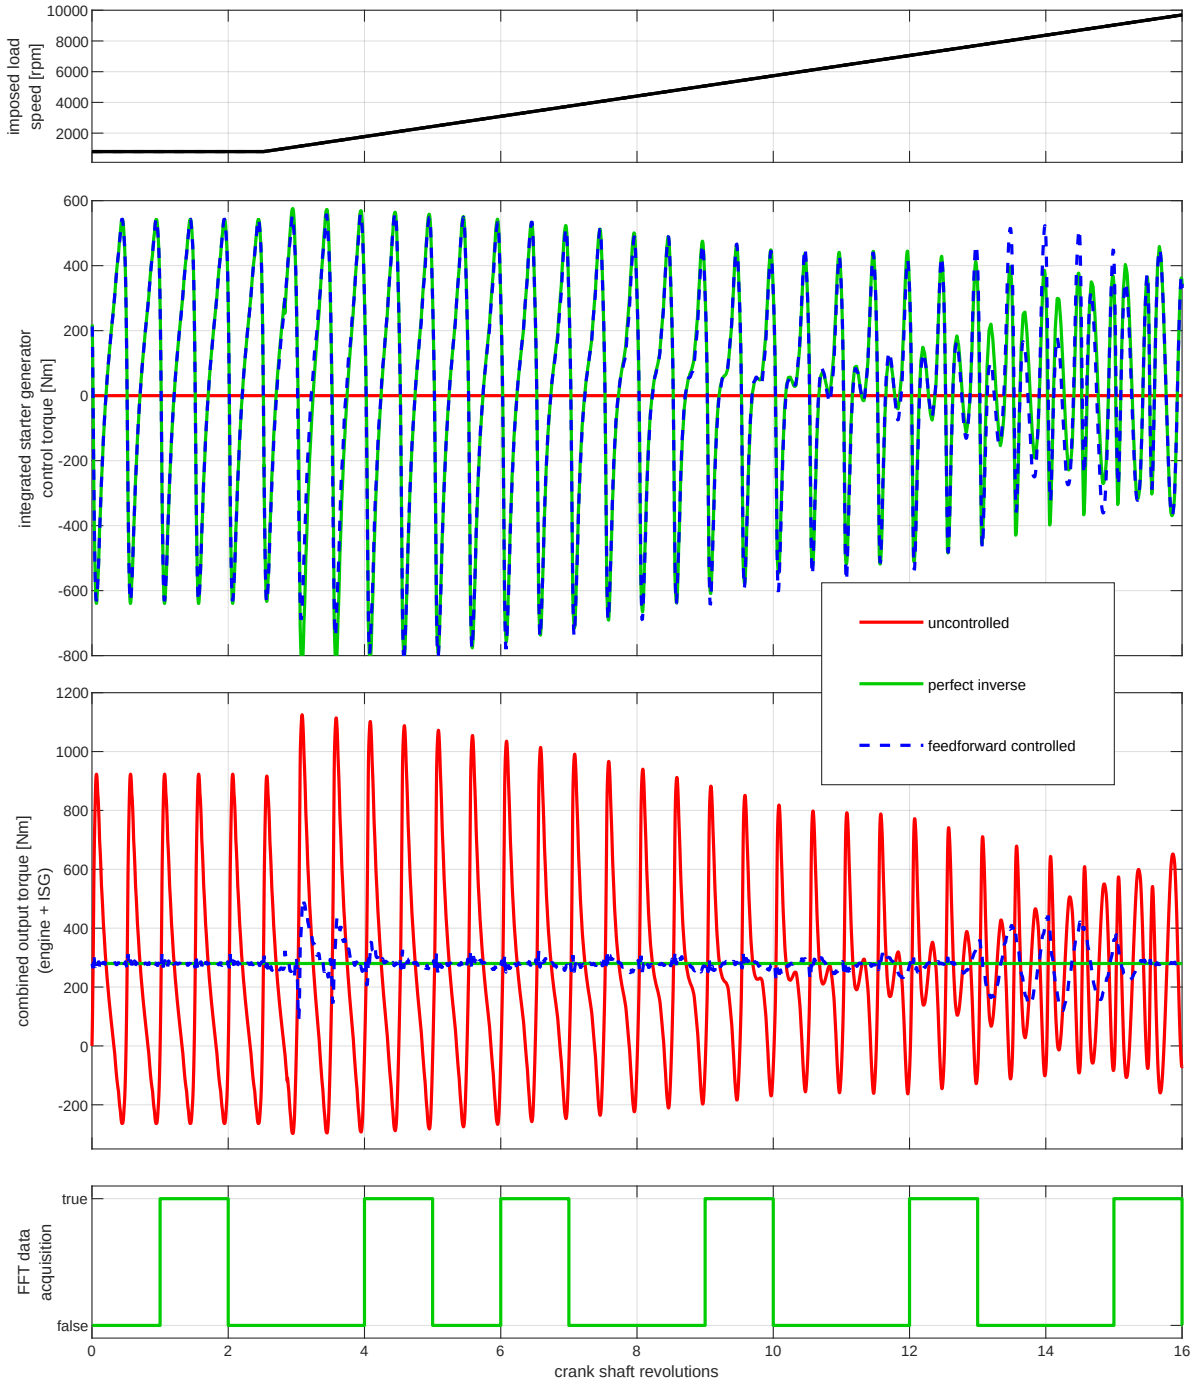

Figure 7. Simulation results comparing various variants of the automotive power train under quasi-periodic disturbance. 1st row plot: rotational speed; 2nd row: ISG control torque; 3rd row: total torque from ICE+ISG; 4th row: data acquisition phases.

DOI
10.3384/ecp218629

speed ramp. By this means, the acceleration is even higher than in a flying start with the purpose that within only few revolutions a large range of speeds is covered. Thus, the speed dependency of the quasi-periodic disturbance is well cognizable in the plots of single simulations. The uppermost plot in Fig. 7 shows the imposed speed of the drive train being the same for all three models. The control input (i.e. the ISG torque) is plotted in the second row plot. The control torque of the uncontrolled base model (corr. to Fig. 4, red line) is zero. The resulting combined output torque of ICE plus ISG exhibits high amplitude quasi-periodic spikes (see third row plot, red line). With model inversion applied (green line each, corr. to Fig. 5) the combined torque is set to zero and the resulting perfect (theoretic) ISG control torque renders quasi-periodic. During the same simulation, data for STFT is acquired in the complete revolutions where the corresponding flag is true, see lowermost plot. After completion of each data acquisition phase, computed Fourier coefficients are stored in the FFT table in a node associated with the mean speed of the past revolution. As usual with interpolation from tabled data, the result is most precise when the query speed is close to one of the speed nodes. This effect can be observed from the simulation results with the feedforward controlled model (corr. to Fig. 6, blue dashed lines). At speeds where FFT data was acquired with the inverse model, the feedforward control performs significantly better in terms of the combined output torque.

6 Conclusion and Outlook

In this paper the combination of the following three Modelica based techniques has been introduced:

- Model inversion for the synthesis of a theoretically perfect feedforward control aiming at compensation of time varying periodic oscillations.
- Repetitive Short-Time Fourier Transform (STFT) of the quasi-periodic control signal.
- Model reduction of the ideal control by approximating it with a correspondingly Fourier synthesized signal depending on varying operation conditions.

A Modelica package has been explicated and the practical application to mitigation of self-excited quasi-periodic disturbances in an automotive hybrid power train was demonstrated.

The effectiveness of the presented feedforward control scheme depends on the periodicity of the disturbances. The operating conditions (for example the rotational speed) should be varying slowly enough such that quasi-periodic behaviour prevails at all times, i.e. the relevant signal should be well approximated in sections by periodic signals. Moreover, a measurement or estimation of the disturbance trigger (e.g. the rotational angle of a shaft) should be available. And, the disturbance to be mitigated should be truly (reproducibly) depending on the trigger. Under these assumptions a feedforward control following the concept described here should be worthwhile to be considered for cancellation of oscillations.

Note that suppression of disturbances which are stochastic (noise) or of other external or non-(quasi-)periodic nature are not in the scope of the approach. Therefore, these were not considered here.

Possible enhancements of the approach include the following:

- The use of more elaborated window functions to mitigate spectral leakage artefacts.
- Currently, the window for data acquisition and Short-Time Fourier Transform covers one shaft revolution, with the shaft angle starting at the next multiple of 2π. An appropriate window shift could handle this issue to get the ω interpolation nodes of the resulting table closer to the scheduled `wnodes` values.
- The Fourier coefficient table employed so far covers a single varying parameter q which was synonymic with ω in this paper. However, a second influencing variable (such as the throttle position in our application example) could be considered and the table could provide bivariate interpolation (using `CombiTable2Ds` instead of `CombiTable1Ds` within `CreateFourierTable`). Of course, this requires an elaborate parameter gridding and approaching schedule (going beyond the previous concept explained with `wnodes`) for the analysis/recording simulation while using the `CreateFourierTable` features.

Abstract

This paper presents Liaison a new open-source tool designed to address challenges related to portability, security, and intellectual property when sharing Functional Mock-up Units. Built on the Functional Mock-up Interface 3.0 standard, Liaison has a server-client architecture that leverages Zenoh for communication. Zenoh is a novel pub/sub/query protocol that supports a variety of network topologies such as peer-to-peer, routed, mesh and brokered communication with minimal configuration, setting Liaison apart from similar tools. An example of a case that led the authors to develop this tool is presented.

Keywords: distributed co-simulations, maritime onboard systems

1 Introduction

The Functional Mock-up Interface (FMI) (Blochwitz et. al, 2011, Blochwitz et. al, 2012, Junghanns et. al, 2021) is a widely adopted standard in system simulation, providing a versatile and vendor-neutral framework for model exchange (ME) and co-simulations (CS) (Gomes et. al, 2018). At its core, FMI defines a set of conventions and interfaces that govern how simulation models interact with simulation environments, allowing for the encapsulation of models as Functional Mock-up Units (FMU). A FMU encapsulates a simulation model along with their associated parameters, inputs, and outputs, as compiled code black-boxes enabling the exchange and utilization across simulation tools that has implemented support for the FMI standard. For ME, the FMU does not include the model's solver, whereas for CS, the FMU also includes the solver of the model.

In practice, several factors can make sharing FMUs unfeasible. Such factors can include, but are not limited to:

- Portability issues (e.g. different operating systems or license requirements for execution of the FMU)
- Intellectual Property (IP) protection.
- Fear of unintended re-distribution of the FMU
- Fear of a FMU containing malicious code.

To overcome these obstacles, a distributed approach can be utilized where the FMU stays within the control and premises of the model owner but connects to a simulation environment over a network when desired. The connection can be made over a local area network or a wide area network such as the Internet.

Table 1 summarizes the issues solved by running distributed co-simulations locally, in a LAN, and in a WAN.

Table 1. Potential issues solved by running distributed co-simulations.

Issue	*Local*	*LAN*	*WAN*
FMU portability	x	x	x
Security	x	x	x
IP protection			x

FMU portability can be addressed by running distributed co-simulations locally, in a LAN, and in a WAN. In both LAN and WAN setups, a computer with a suitable operating system, environment, or hardware, can be used to serve the FMU, while another computer can be used to run the simulation. Meanwhile, security and IP protection can be address by running distributed co-simulations on a WAN across organisations. In this use case, one organisation creates a client FMU from a source FMU and delivers it to another organisation. This approach enables co-simulations without the transfer of intellectual property or risk of running malicious code.

Several tools for such distributed co-simulations have been developed. The most relevant for the work presented in this paper, is the FMU-Proxy (Hatledal et al., 2019) which is an open-source framework for distributed co-simulations supporting FMI 1.0 and 2.0. The original FMU is wrapped into a proxy FMU that is accessed through Remote Procedure Calls (RPCs). In this way, the platform becomes independent of both the FMU implementation language as well as the platform it runs on. FMU-Proxy relies on a combination of different

communication protocols such as HTTP, HTTP2, Websockets and TCP/IP.

In this paper we present Liaison (Liaison 2025), a new open-source tool for distributed co-simulations based on the FMI 3.0 standard and the Zenoh communication protocol (Corsaro et al., 2023). The decision to develop a new tool for distributed co-simulations was motivated by that existing tools at the time of project start did not support FMI 3.0, and that the adoption of Zenoh promised a simple and efficient communication framework (Palma, 2024) supporting also geographically distributed nodes deployed across wide area networks with minimal required network settings configuration (such as opening ports on host and client computers, etc). Zenoh runs on top of traditional communication protocols such as TCP/IP and UDP/IP and transparently bridge across different protocols. It is a pub/sub/query protocol and supports a variety of network topologies such as peer-to-peer, routed, mesh and brokered communication.

This introduction is followed by Section 2 where we present the high-level architecture of Liaison, network topologies and describes its implementation. In Section 3 we present an example case that led the authors to develop this tool (Software-in-the-Loop testing of sail control systems for wind assisted propulsion of ships (Laursen et al. 2023)). Section 4 presents some results connected to the computational overhead for the different use cases and Section 5 presents the outlook and future work.

2 Liaison

Figures 1 to 3 present the three basic configurations on which Liaison can be used. In all the figures, an "original" FMU is made available to a simulation software (co-simulation engine) with a Liaison FMU and a Liaison Server. A Liaison FMU is a client application that substitutes the original FMU and communicates with a Liaison Server. A Liaison Server is a server application that forwards the function calls made to the Liaison FMU by the simulation software to the original FMU.

Figure 1 and 2 present the configurations for running a distributed co-simulation locally and over a LAN. Both configurations are useful for addressing security and portability issues. For example, the FMU can be run inside of a sandbox/Docker environment or in another computer with the appropriate operating system or hardware resources. Meanwhile, Figure 3 corresponds to running a distributed co-simulation in a WAN. In addition to addressing portability and security issues, this configuration also enables running co-simulation without sharing IP across organizations, avoiding the need for non-disclosure agreements, software licenses, obfuscation, and similar practices.

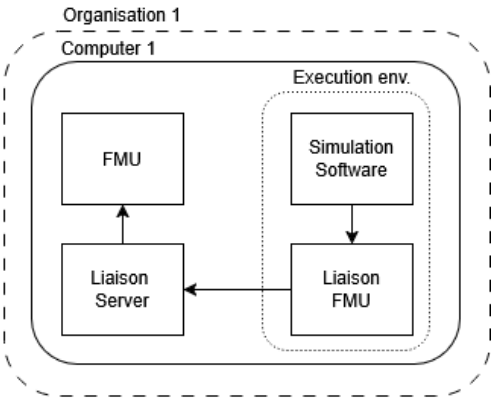

Figure 1. Configuration for running a distributed co-simulation locally with Liaison.

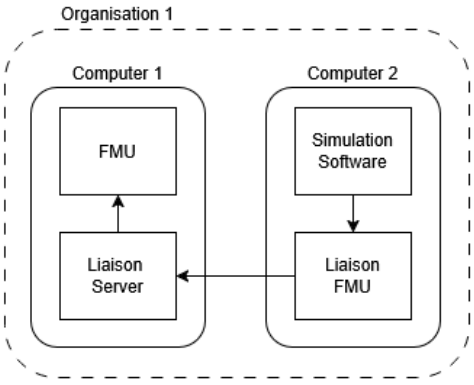

Figure 2. Configuration for running a distributed co-simulation over a LAN with Liaison.

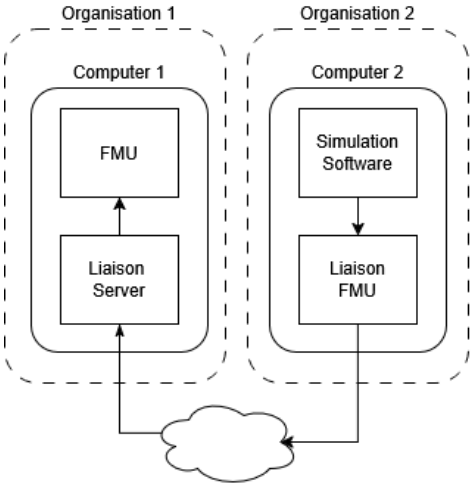

Figure 3. Configuration for running a distributed simulation over a WAN with Liaison.

2.1 Networking

Liaison uses Zenoh for communication. By default, Liaison operates using the "peer" mode in Zenoh which entails that:

- Every node discovers other nodes through a discovery mechanism.

DOI 10.3384/ecp218639

- Every node connects to and maintains a connection to all other nodes found through the discovery mechanism.

A schematic of this setup is illustrated in Figure 4. This setup is a convenient default as it allows for seamless, zero-configuration connections in a LAN.

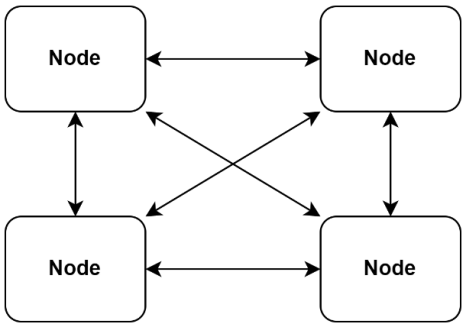

Figure 4. Schematic of 4 nodes connected in peer-to-peer mode. I.e. every node has a direct connection with every other node.

Further, Liaison allows for unimpeded configuration of the underlying Zenoh library. This allows for a range of different network topologies to be used, for details see (Corsaro et al., 2023). The most interesting one for the use of Liaison is the "client" mode which entails that:

- Every node connects to a well-known router on startup.
- The router ensures end-to-end connectivity in between all nodes connected to it.

A schematic of this setup is illustrated in Figure 5.

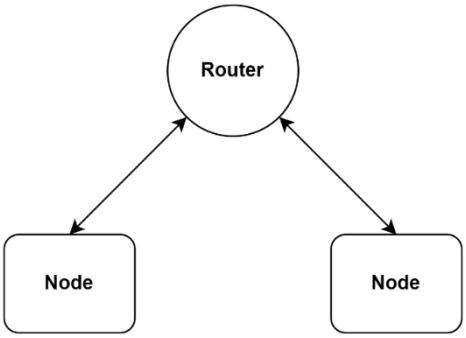

Figure 5. Schematic of two nodes connected in client mode via a (software) router. Each node maintains only a single connection to the router and the router ensures end-to-end connectivity in between nodes.

Although the "client" mode of communication in Zenoh requires every node to make an initial connection to a well-known router, it does not require every node to know the connectivity details (such as IP number and port) of all the other nodes in the network. Effectively, this allows for nodes in different LANs, possibly geographically distributed, to interconnect via a router deployed on a well-known address accessible over a WAN (such as the internet) without the need of knowing the connectivity details of each other. A schematic of this setup is outlined in Figure 6.

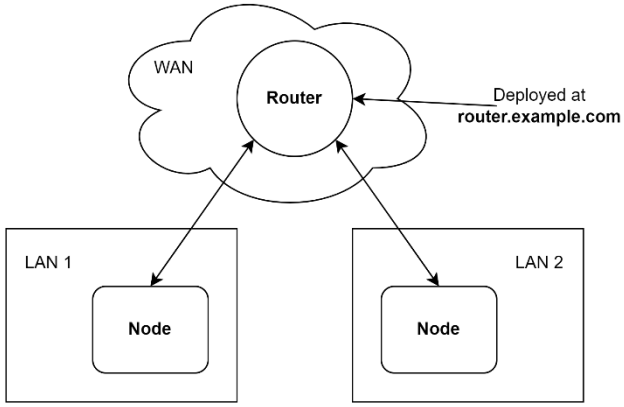

Figure 6. Schematic of 2 nodes connecting across a WAN from two separate LANs in client mode via a (software) router deployed on a well-known address.

Further, the underlying Zenoh library may be configured for secured communication channels, regardless of network topology, using either client/server TLS or mutual TLS.

2.2 Implementation

Liaison is an application written in C++ and compiled for Windows and Linux. It is released as open source under the Apache 2.0 license and is available for download at http://github.com/rise-maritime/liaison. While it depends on standard system libraries, third-party dependencies are bundled with the release, requiring no additional installation.

Liaison consists of a platform specific executable and a set of dynamic libraries that encapsulate the client logic for different platforms. The executable performs two main functions: 1) making a „Liaison FMU" from a standard FMU, and 2) serving an FMU. When making a Liaison FMU, the executable extracts the model description XML file from the source FMU, renames the dynamic libraries according to the model's name, and re-packages it all. In turn, when serving an FMU, the executable loads the source FMU and forwards to it all the incoming queries from the Liaison FMU as seen in Figures 1 to 3.

At the time of writing, only a subset of the FMI 3.0 standard is implemented. For an up to date list of the implemented functions the readers are referred to the project's online repository (Liaison, 2025).

3 Example: Software-In-The-Loop (SIL) for control of a Wind-Assisted Propulsion System

Consider the following made-up example: A ship owner is interested in retrofitting one of its vessels with a wind-assisted propulsion system (Laursen et al. 2023) and is particularly interested in rigid wings as suggested by a potential provider. But, prior to signing a deal, the shipowner wants to ensure the interoperability of the proposed wing sail system (and its controller) with the existing autopilot used on the ship. For that purpose, the ship owner demands a set of co-simulations to be performed to verify the interoperability in a Software-in-the-Loop (SIL) setup.

In this paper we will use the example above to exemplify the usefulness of Liaison in overcoming technical as well as organizational obstacles in sharing software, especially control systems, in the design process of ships. Further, we will use the same setup to investigate the performance penalty introduced by Liaison through different scenarios.

3.1 Simulation setup

Figure 7 presents the simulation setup with the following components:

- **Vessel FMU:** an FMU that encapsulates a hydrodynamic model of a cargo vessel as well as an aerodynamic model of a set of rigid wings mounted on said cargo vessel. The models used in this FMU are built using the RISE in-house ship dynamics solver SEAMAN (Ottosson and Byström, 1991).
- **Controller FMU**: an FMU that encapsulates the controller logic for the wing controller system.
- **Co-simulation engine:** A co-simulation engine that is responsible for stepping the co-simulation forward and handling connections between the two FMUs. The co-simulation engine used for these simulations is Ecos, for details see (Ecos 2025).

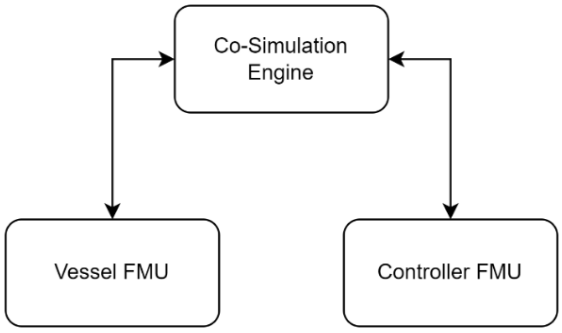

Figure 7. Simulation setup for the example.

The FMUs used in the simulation setup are deliberately kept at minimum level of complexity, using only the bare minimum of the FMI 3.0 specification, to ensure fair comparisons focusing on the performance penalty introduced by Liaison.

3.2 Scenarios

The simulated setup is used in the following scenarios:

- *Reference scenario:* the FMUs are loaded directly by the co-simulation engine, i.e. Liaison is not used.
- *Local scenario:* the FMUs and the co-simulation engine runs on the same physical computer, but Liaison is used as the means of communication.
- *LAN scenario*: the FMUs and the co-simulation engine run on different physical computers (3 computers in total), but in the same LAN.
- *WAN scenario:* the FMUs and the co-simulation engine all run on different physical computers (3 computers in total) on different LANs interconnected via a WAN (the Internet). The communication channels are secured using mTLS.

To investigate the performance penalty of using Liaison, each of the scenarios are run for 600 seconds with three different step sizes: 0.1, 1.0, and 10.0 seconds. To account for variations in execution time, each scenario and step size combination is simulated 10 times, and the average time is recorded.

4 Results

Figure 8 presents the performance penalty associated with using Liaison across various configurations and communication step sizes.

For a communication step size of 0.1 seconds:

- The reference scenario has an average execution time of about 25 seconds.
- The local scenario has an average execution time of 1.4 times that of the reference scenario.
- The LAN configuration scenario has an average execution time that is more than double (2.4 times) that of the reference scenario.
- The WAN scenario has a significantly higher average execution time, 7.6 times that of the reference scenario.

For a communication step size of 1.0 second:

- The reference, local, and WAN scenarios have similar execution times at about 25 seconds.
- The WAN scenario has a higher average execution time, about 1.7 times that of the other scenarios.

For a communication step size of 10.0 seconds:

- All cases exhibit similar average execution times, approximately 25 seconds.

DOI 10.3384/ecp218639

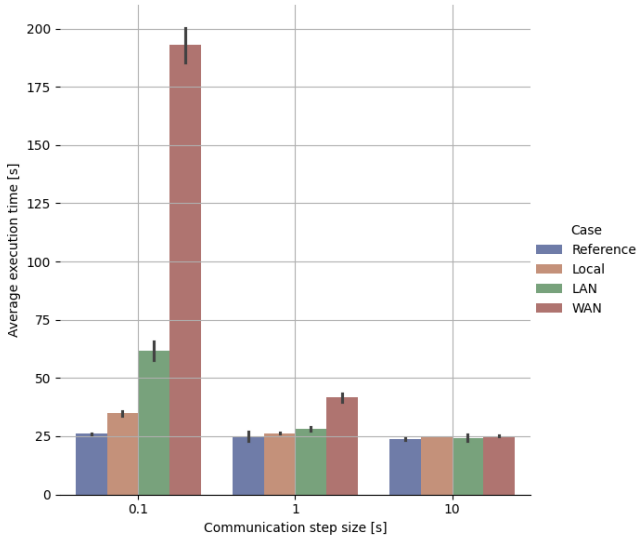

Figure 8. Performance results from different co-simulation scenarios and configurations.

These results indicate that the communication step size has a substantial impact on execution time, particularly in the WAN scenario. The performance is notably better in scenarios with larger communication step sizes and when the components are either on the same physical computer or within the same LAN.

5 Conclusion and future work

Liaison is a general open-source tool for distributed co-simulations and model exchange based on FMI 3.0. The workflow when using Liaison starts with an existing FMU. In the first step, Liaison is used to produce a "Liaison FMU", that can be included in any simulation tool that supports FMI 3.0. For the simulation tool, the Liaison FMU appears as a standard FMU. The Liaison FMU acts as a client and includes all information it needs to communicate with a Liaison server over LAN or WAN (such as the Internet). The communication protocol in Liaison is the Zenoh protocol, which ensures a simple communication configuration by the user and versatile network topologies.

Results presented in this paper shows that running simulations in a distributed fashions with Liaison can have a negative impact on simulation time due to communication events between the distributed Liaison FMUs that are part of the distributed co-simulation. However, this performance drawback can be mitigated by selecting appropriate communication step sizes.

Future work will focus on achieving full compatibility with FMI 3.0 and include support for FMI 2.0, as well as testing Liaison in various simulation software environments. Contributions are welcome!

A Tool for the Implementation of Open Neural Network Exchange Models in Functional Mockup Units

Michele Urbani[1] Michele Bolognese[1] Luca Pratticò[1] Matteo Testi[1]

[1]Hydrogen Technologies and Resilient Energy Systems Unit, Sustainable Energy Centre, Fondazione Bruno Kessler, Via Sommarive 18, 38123, Trento, Italy, {murbani,mbolognese,prattico,testi}@fbk.eu

Abstract

The Functional Mock-up Interface (FMI) standard is a flagship in the co-simulation and model exchange domain. However, the integration of graph-based computational models—particularly neural networks—into Functional Mock-up Units (FMUs) has remained a technical challenge due to interoperability and platform-specific limitations. To address this, we propose ONNX2FMU, a command-line Python tool that facilitates the deployment of Open Neural Network Exchange (ONNX) models into FMUs. According to FMI's good practices, ONNX2FMU generates C source code to wrap ONNX models in Functional Mockup Units, supports FMI versions 2.0 and 3.0, and provides multi-platform compilation capabilities. The tool simplifies the mapping process between model description and ONNX model inputs and outputs via JSON files, ensuring accessibility and flexibility. This paper presents the tool architecture and methodology and showcases its applicability through illustrative examples, including a reduced-order model powered by a recurrent neural network.

Keywords: ONNX, FMI, FMU, ML, AI

1 Introduction

Machine learning (ML) and deep learning (DL) have gained momentum in engineering and science in recent years. There are countless applications of inferential models in engineering: For example, in engineering and manufacturing (Malik et al. 2018), process system engineering (Lee, Shin, and Realff 2018), chemical engineering (Schweidtmann et al. 2021), smart energy systems (Lund et al. 2017), and fluid mechanics (Brunton, Noack, and Koumoutsakos 2020). Better and more efficient computational infrastructures, together with a never-seen-before amount of data, call for the exploitation of these sources of information in simulations (Rueden et al. 2020; Bertsch, Jarmolowitz, and Lenord 2024). However, incorporating ML models into FMUs requires specialised tooling. The existence of several ML frameworks, each with its own scope and peculiarities, advocates for a standard model exchange format. The Open Neural Network Exchange (ONNX) format (*Open Neural Network Exchange* 2025) enables one to describe an ML model through a set of standard operators and ships with its runtime. Several ML frameworks implement their methods to export a model to the ONNX format, thus partly bridging the gap of model interoperability. Therefore, the challenge is developing a tool to write the C code that maps the model's input and outputs to the FMI's C API specifications. Software licensing must guarantee the usability of the tool for many purposes to foster the widespread adoption of inferential models in simulations.

Commercial tools that can wrap ML models into FMUs already exist. Simcenter ROM (*Simcenter Reduced Order Modeling software* 2025) is a software for developing Reduced Order Models (ROM) that presents the FMU export feature, which allows a user to wrap an ML-based ROM in an FMU. Since ML is simply a model order reduction technique (among a few others) in Simcenter ROM, the choice of the ML framework is arbitrary and, to the eye of the user, it is irrelevant as far as the model's accuracy is satisfactory. The generation of an FMU is, therefore, purely functional and does not allow the user any customisation. SimuLink (*Simulink - Simulation and Model-Based Design* 2025) is a commercial software that exports simulation models as FMUs by generating the C code from a set of proprietary primitives. Neural networks, a type of ML model, can be included in a Simulink simulation workflow and shipped in an FMU. The software suite (*NEURECO: Automatic Parsimonious Neural Networks Generation* 2025) presents itself as the *automatic parsimonious neural networks factory*. It can produce neural network-based models and export them to C code, ONNX, and FMUs.

Software licensing is a key feature when selecting a tool. The availability of open-source, open-access software is always valuable to the community. Most open-source software is hosted on platforms like GitHub and GitLab, where we carried out a structured search for ML to FMU wrapping tools. The keywords used for the search were "ONNX" and "FMU", which returned only one relevant result on the GitHub platform. The search results are confirmed by a check of the "Tools" section of the FMI website. MLFMU (*mlfmu* 2025) is the only open-source, open-access tool that enables wrapping ML models to FMUs, and a team of contributors from DNV develops it. The MLFMU's workflow foresees the possibility of exporting an ONNX model with only one input and one output array, to which the physical model quantities need

to be mapped. Input and output mapping is declared using a JSON file, which plays the role of a user interface. The core functionality of MLFMU is the generation of the FMI model description and the C++ code generator to link the ONNX runtime to the FMU. For the generation of C++ code, MLFMU rely on another open source project called "cppfmu". Conan is used as a package manager.

Proposing a new tool for integrating ML models in FMU co-simulation is important because it enables the use of graph-based computational models, e.g., ML models and neural networks. Furthermore, the proposed tool would be a valuable open-access, open-source resource to the Modelica community.

We introduce ONNX2FMU, a command-line interface (CLI)-based Python tool that generates C source code for embedding ONNX models into FMUs, which can be compiled on any target platform. The tool bridges the gap between ML model deployment and FMI-compliant simulation, offering an efficient and user-friendly pipeline. Compared to the existing alternatives, ONNX2FMU:

- Directly generates C source code, improving performance and control over the generation process. Although the use of the C programming language is not mandatory, we preferred to stick with the FMI Standard's indication that the "FMI API is written in C, not C++, to avoid problems with compiler and linker dependent behaviour, and to enable the use of FMUs on embedded systems" (Modelica Association 2025).
- In addition to the FMI 2.0, it supports FMI 3.0, including extended data types.
- Handles models with multiple inputs and outputs mapped to the FMU model according to an arbitrary naming convention.

Generating C code directly exposes the user to the source code in a single file where FMI "get" and "set" functions are declared together with the link to the ONNX runtime. ONNX2FMU is designed for developers who want to bootstrap the creation of FMUs to deliver graph-based computational models, data scientists and researchers operating in model order reduction, and DevOps who need to automate the creation of pipelines of tools. Being distributed as open-source, the tool is highly customizable, and it allows the separation of the C code generation stage and the compilation stage, thus enabling the inspection and modification of the FMU source code. The tool comes with a set of unit tests and a pipeline for continuous integration that guarantees the integrity of the code and its cross-platform compatibility.

An analysis of requirements for the proposed tool and the adopted methodology for creating the tool is outlined in Section 2. Section 3 presents the results and shows two examples where ONNX2FMU is applied. Conclusions close the paper in Section 4.

2 Methodology

Requirements analysis The inspiring principle for the creation of ONNX2FMU was the simplicity of use. This means relieving the user from making many decisions during the tool usage, reducing the number of steps to the final result, and designing a clear interface for mapping ONNX model inputs and outputs to the FMI model description.

FMI standard compliance. The FMI Standard is now in its third major release (Junghanns et al. 2021), the FMI 3.0 version, which differs from the FMI 2.0 version in several aspects. In FMI 3.0, the *scheduled execution* interface type has been added to the *model exchange* and *co-simulation* types, allowing the activation of individual model partitions by an external scheduler. Model partitioning capabilities for concurrency on single-core CPUs are not of interest for executing ML models in a simulation; therefore, we excluded the possibility of generating the scheduled execution interface type. In general, the execution of ML models does not require the FMU to be equipped with a solver. A straightforward choice is hence to implement the model exchange interface type. Since a few modelling environments, e.g., Modelon Impact, allow us to import only co-simulation FMUs, the usability range of a tool for ML model encapsulation is significantly widened by implementing the co-simulation interface. The co-simulation interface brings the burden of having a solver within it that remains unused.

In the first version of ONNX2FMU, we focus on the FMI 2.0 and 3.0 Standard versions. The FMI 2.0 is the industry standard, supported by more than 90% of the tools published on the FMI Standard website[1]. Supporting the FMI 3.0 contributes to the state of the art in ML model implementation in the FMI standard. The two versions of the standard present meaningful differences in the data types that can be specified in the model description: The FMI 2.0 supports only four data types, i.e., float, integer, string, and boolean, whereas the FMI 3.0 extends these data types to support a broader spectrum of data precision and signature. Relevant data types to the scope of this project are the `float` type for the FMI 2.0 and the `Float32` and `Float64` types for the FMI 3.0. All other data types are considered according to the ONNX specifications discussed in the next paragraph. The variability and causality of variables are restricted to the combinations allowed by the standard. If not specified by the user, the causality of model entries is determined by their connections in the ONNX graph model, which divides entries into inputs and outputs. The available variability options for input and output causalities are "discrete" and "continuous". The FMU developer should carefully set the appropriate variability according to the behaviour of the model to be encapsulated; in the co-simulation mode, the capability flag `providesIntermediateUpdate` should be set accordingly. The combinations of platforms and operating

[1] https://fmi-standard.org/tools/

DOI 10.3384/ecp218645

systems in the following are generally supported:

- win32, win64, linux32, linux64, and aarch64-darwin for the FMI 2.0;
- x86_64-darwin, aarch64-darwin, x86-linux, x86_64-linux, aarch64-linux, x86-windows, x86_64-windows, and aarch64-windows for the FMI 3.0.

ONNX standard. The Open Neural Network Exchange (*Open Neural Network Exchange* 2025) is a standard for the interoperability and exchange of ML models. It defines a set of operators typically used in ML and DL models and a common format for moving models through different ML frameworks, tools, runtimes, and compilers.

Deploying an ML model to production requires replicating part of the ecosystem used to train the model. We refer to this ecosystem using the word *runtime*, that is, the code that enables running inference (and training) on a target hardware platform. In addition to guaranteeing interoperability, converting a model to the ONNX format allows developers to use optimised runtime libraries from different providers, see, e.g., those listed in (*Open Neural Network Exchange* 2025). A runtime can be defined in any language suitable for the production application, C, Java, Python, JavaScript, C#, WebAssembly, or ARM. We chose the ONNX runtime among the many available options because of its licensing, the large community of contributors to the project, and the availability of C code examples that allowed us to bootstrap the development of the tool.

Data types conversions. ML models require support for floating point numbers in single or double precision, and eventually, they may include other data types. An ML model supporting single-precision floating point numbers requires casting double-precision inputs/outputs, with a potential loss of accuracy of the model. The model data type dictates how the tool must manage data types internally: If a model is single-precision, a double-precision float must be converted before and after inference; otherwise, no casting operations are required. The same behaviour is adopted for integers.

Inputs, outputs, and naming conventions. A generic ML model can have multiple inputs and output nodes, whose elements must be mapped to the FMI model description. The FMI 2.0 version foresees only scalar variables in the model description. Therefore, arrays must be flattened, and a naming convention is required to map scalars to their original position. A logical choice seems to use the array name suffixed with the element indexes separated by a specific character. Conversely, the FMI 3.0 allows both the declaration of scalar and array variables in the model description. Declaring array variables produces a more compact and comprehensible model description, but poses a hurdle to mapping variables to their physical meaning.

User experience. The interaction with the tool should consist of two subsequent stages. The mapping of the ONNX model entries to the FMI model description occurs first. During this stage, the user can define the variability associated with ONNX model arrays, if different from `continuous`, and, optionally, a description of each element of an array. The latter will likely be shown by the graphical user interface (GUI) of the importer software, thus easing the connection of the model with other components of the simulation.

Once a model mapping scheme and an ONNX model are available, an FMU model can be generated. There are many possible approaches to FMU generation, ranging from a GUI to Python scripting. A GUI would consist of only a few buttons to trigger the generation process, and it would be more effective if it integrated the model mapping declaration. Interaction via CLI is simple to develop and effective in integrating within a pipeline of operations. FMU generation via Python scripting is always possible by calling the tool's functions directly.

3 Results

The result of this research is ONNX2FMU. The design choices are explained in the following with examples.

3.1 Getting started

ONNX2FMUis written in Python to ease code usability, interaction with ONNX models, and to exploit a suite of available open source tools. A Python interpreter is required, and ONNX2FMU has been tested for versions greater than or equal to 3.10. ONNX2FMU is distributed as a Python package available in PyPI (*PyPI, Python Package Index* 2025), and can be installed with

```
pip install onnx2fmu
```

from the command line. To generate FMUs, ONNX2FMU requires a C compiler for the target platform to be installed on the machine and added to the system `PATH` variable.

3.2 FMU model mapping

ONNX2FMU can handle ONNX models presenting multiple input and output nodes. The description of entry variables is organised hierarchically, including global model information and input/output node descriptions. The JSON file format has been chosen for model mapping due to its suitability in representing hierarchically organised information. In the input and output sections, nodes are identified using the same name used in the ONNX model; this allows ONNX2FMU to map the information correctly. A user can specify the variability of each node, which is set to continuous by default. Node variability should be handled carefully because it might cause sequence-based models to return wrong results when they are not called with the right time step. Array elements can be enriched with a description, which is shown in the FMI

model description and might be shown by the importer UI. Descriptions of entries help the user to link them with their physical meaning. If the list of descriptions is provided, it must match the elements in the array; otherwise, a warning is returned, and no description will be present for the elements of that array. The array notation provided by the FMI 3.0 Standard is left out of the scope of this work because it makes it difficult to connect array entries with their physical meaning. However, the authors acknowledge that array notation could be useful when an ONNX model presents several inputs and outputs; for this reason, it will be addressed in a future release of ONNX2FMU.

3.3 FMU build

The FMU build workflow starts with the target model to encapsulate and the model mapping JSON file. If not specified, the target platform is that of the system where the build process is carried out. A template of files and folders to be populated with ONNX model information was developed. The Python interpreter generates the C code by creating a copy of the FMU template and filling it using Jinja2 (*Jinja Project* 2025), a template engine that populates special placeholders in text files with context variables and renders the final document. The CMake build system (*CMake: A Powerful Software Build System* 2025) is used to build the project, download the latest ONNX runtime version, compile the library, and zip it to an FMI-compliant archive. For separation of concerns, ONNX2FMU takes care of template filling and ONNX model information retrieval using Python, whereas compilation issues and packaging are handled by CMake, which natively supports the build and compilation toolchain.

The Python CLI is realised using *typer* (FastAPI 2025), a Python package that creates simple command line applications with documentation, autocompletion, and typing support.

Validation and testing are the last two steps of ONNX2FMU's workflow, which is depicted in Figure 1. The automated validation of the FMU is made possible by the FMPy (*FMPy* 2025) package. Testing a generated FMU can hardly be automated because of the case-specific nature of ML models, which requires appropriate data.

3.4 Examples

Use cases are presented to show the functionalities and the potential of ONNX2FMU in the following paragraphs.

A simple model. To showcase the flexibility of ONNX2FMU, we present how a generic graph-based model can be wrapped in an FMU. The simple model takes three scalar inputs x_1, x_2, x_3 and returns a vector output y. In the model, two calculations occur: $x_4 = x_1 + x_2$ and $x_5 = x_2 - x_3$, and the results are concatenated in $y = [x_4, x_5]$ and returned as output. A graphical representation of the model is depicted in Figure 2, which was obtained using the Netron web app[2]. A Python pseudo-code example for creating the model using the PyTorch framework is reported in Listing 1.

Listing 1. Python code for the creation of a simple graph-based computational model using PyTorch.

```
class ExampleModel(nn.Module):

  def __init__(self):
    super(ExampleModel, self).__init__()

  def forward(self, x1, x2, x3):
    x4 = x1 + x2
    x5 = x2 - x3
    x = torch.cat([x4, x5], dim=0)
    return x
```

Exporting the model is easy in PyTorch as in other ML frameworks and usually, it can be done in a few lines of code. Models can be exported to the ONNX format with or without weights; ONNX aims to define the model structure primarily through its set of primitives. ONNX models are not necessarily shipped with weights either because they do not need them, as in the case of the model above, or because weights might be application-specific.

Once the ONNX model has been exported, inputs and outputs are mapped to the FMU model description. This is achieved through the JSON schema in Listing 2.

Listing 2. The JSON mapping between inputs and outputs of the simple model.

```
{
"name": "simple-model",
"description": "Example description.",
"FMIVersion": "2.0",
"input": [
    {"name": "x_1",
     "description": "A scalar input"},
    {"name": "x_2",
     "description": "A scalar input"},
    {"name": "x_3",
     "description": "A scalar input"}],
"output": [
    {"name": "y",
     "description": "The output array",
     "names": ["output1", "output2"]}]
}
```

Notice that the output array schema presents the `"names"` item, which allows users to describe each array entry in the FMI model description. Finally, FMU generation is triggered via the command line by providing the ONNX model and description as follows

```
onnx2fmu build \\
    model.onnx \\
    modelDescription.json
```

Time series prediction. Predicting temperature variations in a solid exposed to a heat source is a common engineering problem. A partial differential equation (PDE)-based model (Bergman 2011) can describe a temperature field variation in, e.g., an ideal 2D solid of interest. The

[2] https://netron.app/

DOI 10.3384/ecp218645

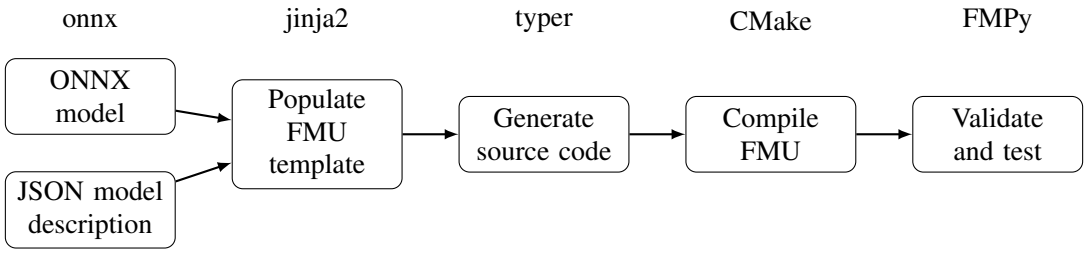

Figure 1. The workflow to embed an ONNX model in an FMU with ONNX2FMU.

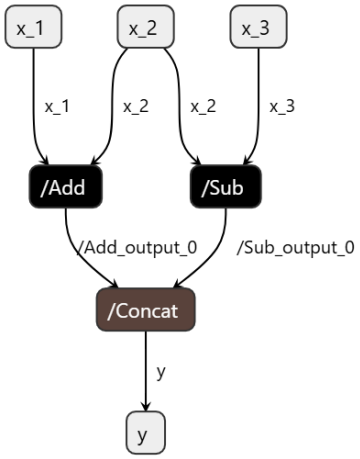

Figure 2. A simple graph-based model for summation and subtraction of inputs.

temperature field equation is

$$\frac{\partial T}{\partial t} = \alpha \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} \right) + T_0, \tag{1}$$

where T is the temperature, t is the time, α is the thermal conductivity of the material, and x and y are the coordinates of a point in the solid. Equation 1 is discretised in time and space and resolved by a custom Python model that is reported in the ONNX2FMU documentation[3]. In the following, we define $\alpha = 0.9$, an initial temperature $T_0 = 100°\text{C}$, and $x, y \in [0, 1]$.

In some engineering applications, we may be interested in predicting the temperature variation at a point of the solid, e.g., $x_a = 0.5, y_a = 0.5$. A surrogate model of the studied solid would avoid resolving the full-scale model to know the temperature only in (x_a, y_a), thus saving a meaningful computational effort. A simple way to create a surrogate model for predicting temperature variations is to train a neural network using a time series of heat source variation $u(t)$ as inputs and temperature variations $y(t)$ as outputs. We use a Recurrent Neural Network (RNN) (Bengio, Goodfellow, Courville, et al. 2017) to extrapolate the temperature in (x_a, y_a). A dataset of temperature trajectories $y(t)$ in (x_a, y_a) is generated resolving (1) with the boundary condition

$$u(t) = (-1)^j 20j \sin(t/8 + j\pi/8) + T_0,$$

applied on the side with $x = 0.0$, where j is the index of a trial input profile, for $t \in [0, 25]$ seconds. An example of the applied temperature profile $u(t)$ and temperature profile $y(t)$ in (x_a, y_a) obtained by simulating the system using the custom Python script is depicted in Figure 3.

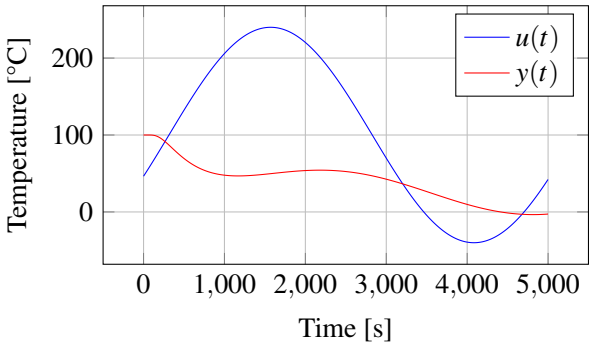

Figure 3. Input temperature profile and the temperature in the centre of the plate.

The model was trained on a dataset with $M = 40$ trajectories, each with 5000 time points sampled at a 1/200 s^{-1} frequency. Data were organised in tuples $(\mathbf{x}, y)$, where $\mathbf{x}$ was a sequence with $R = 200$ consecutive time points, and y was the $(R+1)$-th time point. The mean squared error

$$MSE = \frac{1}{N} \sum_{i}^{N} (y_i - \hat{y}_i)^2$$

measures the predictive power of the RNN, where $\hat{y}_i$ is the value predicted by the RNN, i is the sample index, and N is the number of samples. The efficiency of the RNN model improves if normalised data are used for training. However, it is impractical to deal with normalisation issues in a simulation environment; it would be more useful to provide unscaled data directly with the model. This issue can be easily resolved by adding normalisation and denormalisation steps to the network as shown in Listing 3.

Listing 3. Python code of the RNN model.

```
class HeatRNN(nn.Module):
    def __init__(self, input_size,
        hidden_size, output_size,
        num_layers, norm_params):
```

[3] github.com/HyRES-FBK/onnx2fmu/

```
        super(HeatRNN, self).__init__()
        x_min, x_max, y_min, y_max =
            norm_params
        self.register_buffer("x_min", torch
            .tensor(x_min))
        self.register_buffer("x_max", torch
            .tensor(x_max))
        self.register_buffer("y_min", torch
            .tensor(y_min))
        self.register_buffer("y_max", torch
            .tensor(y_max))
        self.rnn = nn.RNN(input_size,
            hidden_size, num_layers,
            batch_first=True)
        self.fc = nn.Linear(hidden_size,
            output_size)

    def forward(self, x, h=None):
        x = (x - self.x_min) / (self.x_max
            - self.x_min)
        out, _ = self.rnn(x, h)
        out = self.fc(out)
        out = out * (self.y_max - self.
            y_min) + self.y_min
        return out
```

In the code Listing 3, the normalisation parameters are passed as inputs when the network is initialised and stored as *buffers*, that is, they will be part of the network state when exported to the ONNX format, and they will remain untouched by PyTorch optimization algorithms during training. The RNN is initialised with 2 hidden layers, an input size of R, and a 64-unit hidden layer. The RNN output is further processed by a linear layer that maps the RNN output to the output scalar. Figure 4 shows the behaviour of the average value of *MSE* calculated over the training and validation data sets with the number of training epochs. The effectiveness of the trained model was satisfactory for this example after 1000 epochs using the Adam optimiser with a learning rate of 10^{-5}.

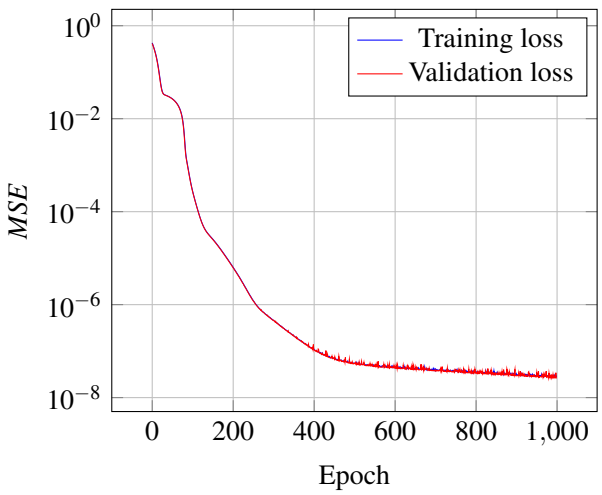

Figure 4. The *MSE* behavior through training epochs.

Finally, the trained RNN model is exported in ONNX format and encapsulated in an FMU for testing. The FMU was tested using FMPy (*FMPy* 2025), a Python toolkit for FMU validation and simulation. An example of the prediction produced by the RNN model is shown in Figure 5. In FMPy, a model can be simulated by providing inputs

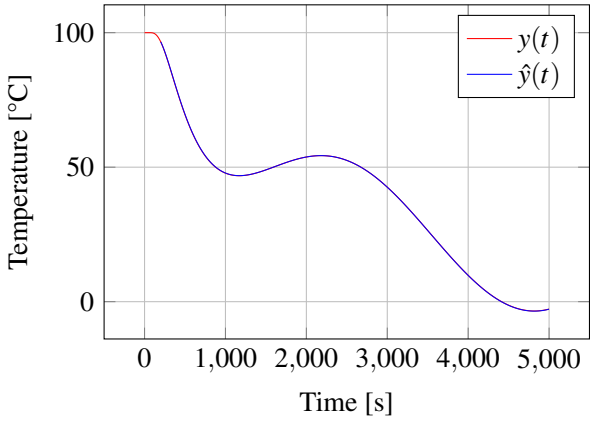

Figure 5. An example of the predicted and analytically obtained temperature profiles in (x_a, y_a).

directly from a text (CSV) file, which simplifies simulation setup when the RNN model presents $R = 200$ inputs. The recursion in the RNN model is carried out by providing R times the number of model variable values at each time step. However, we acknowledge that:

- the length of the input array, $R = 200$, makes the initialisation of such a model impractical and time-consuming in a GUI-based simulator, and
- the repetition of values along rows is memory-wise inefficient.

This aspect will be improved in the next major release of ONNX2FMUby implementing feedback loops declared in the model description.

In this simple example, we showed how a powerful model such as an RNN can be wrapped in an FMU with a few lines of code. The code of the example is released in GitHub[4].

4 Concluding remarks

We presented ONNX2FMU, a tool for converting ONNX models into FMI-compliant FMUs. The tool supports multiple FMI versions and cross-platform compilation and simplifies the deployment of ML models in simulation environments. Future work includes optimising runtime performance, integrating a GUI to favour a broader tool adoption, implementing FMI 3.0 array notation, and develop support for stateful models using feedback loops directly through the model declaration file.

Abstract

We present two methods for speeding up co-simulations under the FMI standards. By smoothing the input signals inside each FMU, the internal integrator may avoid re-initialization. This can significantly reduce the number of model and Jacobian evaluations. To further help the integrator we also propose a predictor compensation technique tailored to the input smoother. The main benefit of our methods is the ease-of-use, requiring no model manipulations, nor any special co-simulation master algorithms. The methods are implemented in Dymola 2025x and validated with both an academic mechanical model as well as industrial thermo-fluid examples where we often observe over 10 times faster co-simulation and, in the best cases, up to 400 times faster. One of these thermo-fluid examples is used in the *OpenSCALING* research project to generate training data for constructing surrogate models, for which the input smoothing is especially important to speed up the dataset creation. *Keywords: FMI, Efficient co-simulation, Input smoothing, Thermo-fluid*

1 Introduction

To facilitate simulation of complex and large systems spanning over multiple technical domains, co-simulation techniques are commonly employed. This may, for example, include the integration of several domain-specific tools into one single simulation.

In this article we present two methods for speeding up co-simulation under the FMI standards, versions 2 and 3 (Modelica Association 2022; Modelica Association 2023). Co-simulation of multiple FMUs face several numerical challenges. Among others, these involve stability, accuracy, efficiency, and step-size control. A wide range of methods for handling these challenges can be found in the literature. For stabilization techniques see for example Benedikt and Drenth (2019) for non-iterative co-simulation and Arnold (2010) for iterative co-simulation. For adaptive co-simulation with step-size control we refer to Schierz, Arnold, and Clauß (2012).

Here we consider the efficiency challenge by proposing two methods to speed up the numerical integration inside each co-simulation FMU. More precisely, our techniques are useful for FMUs using variable-step solvers. Firstly, we apply *input smoothing* to create continuous inputs to the FMUs. Thus, we may avoid restarts of the integrators inside the FMUs. To further help the integrator we also present a *predictor compensation* method.

Input smoothing methods have previously been discussed in the literature, see e.g. Andersson (2016) and Busch (2016) where the smoothing is achieved by the master. These references also include stability and consistency analyses of related smoothing techniques.

However, the main benefit of the input smoothing and predictor compensation presented in this article is the ease-of-use. No special co-simulation master is required. Nor do we require any changes to the models that are exported to FMUs.

Indeed, in our implementation in Dymola 2025x you only need to set the corresponding options before exporting your model to an FMU and the input smoother, with or without predictor compensation, will then be included in the generated code. The resulting FMU can then be used with most co-simulation masters, in particular versions of the classical non-iterative, parallel master.[1] Further, FMUs using input smoothing may be co-simulated with FMUs not using it.

Avoiding integrator re-initialization at communication points may improve performance for any variable step-size solver. But this is especially true for multistep methods as they have to restart at order one, with a tiny internal step size. While ramping up both the order and the step size, several costly model and Jacobian evaluations are required. In this article we consider this class of integrators. More precisely the implementations CVODE and IDA from SUNDIALS (Gardner et al. 2022) and DASSL from Brenan, Campbell, and Petzold (1996).[2] In the context of models exported from Dymola these are arguably the most

[1]The exceptions involve masters that set the input derivatives. Further, since the input to an FMU using input smoothing is delayed, such FMUs cannot be used in co-simulation masters which rely on setting an input and then immediately reading the new output without first performing a `doStep`.

[2]The input smoothing does not depend on which solver is used, but the predictor compensation requires modifications tailored to the solver implementation.

widely used variable-step solvers in co-simulation FMUs. Note that fixed-step solvers, e.g. the commonly used Dymola inline methods, do not benefit from input smoothing.

However, even with smoothed inputs, continuing the integration over communication points comes with additional challenges and problems. We identify and address these issues. To alleviate the main problem caused by avoiding integrators restarts, we arrive at the aforementioned predictor compensation. In Andersson (2016), this technique was discussed in a similar context for integrators with a Nordsieck history representation (e.g. CVODE). In this article we extend the idea to the DAE solvers DASSL and IDA and tailor it to work optimally in combination with input smoothing.

To validate these methods we study their application in both academic models and thermo-fluid examples. One important example is how input smoothing can benefit the creation of datasets for training surrogate models. For this purpose we examine the effect of smoothing inputs on a demonstrator of the *OpenSCALING* research project, delivered by the industry partner *Bosch*.

Finally, we note that FMI 3 comes with the powerful capability *Intermediate Update Mode*, where inputs can be communicated between FMUs also during the communication intervals. This allows for more advanced co-simulation masters and can also be used to reduce the number of integrator restarts. As an example we mention the *Transmission Line Method* (R. Braun and Krus 2013; Robert Braun and Fritzson 2022) where physically motivated time-delays are introduced. While our methods are not motivated by physical considerations, their benefit is that they do not require any special modeling methodology or corresponding co-simulation master.

2 Co-simulation with input smoothing

Co-simulation of multiple FMUs can be performed using a variety of methods. For example iterative methods, higher-order input extrapolation, or non-iterative stabilization techniques. However, we consider this to be out-of-scope for the current presentation. Rather, the purpose of this article is to investigate techniques for speeding up the simulation inside each FMU. Therefore, we here only consider the classical parallel co-simulation algorithm (also known as non-iterative or weak-coupling co-simulation).

2.1 Classical co-simulation

During classical co-simulation the FMUs communicate with each other at *communication points*. This means that the input to each FMU may be computed from outputs of other FMUs. The interval between communication points (the *communication interval*) may vary in size. To advance the time from one communication point to the next, a `doStep` call is made in each FMU. The `doStep` computations may be done in parallel.

The classical approach for handling inputs inside each FMU is to keep any inputs constant throughout the communication interval (zero-order hold). Then, at the next communication point a jump is made to the newly received input values.

We refer to the above algorithm as *classical co-simulation* with each FMU using *classical input handling*.

During a `doStep` call an integrator is employed inside the FMU. The here considered integrators CVODE, IDA, and DASSL are all variable step-size solvers. That is, they have their own step-size sequence. Normally, but not necessarily, there are several integrator steps during each communication interval.

When using classical input handling (zero-order hold) the input signal (as seen by the integrator) is piecewise constant with jumps at the communication points. Therefore, the integrator needs to restart at each such point. This is costly for any variable step-size solver, but especially so for multistep methods.

2.2 Input smoothing

In contrast to classical input handling, the purpose of the proposed input smoothing is to construct input signals which are continuous over communication points. The idea is to do this inside the FMU such that no modifications to the co-simulation master or the exported models are required, cf. Figure 1.

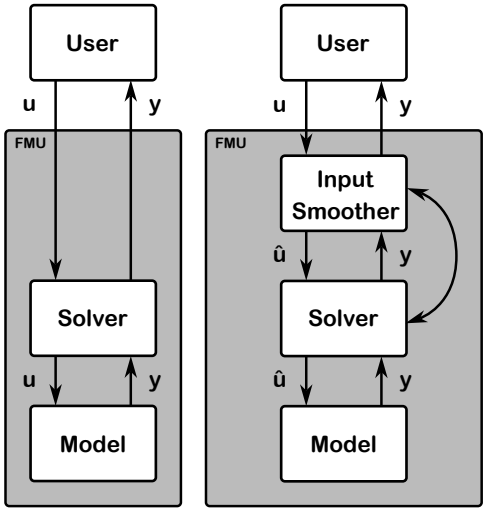

Figure 1. On the left is the abstract structure of a Classical FMU, on the right the modified variant. The input smoothing can be visualized as an additional block between user and model processing the inputs. Input u provided by the user is converted to the interpolated $\hat{u}$ signal. Additionally, an interaction of the input smoothing block and the solver has to be implemented.

Therefore, at each communication point, the input values provided from the master are not immediately set. Instead, we ramp up to these values such that they are reached at the end of the communication interval. In this way, continuous, piece-wise linear input signals are achieved, c.f. Figure 2. This must be done with care to also handle the case of variable communication interval lengths.

DOI 10.3384/ecp218653

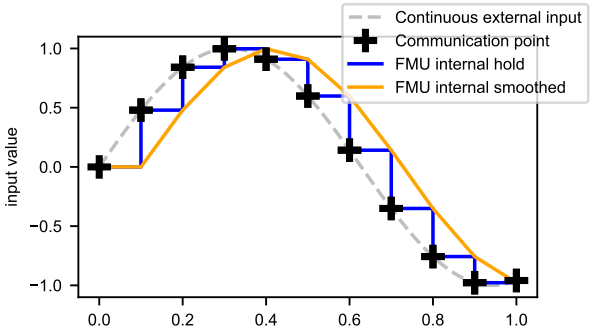

Figure 2. The orange smoothed input signal instead of the blue hold signal is used by the model

As the integrator inside the FMU only sees this smoothed input, then we can allow the integrator to continue integration without restarts at communication points.

An important assumption here is that the integrator does not step past any communication points before receiving new inputs. Otherwise, it would use the previous piecewise linear segment of the input interpolation in the new interval. This is incorrect and also gives a discontinuity in the input signal at the end of the integrator step. An implementation of the input smoothing must make sure that the integrator, at each communication point, has a coinciding internal step. This restriction may lead to an increased number of successful solver steps and Jacobian updates.

The input smoother is enabled in Dymola by setting the flag

`Advanced.FMI.UseInputSmoother`,

and then translating your model to a co-simulation FMU. As algorithm select either CVODE, IDA, or the Dymola solver DASSL. Input smoothing for FMI 2 is supported from Dymola 2025x. FMI 3 support is available from Dymola 2025x Refresh 1.

We have identified two potential problems that may be encountered when using the proposed input smoothing. Firstly, the smoother introduces additional input delays. Secondly, when the integrator uses orders higher than one, mere continuity of the input signals is not enough for optimal performance. These problems are discussed in the upcoming subsections together with proposals for how to handle them.

2.3 Delayed inputs

Already classical input handling introduces input delays as the inputs are set at the communication points and then held throughout the communication interval. The input smoothing makes the situation worse by further delaying the input. This additional delay is effectively half a communication interval as we ramp up to the new inputs, reaching them at the end of the interval. Therefore, input smoothing must be used with care when the co-simulation setup is sensitive to delays.

For such setups, a potential solution may be to slightly reduce the communication interval to compensate for the additional delays. For co-simulation problems where the majority of the CPU time is spent inside the FMUs, then using the input smoother may still be faster, even with the smaller communication interval. This idea is further pursued with the mechanical example model in Section 3.1.

2.4 Discontinuous input derivatives

The input smoothing guarantees that all smoothed inputs seen by the integrator are continuous. But, already the first input derivative is generally discontinuous. When the solver uses any order higher than one, these discontinuities may still cause problems for the integrator.[3] This may result in reduced step size, reduced order, and Jacobian re-evaluations, meaning that we lose some of the benefits from the input smoothing.

The main problem is that the integrator makes bad predictions. The multistep methods considered in this article use old solution values to predict the next step. The predictor can generally be described by a polynomial of the same order as the current order of the BDF method used. This polynomial is evaluated at the time of the next step to get the prediction. For details see Brenan, Campbell, and Petzold (1996) and Radhakrishnan and Hindmarsh (1993).

The prediction is then used as a start guess in the corrector iteration that solves for the actual next step. A bad start guess makes it more difficult for the quasi-Newton method to solve the corrector equations, which may cause extra model evaluations. In the worst case, the Newton method fails, meaning reduced step size, or even Jacobian re-evaluations.

Further, the multistep methods use their predictor to estimate the local error. The estimate is based on the difference between the predictor and the solution of the corrector iterations. When the predictor is bad the error estimate will typically be far too large. The result is that steps are often discarded when they should not be. Even if no steps are discarded, the large error estimates typically result in reduced step sizes and reduced order while the integrator recovers and improves its error estimates.

2.5 Predictor compensation

To alleviate the problem of discontinuous input derivatives, we tailor the predictor compensation of Andersson (2016, Chapter 7) to our input smoother and extend it to the IDA and DASSL solvers. The zeroth- and first-order terms of the predictor polynomial are already reasonable, the first-order term due to the continuity of the input achieved by the input smoothing. Thus, the predictor compensator implemented in Dymola 2025x targets the second-order term. Higher order terms are not considered as they would be computationally too complex to handle with the employed technique, offsetting any benefits.

The predictor compensation is employed as needed at each communication point. It requires an approximation of how the second state derivative is affected by jumps in

[3] In contrast, note that this is not a problem for classical input handling due to the re-initialization done at every communication point.

the input derivative. As the dependency has to be traced through the model, we need to approximate the Jacobian of the state derivatives with respect to the inputs. If the FMU supports directional derivatives (Modelica Association 2022), these can be used for this task.

Dymola FMUs support directional derivatives and require two model evaluations to compute them. This means that the predictor compensation comes with an additional cost that offsets some of the benefits.

To enable the predictor compensation in Dymola, follow the steps in Section 2.2 to enable the input smoothing. In addition, enable the flag

```
Advanced.FMI.UsePredictorCompensation.
```

As algorithm select either CVODE, IDA, or the Dymola solver DASSL. Predictor compensation is supported in the same Dymola versions as input smoothing, except for DASSL where support starts with Dymola 2026x.

3 Applications

We present a simple mechanical model along with two different thermo-fluid examples to highlight the benefit of input smoothing. As mentioned in Section 2.3, the delayed inputs can introduce errors in the simulation. The mechanical example is especially sensitive to delays, and a method to handle it is presented in Section 3.1. The thermo-fluid models studied in Section 3.2 and Section 3.3 are also affected by delays, but for these examples the focus lies on the performance gain of the input smoother.

3.1 Simple mechanical example

To illustrate the effects of input smoothing and predictor compensation we start with a simple mass-spring-damper system. The example is selected not only to showcase the improved simulation statistics, but also to see the effects of input smoothing on a model famously sensitive to co-simulation delays.

3.1.1 Setup

Consider the mass-spring-damper system in Figure 3. We split the model at the connection between the mass component and the spring-damper component. Then we export each submodel into an FMU. From the mass FMU, position and velocity is sent to the spring-damper FMU. The latter sends the force to the former. Please see Table 1 for non-default physical and numerical parameters.

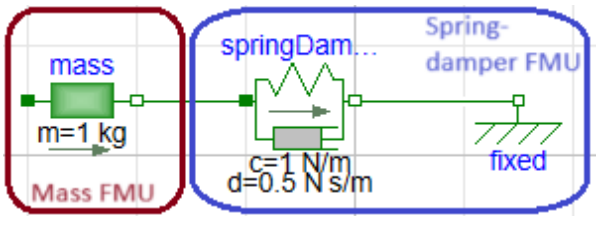

Figure 3. Simple mass-spring-damper model split into two co-simulation FMUs.

Table 1. Physical and numerical parameters of the mass-spring-damper co-simulation problem. Only non-default values are listed.

Parameter	Value
Mass start position	1 m
Mass (m)	1 kg
Spring constant (c)	1 N/m
Damping constant (d)	0.5 Ns/m
Simulation stop time	100 s
Communication interval	0.2 s

The co-simulation is performed using a classical non-iterative master. For the mass FMU we include either CVODE, IDA, or DASSL as solver inside the FMU to integrate its two states: position s and velocity v. For this FMU we either use classical input handling or input smoothing with or without predictor compensation. The spring-damper FMU has no states so it uses no integrator and only uses classical input handling.

3.1.2 Result and analysis

Select simulation statistics for all combinations of solvers and input options are listed in Table 2. In each case, the number of f-evaluations is significantly reduced by input smoothing. The additional evaluations required by the predictor compensation is more than repaid by the further reductions in f-evaluations made by the solvers. Especially for CVODE and IDA. On top of that, the more expensive Jacobian-evaluations are significantly fewer.

When using classical input handling, CVODE constructs one Jacobian at the start of each communication interval (due to the integrator restart) and then keeps it throughout the interval. Enabling input smoothing reveals that these Jacobians actually can be kept for a longer time, resulting in only 40 Jacobian evaluations throughout the co-simulation. Also enabling the predictor compensation helps CVODE's nonlinear solver and reduces the number of required Jacobians to only 14.

For IDA, the reduction in Jacobian-evaluations given by the predictor compensation is not significant. However, when only using input smoothing, then IDAs nonlinear solver fails to converge seven times during the co-simulation. With the help of predictor compensation to improve the start guesses, all of these failures are eliminated revealing the numerical soundness of this technique.

The position of the mass (s) is plotted over time in Figure 4 for the co-simulations using IDA in the mass FMU. A direct simulation of the full system is provided as reference. As expected the classical non-iterative co-simulation attenuates the oscillations. This is made worse by the extra delays introduced by the input smoothing. As previously discussed, the predictor compensation has no direct effects on the simulation results, but rather only helps the solver. Since the result of the input smoother with predictor compensation coincides with that without compensation, we do not include it in the figure.

DOI
10.3384/ecp218653

Table 2. Simulation statistics for the mass FMU from the mass-spring-damper co-simulation problem. Three different solvers are tested with classical input handling or input smoothing (IS) with or without predictor compensation (PC). The statistics are the number of times the model is evaluated by the solver (f-evals), the number of times the solver Jacobian is approximated (Jac-evals), and the number of times the predictor compensation evaluates the model (PC f-evals).

	CVODE			IDA			DASSL		
Option	f-evals	Jac-evals	PC f-evals	f-evals	Jac-evals	PC f-evals	f-evals	Jac-evals	PC f-evals
Classical	5471	499		5958	4960		5042	4543	
IS	2708	40		4715	1030		2653	534	
IS & PC	853	14	996	2692	916	996	1481	259	996

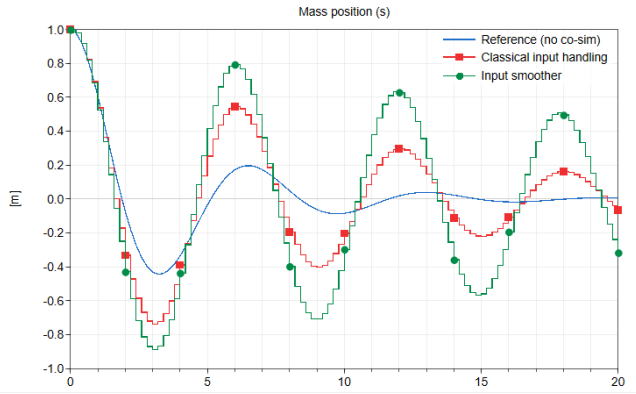

Figure 4. The mass position (s) over the first 20 s of simulation of the mass-spring-damper co-simulation problem with communication interval $H = 0.2$ s, with or without input smoothing. The reference solution is given by simulating the full model directly in Dymola.

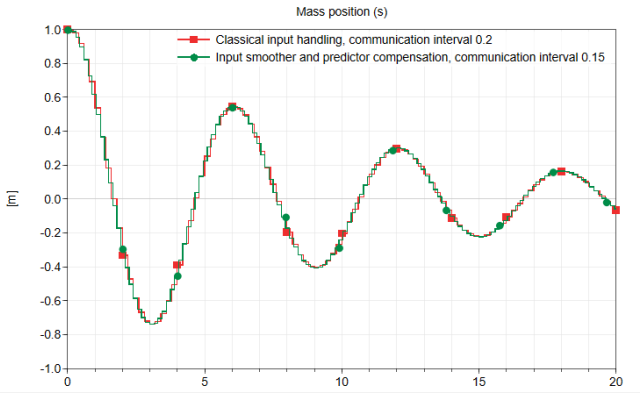

Figure 5. The mass position (s) over the first 20 s of simulation of the mass-spring-damper co-simulation problem. The simulation with input smoothing and the predictor compensation has a reduced communication interval to compensate for the additional co-simulation delay. Under these settings the results are similar.

Table 3. Simulation statistics for the mass FMU from the mass-spring-damper co-simulation problem. The co-simulations are run using IDA. The simulation statistics for communication interval $H = 0.2$ s is as in the previous experiments, cf. Figure 4 and Table 2. To compensate for the additional delay, the interval has been reduced to $H = 0.15$ s for the simulations with input smoothing, cf. Figure 5.

		IDA		
Option	H [s]	f-evals	Jac-evals	PC f-evals
Classical	0.2	5958	4960	
IS	0.2	4715	1030	
IS & PC	0.2	2692	916	996
IS	0.15	2380	471	
IS & PC	0.15	1506	357	1330

As a final experiment we reduce the communication interval to $H = 0.15$ s for the simulations with input smoothing to compensate for the additional delay. With this choice of H, the result is similar to the result when using classical input handling with $H = 0.2$ s, cf. Figure 5. From Table 3 we can see that even with this smaller communication interval the simulations with input smoothing are cheaper in terms of f-evaluations and Jacobian-evaluations inside the mass FMU. Indeed, the statistics are even better compared to Table 2.

A disadvantage is that the master has to handle inputs and outputs more often. Thus, in a larger system, reducing the communication interval could increase the number of function evaluations in other part of the coupled system. Further, in practice, it is not always possible to arbitrarily change the communication interval, e.g. due to real-time requirements.

3.2 HIL simulation of a heat pump

In this section the model of a heat pump as used for Hardware-in-the-Loop (HiL) is examined. On the HiL environment the model is simulated with a (usually) fixed synchronization rate. The input signals of the model are updated in each step. The input signal often has a small noise. In this section we only replicate the boundary conditions by applying a constant input signal with a small noise. The example uses a single FMU, the surrounding environment is represented by the input signals. This example is focussed on the overall performance gain, it does not examine the effect on the results due the modified input trajectory, or the introduced delay.

3.2.1 Setup

The domestic heat pump used in this example is based on the HiL use case of (Schulze, Gräber, and Huhn 2011) and uses the TIL-Suite (TLK-Thermo GmbH 2024). It is a simple vapor compression cycle with efficiency-

based compressor, Bernoulli expansion valve, two 1D-discretized TubeAndTube HX (heat exchangers) and an ideal separator model. The refrigerant is R-407C.

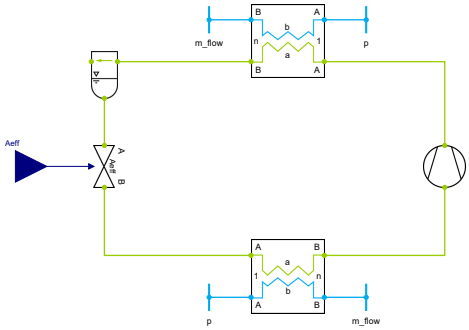

Figure 6. The valve opening area is input of this domestic heat pump model.

A large simulation study with almost 17000 single simulations was conducted to analyze the CPU time performance. The cumulative CPU time exceeded 5 days and 16 hours. The model is exported as FMU 2.0. The solver tolerance is set to 10^{-5}. Five independent "dimensions" have been varied: The solver (CVODE, DASSL and IDA), the smoothing method (Classical, IS, and IS & PC), model variant, the boundary condition (constant, small noise, large perturbation), the `doStep` interval length.

The model variants are:

- Baseline (1 s): Low number of HX volumes with num. ODE-Jacobian and 1 s stop time, 83 continuous-time states, Helmholtz fundamental equation of state.
- Baseline (100 s): Low number of HX volumes with num. ODE-Jacobian and 100 s stop time, 83 continuous-time states, Helmholtz fundamental equation of state. Used to display what happens if the time constants of the model are relatively smaller compared to the `doStep` interval lengths.
- High-Resolution (1 s): High number of HX volumes with num. ODE-Jacobian and 1 s stop time, 403 continuous-time states, Helmholtz fundamental equation of state. Used to display the influence of the model complexity.
- Analytical Jacobian (1 s): Low number of HX volumes with analytical ODE-Jacobian and 1 s stop time, 83 continuous-time states, spline-based fluid properties. Used to display the influence of the computation of the ODE-Jacobian.

There are three types of boundary conditions for the effective valve opening area:

- Constant input: 1mm^2
- Small noise: 1mm^2 plus a small random number varying at each time step with an amplitude of 0.1%, simulating signal noise.
- Large stochastic perturbation: 1mm^2 plus a large random number varying at each time step with an amplitude of 50%, replicating abrupt controller output changes.

The time constants of the Baseline model with 83 continuous-time states range from 0.1 s to 65 s with a mean of 2.1 s and a median of 0.58 s. The time constants of the High-Resolution model with 403 continuous-time states range from 0.023 s to 52 s with a mean of 0.6 s and a median of 0.1 s.

3.2.2 Result and analysis

Figure 7 shows the performance gain of CPU time relative to the reference case plotted against the number of `doStep` calls. The Classical FMU is the fastest scenario if the inputs are constant (best-case scenario). If the input of the Classical FMU is updated, then the solver is reset and the CPU time increases significantly (worst-case scenario). The IS variant has a limited solver step size, and an increased number of Jacobian evaluations compared to the Classical variant with constant input signal, as mentioned in Section 2.2.

The Baseline (100 s) demonstrates smaller performance gains if the input is subject to large perturbations. The model responds comparatively quickly because the `doStep` interval length is larger compared to the model time constants. The model has to be brought closer to the steady state, and hence the computational effort is higher. The effect of input smoothing diminishes. Using constant input values (dotted line, best-case scenario) is significantly faster, but also the results are significantly different.

The High-Resolution model demonstrates that as the number of continuous-time states of the model increases, the computational cost of the f- and Jacobian-evaluation also rises. Consequently, the speed-up factor of the IS and IS & PC method becomes more significant. The model variant with analytic Jacobian is generally faster than the Baseline with num. Jacobian. In all cases, the speed-up factor with analytic Jacobian is at a lower level, but the overall picture is unchanged.

The minimum and maximum speed-up summarized in Table 4 of the variants shown in Figure 7 illustrate that input smoothing is beneficial, if inputs have to be updated and the synchronization step size is low.

Augmenting the input smoother with predictor compensation is occasionally very beneficial. In Figure 7 we see the benefits when the input is altered by large perturbation and IDA or DASSL is used. When only the input smoother is used, these represent the cases where the solver runs into severe problems due to the large changes in the derivative of the smoothed input signal. Investing a few extra model evaluations at communication points to help the solver predictor is repaid many times over. In the best cases, we see about 10 times faster simulation compared to only using input smoothing (about 100 times faster compared to the reference). The most striking is that the number of Jacobian evaluations is reduced from about 1000 (IS) to

DOI

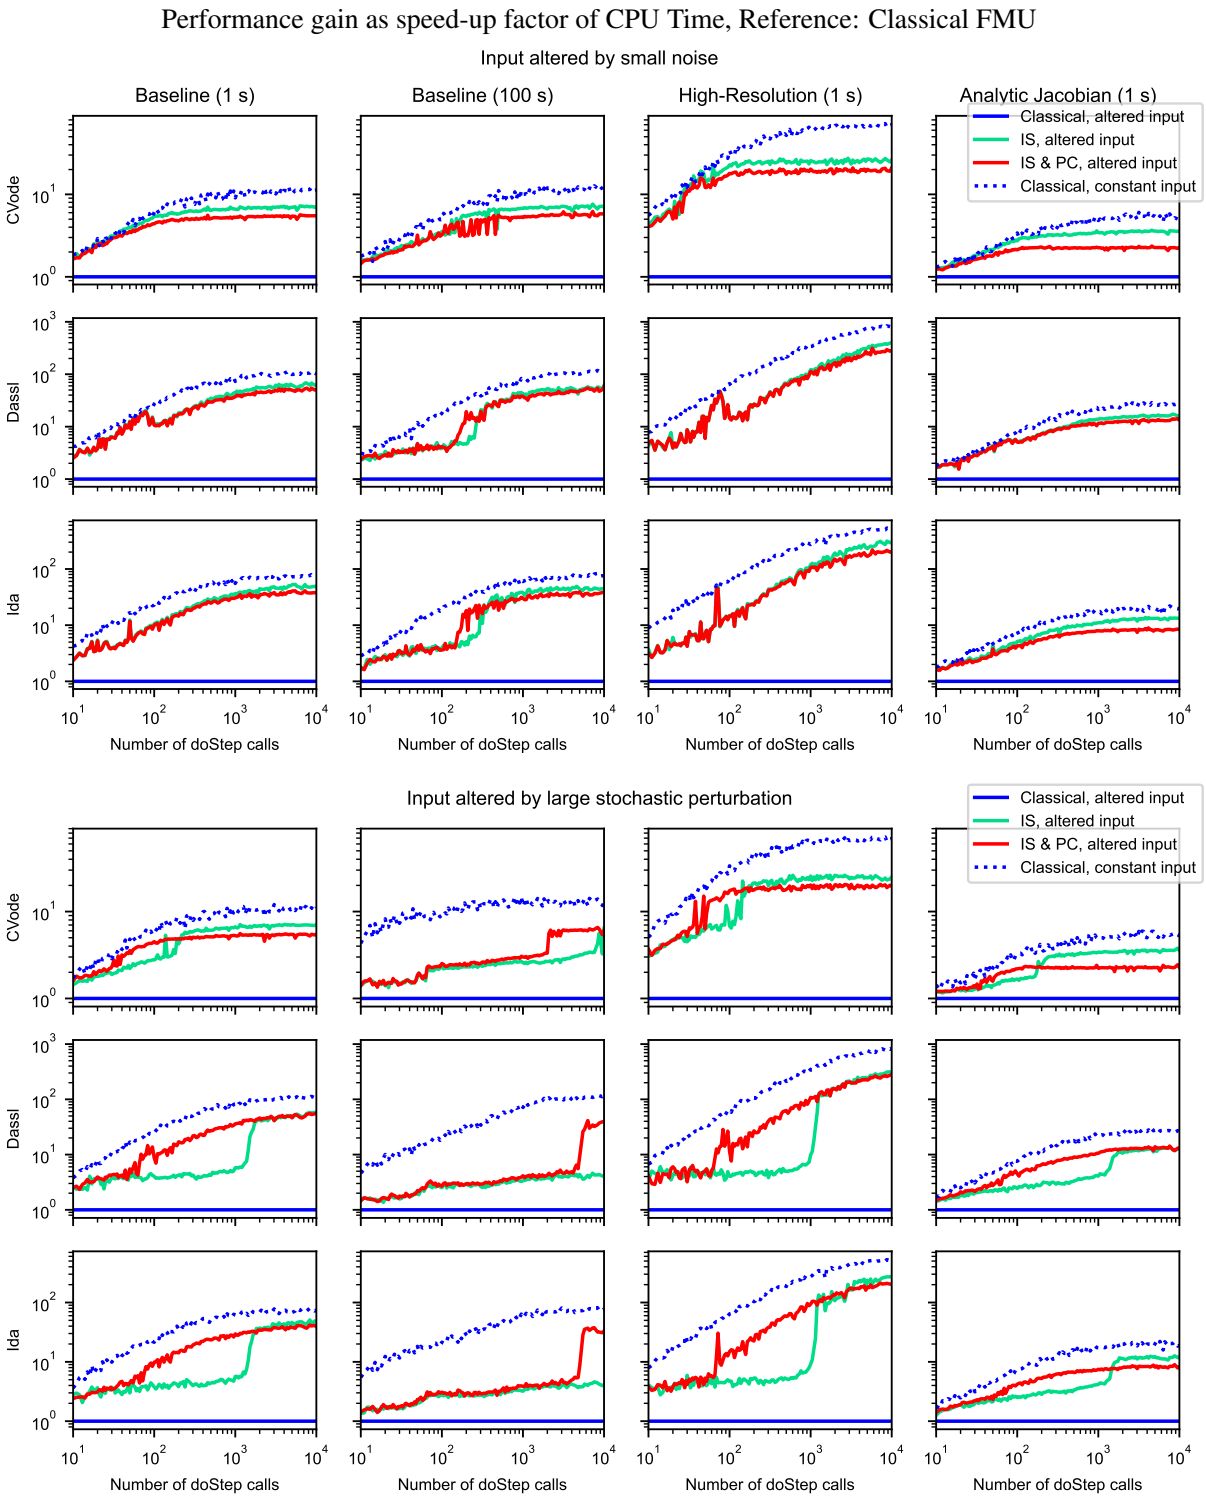

Figure 7. The figure illustrates the CPU time performance gain across various simulations, represented as a speed-up factor relative to the solid blue reference scenario. The x-axis indicates the number of `doStep` calls required to reach the fixed stop time. The upper half of the figure represents simulations with small noise in the boundary condition, while the lower half shows results under large stochastic perturbations. The reference scenario, defined as the Classical FMU with altered input (regardless of perturbation amplitude), represents the worst-case in terms of performance. Conversely, the Classical FMU with constant input exhibits the fastest execution and serves as the best-case scenario. As the number of `doStep` calls with the same stop time increases, the performance gain improves in all plots. The Baseline (100 s) shows smaller performance gains under large perturbation, as the model responds comparatively quickly. With increasing model complexity (High-Resolution), the performance gain becomes more pronounced. Utilizing an analytic Jacobian reduces the impact of input smoothing while preserving the overall trend. Adding predictor compensation is sometimes very beneficial with large perturbation boundary conditions using DASSL or IDA, reaching about a factor of 10 times faster simulations compared to when only using input smoothing.

Table 4. The table provides a summary of Figure 7, presenting the minimum and maximum speed-up factors across selected number of `doStep` calls. The range reflects the differences among model variants and boundary conditions. The rows compare the IS and IS & PC performance with updated inputs to the best case scenario. Across all scenarios, IS consistently improved performance. However, the speed-up factor is highly influenced by time constants, model complexity and the input trajectory.

		Speed-up factor			
Solver	**Variant**	Number of doStep calls			
		10	100	1000	10000
CVODE	Classical with constant input	1.3 - 5.5	3.1 - 34.0	4.8 - 61.4	5.2 - 70.1
	IS, altered input	1.2 - 4.5	1.7 - 22.8	2.6 - 25.7	3.6 - 26.2
	IS & PC, altered input	1.2 - 4.1	2.1 - 18.0	2.2 - 20.3	2.3 - 21.0
DASSL	Classical with constant input	1.8 - 7.8	7.6 - 66.5	21.3 - 338.9	25.8 - 847.2
	IS, altered input	1.4 - 4.3	2.4 - 14.6	3.4 - 122.0	4.1 - 403.0
	IS & PC, altered input	1.5 - 4.9	2.7 - 14.6	4.1 - 113.2	13.1 - 282.1
IDA	Classical with constant input	1.8 - 8.8	7.1 - 67.8	17.2 - 272.5	19.0 - 532.2
	IS, altered input	1.3 - 4.1	2.5 - 14.9	3.2 - 119.6	4.1 - 299.2
	IS & PC, altered input	1.4 - 3.8	3.1 - 14.9	3.8 - 105.9	8.3 - 206.2

about 50 (IS & PC), showcasing the numerical soundness of the predictor compensation.

With that said, we can also see that predictor compensation is not always needed. When the input is altered by small noise, then the changes in input are small enough for the integrator to function well, even without the help of predictor compensation. This is evident by looking at the internal step-size sequence of the integrator inside the FMU. Very often the integrator takes the largest possible step, i.e. the length of the communication interval. In these cases, the predictor compensation only contributes its additional f-evaluations and therefore worsens performance. This is also the case in the experiments with CVODE when the input is altered by large perturbation and the number of `doStep` calls is large.

It is important to note that the results of the simulations performed are not identical. The user must evaluate whether the results are still within tolerance, even with the altered input trajectory effectively causing additional time delay.

3.3 Heat pump simulation data for training surrogate models

To show the possible improvements for industry-relevant applications, we investigate the application for a detailed model of an air-source heat pump. The used model is a demonstrator of the *OpenSCALING* research project, delivered by the industry partner *Bosch*. It consists of a refrigeration cycle with controller and is modeled using the TIL-library of *TLK-Thermo*. The outdoor heat exchanger is especially detailed; apart from the liquid-vapor behavior of the R-290 refrigerant, it models the moist air flow including condensation and frost formation on the heat exchanger surface. The diagram view of the R-290 refrigeration cycle (or just model) can be seen in Figure 8.

In practice, system models including refrigerant cycles can be computationally expensive, due to the detailed representation of the physical phenomena (evaporation, condensation, ice formation, ...). Required simulation times

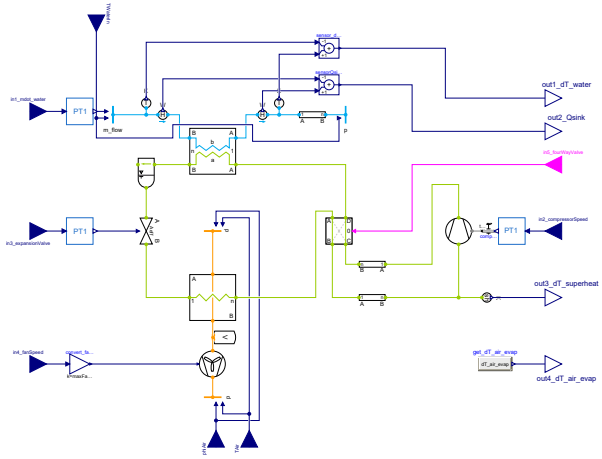

Figure 8. Diagram of the R-290 refrigerant with 7 inputs.

and computational resources set limits to repeated evaluation of the models. This restricts how the model can be used, for example in virtual testing, controller design or setpoint optimization. Here, data-driven surrogate modeling comes into play: By sampling input signals to the physical simulation model, a dataset is created, with which surrogate models are trained. This means that one has to accept a high computational upfront cost for generating the surrogate model; but once it is trained, its evaluation becomes really cheap and can be easily used for millions of evaluations. For example, *University of Augsburg* examines in the research project *OpenSCALING* Balanced Neural ODEs for generating surrogates. This method has been demonstrated to decrease computation times by a factor up to 100 (Aka et al. 2025).

3.3.1 Operating points

Evaluation times of the heat pump model can considerably differ depending on the operation point; it is especially high for reverse-cycle operation to defrost the outdoor heat exchanger, or for oscillating controller behavior, that frequently arises during virtual controller devel-

DOI
10.3384/ecp218653

opment. On the other hand, if steady state operating conditions are reached, adaptive-step size solvers quickly solve the model. To evaluate the impact of the input smoother for these different cases, we include it with (1) tuned controllers that avoid oscillating behavior and (2) controller with high gains to enforce oscillations. Additionally, the model is operated at air-conditions that avoid frost formation.

3.3.2 Setup

The heat pump system consisting of the refrigeration cycle and controllers is exported as a co-simulation FMU 2.0 with DASSL as solver. The inputs are defined in a co-simulation master. Moreover, the heat-pump model with setup for controllers is also implemented in pure Modelica and simulated for comparison.

3.3.3 Result and analysis

The results for the simulation statistics related to the solver are found in Table 5, while computational time measured is presented in Table 6.

Table 5. Simulation statistics of the solver for the heat pump co-simulation FMU exported with DASSL, from the controller model for the two different operation points. Simulated to $T = 500$ s with communication interval $H = 1$. In addition the model is simulated using pure Modelica, with applicable statistics for f-evals and Jac-evals. The model with tuned controllers that avoid oscillating behavior in the output is labeled *Low Oscillations* while the model with controllers with high gains to enforce oscillations in the output is labeled *High Oscillations*.

Low Oscillations				
Option	f-evals	Jac-evals	Events	PC f-evals
Classical	8251	4546	506	
IS	1950	209	6	
IS & PC	1910	222	6	998
Modelica	1038	140		

High Oscillations				
Option	f-evals	Jac-evals	Events	PC f-evals
Classical	71939	9073	514	
IS	70734	7011	16	
IS & PC	70442	6936	16	926
Modelica	35343	6113		

When the controller is tuned to avoid oscillating behavior (Low Oscillations) the input smoother performs well, reaching over 40 times faster co-simulation. This is clear from looking at the reduced number of events in Table 5. The Classical FMUs generate events every time the integrator re-initializes. Thanks to the continuity of the input these re-initializations are not needed, drastically speeding up the simulation. On the other hand, adding predictor compensation slightly worsens performance for the same reason as described in Section 3.2.2 when the input is altered by small noise, c.f. Figure 7.

Although still having a positive impact, input smoothing is less effective for the model containing high oscillations. The reason is that the simulation inside the heat pump FMU is challenging for the integrator given the used communication interval. The work is dominated by a lot of internal steps in each interval, overshadowing the performance gained by avoiding restarts at communication points. Adding predictor compensation improves performance slightly.

Table 6. CPU-time statistics of the solver for the heat pump co-simulation FMU exported with DASSL, from the controller model for the two different operation points. CPU-time gain is calculated with classical FMU as baseline. Simulated to $T = 500$ s with communication interval $H = 1$. In addition the model is simulated using pure Modelica. The model with tuned controllers that avoid oscillating behavior in the output is labeled *Low Oscillations* while the model with controllers with high gains to enforce oscillations in the output is labeled *High Oscillations*.

Low Oscillations		
Option	CPU-time [s]	CPU-time gain
Classical	129	1
IS	3.11	41.5
IS & PC	3.27	39.5
Modelica	2.35	54.9

High Oscillations		
Option	CPU-time [s]	CPU-time gain
Classical	321	1
IS	273	1.18
IS & PC	255	1.26
Modelica	183	1.75

In all cases it is most efficient to simulate the model using pure Modelica, but employing input smoothing techniques decreases computational effort to be more in level with the Modelica implementation.

4 Conclusion

In this article we have introduced techniques that may speed up co-simulation by orders of magnitude, namely input smoothing and predictor compensation. The main benefit is their ease-of-use. No special co-simulation master is required, nor any manipulations of the models that are being exported to FMUs. Rather, the options are easily enabled in Dymola 2025x and the logic is handled entirely by the generated code.

By smoothing the input to the FMU, integrator re-initializations at communication points can be avoided. For multistep solvers like CVODE, IDA, and DASSL, this may heavily reduce the number of model and Jacobian evaluations. The benefits of smoothing the input were observed for the examples studied in this article, with some configurations seeing over 400 times faster co-simulation.

However, the smoothed input may still have discontinuous derivatives. To handle this problem we proposed the use of predictor compensation to help the integrator inside

the FMU. When enabled, additional model evaluations are performed to improve the guess for the next internal state. In the best cases we observed performance gains of a factor 10 compared to only using input smoothing.

Based on the experiments with the thermo-fluid applications we conclude that input smoothing gives the greatest benefits when the co-simulation FMU is computationally heavy but the communication interval is small compared to the dynamics of the model inside the FMU. This is a commonn case in applications as the communication interval often is set by external factors, such as stability and accuracy of the overall co-simulation problem or real-time requirements, c.f. Sections 3.2.

Predictor compensation is most beneficial when, additionally, the integration with input smoothing is not too trivial. Thereby, predictor compensation performs best within a sweet spot where the integration inside the FMU is not too simple, nor too difficult. In our experiments IDA and DASSL are more often helped by predictor compensation.

Although, the results presented in this article are very promising, further work is needed to study the effect of input smoothing and predictor compensation for co-simulation setups containing several coupled FMUs.

5 Acknowledgments

The authors would like to thank Vaillant and Airbus for their invaluable contributions in developing and testing the input smoothing technology.

Research for the input smoother was funded by the German Federal Ministry for Education and Research (BMBF) under the research project “MODAK” (Grant 01IS17006C).

The inclusion of the air-source heat pump example for training surrogate models has been supported by VINNOVA (grant number 2023-00969) and by the ITEA 4 project OpenSCALING (Open standards for SCALable virtual engineerING and operation) N°22013 under grant number 01IS23062H.

Abstract

LookAhead is a lightweight algorithm that improves event handling in co-simulation by predicting events and adjusting the communication step size beforehand. It operates without requiring subsystem event handling capabilities. This paper compares LookAhead with other event handling methods, namely Rollback and Early Return, from the perspective of performance and applicability. Results from the presented example show that LookAhead performs on par with iterative co-simulation methods and is particularly well-suited for handling shared state events.
Keywords: co-simulation, non-iterative co-simulation, hybrid simulation, event handling

1 Introduction

In co-simulation, the continuousness of signals is critical for performance and accuracy. The coupling error at coupling time steps can introduce discontinuities in a signal that might lead to slower computation, as a subsystem's solver algorithm might have to reset or use smaller steps. Methods like anti-aliasing can be used to smoothen input signals and improve co-simulation results. Such signals usually represent physical quantities that are continuous in nature. In other cases, a signal can actually be discrete, which can pose a particular challenge for co-simulation. This is a common challenge in the simulation of cyber-physical systems, where physical systems interact with or are being controlled by discrete control signals. A discrete change in signals, state or behaviour in a simulation model in general is called an event.
Events can be the result of different types of causes (Cellier and Kofman 2006). An event that is triggered at a certain moment in time, irrespective of the system's state (within limitations), is called a time event. An event that is directly caused by the system reaching a certain state on the other hand is called a state event.
A challenge of discrete signals unique to co-simulation are shared events, where events are being triggered in multiple subsystems by the same cause; if such an event occurs in only some subsystems or at different times, it can lead to incorrect and unphysical behaviour like violating boundary conditions or conservation of energy.
Due to the evolving sophistication of co-simulation techniques and the increasing importance of simulation and co-simulation in industrial development, proper event handling has become more and more important and has been a major focus in the development of the fmi3 standard.

2 Algorithm Description

2.1 LookAhead

For systems that lack sophisticated event handling support, LookAhead can improve the results of a co-simulation by predicting events and adapting the communication step size (Tischer et al. 2023). It does so by defining event indicators, which are sets of functions of a subsystem's inputs, outputs, and parameters. Each function z in an event indicator (called an event condition) is defined in a way such that $z < 0$ means that this condition of the event is fulfilled. An event occurs when all conditions are fulfilled, which is equivalent to when the last condition function crosses zero. Via extrapolation of these event condition functions, an event can be predicted, and the communication time step can be reduced and adapted in advance to hit the event precisely. For a more thorough description, see (Tischer et al. 2023).
As LookAhead only relies on a subsystem's interface, it can be used with any subsystem regardless of its own event handling capability and whether it is a black-box or not. On the other hand, knowledge about its events is needed to a degree that their conditions can be modelled; additionally, the event conditions also need to be able to be modelled in this manner instead of relying on internal variables.

2.2 Rollback

Rollback capability means that a system's state can be reset to a prior point in simulation, usually the previous time step. FMUs with the *canGetAndSetFMUstate* attribute are able to store their state at any point in a simulation and thus support Rollback.
To improve event handling in our use case, the subsystems store their state at every communication time step.

This save state is being stored externally (meaning, outside of the FMU by the importer) for one communication time step, when it is being overwritten by the new one if the step finished successfully. If the step fails, both FMUs in the example system (see following section) are being reset to the beginning of the step, and a new step size is chosen. In our example, if an event occurs in the middle of a communication time step, the simulation is being rolled back to the last time step and then a new communication step size is chosen so that the event occurs at the communication point.

2.3 Early Return

Early Return is an fmi3 functionality (Modelica Association 2024) where an FMU can do a simulation step and, for example when encountering an event, stop and return early from the step. This is different from Rollback in that the step was still finished successfully and does not have to be repeated. The importer has to declare to the FMU that it supports Early Return and can handle subsystems not finishing a whole step. In our example, the FMUs return early when encountering an event to allow for additional exchange of signals.
Early Return can be requested from the outside by the importer as well via callback functions, but this has not been utilised in this setup.

3 Example Setup

3.1 Example System

The example system that the algorithms are being tested on consists of two connected spring-damper-mass systems. The upper mass is connected to a fixed ceiling at height $x = 0$ while the lower mass is connected to the upper one. Both connections have the same stiffness and damping coefficients, $k = 100, d = 1$. This system was introduced in (Dejaco and Benedikt 2017) and was slightly adapted from there.
The system's state is described by four variables, the positions and velocities of both blocks, which can be described by the following system of first order differential equations:

$$\begin{aligned} \dot{x}_1 &= v_1 \\ \dot{x}_2 &= v_2 \\ \dot{v}_1 &= -\frac{2k}{m_1}x_1 - \frac{2d}{m_1}v_1 + \frac{k}{m_1}x_2 + \frac{d}{m_1}v_2 - g \\ \dot{v}_2 &= -\frac{k}{m_2}x_2 - \frac{d}{m_2}v_2 + \frac{k}{m_2}x_1 + \frac{d}{m_2}v_1 - g \end{aligned} \tag{1}$$

with $i \in 1,2$ denoting the upper and lower block and x, v their position and velocity, respectively. The half height of each block is $\Delta x = 0.55$. When splitting the system up into two subsystems, each block takes the other one's position and velocity as inputs and provides its own as outputs.
This simple, continuous-state system is being complicated by two collision events. The upper block can collide with the ceiling, and both blocks can collide with each other. The former is a private event that only affects the upper block, while the latter is a shared event between both blocks.

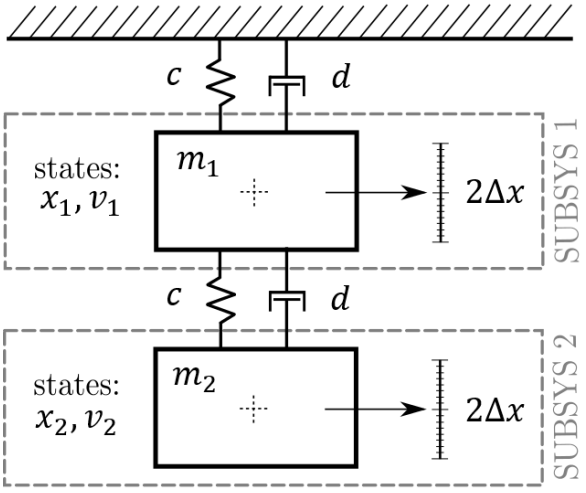

Figure 1. Schematic of the spring-damper-mass system. Figure was taken from (Dejaco and Benedikt 2017) and adapted.

The conditions for the wall block's private event, the collision with the ceiling, are

$$\begin{aligned} -v_1 &< 0 \\ -x_1 &< \Delta x. \end{aligned} \tag{2}$$

The ceiling collision is handled internally and simply by subsystem 1 by flipping its velocity:

$$v_1' = -v_1. \tag{3}$$

Primed variables denote variables after the event. The conditions for the shared event, the collision between the blocks, are

$$\begin{aligned} v_1 - v_2 &< 0 \\ x_1 - x_2 &< 2\Delta x. \end{aligned} \tag{4}$$

The binary collision is handled internally (and seperataly) in both blocks. Each block does this by using the formulas for elastic collisions to calculate the post-collision velocities. For calculating the time steps between collision and the next communication step with the other block, not only the block's own velocity is being calculated but also the other one's to prevent the possibility of false succeeding collisions.
The calculation is being done by these formulas:

$$\begin{aligned} v_1' &= \frac{m_1 - m_2}{m_1 + m_2}v_1 + \frac{2m_2}{m_1 + m_2}v_2 \\ v_2' &= \frac{m_2 - m_1}{m_1 + m_2}v_2 + \frac{2m_1}{m_1 + m_2}v_1. \end{aligned} \tag{5}$$

Even though the equations are the same in both blocks, the results can differ, as each block can only access the other's velocity as an input (that is dependent on

DOI 10.3384/ecp218663

coupling step size and method, and is therefore affected by coupling error), and not the exact state value.

Similarly to how the event prediction works in LookAhead, the FMUs use event indicators to trigger their events internally. For an event E_i, we call its event indicator $M_i(z)$, analogously to the naming conventions of the fmi standard. Then, the event E_i occurs if and only if $M_i(z) < 0$. To use the event conditions Equation 2 and Equation 4, we just define the $M_i(z)$ for each event as the minimum of its event conditions:

$$M_i(z) = min_j z_{ij}, \tag{6}$$

where z_{ij} is the j-th event condition for event E_i.

3.2 Co-simulation Setup

The subsystems have been compiled as FMUs, using the Modelica Reference FMUs as a basis. Three versions have been compiled of each subsystem: one without any additional event handling methods, one implementing Rollback, and one implementing Early Return. The simulated time is 20 seconds, the longest time in which the described system shows interesting behaviour. After that, the system reaches a somewhat stable configuration and no more events occur.
The co-simulations have been carried out in Python, using the fmpy package to import and simulate the FMUs. The Early Return FMUs are equipped with Intermediate Update (Modelica Association 2024) support, which is used to log the FMUs' states at every microstep.
In total, simulations with five different setups have been carried out.

- The first, the monolithic simulation, serves as ground truth for our analysis; this was not a co-simulation, but was in fact a simulation of the total system of four equations that the two subsystems consist of. The results have been saved with a time step of $\Delta t = 0.001s$, which is the time step of the fixed step solver integrated in the FMUs.

- The second setup is the standard co-simulation, where no event handling has taken place. This means that collisions are only being handled internally by the subsystems, and the master is only exchanging information between them without any additional handling such as inter- or extrapolation, event triggering, or time step adaptations. It has been carried out with a fixed communication step size of $\Delta t = 0.08s$, which was also the default for the following setups.

- The third setup is similar to the second, except the addition of the LookAhead algorithm turned on, evaluating the event indicators once per simulation loop and adapting the communication step size when an event is being predicted. The minimum step size for LookAhead was equal to the solver step size of $\Delta t = 0.001s$.

- The fourth setup used Rollback. The Rollback FMUs were equipped not only with the capability to reset their state, but also with two additional output signals to indicate if (called EventSensor) and when (called EventTime) an event occurred. If an event occurred at a time that was too far away from a communication point, the co-simulation algorithm would reset the last simulation step and repeat it with the event time as target time.

- The final setup utilises Early Return. The FMUs have been adapted in such a way that, when they are being initialised with $earlyReturnAllowed = True$, they return early immediately before an event occurs. For this, the event indicators $M(z_i)$ have been slightly changed by subtracting a small threshold $m = 0.05$ from their final value, but also changing the condition for triggering the event to $M(z_i) < m$. This makes it so that the event trigger remains unchanged, but the FMU returns early right before the event to allow for exchange of signals before it.

4 Analysis

4.1 Criteria

To compare and analyse the different co-simulation methods, the position error is used as a key metric. This error is calculated as the absolute difference between the position and a reference or ground truth over time, as given in Equation 7, where x_i is the position of block i in the co-simulation and $\hat{x}_i$ is its counterpart in the reference solution. By examining the magnitude and trend of this error, we can assess the accuracy and performance of each co-simulation method.
By taking the root mean square of it, we can get an average error as well. The RMS provides a single scalar value that reflects the overall magnitude of the error, smoothing out noise and highlighting consistent deviations. By evaluating the RMS error up to different points in time, we can observe how the accuracy of the simulation evolves and compare the performance between the different methods. This time-resolved analysis helps to identify when and where the simulation performs well and when it diverges.

As the performance of a hybrid system can depend heavily on how well the events are being handled, the temporal accuracy of events (especially the shared event) is also an important metric that has a direct effect on the position error. Temporal accuracy refers to how closely the timing of key events in the simulation aligns with those in the reference solution. To evaluate temporal accuracy, timestamps of the collision events are compared across simulations, and any deviations are measured as time offsets.

This is defined in Equation 8, analogously to the position error, summing up the time differences of all n events that occur during simulation. To get a meaningful result for the time error, all the events in the reference solution have to have a counterpart in the co-simulation. If the co-simulation has events that do not occur in the reference, or any events of the reference do not occur in the co-simulation (or, if it is a shared event, do so only in some of the partaking subsystems) the time error can not be calculated.

$$e_{pos} = |x_1 - \hat{x}_1| + |x_2 - \hat{x}_2| \tag{7}$$

$$e_{time} = \sum_{i}^{n} |t_i - \hat{t}_i| \tag{8}$$

4.2 Results

In Figure 2 we can see the results of the five simulations described in subsection 3.2. One can see that the shared events are the main contributor to the position error; after each collision the deviation from the reference increases.
Table 1 shows the RMS position error for each simulation co-simulation method evaluated at three different time points: 2 seconds, 10 seconds, and at stop time of 20 seconds. The standard co-simulation already has a large error at $t = 2s$ of 0.609 m after just 2 events, and increases by a factor of ten at $t = 10s$. At this point, the simulation is already far off from the reference solution.
In contrast, LookAhead and Rollback maintain consistently low errors across the entire simulation, indicating strong and stable accuracy. Finally, Early Return starts off with the lowest error at $t = 2s$ ($0.071m$), but experiences a significant jump to $2.036m$ at $t = 10s$ and a slightly lower $1.936m$ at $t = 20s$. This accumulating error leads to a diverging behaviour and indicates that the events have not been handled well enough. Overall, LookAhead and Rollback demonstrate the most stable and accurate performance over time, while Early Return is accurate at first, but diverges later in the simulation.
One can see that the Rollback and LookAhead co-simulations performed better than the standard co-simulation and the one using Early Return; we split the result analysis into these two groups.

When looking at the results for the standard and Early Return variants (Figure 3), we can see that not only the trajectories diverge, but also the event times do not match and, at a simulation time of about 12 seconds, an additional collision takes place which changes the following trajectory so much that the position error is no longer a meaningful metric. The issue with Early Return is that, unlike Rollback, it is not possible to reset a simulation, so when one subsystem returns early but the other has completed its step (or stopped at a later time during the step), it is no longer possible to reset the simulation to the point of the event. The early returned subsystem can be fed with updated inputs, but the other one not. Two possible ways to solve this problem is to either schedule the subsystems sequentially, which works when one of them tends to stop earlier, or to allow the FMUs to be stopped externally, which introduces non-deterministic behaviour (Broman 2017). If there is an untreated discrepancy in event times between the involved subsystems, an additional error is introduced, possibly leading to a bigger time discrepancy at the next shared event and explaining the increasing position error.

On the other hand, the Rollback and LookAhead methods (Figure 4) performed much more accurate, with no additional events occurring. From a first impression, one might assume that Rollback and Early Return perform the same; in both cases, the simulation introduces an additional communication step at the event time, and calculating exactly the same outside of any events. The difference is that, as Rollback is an iterative co-simulation technique, the system has more accurate information during subsequent repeated calculation steps, resulting in reduced error — independent of how the event is handled. Unlike Early Return, both subsystems in Rollback calculate to the same event time as their communication step is governed by the co-simulation algorithm, preventing any time discrepancy errors.
LookAhead handles shared events as well as Rollback does, even though it is non-iterative. It accomplishes this by reducing the communication step size just before the event, introducing additional communication steps. Since collisions significantly contribute to position error, the co-simulation improves accuracy by increasing signal exchange when it matters most, while maintaining larger step sizes elsewhere to optimize performance.

Table 1. Root mean square position error at different times.

Variant	RMS@2s	RMS@10s	RMS@end
Standard	0.609	6.060	4.578
LookAhead	0.146	0.100	0.132
Rollback	0.139	0.178	0.159
Early Return	0.071	2.036	1.936

5 Summary, Conclusion and Future Work

We have introduced the LookAhead algorithm, a lightweight event handling algorithm that works by predicting upcoming state events and reducing the communication step size, and compared it to two other event handling methods, the iterative Rollback mechanism and fmi3's Early Return functionality. Based on an example system that has proven itself to be a hard task to simulate correctly due to the shared events having such a large influence on the error, we compared each method's

DOI 10.3384/ecp218663

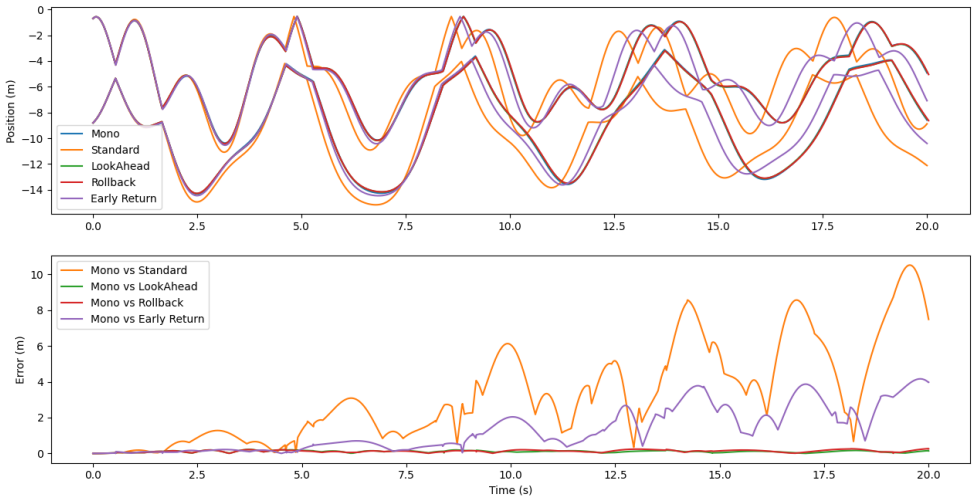

Figure 2. An overview over all 5 co-simulation results. The upper panel shows the trajectories of both blocks, while the lower panel shows the position error e_{pos} as calculated in Equation 7.

performance to the monolithic reference solution, a co-simulation algorithm without any event handling, and to each other. All three methods have their strengths, each one having the high ground in different systems.

Rollback can significantly enhance the accuracy of a co-simulation with comparatively small programming effort. This is achieved by enabling a subsystem to access and restore its internal state, and by providing a mechanism to notify the importer when such operations should occur. (We assume here that the importer supports this functionality for all three methods.) However, the main drawback lies in the potential computational cost: for complex models, saving and restoring system states can be computationally expensive. If states are stored thousands of times for an event that occurs only a few times, the overhead may outweigh the benefits. This limitation can be mitigated by storing the system state less frequently and, if a reset is required, reverting to an earlier point in time. Furthermore, if not all subsystems support Rollback, sequential coupling must be employed. In this case, the Rollback-capable subsystems are executed first, while the remaining components proceed only after a successful communication step has been completed.

Early Return has its strengths in handling private events. It not only enables recording the exact time and state at which an event occurs, but also allows this information to be propagated to other system components, thereby improving overall accuracy. To maximise this advantage, similarly to Rollback, Early Return FMUs can be calculated first in a sequential coupling scheme. The problem that we encountered in this setup is that two components utilising Early Return can give contradicting information on when an event takes place, leading to time discrepancies. This problem arises only under specific circumstances, but can lead to uncertain credibility in systems with events in more than one subsystem. Another big advantage of Early Return is its versatility in how it can be used, as aspects such as the ability to trigger Early Return from the outside (Modelica Association 2024) have not been explored in this setup.

LookAhead operates at the importer level, managing the communication step size of the entire co-simulation. While this global approach may be less optimal for a single component, it is unaffected by multiple concurrent events. When LookAhead predicts an event, it sets the next communication point and thus ensures that all subsystems are synchronized. This method remains effective regardless of the number of events or event sources, making it robust in managing both shared and simultaneous events. However, its main limitation lies in the types of events it can handle. Events must be predictable from the component's interface (its inputs and outputs) which can be challenging for events that occur deep in complex subsystems. Even though LookAhead can be applied to any black-box subsystem, knowledge about the system's events is necessary to implement its event detection. Additionally, the event must be reliably predictable: sudden state events triggered by rapidly evolving conditions can be difficult to anticipate and may indicate the need to reduce the communication step size of the continuous portion of the model.

Future work aims to improve usability by supporting internal event indicators and devising a method to automatically associate signals with events. On a technical level, LookAhead is being expanded to work with other coupling schemes than the standard parallel coupling, such as sequential coupling and parallel or sequential coupling for different communication step sizes. LookAhead is be-

Abstract

Uncertainty Quantification (UQ) studies allow us to determine whether a model is fit for a particular purpose, as well as the operational domain in which it can be used. Standardising the UQ analysis setup and result summary enables the iterative composition of UQ information, which is a crucial step in evaluating model credibility. In this paper, we present an initial attempt to specify UQ information as a cross-layer standard for Modelica-, FMI-, and SSP-based workflows subject to two essential restrictions: (a) uncertainties can only be described in terms of parameters, and (b) analysis is limited to forward uncertainty propagation and sensitivity analysis of nonlinear models. More analysis features are planned for the future. The approach is illustrated using both a simple example and an industrial use case.

Keywords: Uncertainty Quantification, Credibility, Standardization, Operational Domain, FMI, SSP, Modelica

1 Introduction

Simulation models provide an approximation of reality with different degrees of accuracy, which has a direct impact on the context in which these models are usable. Through use case analysis in the ITEA OpenSCALING research project[1], we have identified the following workflows that rely on UQ:

- choosing a model with the appropriate level of representativeness and complexity for the specific application context,
- evaluating the model's overall uncertainty based on the propagation of uncertain parameters,
- performing model validation,
- conducting global sensitivity analysis of parameters, and
- improving the accuracy of data measurements.

In this paper, we propose a data model for capturing uncertainty quantification in a unified way across different workflows and thus facilitating the exchange of models, including metadata, between different stakeholders.

Furthermore, we show how this data model can be integrated into Modelica[2], Functional Mock-up Interface (FMI)[3], and System Structure and Parametrization (SSP)[4] based workflows.

The paper is structured as follows; Section 2 provides the motivation for the standard. Section 3 presents a simple forward UQ study while Section 4 introduces an industrial use case. The data model is outlined in Section 5, and Section 6 describes integration mechanisms with Modelica Association (MA) standards. Finally, Section 7 outlines future directions, and Section 8 concludes the paper.

2 Background and Motivation

Machine-interoperable traceability is vital for transparent model validation and reduces reliance on implicit knowledge transfer (Rosenlund et al. 2025; Otter et al. 2022). The *SSP Traceability standard* draft (SSP LS Traceability)[5] incorporates Simulation Resource Meta Data (SRMD) to capture verification activities, intended use, and operational domain, supporting automated model suitability evaluations. Embedding such structured metadata, either via SRMD or directly in models, streamlines validation, supports long-term credibility assessments, and aligns with industry standards like NASA STD-7009 [6]and LOTAR[7]. The recent Credible Simulation Process (CSP) initiative formalizes continuous simulation credibility processes using SSP-based layering (Ahmann et al. 2022; Heinkel and Steinkirchner 2021).

A model's credibility depends on how accurately it represents reality. Ensuring credibility requires rigorous verification, validation, and UQ frameworks, see, e.g., *the NASA Handbook for Models and Simulations* [8] (Roy and

Oberkampf 2011; Riedmaier et al. 2021). UQ systematically evaluates confidence in model predictions. Techniques such as probabilistic analysis and sensitivity studies help quantify and propagate uncertainties, guiding confident interpretation of simulation results (Hällqvist et al. 2023; Otter et al. 2022).

Predictive capability extends validation by assessing model performance across the entire feasible input space, not just tested scenarios. Hallqvist et al. (Hällqvist et al. 2023) propose *entropy-based* (Shannon 1949; Kullback and Leibler 1951) and *coverage-based* (Atamturktur et al. 2015) metrics to quantify a model's numerical representativeness in both interpolation and extrapolation scenarios. These metrics provide a quantitative foundation for evaluating whether a model remains valid when applied outside its validated input and parameter space.

3 Simple Use-Case: DC Motor

This section presents a forward UQ study propagating uncertainties in a simple DC motor model. This kind of study can be used to answer engineering questions, such as whether at least 95% of the produced DC motors meet the requirement of reaching the declared idle speed. In other words, the aim is to assess the impact of production and material tolerances on the DC motor's steady-state idle speed.

It is assumed that a standardized procedure and supporting tooling are in place to enable this type of analysis independently of the chosen modeling tool. The task of developing a functional behavioral model of the DC motor is assigned to a simulation engineer, who is free to select the most appropriate modeling environment. The resulting model is delivered in executable form, accompanied by a specification of the experiment setup. This setup defines the static boundary conditions, parameter values, estimated distributions for uncertain parameters, and the quantities of interest to be analyzed. In addition, all metadata required to perform the analysis in the target environment in a repeatable and automated manner must be provided in a machine-readable format.

An investigation of the physical behavior of the DC motor found that the relevant dynamics can be captured by the balance equations for electrical voltage and mechanical torque, resulting in the two differential Equations (1) and (2) implemented in Modelica.

$$V = R \cdot I + L\frac{dI}{dt} + c_m \cdot \omega \tag{1}$$

$$J \cdot \frac{d\omega}{dt} = c_g \cdot I - d \cdot \omega + T_{load,mech} \tag{2}$$

In both equations, the following variables are defined:

- V $[V]$: Supply voltage,
- I $[A]$: Winding current,
- R $[\Omega]$: Winding resistance,
- L $[H]$: Winding inductance,
- c_m $[V \cdot s/rad]$: Electrical motor constant,
- $T_{load,mech}$ $[Nm]$: Mechanical load,
- ω $[rad/s]$: Motor velocity,
- $J[kg \cdot m^2]$: Rotor inertia,
- c_g $[N \cdot m/A]$: Mechanical motor constant,
- d $[N \cdot m \cdot s/rad]$: Mechanical friction coefficient.

To keep the investigations simple, only two physical parameters are defined as *uncertain parameters* and are described with the following two stochastic distributions:

- R: $\mathcal{N}(\mu = 0.1\ [\Omega], \sigma = 0.01\ [\Omega])$
- L: $\mathcal{U}([0.105,\ 0.115]\ [mH])$

The Probability Density Functions (PDFs) related to R and L are displayed in Figure 1, assuming a Gaussian normal distribution[9] $\mathcal{N}$ and resp. a uniform distribution[10] $\mathcal{U}$.

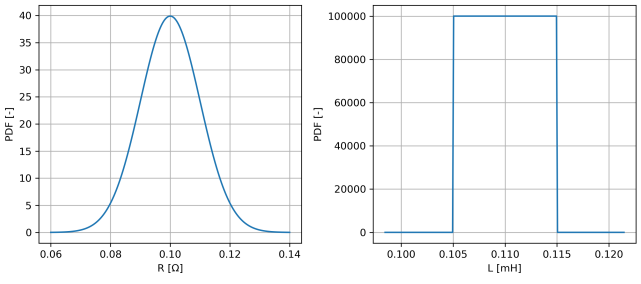

Figure 1. Representation of the uncertain parameters R and L as PDF

The remaining physical parameters are kept constant along with the voltage at the terminals and the mechanical load.

The motor is initially at rest ($I(t=0) = 0\ [A], \omega(t=0) = 0\ [rad/s]$) and accelerates in response to the input voltage V, assuming zero mechanical load torque ($T_{load,mech} = 0$), until it reaches steady-state. The objective is to quantify the uncertainty in the steady-state motor speed, expressed as $\omega_\infty[\mathrm{rad/s}]$ or equivalently $n_{\mathrm{rpm},\infty} = \omega_\infty \cdot \frac{30}{\pi}[\mathrm{rpm}]$, based on the uncertainties in the electrical parameters R and L. To this end, the uncertain parameters are sampled using Latin Hypercube Sampling, and a simulation is carried out for each sample. The resulting data is used to estimate the Probability Density Function (PDF) and Cumulative Distribution Function (CDF) of the steady-state motor speed.

All the information required to configure the forward UQ experiment, such as the problem description, model reference, parameter definitions, observed variables, experiment settings, and desired results, is listed in a corresponding `.xml` file. In this file, a reference to an `.ssv` file might be present, which is the standard way in SSP to store parameters and their values. The UQ XML file can be accessed via scripting during all stages of a forward UQ workflow, including pre-processing, simulation,

[9] https://en.wikipedia.org/wiki/Normal_distribution

[10] https://en.wikipedia.org/wiki/Continuous_uniform_distribution

DOI 10.3384/ecp218671

and post-processing. External references to result files or summaries are included where needed, see Figure 2.

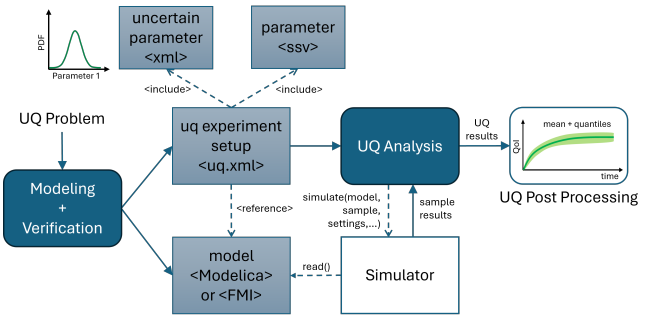

Figure 2. Forward-UQ workflow: Artifacts and processing steps

For the simple DC motor example, the following data is provided in the `.xml-file` defining the forward UQ experiment:

```
<!-- ... -->
 <uq:ParameterSet> <!-- Super set of SSP -->
  <uq:Parameters>
    <uq:UncertainParameter name="R">
      <uq:Normal mu="0.1" sigma="0.01"
        unit="Ohm"/>
    </uq:UncertainParameter>

    <uq:UncertainParameter name="dcMotor.L">
      <uq:Uniform minimum="1.05e-4"
       maximum="1.15e-4" unit="H"/>
    </uq:UncertainParameter>
  </uq:Parameters>

  <uq:Units> <!-- SSP Units -->
    <!-- ... -->
  </uq:Units>
</uq:ParameterSet>

<uq:ObservedVariables>
  <uq:ObservedVariable name ="omega"/>
</uq:ObservedVariables>

<uq:DesiredResults
  data = "dc_motor.mat"
  summary = "dc_motor_result_summary.xml"
  scope = "Trajectory"
  mean = "true"
  pdf = "true"
  cdf = "true">
  <uq:Percentiles level="0.05 0.95"/>
  <uq:SobolIndices order="2" total="true"/>
</uq:DesiredResults>

<uq:SimulationSettings
  stopTime = "0.5"
  interval = "0.01"
  tolerance = "1e-4"
  solver = "DASSL"/>

<uq:SamplingMethod>
  <uq:LatinHypercube numberOfSamples="1000"/>
</uq:SamplingMethod>
```

Note, for every uncertain parameter, a *nominal* value is required that can, for example, be used if only a single simulation run shall be performed. From this data, it is possible to perform the forward UQ experiment computations and to display typical outcomes like:

- The time response of the spreading motor speed $n_{rpm}(t)$, see Figure 3,
- The PDF of the idle motor speed in steady-state, see Figure 4 on the left,
- The CDF of the idle motor speed in steady-state, see Figure 4 on the right,
- The first-order global sensitivity analysis related to the motor speed trajectory over time, see Figure 5.

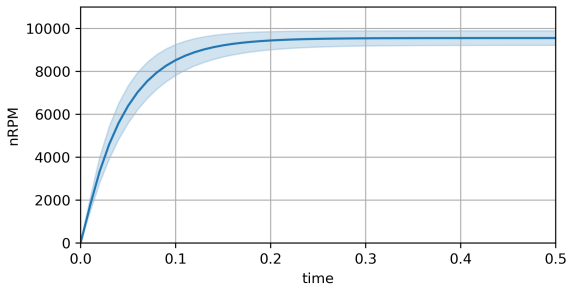

Figure 3. Mean, 5th and 95th percentile of the motor speed time response

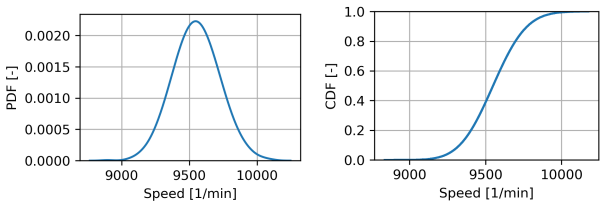

Figure 4. PDF and CDF of the motor speed at steady-state

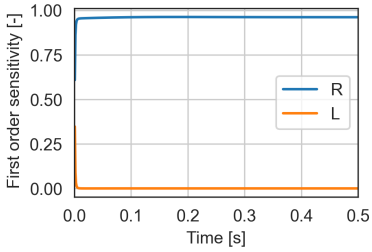

Figure 5. First order sensitivities of the motor speed w.r.t. the uncertain parameters R and L over time until reaching steady-state. The interpretation is that the uncertainty of L is of relevance only during the early start-up phase, while the uncertainty of R dominates the uncertainty of the motor speed at steady-state.

In these investigations,

- The UQ analysis of the DC motor is evaluated for only one operational point (supply voltage $V = 12\ [V]$ and constant mechanical load $T_{load,mech} = 0\ [N \cdot m]$),

- Python[11] has been used to evaluate the forward UQ experiment based on a Modelica model of the DC motor and the experiment definitions from the .xml-file, generating the samples, evaluating the simulations through OMPython[12] and OpenModelica[13], and performing the post-processing to produce the desired results.

This illustrates how the Modelica model, together with the estimated distributions of the uncertain parameter values and the .xml experiment settings based on the draft UQ standard, was used to perform Forward UQ analysis with open-source tools. The complete setup of the open-source tools is available in the draft specification[14]. In the future, the UQ .xml file will most likely be supported by many other tools, such as Modelica-based tools[15] or FMI-based tools[16].

4 Industrial Use Case: Mobile Valve

Parker Hannifin's Hydraulic Valve Systems Division Europe[17] manufactures fluid power valves for a wide range of applications. The factory in Borås, Sweden, specializes in directional valves for mobile working machines. Recently, an increased demand for valve simulation models has been noticed both from customers and internally at Parker. Simulation models are, for instance, useful in control strategy development, energy loss minimization, and functionality verification. To meet these demands, a process for auto-generation of valve models, based on valve specification data, has been developed. During this development, several challenges emerged:

- ensuring simulation tool independence,
- protecting company Intellectual Property (IP),
- shipping model credibility information, such as UQ experiments results, with the models.

The initial solution was to use the FMI standard and ship the models as Functional Mock-up Units (FMUs) providing credibility metadata in the `index.html` file inside the model's FMU directory. However, this limits the reusability of the credibility information in the simulation tool and has a negative impact on traceability, hence the need for a standardized way of shipping model credibility information with simulation models. Within the ITEA OpenSCALING project, Parker has identified a representative use case where a UQ experiment is carried out on a valve model. The UQ results are then packaged along with the model in the standard format proposed in this paper.

4.1 Valve Model

The valve model is based on the orifice equation, where the relationship between volumetric flow q and pressure drop, $\Delta P = P_1 - P_2$, across the orifice is described according to the time-invariant relationship:

$$q = A\sqrt{\frac{(P_1 - P_2)}{K}} \tag{3}$$

where the parameter K lumps the discharge coefficient and fluid density, see e.g. (Merritt 1967; Miller 1990). The orifice area, A, and K may be identified as uncertain parameters. A model of such an orifice can be defined as having two time-dependent inputs, P_1 and P_2, and two time-dependent outputs $q_1 = q_2 = q$ under the assumption of incompressible flow. The Operational Domain (OD) of this model could be viewed as a space containing all the different feasible combinations of the two inputs P_1 and P_2. The two-dimensional area, encompassing all feasible inputs, can be summarized through a set of points that define (for example) a convex hull.

The valve used in the UQ study is one work section of a proportional, load-sensing, pre-compensated mobile directional control valve in the Parker L90LS series. The core functionality of the valve is to generate a flow[18] that is proportional to an input control current, independently of pump and load pressure variations.

4.2 Scenario

A typical valve test scenario is to connect its work ports to a volume in a closed loop, feed it with constant pump pressure, and investigate the flow and counter-pressure characteristics for different input currents. Manufacturing tolerances lead to uncertainties in valve discharge coefficients, so UQ experiments must be performed to investigate the effect of these uncertainties on flow and counterpressure.

4.3 Experiment Setup

Figure 6 shows the schematics of the model used to carry out the UQ experiment. The UQ model contains the valve model, a hydraulic volume, and other valve model boundaries (e.g., constant pump supply). The valve contains Meter-In (MI) and Meter-Out (MO) orifices that are modelled according to Equation (3). The MI and MO areas (A_{MI}, A_{MO}) are determined by the main spool geometry and controlled by the main spool position via current-controlled pilot valves. In the UQ experiment described here, direction PABT is considered, which means that the main spool position is controlled by input current u_A. Pump (p_p) and load (p_A) pressure-independent flow is realized with a pressure compensator which controls the pressure drop over the MI orifice. Briefly explained, the MI orifice determines the flow (q_A), while the steady-state counterpressure (p_A) is determined by the resistance of the MO orifice for a given flow (q_A).

[18] For example, to a cylinder that controls the boom function of a forestry crane.

DOI 10.3384/ecp218671

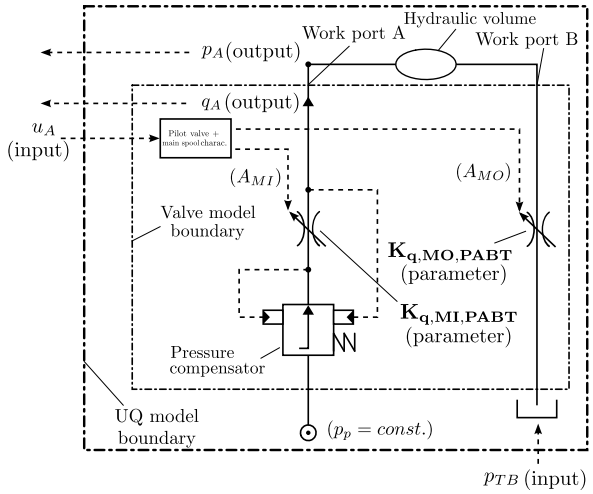

Figure 6. Schematics of the model used for UQ in the Mobile Valve use case. Variables within parentheses represent internal states.

Table 1. UQ model variables.

Variable	Causality	Description
u_A [mA]	input	Valve input A current
p_{TB} [bar]	input	Valve port TB pressure
q_A [l/min]	output	Valve work port A flow
p_A [bar]	output	Volume port A pressure
$K_{q,MI,PABT,gain}$	parameter	MI orifice discharge coefficient (rel.)
$K_{q,MO,PABT,gain}$	parameter	MO orifice discharge coefficient (rel.)

The model is packaged as an SSP-file, where the valve model FMU is connected to another FMU, exported from Hopsan [19], which contains the volume and other valve boundaries. The UQ model has the variables listed in Table 1.

According to the specification, the current $u_A \in [0, 900]$ mA, while the tank pressure $p_{TB} \in [0, 20]$ bar. The model's OD may thus be represented as a rectangle with corner points as listed in Table 2 and illustrated in Figure 7. Note that Figure 7 also shows the UQ model's Domain of Uncertainty Quantification (DoUQ), which is described in the next section.

Table 2. Valve UQ model operational domain coordinates.

Point nr.	u_A [mA]	p_{TB} [bar]
1	0	0
2	0	20
3	900	20
4	900	0

4.4 UQ Definition

For this example, UQ experiments are carried out at points whose coordinates are listed in Table 3, representing locations within the model's OD.

[19] https://liu.se/en/research/hopsan

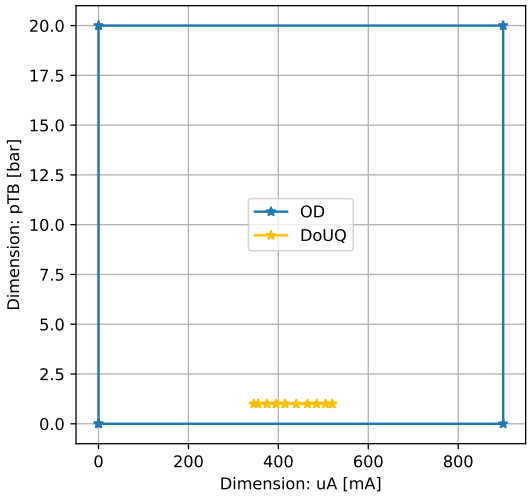

Figure 7. Operational domain (OD) and domain of uncertainty quantification (DoUQ) of the valve UQ model.

Table 3. Valve UQ model domain of uncertainty quantification points.

Point nr.	u_A [mA]	p_{TB} [bar]
1	345	1
2	355	1
3	375	1
4	395	1
5	415	1
6	440	1
7	465	1
8	485	1
9	505	1
10	525	1

Within the UQ experiment, uncertain model parameters are defined explicitly, while the resulting model output uncertainties represent the experiment outcomes. The relative discharge coefficients of the MI and MO orifices are assumed to be uncertain and follow truncated normal distributions, as specified in Table 4.

The experiments conducted here constitute forward UQ, where the uncertainties in the relative discharge coefficients are propagated through to the port A flow and pressure (q_A and p_A). For this example, the relationships between the uncertain parameters and these observed variables can be described by the simplified expressions given in Equation (4).

$$\begin{aligned} q_A &= A_{MI}\sqrt{\frac{\Delta p_{MI}}{K_{q,MI,PABT}}} \\ p_A &= p_{TB} + \left(\frac{A_{MI}}{A_{MO}}\right)^2 \Delta p_{MI}\frac{K_{q,MO,PABT}}{K_{q,MI,PABT}}. \end{aligned} \tag{4}$$

Table 4. Valve UQ model domain of uncertainty quantification coordinates. The uncertainties of the two parameters are estimated and are described with truncated normal distributions with parameters μ, σ. *: The valve model's name in the SSP-file is "valve_model".

Uncertain Parameter	Minimum	Maximum	μ	σ
valve_model.KqMI_PABT_gain*	0.8	1.2	1	0.1

4.5 UQ study in FMI

A MonteCarlo-sampling with 1000 samples was done to generate samples of the two observed variables q_A, p_A, using the UQPy python package (Olivier et al. 2020). Figure 8 shows histograms of the sample sets.

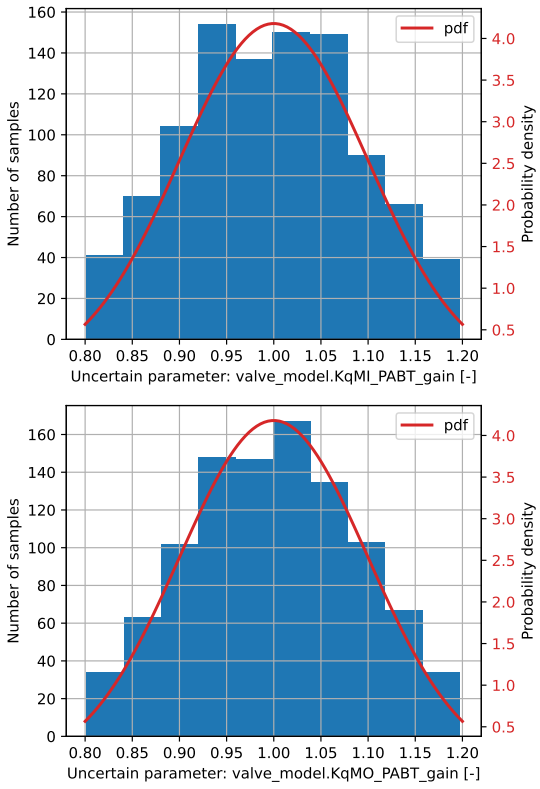

Figure 8. Histogram of 1000 samples of each of the uncertain parameters.

The UQ model was simulated with the Python API of OMSimulator. The simulation was executed for all samples at each coordinate of the DoUQ. Each simulation was run until a steady-state was reached on all model outputs. This resulted in one sample set for each output at each operating point, with 1000 samples in each set. These sample sets were then fitted to truncated normal distributions with minimum, maximum, mean (μ), and standard deviation (σ). Figure 9 shows an example of the distribution of the two observed variables at one operating point. Table 5 and 6 show the resulting fits at all experiment points for the observed variables q_a and p_A, respectively.

Figure 10 shows violin plots of the data in Tables 5 and 6. Based on these results some observations can be made:

- Uncertainty in flow q_A due to uncertainty in discharge coefficient is higher at higher current (u_A) levels, as the MI orifice area (A_{MI}) is higher at higher currents. This, in turn, results in a greater amplification $K_{q,MI,PABT} \rightarrow q_A$ (see Equation (3)). A similar reasoning may be applied to explain the larger uncertainty in p_A at higher current levels,
- Uncertainty in orifice discharge coefficients has a higher impact on the uncertainty of p_A than that of q_A. This may be illustrated by the simplified analytical expressions of q_A and p_A in equation (4); q_A primarily depends on $K_{q,MI,PABT}$, while p_A depends on both discharge coefficients.

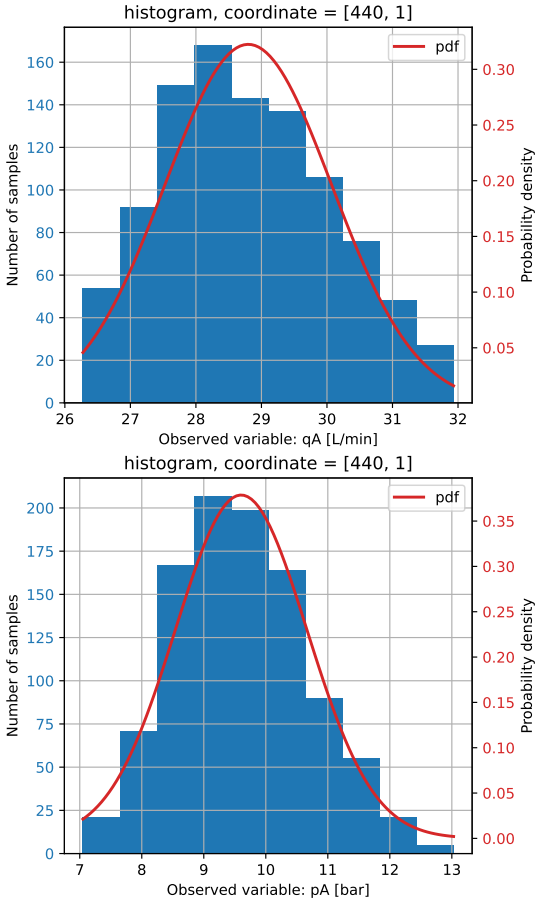

Figure 9. Histogram of 1000 samples from one Monte Carlo simulation run for each of the observed variables at operating point $u_A = 400$ mA, $p_{TB} = 1$ bar.

The .xml definition of the Forward UQ Experiment and the results are shown in Listing 1 and Tables 5-6, respectively.

Table 5. Statistical data of the observed variable q_A [L/min] for all UQ experiments fitted to truncated normal distributions.

		q_A [L/min]

4.6 UQ study in Dymola

The proposal is that a Modelica tool will have the option to import the .xml-file and provide the user the choice to both modify, run, and verify the forward uncertainty quantification from the provided information. The tool should also be able to export any new UQ results and setups.

For this example, the mobile valve model is packaged as an SSP and imported into Dymola. This study will concern only one point, with coordinates $(u_A, p_{TB}) = (415\ \text{mA}, 1\ \text{bar})$.

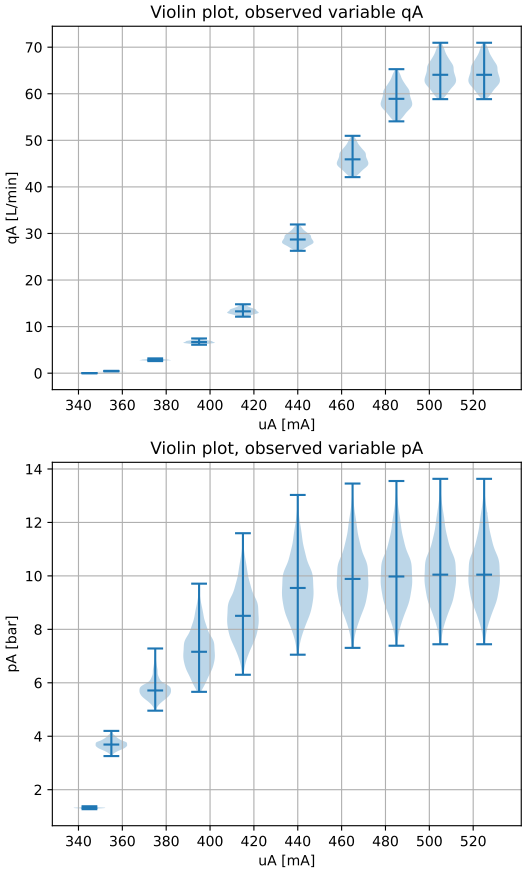

Figure 10. Violin plots of the data in Tables 5 and 6.

4.7 Verification of UQ

Using the data provided from the .xml-file, an UQ analysis with 1000 Monte Carlo samples can be performed to validate the result of previous UQ experiments. The results show that statistics such as mean value and standard deviation agree with those presented in Table 5.

In the previous step, the uncertain parameters $K_{q,MI,PABT}$ and $K_{q,MO,PABT}$ were propagated to the observed variables p_A and q_A. In addition, it can be useful to quantify exactly how much specific parameters contribute to the output variance of p_A and q_A. This helps to isolate the most important variables in a complex model with multiple parameters. The idea is to append the .xml file with additional attributes for the sensitivity analysis, such as the sampling method and the choice of sensitivity indices.

In this case, the experiment performs *global* variance-based sensitivity analysis using Sobol indices. The experiment is conducted on both p_A and q_A at the point $(u_A, p_{TB}) = (415\ \text{mA}, 1\ \text{bar})$. Three separate Monte Carlo runs with 10000 samples each are performed to evaluate q_A and p_A, where the uncertain parameters are sampled using the Latin Hypercube method. These 10000 samples are then bootstrapped 1000 times to provide confidence intervals for the first and total order Sobol indices.

The results are presented in Table 7. For the observed variable q_A, the first and total order indices are approximately equal, indicating that there are no interactions.

The Sobol indices for the parameters on the outcome p_A show that most of the variability comes from the parameters varying on their own, but there is no statistical significance in higher order interactions.

5 Data Model

The data model for UQ is designed to be tool-agnostic and compatible with multiple standards, including Modelica, FMI, and SSP. This ensures seamless integration across diverse simulation environments while maintaining flexibility to support both simple and complex UQ workflows. To achieve this, the model employs a modular structure where many elements are optional, allowing users to specify UQ data either inline within the model or in separate files as needed. The data model reuses existing SSP elements, such as `Units` and `ParameterSet`.

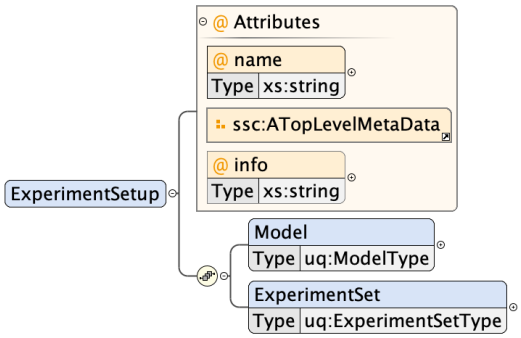

Figure 11. The structure of the `<ExperimentSetup>` element. The **`Model`** contains optional details about the simulation model, such as `name`, `file`, `model`, and `modelResourceMetaData`, the latter enabling linkage to an SRMD file for SSP traceability integration. **`ExperimentSet`** defines the experiments to be conducted on the model

The top element of the UQ model is `ExperimentSetup`, see Figure 11.
The setup can contain different types of experiments, such as `ForwardUncertaintyQuantification` (see Figure 12):

- **`ParameterSet`**: Extends the SSP `ssv:ParameterSet` by enabling the description of stochastic distributions for uncertain parameters alongside deterministic values. A reference to a standard SSP parameter file (SVV) can be used to include a standard (non-UQ) set of parameter values.
- **`ObservedVariables`**: Specifies the model variables for which results shall be computed and stored. Optionally, the attribute `distributionApproximation` may be used to indicate that the result at a given time point should be approximated by the defined distribution.
- **`DesiredResults`**: Defines which results are to be computed for all observed variables and where the resulting data shall be stored. The `data` attribute typically points to a tool-specific result file (e.g.,

DOI 10.3384/ecp218671

Table 7. The mean values and 95% confidence intervals for the Sobol Indices of the valve model, at coordinates $(u_A, p_{TB}) = (415\text{ mA}, 1\text{ bar})$, estimated using a Monte Carlo method with 10000 Latin hypercube samples bootstrapped 1000 times.

Observed variable	Uncertain parameter	First Order	Confidence	Total Order	Confidence
pA	KqMI	48.79%	+/-0.56%	50.40%	+/- 0.41%
	KqMO	49.5%	+/-0.57%	50.37%	+/-1.32%
qA	KqMI	100.00%	+/- 0%	99.44%	+/- 2.01%
	KqMO	0.01%	+/-2.01%	-0.10%	+/-4.06%

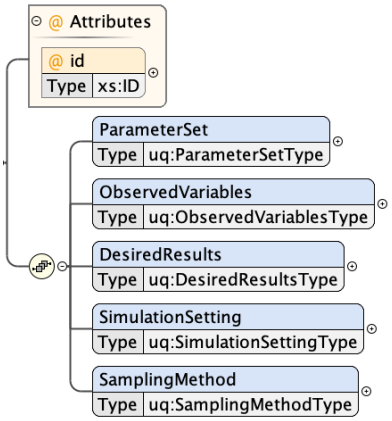

Figure 12. Structure of the `ForwardUncertainty Quantification` element

`dc_motor.mat`) and can also refer to a directory if results are stored in multiple files. The optional `summary` attribute is used to reference a separate file that contains aggregated or post-processed statistical information.

- **`SimulationSetting`**: Specifies the most important parameters for one simulation run. Optionally, tool-specific settings can be added.
- **`SamplingMethod`**: Describes the sampling method to be used in the Monte Carlo simulation, along with all required parameters for generating samples. Tool specific parameterization can included if needed.

6 Integration with MA Standards

Uncertainty data can come from multiple sources, and it needs to be easy to export and import between tools in a unified way. For instance, a component manufacturer might evaluate the accuracy of the model for a single component in Modelica and would wish to deliver this information together with the model as an FMU. This information could then be used as input to a larger UQ study for the entire system. The suggested approach is a Cross Layered Standard that uses the same definition of UQ concepts across Modelica, FMI, and SSP models.

6.1 Integration with FMI and SSP

FMI and SSP have general extension mechanisms. Every extension must keep an FMU or SSP component still compliant, so tools can ignore elements of an extension that they do not know or support.

The extension mechanism in FMI is called *layered standard* and is described in section 2.6 of FMI 3.0[20]. It is used for the UQ standard by storing the UQ XML file in a new folder inside the FMU extra-folder and by adding the required `fmi-ls-manifest.xml` in this folder.

From the SSP Traceability layered standard perspective (i.e., which information is involved related to the modeling and simulation activity, where does it come from and where shall it be propagated), the current concept would consist of referring to the *uq.xml* file containing the UQ data e.g., from further *.xml*-files that are hosted in the different activities (i.e., Analysis, Requirements, Design, Implementation, Execution, Evaluation, Fulfillment) of the Credible Simulation Process (CSP). Each file would provide information related to a given CSP activity that could be easily read and processed by a dedicated tool (e.g., *easySSP*[21] for the Requirements, *Dymola*[22] for the Execution).

6.2 Mapping to Modelica

The Modelica Language has annotations with modifier syntax that can be used to represent the information extracted from the XML UQ file in a *backwards compatible way*. A benefit of storing the information inside the model is that references to variables are syntactically variable references and not strings, and that the information is naturally moved together with the model. The Modelica Language also supports a hierarchical `Resources` folder inside a Modelica package where the different parts are referenced using Modelica URIs. In this folder, large tables could be stored, e.g., the coordinates of the experiment points in the operational domain, including the values (that can be reused for different experiments).

On the other hand, the UQ analysis supported by a tool is typically tool-specific, and a tool could provide many more features and options as standardized by the draft specification proposed in this paper. A Modelica tool would store its UQ setup in tool-specific annotations. For this reason, currently the conservative approach is used, that which no mapping of the XML-file to Modelica annotations is defined. Instead, (a) the UQ XML file can be imported in a Modelica tool and the tool stores its UQ setup in tool specific annotations, and (b) the tool can export its UQ setup and store it in the proposed UQ XML file format (tool specific settings can be stored in tool-specific

[20] `https://fmi-standard.org/docs/3.0.2/#VersioningLayered`
[21] `https://www.easy-ssp.com/`
[22] `https://www.3ds.com/products/catia/dymola`

annotations of the XML file).

7 Outlook

The data model describes a container, which can be applied on any system level, in an iterative composition-based process. This paper showcases applications in forward uncertainty propagation and sensitivity analysis of nonlinear models. The next step is to extend the specification with model validation against in-situ measurements as presented in (Hällqvist et al. 2023).

The standard presented in this paper is driven by the analysis of existing use cases and supports common concepts used in the UQ domain. In the future, if the need for additional elements is identified, the definitions can be expanded. For instance, while the current schema includes Latin Hypercube and pseudo-random sampling, and supports basic statistical outputs (e.g., mean, percentiles), future versions may incorporate additional sampling strategies, surrogate modeling techniques, sensitivity measures, and probabilistic inference methods.

The aim is to support simple as well as advanced workflows. The presented use-cases have the modeler's role at the center of the workflow and all the information is centralised in a single file; in the future, the UQ data should be traceable via the SSP Traceability Layered Standard. This will enable quality tracking and more efficient information reuse.

Another aspect to be considered is the scalability of the approach and enabling the definition of large data quantities through references to external resources, as well as being able to associate different parameterisations to the same experiment and maximize data reuse.

8 Conclusions

Storing UQ, sensitivity analysis and validation, and verification experiments in a standardized manner is an important step toward ensuring credibility and qualifying whether a model is fit for a particular purpose.

These kinds of computations require evaluations of multiple uncertain variables, which in larger models can be a very computationally complex task. An iterative approach, where the results of a previous study for a single component can be exported and composed with the results of experiments for other components, allows for managing this complexity.

A cross-layered standard is an enabler for interoperability, where studies can be performed in different simulation tools and packaged in FMI or SSP format.

The next steps are the validation of this approach on larger use-cases with composition of UQ information from several sources and the implementation of tool support for import, export, update, and analysis of UQ data in Modelica, FMI and SSP tools.

Abstract

The Functional Mock-up Interface (FMI) is *the* standard for exchanging industrial simulation models in a variety of different applications. Although sensitivity analysis for continuously differentiable systems is directly supported by the standard, for systems with state discontinuities, it is only possible to determine correct sensitivities to a limited extent. In this position paper, we investigate how sensitivity analysis for discontinuous Functional Mock-up Units (FMUs), i.e. including state and time events, works in theory and which additional steps are required to obtain correct results in practice. We further investigate that these steps are unnecessarily computationally intensive from a mathematical point of view, but cannot be implemented in a more efficient way under the current restrictions of the standard. We therefore make a concrete proposal for the new *layered standard sensitivity analysis* (LS-SA) that remedies the current deficits of FMI in the sensitivity analysis of discontinuous systems. In this way, *LS-SA* opens FMI towards a variety of next-level applications — including (scientific) machine learning and optimal control — by providing fully differentiable FMUs under high computational performance.

Keywords: Functional Mock-up Unit, Functional Mock-up Interface, Discontinuous, Events, Machine Learning, Scientific Machine Learning, Neural FMU, Layered Standard

1 Introduction

We start by motivating the actual topic, followed by a brief introduction to the relevant basics to understand the paper.

1.1 Motivation & Goal

The FMI standard was created to allow the exchange of standardized models within and outside of company boundaries. The topic of Sensitivity Analysis (SA) has already played a role in the development of the standard, for example, to be able to perform uncertainty assessments on models. The groundbreaking developments in the field of machine learning in recent years have led to an increasing fusion of classical engineering disciplines such as scientific computing with machine learning, establishing the research field of *Scientific Machine Learning* (Baker et al. 2019; Rackauckas, Ma, et al. 2021). The backbone of (scientific) machine learning is efficient SA. Therefore, in our view, enhancing SA capabilities for FMUs is a crucial step toward advancing the standard for future applications in research and industry. This improvement will facilitate the use of FMI in machine learning, advanced dynamic optimization, and other fields.

Today, many industrial optimization platforms are used to improve energy efficiency, reduce operational costs, and improve sustainability in various sectors, for example, ABB OPTIMAX@ (Franke et al. 2008) and TLK-Thermo (Petr, Tegethoff, and Köhler 2017). Such platforms often operate based on FMUs because of the seamless integration of physics-based models and efficient handling of complex multi-domain systems. Enabling proper SA in FMUs becomes more and more important, because many industrial optimization problems are highly nonlinear, nonconvex and discontinuous.

While FMI already offers possibilities for SA, for example for integration of FMUs into frameworks for Automatic Differentiation (AD) (s. Sec. 3.4), these are only sufficient to perform SA correctly for continuously differentiable systems. However, for discontinuous systems, further measures are necessary for a correct SA, as we will investigate further. This is of crucial relevance for industrial applications, where most models include discontinuities.

In this position paper, we want to show what is currently possible in FMI and what should be made possible to be open to current and future research fields, e.g., neural FMUs (Thummerer, Mikelsons, and Kircher 2021), the combination of FMUs and Arifical Neural Networks (ANNs). We start by investigating two applications of current research that we believe should be made solvable with FMI. We then examine the current interface offered by FMI and collect requirements with respect to unsolved tasks within these applications. Based on these requirements, we make concrete proposals for an extension of

FMI on the basis of a Layered Standard (LS), i.e. without adjustments to the actual standard release. In parallel, we are already working on a prototype implementation, i.e. the suggestions made are already being tested.

In the following, we provide a brief introduction to the foundational concepts necessary to understand the paper.

1.2 Functional Mock-up Interface (FMI)

The Functional Mock-up Interface (FMI) is an open standard that defines an interface to exchange dynamic models in the form of a ZIP container which stores the model as a combination of XML files, binaries, and C code. There are three major releases, the most recent version is 3.0.2 (Modelica Association 2024b), while version 2.0.5 might still be the release with the broadest implementation (Modelica Association 2024a). Motivated by different application scenarios for simulation models, FMI supports three different simulation types, while we focus only on the most relevant for SA, which is Model-Exchange (ME) and is further introduced in the next paragraph. Because ME requires external implementation of the solver and event handling routines, incorporation of SA is more straightforward, for example compared to Co-Simulation (CS). Throughout the paper, for readability reasons, we only use the FMI3 command terminology, and are also focusing specifically on the development of the LS for FMI3. However, the proposed adjustments should also be compatible with FMI2 and we try to highlight the necessary adjustments if not.

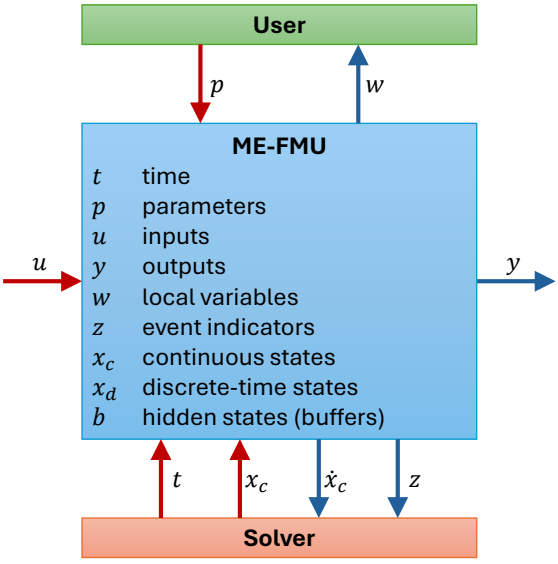

Figure 1. The ME-FMU and its interface signals. Figure adapted from the official standard document (Modelica Association 2024b).

ME-FMUs provide an interface heavily motivated by Ordinary Differential Equations (ODEs) (as further introduced in 1.4) and are therefore paired with ODE solvers to obtain a solution (referred to as *simulation*), see Fig. 1.

The FMI standard facilitates the transfer and exchange of models in simulation tools. However, it has limitations, when the calculation of a model's sensitivity is required.

Layered Standard (LS) The development of the FMI standard is subject to long release cycles to ensure quality and safety of investments, as the standard is widely used in industry. On the other hand, to allow innovation, in FMI 3.0 the concept of Layered Standard (LS) was put in place to be able to introduce new features in an optional and backward compatible way (Bertsch et al. 2023). A LS can add standardized annotations, standardized extra files, and/or new C-API functions.

1.3 Sensitivity Analysis (SA)

Sensitivity Analysis (SA) in the context of FMUs involves studying the influence on the quantities computed by the model (e.g., outputs and state derivatives) w.r.t. variations in quantities that are input to the model (like parameters, states, and inputs). Among others, SA is especially useful for parameter estimation, uncertainty quantification, and optimization.

For example, in optimal chemical production scheduling problems, a mixed-integer linear programming (MILP) solver may be often trapped in suboptimal solutions due to strict reactor start-up time constraints. One can use SA to prioritize the most influential constraints to prevent suboptimal schedules. Moreover, SA can support uncertainty quantification and risk assessment, as industrial systems operate under various uncertainties. By evaluating the range of possible outcomes w.r.t. input variations, SA enhances confidence in optimization results. A further practical example is in hydrogen plant sizing, where SA can assess the impact of load fluctuations, future demand uncertainties, and thermal constraints on transformer efficiency and longevity. This reduces the risk of over- or under-sizing, ensuring that transformers operate within safe margins while optimizing cost and reliability (Gutermuth, Primas, and Bitta 2023).

Last but not least, efficient computation of SA is essential for many modeling and analysis tasks, including hybrid modeling (combining physical and machine learning models) and scientific machine learning. Supporting SA for FMUs is therefore a key enabler for integrating large-scale industrial simulation models into data-driven workflows, es for example required in *neural FMUs* (Thummerer, Mikelsons, and Kircher 2021).

1.4 Ordinary Differential Equations (ODEs)

ME-FMUs without events can be interpreted straightforward as ODEs. The ODE within this work is denoted with

$$\dot{x} = f(x, p, t), \tag{1}$$

where the function f is referred to as *right-hand side*, x the system state, $\dot{x}$ the system state derivative, p parameters and t the time. Note that external inputs to the system could be implemented by augmenting x or p. In this work,

DOI 10.3384/ecp218681

we use this formalism for a simplified description of ME-FMUs without events.

To solve an ODE, a variety of numerical integration schemes exist, that are often incorporated into an abstract definition for arbitrary ODE solvers:

$$x(t) = ODESolve(f, x_0, p, t_0, t), \tag{2}$$

where x_0 and t_0 are the initial state and time to solve the ODE, (Hairer, Nørsett, and Wanner 1992). To obtain a time-discretized solution for f, *ODESolve* can be called recurrently, leading to a *simulation loop* as in Alg. 1.

Algorithm 1 *ODESim*: Simple simulation loop without events.

Input: right-hand side f
Input: time points t_i for $i \in \{0,...,N\}$
Input: initial state x_0, parameters p
$n = 0$ ▷ initialize step counter
while $t_n < t_N$ **do** ▷ final time not reached
  $x_{n+1} = ODESolve(f, x_n, p, t_n, t_{n+1})$
  $n = n + 1$
end while
Output: states $X = \{x_0, ..., x_N\}$

In addition, this concept can be extended to ODEs including *events*. Events are points in time where the system is allowed to change discontinuously. The time point of an event can be known in advance or depend on the system state by defining an event indicator (Modelica Association 2024b). However, this requires a different interface for *ODESolve*, because the termination time for the solver is now not known beforehand (Hairer, Nørsett, and Wanner 1992) and (Chen, Amos, and Nickel 2020):

$$t^*, x(t^*) = ODESolveEvent(f, c, x_0, p, t_0, t). \tag{3}$$

Here, t^* is the event time and the event function c is defined as zero at any event time:

$$c(x(t^*), p, t^*) = 0. \tag{4}$$

This is a simplified view, and in practice a common approach is to monitor changes in signs of a vector containing multiple event indicators, instead of an event function stopping exactly at zero. An event often corresponds to a discontinuous change in the function f. In essence, processing events (so-called *event handling*) captures the following steps: The event time point is determined (by investigation of the event function zero crossing), the solver is stopped, the discontinuous state change is performed (here, by calling the event affect function a) and a fresh integration is started from the new state after the event. The event affect function a computes a new state for after the event $x(t^+)$ based on the quantities at time t^- before the event, and is defined as:

$$x(t^+) = a(x(t^-), p, t^-) = 0. \tag{5}$$

In the actual implementation, it is distinguished between events that solely depend on time (*time events*) or also on states (*state events*). A more detailed introduction on the topic of event handling is not relevant for this work and is omitted for brevity.

Algorithm 2 *ODESimEvent* : Simple simulation loop with events.

Input: right-hand side f
Input: condition c, affect a
Input: time points t_i for $i \in \{0,...,N\}$
Input: initial state x_0, parameters p
$n = 0$ ▷ initialize step counter
$\tilde{t} = t_0$ ▷ init. current time
$\tilde{x} = x_0$ ▷ init. current state
while $t_n < t_N$ **do** ▷ final time not reached
  $\tilde{t}, \tilde{x} = ODESolveEvent(f, c, \tilde{x}, p, \tilde{t}, t_{n+1})$
  while $\tilde{t} \neq t_{n+1}$ **do** ▷ next sol. time point not reached
    $\tilde{x} = a(\tilde{x}, p, \tilde{t})$ ▷ handle event
    $\tilde{t}, \tilde{x} = ODESolveEvent(f, c, \tilde{x}, p, \tilde{t}, t_{n+1})$
  end while
  $x_{n+1} = \tilde{x}$
  $n = n + 1$
end while
Output: states $X = \{x_0, ..., x_N\}$

Further, in the FMI specification, the concept of *superdense* time is applied, allowing events to be ordered even if they are triggered for the same t. For reasons of clarity, this was simplified within this work. In general, the FMI specification (Modelica Association 2024a; Modelica Association 2024b) provides a valuable source for this topic in detail.

2 Related Work

We now turn to related work on SA for FMUs, with a particular focus on discontinuous systems.

FMISensitivity.jl The Julia library *FMISensitivity.jl*[1] implements fully differentiable FMUs using built-in FMI functions as far as available, while sensitivities not considered in FMI are approximated by finite differences. Further, SA relevant to practice, in terms of reasonable computing effort, requires additional but optional FMI features, like `fmi3Get/SetFMUState` for getting and setting the FMU memory state. The implemented workarounds are investigated in more detail in Sec. 3. Before porting the functionality to *FMISensitivity.jl* in 2023, these features were implemented as part of *FMIFlux.jl*.

Time-freezing This approach reformulates non-smooth systems with state jumps into systems that appear smooth from the perspective of a numerical solver (Nurkanović, Sartor, et al. 2021). It introduces a pseudo-time variable and clock state to enforce the discontinuities to lay

[1] `https://github.com/ThummeTo/FMISensitivity.jl`.

in the derivative rater than in the state itself. During the frozen phases, an auxiliary dynamic system evolves the state smoothly in pseudo-time to mimic the effect of the jump. As a result, the original non-smooth problem is more suitable to conventional ODE solvers without adding integer variables. However, constructing such an auxiliary differential equation is not trivial, and introducing pseudo-time variables may increase the computational effort.

Finite Elements with Switch Detection (FESD) This discretization scheme embeds switch detection directly into the time discretization process (Nurkanović, Sperl, et al. 2024). Essentially, it detects state jumps using complementarity constraints and the collocation method. Hence, FESD is able to pose the time points exactly where events happen without relying on the event handling process. The main challenges remain the implementation overhead of a robust switch detection mechanism within a finite element framework and the computational complexity due to the increase of optimization variables and constraints. An implementation of this, as well as the time-freezing approach, can be found as part of the NOSNOC software package (Nurkanović and Diehl 2022).

CasADi In (J. Andersson and Goppert 2024), the integration of SA for discontinuous systems within the *CasADi* tool (J. A. Andersson et al. 2019) is investigated. The paper also gives a rough outlook on how to make discontinuous SA available for FMUs under similar considerations to those we make in the course of this work. However, the authors omitted existing work regarding SA for FMUs: Integrate-then-differentiate, as well as differentiate-then-integrate approach, is available since 2021[2] as part of *FMIFlux.jl* and since 2023 as part of *FMISensitivity.jl*, both providing seamless integration with *SciMLSensitivity.jl* (Rackauckas, Ma, et al. 2021) and *DiffEqCallbacks.jl* (Rackauckas and Nie 2017) that provide implementations for a multitude of SA approaches.

Finite Differences The most obvious approach to SA would be to perform numerical differentiation of the output of *ODESolve*. There are two main disadvantages: a high amount of numerical noise which can be avoided by freezing the step-sizes and number of iterations or alternatively by internally differentiating (Hairer, Nørsett, and Wanner 1992), and that the cost increases linearly with the number of parameters — using adjoint equations avoids this second issue. On the other hand, there is the great advantage that even systems with discontinuities can be analyzed, which is why this method can be found in practical application despite its poor computational performance.

However, all the investigated solutions are suboptimal from a mathematical perspective and are either not generally applicable or scale insufficiently with the size of the problem due to limitations in FMI. This strongly motivates the derivation of an addition to the standard (Layered Standard), that is able to provide access to computational efficient SA, while still being fully backward compatible with FMI.

[2]Experimental 2021, stable release in 2022 (Thummerer, Stoljar, and Mikelsons 2022).

3 Requirements Analysis

In this section, we want to derive requirements for the LS. The essential part of the requirements is the availability of the various Jacobians that are needed for a correct SA. However, it is important to remember that in many cases we are actually interested in *results* of operations *including* the Jacobian, rather than the Jacobian itself. This especially captures Jacobian-Vector Products (JVPs) and Vector-Jacobian Products (VJPs). Note that JVPs are not only useful for SA, but also for solving large ODEs (Ascher and Petzold 1998) with implicit solvers using iterative approaches (e.g., Krylov subspace methods).

We start collecting requirements by investigating two use cases that should enabled with the new LS. Both applications share the question posed by SA, but look at the actual problem from two different perspectives: while a *parameter optimization* task (s. Sec. 3.1) is defined by the problem of identifying sensitivities for variables *within* the FMU, the *neural FMU* approach (s. Sec. 3.2) requires determination of sensitivities for variables *outside* the actual FMU. As a result, different sensitivities are required to solve both tasks.

3.1 Parameter Optimization

One of the most common applications of SA in the field is the optimization of ODE parameters within a model, often referred to as *model calibration*. When optimizing ODEs, an objective l is defined that is either minimized (e.g., *loss* in supervised machine learning) or maximized (e.g., *reward* in reinforcement learning). Typically, this loss is not defined on the right-hand side of the ODE itself, but on the *solution* of the ODE.

The gradient of a loss function defined on the ODE solution X, can be derived by applying the chain rule:

$$\frac{dl(X(p),p)}{dp} = \frac{\partial l(X(p),p)}{\partial X(p)} \frac{\partial X(p)}{\partial p} + \frac{\partial l(X(p),p)}{\partial p}, \quad (6)$$

where the ODE solution X can stem from *ODESim*, as well as *ODESimEvent*.

SA for *ODESim* As can be investigated in algorithm 1, the consecutive evaluation of *ODESolve* leads to the determination of X. On derivative level, this results in a chain of Jacobians containing

$$\frac{\partial x_{n+1}}{\partial x_n} = \frac{\partial ODESolve(f, x_n, p, t_n, t_{n+1})}{\partial x_n}, \quad (7)$$

growing with every step of *ODESolve* that needs to be performed to determine the required Jacobian $\partial X / \partial p$. Most

DOI 10.3384/ecp218681

ODE solvers, for example explicit and implicit Runge-Kutta methods, determine x_{n+1} by one or more evaluations of f. This results in differentiation of f with respect to state and parameters, so $\partial f/\partial x_n$ and $\partial f/\partial p$. These Jacobians can also be found by investigating the sensitivities required for the continuous adjoint method (Céa 1986; Serban and Hindmarsh 2003; Sapienza et al. 2024). If the right-hand side depends on time, further the time gradient $\partial f/\partial t$ is required. Of course, to obtain a complete derivative chain, also the arithmetic operations inside the ODE solver need to be differentiated. However, the detailed chain of Jacobians depends on the type and implementation of the numerical solver and is therefore omitted.

SA for *ODESimEvent* Very similar to *ODESim*, sensitivities for *ODESimEvent* can be collected by investigation of algorithm 2. However, there are differences: First, *ODESimEvent* also determines the event time t^* besides the system state, therefore differentiation over *ODESolveEvent* results in determination of the Jacobian $\partial x^*/\partial x_n$ and the additional time gradient $\partial t^*/\partial x_n$. Second, the event time t^* depends on the zero crossing of the event condition c, which involves differentiation of the event condition with respect to its arguments, so $\partial c/\partial x_n$ and $\partial c/\partial t$. These sensitivities can also be found by investigating the continuous adjoint method for event-ODEs (Chen, Amos, and Nickel 2020; Pfeiffer 2008). Finally, also the derivative of the new state after the event is needed by differentiation of the *affect* function a, in particular the Jacobian of the state after the event w.r.t. to the state before the event $\partial x^+/\partial x^-$.

SA for calculated Parameters In practice there are often also calculated parameters $b = g(p)$ that are computed at the start of the simulation. These calculations may be trivial (e.g., calculating the mass based on the density and volume parameters), or complicated, as, for example, calculating polynomial coefficients based on curve fitting. The set of parameters can be extended to calculated parameters to accumulate sensitivities with respect to b and then only compute the VJPs for $\partial g/\partial p$ once. Differentiating these functions should be straightforward even if they are not needed for analytic Jacobians. Parameter subexpressions can be treated together with calculated parameters, as we are not interested in individual calculated parameters but only in their overall impact.

3.2 Neural FMUs

In (Thummerer, Mikelsons, and Kircher 2021), neural FMUs where introduced as the combination of FMUs, ANNs and a numerical ODE solver. In the easiest case, only a single FMU and a single ANN are connected. Even if a common scenario is the modification of the FMU state derivative by the ANN, a variety of different combination schemes are possible. Whereas neural FMUs are in general not restricted to ME-FMUs, we only focus on ME within this work, because we see this as more relevant for the topic of proper SA, and it is definitely more relevant within the topic of neural FMUs. However, we give a short outlook on CS in the conclusion section.

As introduced, within neural FMUs, no restrictions are made with respect to the connections between the FMU and ANN(s). To make this more tangible, in Fig. 2 all possible positions to extend a ME-FMU by ANNs are given. In addition to the theoretical possibility of doing this, there is of course also the question of practical relevance, which we shall examine below by a brief investigation of fields of applications:

- One of the first applications of hybrid modeling (in terms of combining physical and machine learning models) was the **correction of parameters** by an ANN (Psichogios and Ungar 1992). This is still a meaningful measure within similar applications.
- The most valuable point of intervention is the **correction of state derivatives**. Note that this allows, for example, to incorporate additional forces (like friction) to a system because forces act on the state derivative (acceleration). Manipulation of the state derivative allows us to change the entire behavior of the system because it allows us to overwrite or extend the actual right-hand side of the ME-FMU.
- Time can be manipulated to induce, e.g., **time shifts** to compensate for unsynchronized measurements. In the parallel contribution (Thummerer, Jarmolowitz, et al. 2025), this is investigated.
- By changing the **system input**, corrections can be made to faulty signals. This further opens up the topic of learning an input trajectory to achieve *optimal control*.
- If only the **system outputs** (or local variables) are changed, the correction is learned on top of the simulation performed, without actually influencing the ODE solution, leading in general to less generalization within the ANN. However, this can still be useful in applications where generalizability is less important.
- Manipulation of event indicators allows, for example, for **augmentation of the event indicators** to learn for not modeled event conditions and therefore new discontinuities.
- **Correcting the system state** before passing it to the FMU allows for correcting modeling errors like general shifts in state-space (Thummerer, Mikelsons, and Kircher 2021) or equilibrium position for fluid simulations such as in (Thummerer, Tintenherr, and Mikelsons 2021).

Based on the finding that such architectures have practical relevance, the question arises as to which sensitivities are required for optimization including such architectures.

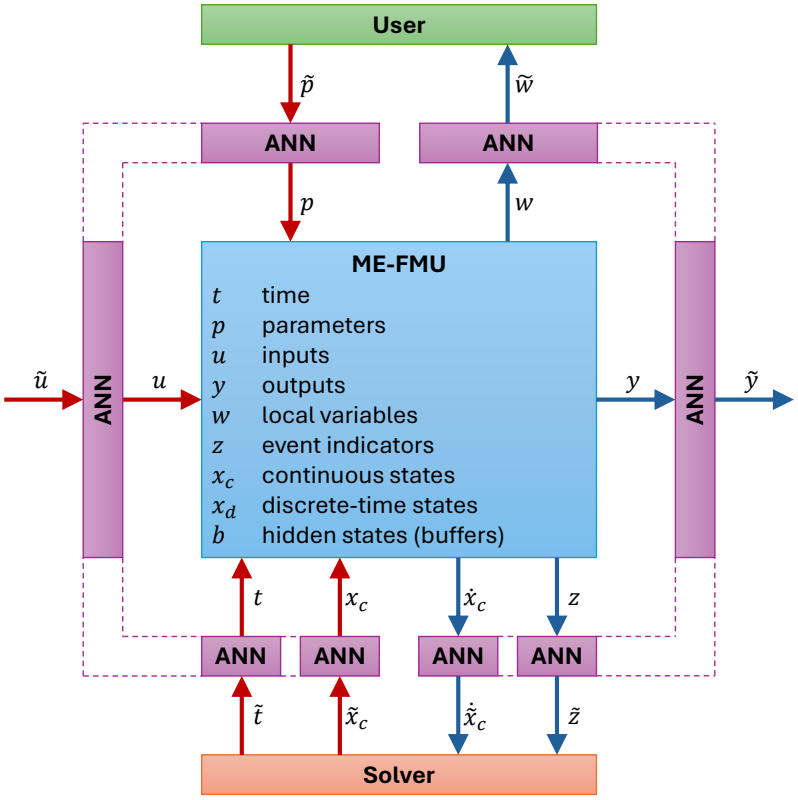

Figure 2. The neural FMU (ME), showing possible intervention points where ANNs can be incorporated to extend the ME-FMU. Individual ANNs could be used for each signal, or all causal input ANNs (p, u, t and x_c) could be merged to obtain a single input ANN (purple, dashed silhouettes). The same applies for the causal output ANNs (w, y, $\dot{x}_c$ and z). The discrete-time state x_d and the buffer b are not accessible from outside the FMU within the standard definition, granted access to x_d is part of the LS-SA, however.

Since all possible permutations of existing ANNs are to be investigated, it is expedient to assume the most complex case: All ANNs are incorporated.

3.3 Required Sensitivities

Based on the two fields of applications introduced and the corresponding observations, all necessary sensitivities are collected below. It is required to allow for JVP and VJP operations involving the Jacobians[3] $\partial\gamma/\partial\upsilon$, where $\upsilon \in \{t, x_c, u, p\}$ and $\gamma \in \{\dot{x}_c, z, y, w\}$. Furthermore, the actual event affect function that computes the new state of the system after event x_c^+ based on the system state before the event x_c^- is required but neglected in the picture to be compatible with the illustration in the standard specification. Furthermore, sensitivities are required not only for the continuous state, but also for the entire state of the system, which additionally requires the discrete state x_d. In summary, the required sensitivities are $\upsilon \in \{t, x_c^-, x_d^-, u, p\}$ and $\gamma \in \{\dot{x}_c, x_c^+, x_d^+, z, y, w\}$.

3.4 Available methods within FMI

In FMI, there are two commands available that allow to access partial derivatives over an FMU. First, `fmi3GetDirectionalDerivative` allows for JVP-multiplication with a custom seed vector, while `fmi3GetAdjointDerivative` provides functionality for VJP-multiplication. Although this does not allow one to directly access the Jacobians, it allows a straightforward integration within AD frameworks. Forward-mode AD involves consecutive evaluations of JVPs, which allows for a natural propagation of the current sensitivity seed through the FMU with `fmi3GetDirectionalDerivative`. The other way round, for reverse-mode AD, consecutive VJPs are computed and `fmi3GetAdjointDerivative` provides an interface for backpropagation of the adjoint sensitivity (or co-tangent) through the FMU. However, there are two issues with these commands: First, the implementation is optional, and, therefore, only a fraction of tools support these commands. Second, and even more important, not all required sensitivities (value references) are accessible by these commands, event if they are implemented. This is investigated in detail, along with solution proposals, in the next section.

[3] For the case of $\gamma = t$ (scalar time) it is more common to refer to a *gradient* than *Jacobian*.

4 Layered Standard

In the following subsections, we investigate all open issues derived from the introduced applications. For each issue, we will highlight the problem and available workarounds.

DOI
10.3384/ecp218681

Workarounds already implemented within *FMISensitivity.jl* and *FMIFlux.jl* are briefly described below. Finally, possible solutions and their technical implementation in the form of a LS are investigated. We explicitly try to reuse the existing command interface as much as possible, as we want to minimize the implementation effort in the tools and enable a wide adaptation of the LS-SA.

4.1 Event condition

The FMI standard allows for the calculation of derivatives of state derivatives $\dot{x}$ and outputs y with respect to states x and inputs u. If the system is subject to events, a complete SA requires the sensitivity of the point in time where an event occurs. As indicated in subsection 3.1, this requires derivatives of the event condition, or as it is named in FMI, the event indicator. Since FMI3, event indicators are part of the model variables (so they are exposed), which was not the case for FMI2. Within the FMI specification, there is no restriction that prohibits providing sensitivities for event indicators via the directional or adjoint derivative commands, however it is also not enforced.

Workaround The only generally applicable workaround to obtain partial derivatives w.r.t. event indicators is to sample them via finite differences. This way it is implemented in *FMISensitivity.jl*. The required number of samples scales linearly with the Jacobian size to multiply with, that is, linearly with the number of rows for forward AD or the number of columns for reverse AD.

Proposed Solution (LS-SA) The proposed solution for the LS-SA is straight-forward: Because the model variables of the event indicators are already known in FMI3, it is only necessary to provide sensitivities for the event indicators via `fmi3GetDirectionalDerivative` and `fmi3GetAdjointDerivative`. For FMI2, it is additionally required to expose the event indicators in the same way as they are exposed in FMI3, by adding the corresponding entries to the section `<ModelStructure>` in the model description.

4.2 Discontinuous State Change

After the event is handled, the numerical integration is restarted with a new state x^+. However, also this new state may depend on the state before the event x^-, time, inputs before the event and/or parameters. These sensitivities are not present within FMI — in general, it is not possible to access sensitivities w.r.t. to quantities *before* an event after event handling was performed.

Workaround One could sample the required sensitivity by restarting the simulation and disturbing the investigated variable right before the event (finite differences). This is computationally infeasible, because this requires a new simulation for every required sensitive state / input / parameter.

In *FMIFlux.jl*, a much more performant approach is implemented, however, this requires the optional FMI features `fmi3Get/SetFMUState`. If these commands are available, a memory snapshot of the FMU can be made right before the event. In this way, sampling becomes much more efficient because the snapshot can be used to reinitialize right before the event to disturb the signals for sampling, instead of starting a new simulation. In this way, the complexity reduces to only performing one evaluation of the system of equations rather than performing an entire simulation.

Proposed Solution (LS-SA) The challenge is that the x^+ and x^-, which are required for the Jacobian $\partial x^+ / \partial x^-$, represent the same state (model variable) at different locations in (super-dense) time. In FMI, there is no mechanism to access partial derivatives w.r.t to the same variable at different points in super-dense time, because the state before and after the event have the same value reference.

However, in the Modelica modeling language, previous values before event handling can be accessed using the function `pre`. We therefore propose to introduce new model variables that can be used to access previous values of states. This captures the continuous, as well as the discrete-time state. Because derivatives of continuous states are introduced with the `derivative` keyword within the definition of the model variable, we propose a new keyword `previous` for previous states before the event. A code snippet for this is given in Listing 1.

Listing 1. Example for a state definition within the model description, including the new *previous* attribute.

```
<Float64
    name="mass.s"
    valueReference="33554432"
    description="absolute position of mass"
    unit="m"
</Float64>
<Float64
    name="der(mass.s)"
    valueReference="587202560"
    description="derivative of mass.s"
    unit="m/s"
    derivative="33554432">
</Float64>
<Float64
    name="pre(mass.s)"
    valueReference="587202561"
    description="previous value for mass.s"
    unit="m"
    previous="33554432">
</Float64>
```

In case of multiple events occurring at the same point in time, the `previous` model variable actually refers to the *previous* value before the last event handled, and not the value before the first event at the time instant. Finally, note that this measure is not necessary for other relevant inputs like u and p, because they do not change in super-dense time, for example $\partial x^+ / \partial p^- = \partial x^+ / \partial p^+$.

4.3 Time Gradients

As investigated, the gradient with respect to time is needed. Since FMI3, time (or the independent variable

in general) is registered as special model variable with `causality="independent"`. However, there is no enforced possibility within FMI to request partial derivatives w.r.t. time.

Workaround As for the event condition, the influence of time, e.g. on the state derivative or outputs, can be sampled straightforwardly during continuous time by disturbing only the time and re-evaluation of the FMU.

Proposed Solution (LS-SA) We would like to enforce that directional and adjoint derivatives are allowed to be requested w.r.t. the independent variable during continuous time.

4.4 Event Time

In addition to event indicators that depend on state and time, events can be registered solely depending on time. The time of these events is known exactly, but only stepwise, the next event time is determined during initialization (the first time event) or during event handling (for the upcoming time events). Such events are not determined by zero crossings of event indicators, hence their influence on the FMU's outputs has to be determined separately.

Workaround To calculate the influence on the current state or parameter on the next event time, a sampling-based approach is used as for the state change in the previous Sec. 4.2: Before actually handling the current time event, a memory snapshot (`fmi3GetFMUState`) is performed, and the influence of the state and parameters can be successively sampled by disturbing one input to SA, handling the time event and quantifying the influence on the determined event time. This requires at least one sample (one event handling procedure) for every state and parameter in the system and is therefore expensive for large simulations.

Proposed Solution (LS-SA) As outlined, the next event time may also depend on the current time. Therefore, it is not sufficient to require the time to be defined as model variable (cf. Sec. 4.3), but necessary to require an additional one for the *next* event time. This enables to calculate the sensitivity of the next event time w.r.t. state and parameters as well as the influence of the current event time on the next event time. Although these sensitivities are required for SA at the next event, they already have to be calculated at the current event and need to be cached.

4.5 Parameter Sensitivities

Even if FMI supports functions to obtain directional derivatives, it is important to state that parameter sensitivities are not available during the actual simulation. Even tunable parameters are only available in event mode (Modelica Association 2024b), which is not useful during continuous-time simulation. This is of course a huge problem and actively prevents parameter SA for FMUs. There are also good reasons to not treat these parameters as tunable, as we are often (e.g., in case of parameter SA) considering the impact for the entire simulation. Furthermore, tunable parameters can complicate the storage of the memory state, and SA requires storing a large number of memory states.

Workaround To our knowledge, there is no obvious workaround to this. However, we observed that some FMU implementations do not implement this limitation and provide correct parameter sensitivities even during continuous-time mode.

Proposed Solution (LS-SA) The proposed solution is straightforward: Within the LS, we enforce that parameter sensitivities (at least for tunable parameters) must be accessible via the already existing interface for directional and adjoint derivatives.

Beyond the listed issues, we would also like to add requirements for the application of neural FMUs in the field. In addition to the mathematical considerations for a comprehensive SA, the optimization or training process can be made more efficient and robust with the following enhancements.

4.6 Get/Set Discrete State

A common technique in the training of neural FMUs, and in machine learning in general, is mini-batching. Training data is divided into chunks called *mini-batches*, and parameter gradients are determined for each chunk rather than the entire dataset. A new batch is selected for each training step, either algorithmically or randomly.

If mini-batching is paired with neural FMUs, or mixed continuous-discrete systems in general, a new challenge pops up: The system needs to be initialized for the initial state of every mini-batch. This covers the continuous state, but also the discrete-time state of the FMU. Note that the discrete state can influence the system dynamics, in the extreme case, the discrete state can be used to switch between completely different sets of equations for the continuous right-hand side. In this case, the discrete state is sometimes referred to as *mode* of the system.

By default, FMI completely hides the discrete-time state of the FMU. It is neither readable nor writable from the outside. However, this is required to initialize the system based on data. However, it is important to state that for proper initialization the continuous and discrete states must *match*. Depending on the system model, not every combination of continuous and discrete states is meaningful and leads to a solvable system.

Workaround For now, FMI does not provide an interface to directly access the discrete state, but an interface to catch it *indirectly*. The corresponding commands are `fmi3Get/SetFMUState`, which create (or activate) a memory copy of the entire FMU memory state, including the continuous and discrete state, but also additional variables, such as starting values for iteration of algebraic loops. It is also important that commands for the memory

DOI
10.3384/ecp218681

states are declared *optional* in the FMI specification and only a fraction of tools implemented these.

Furthermore, while these commands can be used to *revisit* a discrete state after capturing it once, they do not allow one to actually modify the discrete state. For example, if the system needs to be initialized in a very specific discrete state, one needs to *guide* the system to this specific state, e.g. by controlling inputs, in order to capture the intended discrete state. This is an immense effort and is generally not feasible in the case of a complex simulation model. This workaround should therefore only be regarded as a makeshift solution.

Proposed Solution (LS-SA) Even if this step is associated with technical challenges, we see no alternative to allowing reading / writing of the discrete state of the system, as is allowed for the continuous part of the state within FMI. We propose the following additions to FMI:

1. Because the data type of the discrete state may vary, compared to the continuous state which is always `Float64` / `Float32`, we do not suggest introducing new commands such as `fmi3Get/SetDiscreteState`. We propose to reuse the existing commands for reading/writing variables of the FMU, like e.g. `fmi3Get/SetInt32`. This way, no new commands are introduced, which we see as the main obstacle when implementing a LS, and there is no problem with multiple data types used for the discrete state, as it can be set/get by multiple consecutive calls (e.g. mixing boolean and integer values).

2. The value references of the discrete states must be made available from outside the FMU, in order to allow for setting/getting the discrete state. We propose to add this information to the model description, as part of the section `<ModelStructure>`. There, we like to add a new section `<DiscreteState>`, where value references of discrete states are listed in the same way as, e.g. for outputs. Because FMI does not allow us to add new fields to the standardized model description, the addition of fields does not happen within the existing model description. Technically speaking, a separate file is created consisting only of the new fields and a minimum representation of the model description XML tree around.

3. Discrete states are only required to be settable in event mode (where the discrete state changes during regular simulation), and we propose to require triggering event handling consecutively to ensure that the given continuous states match the discrete states.

4.7 Comply with Assertions

The use of assertions when modeling large systems is a meaningful measure in developing correct and easily maintainable simulation models. Typically, assertions are formulated in binary form, i.e. they remain unnoticed until a condition is violated. The existence of an assertion and the monitored condition cannot be seen outside the FMU. This has drastic effects on the application of hybrid modeling with FMUs (e.g. neural FMUs). If, for example, the system dynamics is changed by an ANN, the violation of a condition within an assertion can only be detected when it is already too late and an exception is thrown, which often leads to the termination of the simulation and thus the SA.

To our knowledge, there is **no workaround** to this.

Proposed Solution (LS-SA) We propose to introduce a concept related to the event indicator interface, which we call straightforward *error indicators*. Error indicators provide a distance measure for the violation of modeling errors. Unlike event indicators, the sign is important. Negative error indicators identify the non-existence of a modeling error, whereas positive error indicators show that a modeling error occurred. For the case of at least one positive error indicator, we do not expect the FMU to provide meaningful values, e.g. returning `fmi3StatusError` or `fmi3StatusDiscard` for calls to `fmi3GetX`. To implement error indicators, we propose the following modifications:

1. Error indicators are introduced as model variables in the same way as event indicators, and are made public in the section `<ModelStructure>` in the model description, where we add a new subsection `<ErrorIndicator>`, again in the same way as for `<EventIndicator>`. As for the discrete state in 4.6, this measure is implemented in a parallel model description file and not by modification of the standardized FMI model description.

2. To make the values of error indicators accessible, two obvious strategies are available. First, the error indicators could be accessed through `fmi3GetFloat64` as any other (`Float64`) model variable. For now, we see no reason to not enforce all error indicators to be of type `Float64` (for 64-bit FMUs). Second, because all event indicators share the same data type, a new command could be introduced in analogy to `fmi3GetEventIndicators`, see code 2, that allows capturing all error indicators at once.

3. As proposed for event indicators, we also like to keep error indicators differentiable. Although this is not required for proper SA, this opens up an interesting and valuable new use case: Explicit regularization. If not only the distance to an error is known, but also in which direction parameter changes influence the error (*gradient*), error indicators can be used to actively prevent errors during training, for example by adding the (differentiable) error indicators to the training objective as additional summands (referred to as *regu-*

larization terms). Sensitivities could be accessed in analogy to the event indicators.

Listing 2. The new error indicator function.

```
typedef fmi3Status fmi3GetErrorIndicators(
    fmi3Instance instance,
    fmi3Float64 errorIndicators[],
    size_t nErrorIndicators);
```

Although we consider all the proposed measures within this section important, we have sorted them in descending priority order (with the aim of carrying out a correct SA) in order to support a targeted implementation.

5 Conclusion

In summary, we have investigated the opportunities that already exist for SA in FMI. By investigating two example applications (parameter SA and neural FMUs), we were able to identify deficits, particularly in the analysis of discontinuous systems. We went on to consider how we could close these gaps (mathematically and technically) and made a concrete proposal for the LS-SA, which will be able to solve the issues investigated under reasonable computational performance.

Current & Future Work Even if the LS is not yet fully implemented, a dedicated working group within the research project *OpenSCALING*, including tool vendors, users, and academia, continues to develop and implement the LS to be able to publish it during the project period. As soon as more prototypes of tool implementations are available, we want to examine and quantify the practical computational benefits of the LS besides the theoretical considerations.

One major part of future work is a more detailed investigation and specification of the proposed measures, e.g. it is necessary to specify allowed (or forbidden) attributes for the newly introduced model variables.

Of course, the development of LS-SA is also strongly driven by *specific* applications for which we are aiming, which will benefit greatly from the realization of the standard extension. For example, training of neural FMUs, the combination of ANNs and physics-based simulation models captured in an FMU, will benefit from a significantly faster training process (multiple factors, depending on the number of states and events).

In theory, the proposed LS-SA can be extended for CS-FMUs. However, this introduces additional challenges because parts of SA, which are now part of the simulator, need to be incorporated to the FMU. Further, a clever interface needs to be discussed that allows for efficient determination of sensitivities, for example by defining required sensitivities before starting the actual simulation (e.g. during the setup of experiment).

This publication lays the methodological foundation for further discussions on a large and importing topic within the standard, as well as prototype implementations within importing and exporting tools. It is important for us to point out that the LS is in active development, but not officially released. We would like to draw the community's attention to the development, as well as the intended measures, and we hope to achieve a broad discussion of this topic in the community so that a strong LS with broad adoption can emerge from this. We welcome any kind of participation.

Funding

Abstract

This paper introduces the FMI 3.0 Layered Standard for Network Communication (FMI-LS-BUS), an extension of the Functional Mock-up Interface 3.0 (FMI 3.0) standard designed to address interoperability challenges in simulating distributed, networked systems, particularly in automotive applications. By leveraging FMI 3.0 features such as clocks, clocked variables, and hierarchical terminals, the standard defines two complementary abstraction layers:

Physical Signal Abstraction (High-Cut): Representing physical signal values as clocked variables.

Network Abstraction (Low-Cut): Emulates hardware-level bus protocols (e.g., CAN, Ethernet) using FMI 3.0's clocked binary variables.

Aligning with the V-model development process, we demonstrate how these layers address distinct challenges in different design phases: High-Cut supports requirements engineering and functional testing by simplifying signal exchange during Virtual Electronic Control Unit (vECU) integration. Low-Cut enables later phases of the design validation by replicating network timing and protocol specific properties, such as error handling.

The standard's applicability currently focuses on automotive use cases (e.g., CAN, CAN FD, CAN XL, Ethernet, FlexRay, LIN) but can be extended to industrial automation and IoT, facilitated by its domain-agnostic structure.

Keywords: FMI, layered standard, network communication, bus, V-model, High-Cut, Low-Cut, Physical Signal Abstraction, Network Abstraction, FMU, vECU

1 Motivation

The development of complex cyber-physical systems in the modern automotive industry pushes the boundaries of engineering complexity, demanding new standardized methods, virtual validation, and simulation-based testing practices (Rausch 2022). As vehicles become increasingly software-driven, the need for virtual validation is particularly evident since advanced vehicle functions like Advanced Driver Assistance Systems (ADAS) are extensive and resource-intensive (dSPACE 2025). Real-world testing and hardware-in-the-loop (HiL) systems alone cannot adequately cover all test scenarios. Existing development methodologies, such as the Vehicle Development V-model (Müller-Ettrich 1998), provide a well-established framework for system design and verification. However, these methods must be complemented by adapting processes, methods and tools to the new requirements. Therefore, new approaches are being developed to validate vehicle functions, ECU software components and network communication. Strengthening support for communication protocols and system interactions is essential to ensure performance, reliability, and functional safety in the development of modern vehicles.

Furthermore, the development of these complex, cyber-physical systems and their components is highly distributed, with development of critical functionalities spread across multiple suppliers and engineering teams, introducing significant challenges in requirements specification, system integration and validation (Lawrenz 2013). A single vehicle's electronic architecture may involve numerous Original Equipment Manufacturers (OEMs) and a diverse network of tier suppliers, such as Tier 1 and Tier 2, each with different roles in the development process of ECUs. These ECUs rely on various automotive bus protocols, such as CAN, LIN, FlexRay, and Automotive Ethernet (Rausch 2022), to exchange data and coordinate system behavior. Each supplier may employ different simulation environments, modeling methodologies, and protocol implementations, making it difficult to achieve a unified, end-to-end system simulation. Ensuring seamless interoperability between simulation tools and across different teams and companies has become essential. Engineers encounter substantial challenges in:

- Verifying end-to-end system behavior across diverse

ECUs and networks

- Ensuring consistent communication between heterogeneous components and network technologies
- Validating system performance at different stages of development
- Reducing time-to-market while managing escalating development costs
- Maintaining comprehensive system reliability, safety, and compliance with standards such as ISO 26262 (ISO 2011)

A key enabler for addressing these interoperability challenges is the Functional Mock-up Interface (FMI) (Blochwitz 2011) (Blochwitz 2012) (Junghanns 2021), which is a non-proprietary, free standard for model exchange and co-simulation, allowing simulation artifacts from different sources and different simulation tools to interact seamlessly instead of existing proprietary and incompatible solutions from different software manufacturers. By integrating bus simulations into an FMI-based workflow, engineers can achieve a more modular, reusable, and interoperable simulation environment. Since the FMI 3.0 standard does not cover bus or network communication, the Layered Standard (Bertsch 2023) FMI-LS-BUS extends the capabilities of FMI 3.0 by standardizing network simulations using only features of FMI 3.0. This enables the validation of communication protocols at both the frame level (Low-Cut simulation) and the signal level (High-Cut simulation) while ensuring consistency across different tool chains (dSPACE 2024).

2 Concepts

This section delves into the general concept of the FMI-LS-BUS. First, the existing system compositions are presented. Second, the two specified abstraction layers are explained and differentiated.

The FMI 3.0 standard itself allows interoperability between the tool chains of different software manufacturers and reflects a fundamental need and the necessity of users who have to develop and secure software in a distributed manner. For example, across company boundaries in an OEM and supplier relationship or across departmental boundaries in large companies. Based on this stable foundation, the FMI-LS-BUS (MAP FMI 2025a) specifies an extension of the FMI 3.0 standard that enables the simulation of network communication. This extension supports various bus systems such as CAN, CAN FD, CAN XL, FlexRay, Ethernet and LIN and uses native FMI 3.0 features such as binary variables, clocks and terminals. With two different abstraction layers, the High-Cut and the Low-Cut, it also offers users the necessary flexibility and variety to simulate a network of controllers at their current phase of development.

- Physical Signal Abstraction ("High-Cut"): Use individual, clocked signal variables to transport logical, unit-based values between vECUs, ignoring transport layer-specific properties. The layered standard for this abstraction basically defines how bus signals have to be described in the model description file.
- Network Abstraction (Low-Cut): This abstraction allows for the implementation of virtual bus drivers within FMUs on the level of a hardware abstraction layer. It uses clocked binary variables to exchange bus operations between FMUs based on a lightweight protocol defined by the layered standard. Bus operations are used to transmit bus messages as well as bus events like acknowledge or error events. This enables both ideal and more realistic bus simulations depending on the capabilities of both sides of the API: The FMU and the importer. These capabilities can include timing, arbitration, error handling, status monitoring and other effects.

Since the FMI-LS-BUS is constrained to the description of the FMU interface, it remains neutral and agnostic to the actual bus communication process. For supported bus technologies, convenient templates are available to keep the integration effort low.

2.1 System Compositions

The FMI-LS-BUS supports three different ways of system compositions for integration into a specific simulation platform. Each individual system composition offers different advantages that are relevant depending on the user's concrete needs. The integrated FMUs across the different system compositions are the same, so that the same FMU can be integrated in all three communication architectures.

2.1.1 Direct Connection

The first option is to use a common FMU importer. Within this configuration, the FMU importer does not require any special features for simulating buses, apart from supporting FMI variables, clocks and terminals. Figure 1 illustrates the direct communication of two FMUs.

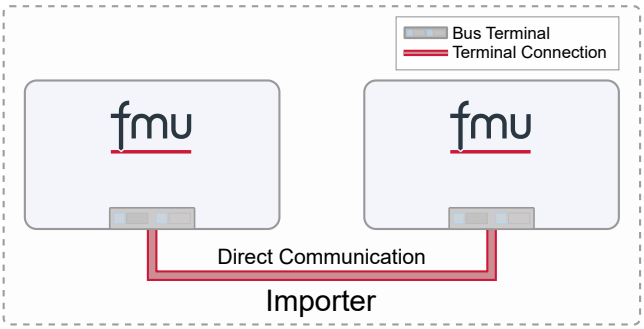

Figure 1. The first system composition allows the connection of exactly two FMUs using a common FMU importer to simulate bus systems.

DOI 10.3384/ecp218693

Direct bus communication is limited to exactly two FMUs. The idealized bus simulation does not consider bus-specific properties like the simulation of transmission timing or arbitration and, therefore, differs from physical networks. The main points resulting from this are as follows:

- Network congestion/bandwidth: The respective bus transmits the specific messages at an infinite speed. Baud rate considerations are not taken into account.
- Arbitration of network frames: All frames are transmitted at the same time without delay, which means that network-specific priority rules are not considered.
- Bus-specific protocol functions: All frames are transmitted at the same time without any delay. Protocol-specific functionalities, such as the acknowledgment of frames in CAN or any other network protocol, are ignored.
- Incoming buffer overflow: The Network FMU will receive all frames, regardless of buffer size or other hardware limitations and would need to handle those internally.

2.1.2 Composition with a dedicated Bus Simulation FMU

To simulate more realistic network characteristics, a bus simulation must usually be integrated, which simulates bus-specific properties like arbitration or the actual transmission time. One option is to implement this behavior in a separate FMU, the so-called Bus Simulation FMU. This FMU is responsible for simulating the respective bus behavior depending on the specified bus type (e.g., CAN, Ethernet, or any other bus) and simulates transmission times and failures of bus messages. Also it realizes the connections between the different FMUs that want to exchange network data (Network FMUs). The primary idea behind this concept is: All Network FMUs send their bus messages to the Bus Simulation FMU, which can confirm, delay or reject, and forward them. This approach allows for detailed bus simulations using common FMU importers. Figure 2 shows two Network FMUs connected to a Bus Simulation FMU; a total of three FMUs are running on an FMU importer.

This type of communication allows for the simulation of all required bus features:

- Transmission timing: An essential and one of the important features of bus-specific simulations is the consideration of transmission times for specific transmissions.
- n:m Bus Communication: The Bus Simulation FMU can provide the appropriate number of inputs and outputs to connect all Network FMUs within the complete bus network.

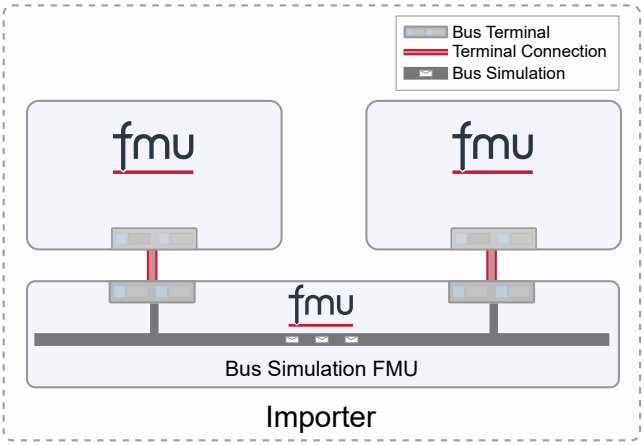

Figure 2. Bus simulation using a dedicated Bus Simulation FMU allows the simulation of n:m bus systems and very detailed simulations based on common FMU importers.

- Failure injection: Both the FMI-LS-BUS and this system composition in which all network data is routed via central Bus Simulation FMU(s) allow the possible targeted injection of transmission errors for simplified testability.
- Arbitration of network frames: Depending on the bus type and the specific arbitration requirements, appropriate implementations can be carried out via the central Bus Simulation FMU.

2.1.3 Importer with integrated Bus Simulation

Within this system composition, the functionality of the Bus Simulation FMU is integrated into the importer or simulator, so it allows the integration of the FMI-LS-BUS into an already existing manufacturer-specific simulator. These simulators may implement network communication with proprietary interfaces.

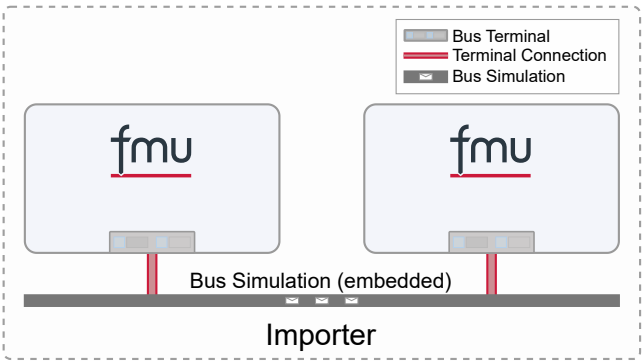

Figure 3. Bus simulation by using an importer with integrated Bus Simulation allows proprietary simulators to integrate FMI-LS-BUS specific FMUs.

This kind of system composition supports the same bus features as the setup with a dedicated Bus Simulation FMU, but with importer-specific benefits or constraints.

Figure 3 shows two Network FMUs integrated by an importer that supports the FMI-LS-BUS standard without the need for an additional Bus Simulation FMU.

2.2 Physical Signal Abstraction ("High-Cut")

Physical Signal Abstraction, or shortly called High-Cut, allows the exchange of unit-based physical signals between FMUs. Variables representing these physical signals are clocked to reflect the bus timing aspects of the information flow. The activation of these clocks always indicate that new network data is available at a given point of time.

As shown in figure 4, the core idea of the High-Cut consists of the bus signals, which are modeled as FMI 3.0 variables. These FMI variables are grouped into Protocol Data Unit (PDU) terminals, which are then grouped into frame terminals to declare their structure according to the network description.

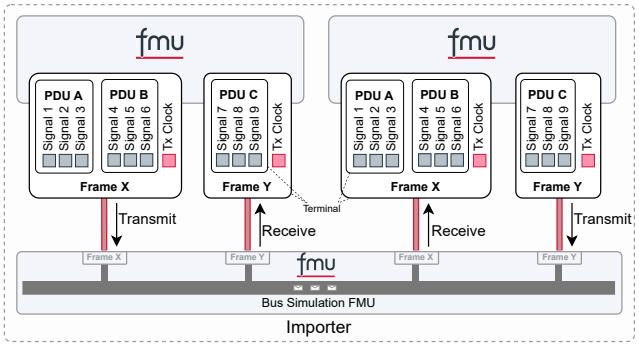

Figure 4. The figure shows an example architecture of a Physical Signal Abstraction. The signals (Signal 1…9) are modeled as clocked FMU variables of a specific type. The corresponding signals are structurally combined using PDUs, which in turn are assigned to frames. The PDU and frame structuring is done via terminals (PDU A, B, C and Frame X, Y).[1]

This approach of loose coupling between the physical signals and the lightweight PDU/frame grouping communication structure allows for easy creation of such High-Cut-based Network FMUs without the need for complex communication stacks. These configurations make them perfect for the rapid creation or prototyping in an agile, iterative development of the final communication structure. The High-Cut is therefore primarily suitable for early development phases, where its data-based simplicity offers efficiency advantages, rather than being disrupted by the fact that it lacks complete accuracy in simulating specific bus systems.

2.3 Network Abstraction ("Low-Cut")

The Network Abstraction, or shortly called "Low-Cut", allows the exchange of bus operations between FMUs over binary clocked variables. Bus operations are defined for different bus types and allow the emulation of the respective bus system above an electrical level. The focus here is on the level of abstraction for virtual scenarios and execution performance. Each operation consists of an OP-code and optional arguments. The primary operation is *Transmit*, which indicates that a Network FMU, connected to the bus, intends to send a payload. The payload content mirrors that of a real bus payload, with additional arguments to provide necessary communication frame data, as shown in figure 5 for a *CAN Transmit* bus operation corresponding to a CAN Standard Data Frame. A corresponding Bus Simulation typically responds with a *Confirm* operation to acknowledge receipt of the frame, but it may also reply with a *Bus Error* or other bus system specific operations. The set of provided bus operations ensures that a particular bus system can be simulated to the required level of detail.

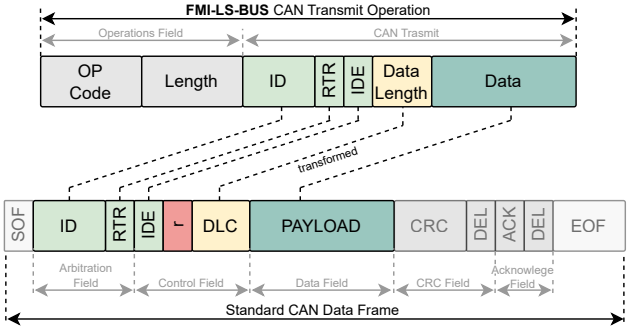

Figure 5. Shows the mapping of the FMI-LS-BUS *CAN Transmit* bus operation to a CAN Standard Data Frame. The information that can be mapped directly is shown in green. The yellow representation describes transformed values and the information shown in red is not used.

In contrast to the High-Cut approach, only one terminal per bus is needed. It consists of a binary variable and a clock variable for each direction of communication (transmission and reception). With the aid of bus specific operations, definition any message on the particular bus can be transported.

Thus, the sum of the instruments of the bus operations, as well as the bus terminals specified for the interconnection of Network FMUs, provides the possibility to use the Network Abstraction within the presented system compositions (see section 2.1). Figure 6 illustrates two Network FMUs integrated via an importer with an integrated Bus Simulation.

Network Abstraction allows a detailed and precise simulation of bus systems. This allows extensive tests using a suitable simulator in later development stages, when it comes to ensuring the functionality of a communication stack and software based on it. Currently, the bus systems planned for Network Abstraction are CAN, CAN FD, CAN XL, FlexRay Ethernet and LIN. However, this list might be extended to include other domains in the future.

[1] The term *Tx Clock* was chosen as an abbreviation for *Transmission-Clock* within the figure.

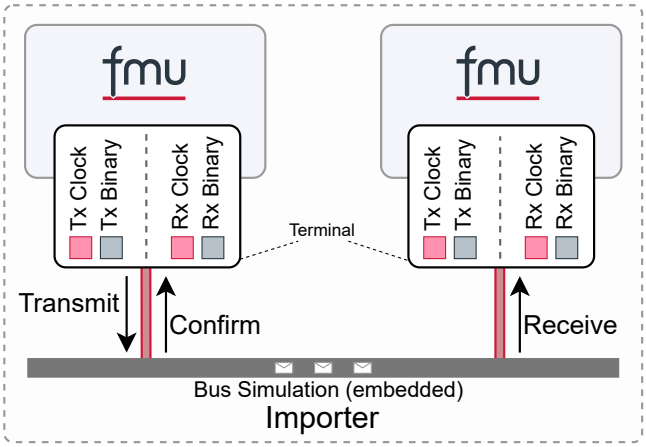

Figure 6. Two Network FMUs integrated via an importer which is coming with integrated Bus Simulation support, based on the Network Abstraction.

2.4 Principle of FMI-LS-BUS

Based on FMI 3.0, FMI-LS-BUS defines the API between FMU and importer and its semantics: What a variable and its values mean, how and when to exchange values and how to interpret those values.

Neither FMI 3.0, nor FMI-LS-BUS, specify what happens inside FMUs and importers. Both standards are agnostic of the FMU generation process (e.g. hand written, generated, wrapper or tool connector) or its content (e.g. AUTOSAR (AUTOSAR R24-11) vECU, file access for replay, aerospace line-replaceable unit (LRU)).

By not defining the internals of either side of the FMI-LS-BUS API's participants, FMI-LS-BUS can be used for many different use cases, as described above: Rough or detailed functional behavior, function emulations or production behavior wrapped in a thin FMI-LS-BUS wrapper.

3 Benefits of Integrating FMUs with FMI-LS-BUS within the Development Process

This section proposes an enhanced V-model, tailored to address the complexities of modern automotive development (see figure 7). This approach uses FMUs as central, standardized exchange artifacts across the entire development lifecycle. Being inherently tool-agnostic, FMI proves particularly valuable in distributed development by facilitating seamless integration at the interfaces between diverse domains (e.g., controls, sensor fusion, vision), distinct development stages (design, implementation, testing), and across heterogeneous tool chains.

During the initial design phases on the left side of the V-model, requirements decomposition occurs, leading to system and architectural decisions, including function distribution. This involves the definition of software components (SWCs) and their specific network interactions. These designs, including functional behavior, parameters, interface definitions, and network information, are then abstracted and encapsulated into executable FMUs, potentially leveraging FMI 3.0 features and the FMI-LS-BUS.

The availability of executable FMUs enables early and continuous virtual integration testing (e.g., MIL/SIL) on the verification branch of the V-model. For example, FMUs representing distinct ECUs, potentially created from multiple suppliers, can be simulated together using FMI-LS-BUS. By enhancing conventional methods (which typically rely on static documentation and interface specifications) by integrating executable specifications, we can substantially reduce ambiguity and error potential. A key benefit of this integration is the ability to formulate and apply test cases early on, enabling the early identification and resolution of inconsistencies that might otherwise arise from interpretation mismatches or format translations between different development stages and tools. This includes managing inconsistent signal definitions across different tool domains, simulating realistic network requirements, and validating end-to-end timing, interactions, and protocol adherence.

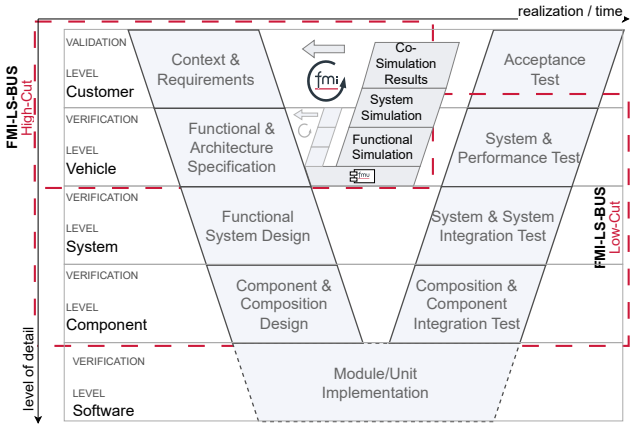

Figure 7. Enhanced V-model incorporating FMI-LS-BUS. This model illustrates the application of High-Cut and Low-Cut FMUs throughout distinct phases of the automotive development and verification life cycle.

This tight coupling between design and validation aspects of the V-model, facilitated by executable FMUs, enables an agile, iterative methodology, thereby supporting Continuous Integration/Continuous Testing (CI/CT) practices. Smaller, faster development cycles for components or subsystems provide rapid feedback. This significantly reduces integration risks later in the process and enhances overall efficiency, traceability, and the capacity to manage the complexity inherent in modern vehicle compositions. Furthermore, the standardized nature of FMUs promotes model reuse across different projects, simulation environments, and even between collaborating organizations (e.g., OEM and Tiers), maximizing the return on modeling effort.

Figure 7 illustrates this enhanced V-model framework that integrates FMI-LS-BUS to support both High-Cut and

Low-Cut FMUs, targeting different phases in the development process. Typically, High-Cut FMUs encapsulate application logic or functional behavior (often derived early in the design), while Low-Cut FMUs focus on detailed network interface behavior and network stack implementations (like AUTOSAR Classic), enabling verification at different integration levels as development progresses.

3.1 System Requirements and Architecture Definition

The High-Cut variant addresses the "top-left" of the development process, including requirements decomposition, system architecture definition, and the allocation of functions to logical or preliminary architectural components (see figure 8).

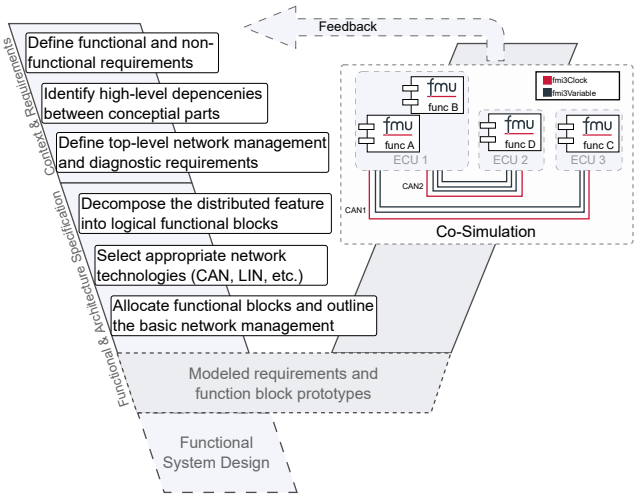

Figure 8. High-Cut use cases in the V-model. A proposed workflow for a quick development testing feedback loop using FMI-LS-BUS High-Cut features.

In this context, FMUs become executable design objects that embody requirements and components, offering a precise and verified definition early in the development lifecycle. The relationship between requirements and executable models improves traceability, verification, and impact analysis. The interoperability of the FMI standard can be a significant improvement in addition to traditional document-centric methods, allowing experts to integrate models from diverse tools like MBSE platforms and domain-specific simulators. These models serve as preliminary executable definitions that yield insights more rapidly and accelerate the specification process.

One example usecase is the allocation of distributed functions within a vehicle network, where a function is spread across multiple components. Simulation can be used to assess the impact of moving a function from one control unit to another, revealing how the change affects system behavior and communication. FMI-LS-BUS describes the interaction between these functional FMUs as part of automotive networks at a High-Cut abstraction level by modeling the interaction between these FMUs at the "signal level. This abstraction emphasizes the validation of functional data exchange between components while omitting the characteristics of network protocols.

The primary validation objective in this design phase is to confirm the architecture's functional accuracy, validate data flows, and detect conceptual errors in distributed logic before they are implemented. By enabling Verification and Validation activities much earlier than conventional, late-stage integration methods, High-Cut simulations with FMI-LS-BUS allow teams to identify and correct architectural flaws before they propagate into more costly development stages. Crucially, even with signal-level abstraction, this approach facilitates the early evaluation of closed-loop behavior, capturing essential timing factors and discretization effects that might otherwise be overlooked. Moreover, these FMUs serve as a shared, executable specification that improves collaboration between system architects and implementation teams. This single source of truth provides a clear, unambiguous, and validated artifact that can be shared with suppliers, which is especially beneficial when developing functions across organizational boundaries.

3.2 ECU Software Development and Component Testing

Building on the validated architecture, this iteration concentrates on the detailed development of Software Components (SWCs) and their integration into virtual ECUs (vECUs). Function developers and software engineers refine the FMUs with the executable specification or create new, more detailed FMUs representing concrete SWCs or vECUs, potentially incorporating auto-generated or hand-written code. The adoption of FMUs supporting FMI-LS-BUS substantially enhances the workflow, enabling early virtual integration and testing of software long before hardware is available. For instance, an OEM can easily integrate and test vECUs from multiple suppliers in a common simulation environment. This early, hardware-independent validation results in robust vECUs that serve as reliable deliverables for the next stage, significantly accelerating the overall development cycle.

In advance, network communication can be verified at a more detailed "Low-Cut" abstraction level using FMI-LS-BUS. This involves simulating the AUTOSAR communication stack, including the packing and unpacking of signals into network messages (e.g., CAN frames) based on standard description formats like DBC or ARXML. Simulating these vECUs together allows for thorough testing of the communication software, ensuring the implementation meets network interface requirements. This helps developers identify critical errors, such as incorrect signal packing or protocol deviations, preventing them from becoming costly problems during later hardware integration phases. The simulation can also be extended to model key characteristics of the bus itself, enabling the analysis of network-level phenomena such as timing effects and the correctness of error-handling mechanisms like mes-

sage retransmission.

3.3 System Testing

Proceeding from the integrated vECU developed and validated in section 3.2, this final virtual iteration assembles the individual vECUs into a complete system simulation. The primary objective is comprehensive testing in a realistic environment to create a high-confidence virtual release candidate. System integration and test teams utilize the collection of vECUs alongside potentially more sophisticated Bus Simulation FMUs (see section 2.1.2) or use an integrated Bus Simulation (see section 2.1.3) representing the network bus itself. These Bus Simulations, also leveraging FMI-LS-BUS (Low-Cut), incorporate enhanced capabilities beyond simple message transport, such as detailed timing models and error injection mechanisms, providing a realistic virtual testbed. The standardized FMU interface within this iteration affords significant flexibility, allowing test teams to readily combine vECUs from various sources (different internal teams or external partners) with advanced bus models and test harnesses, potentially originating from different tool vendors. This enhances test flexibility, coverage, and the ability to simulate realistic system conditions, ensuring functional requirements and communication specifications are met at the system level.

The validation at this system level is thorough, intended for ensuring end-to-end correctness and identifying integration problems that isolated component tests may not detect. The procedure include validating functional performance throughout the complete virtual system and evaluating detailed network attributes such as latencies, scheduling conformity, and bus load. By systematically injecting network errors—such as message loss, data corruption, or node failures—through the advanced bus simulation, the system's reaction can be properly assessed against its requirements. Successful completion of this virtual testing phase provides high confidence in the system's correctness, performance, and robustness. The validated set of integrated FMUs represents a comprehensive virtual prototype, ready to be shared with other stakeholders (e.g., for calibration or HiL testing) as part of the distributed development and release process, ensuring consistency prior or in parallel to hardware deployment.

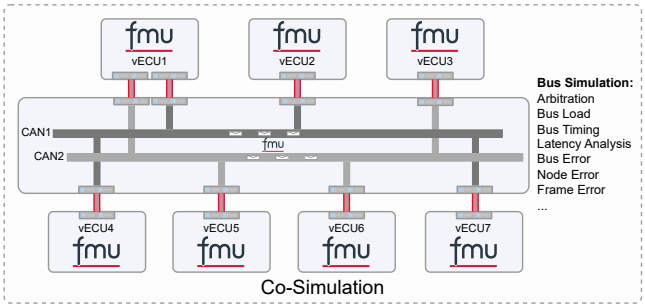

Figure 10. This figure illustrates a total of seven VECU FMUs connected via two virtual CAN bus lines (CAN1 and CAN2). A portion of the VECU FMUs is connected via both bus lines and thus communicates in both CAN networks. Using the Low-Cut approach, very detailed and global tests on a system level are possible to ensure the functionality of the various vECU FMUs in various scenarios.

3.4 Operation and Maintenance

The integration of FMUs connected via FMI-LS-BUS extends its benefits beyond initial development and testing into the vehicle's operational phase and subsequent main-

tenance activities. Virtual models and test environments created during the development life cycle, encompassing a wide range of potential vehicle configurations, become valuable assets for post-release tasks.

Managing Variant Complexity with Virtual Fleets: A virtual fleet enhances troubleshooting capabilities. When addressing field-reported issues potentially specific to certain variants, the corresponding virtual configuration can be quickly instantiated to reproduce the fault condition. Validated system representations, containerized as FMUs, are used within these simulations. Field recordings are utilized to stimulate the simulation. Therefore, the Low-Cut abstraction is especially useful since the captured traces can be easily transformed to the FMI-LS-BUS datagram. Furthermore, operational data collected from vehicles in the field can then be added into the simulation database to improve and correlate the original FMU models, gradually increasing accuracy over time.

Quality Assurance of Updates Across Variants: A virtual system environment, representing the necessary variants from the virtual fleet, is crucial for validating software upgrades before deployment, especially for Over-the-Air (OTA) updates. Prior to releasing updates, their compatibility and performance can be rigorously tested across all relevant deployed configurations within the FMI-LS-BUS simulation system. This pre-deployment validation against the virtual fleet acts as essential quality assurance, significantly reducing the risk of introducing variant-specific defects or regressions into operational vehicles, thereby safeguarding the safety and reliability of OTA updates across the diverse product range.

Digital Twin for Long-Term Maintenance: The containerized nature of FMUs simplifies archiving specific system configurations and component baselines for each variant (Coïc 2021). This supports consistent, traceable long-term maintenance across the entire vehicle portfolio. A specific configuration from the virtual fleet, potentially updated with operational data for a particular physical vehicle, can function as a key component of that vehicle's Digital Twin, enabling variant-specific analysis and prediction.

Service Training: The library of FMU models, covering various vehicle configurations, serves as an effective tool for the supplementary training of service technicians. They can learn about variant-specific systems and diagnostics in a virtual environment, enhancing competence without the constraints and costs associated with accessing diverse physical hardware.

3.5 Conclusion

By establishing FMUs as standardized, executable exchange artifacts throughout the proposed "enhanced" V-model development process, FMUs close critical gaps between development domains, stages, tools, teams and companies. The iterative application of this methodology, leveraging both High-Cut (signal-level) and Low-Cut (message-level) FMI-LS-BUS abstractions, enables the following significant benefits:

This methodology improves efficiency, reduces integration risks and costs, enhances quality and reliability, fosters collaboration, and manages the inherent complexity in developing modern, distributed automotive electronic systems through standardization, virtualization, and early, continuous validation.

4 Validation of FMI-LS-BUS

Interoperability is an essential aspect of modern model-based systems engineering, enabled by standards like the FMI. FMI encourages exchange and simulation of dynamic models created with various authoring tools. The FMI 3.0 Layered Standard for Network Communication (FMI-LS-BUS) has been developed to extend these capabilities to distributed systems and network-based simulation architectures. The demonstrated interoperability across a wide range of technologies and organizations is an important measure of such standards' success and practical adoption.

At the ASAM International Conference 2024 (Bertsch 2024), the FMI-Design Group demonstrated the seamless interoperability between different tools. This demonstration showcased the High-Cut and Low-Cut capabilities based on automotive simulation use cases.

Well-known SiL software tool vendors such as Akkodis, Altair, AVL, Bosch, dSPACE, PMSF IT Consulting and Synopsys participated in this demonstration with their tools (Bertsch 2024).

5 Other usage domains

The current focus of standard network protocols predominantly targets technologies utilized within the automotive sector. However, other industries, such as shipping, aerospace, off-road machinery, and agriculture, employ distinct network technologies tailored to their specific requirements. Examples include CANaerospace, ARINC 667, AFDX, MIL-STD-1553, and ISOBUS.

With the successful integration of automotive network technologies into the FMI-LS-BUS, there is potential for incorporating additional domain-specific technologies. This process can be facilitated by interested parties from both within and outside the FMI community. Such integrations may occur with or without formal endorsement from the Modelica Association Project FMI.

6 Summary and Outlook

The increasing complexity of products and development processes necessitates not only the standardization of signal exchange but also the harmonization of network message exchange for simulation artifacts. The FMI-LS-BUS addresses this need by providing a standardized framework for network simulation, building upon the widely adopted FMI 3.0 standard. By introducing two abstraction layers, the standard enables flexible utilization of network

DOI 10.3384/ecp218693

communication throughout all phases of product development. Early development stages can leverage high-level abstractions (High-Cut), while later stages can adopt low-level details (Low-Cut) as more specific network behaviors are defined.

FMI is already a standard for many OEMs and suppliers when developing and exchanging vECUs. The FMI-LS-BUS, as a key technology for cross-manufacturer description of bus simulations in FMUs, will strengthen the core FMI standard itself and allow users to use it in new and unprecedented areas of application. To facilitate implementation, a range of resources is available, including an FMI-LS-BUS Implementers' Guide (MAP FMI 2025b) and reference FMUs, which are accessible via the FMI website *www.fmi-standard.org*. These resources aim to streamline integration efforts for tool providers and their developers.

Regarding a possible description format for the system interconnection of buses described in FMUs for the FMI-LS-BUS, the SSP standard (MAP SSP 2024) is a suitable option. Current analyses regarding the possible specification are part of ongoing work. This could offer further simplifications for users.

Additionally, stakeholders are encouraged to participate in the FMI community or develop their own layered standards on top of FMI 3.0. Such initiatives can occur independently or in collaboration with the FMI project, fostering innovation and extending the applicability of FMI standards across diverse domains.

Acknowledgments

We would like to thank all contributors to the FMI Standard and the Layered Standards built on top of it. Numerous ideas and feedback from FMI users and the Advisory Board supported us throughout the design process and provided valuable insights. We thank the companies, especially those of the authors, for their support, which enable us to continue the standardization.

An innovative heterogeneous modeling approach to build a cooling system for battery thermal management with common fluid properties involving FMI terminals

Karim Besbes

Siemens Digital Industry Software, France
karim.besbes@siemens.com

Abstract

In this paper, a new modeling approach combining native Simcenter Amesim submodels and Modelica submodels is presented. FMI terminals are used to enable the physical connection of fluids between Simcenter Amesim and Modelica. The innovation lies in the fluid properties that are computed in the causal and acausal worlds using the same technology. The architecture of a new Modelica AmeTpfMedia library developed to ensure continuity of fluid properties is presented, along with its accuracy and performance. Using this new approach, a demonstrator of a closed-loop heterogeneous cooling system for battery thermal management is built, opening the door to a new way of thinking complex multi-physics systems.
Keywords: Simcenter Amesim, Heterogeneous Modeling, FMI Terminals, Fluid Properties, Battery Thermal Management

1 Introduction

In multi-physics modeling, the choice between causal and acausal modeling paradigms, aligned with the needs of the modeling project, requires careful consideration.

The causal approach, commonly used in the Bond-Graph method (Hermien and Wiyatini 2021), consists of fixing the input and output status of variables of a model and each of its submodels, creating a causal relationship between inputs and outputs. This traditional approach makes it possible to build robust models. It allows precise control of system behavior, making it easier to interpret and understand system dynamics.

By contrast, acausal modeling, for which Modelica is particularly well suited, is based on equations (Fritzson 2014). In such a modeling paradigm, the only requirement is a well-balanced mathematical system defined by all declared equations, variables and data sets. Then, causality is naturally fixed by solving the mathematical system. This approach, more flexible, offers a convincing alternative when dealing with highly interconnected systems.

To meet the ever-increasing modeling challenges of tomorrow, with increasingly complex and interconnected systems, modeling techniques need to become ever more innovative and sophisticated. Combining causal and acausal paradigms, to build an heterogeneous system, can be one such innovative solutions.

Thanks to the Functional Mock-up Interface (FMI) standard and especially the 3.0 (Modelica Association 2022), such combined modeling approach is simplified, since it allows to regroup different signals in one connector. It then becomes conceivable to build an heterogeneous model involving fluids, as long as the mechanism used to calculate the thermodynamic properties in each submodel is the same.

This article aims to present an innovative heterogeneous modeling approach in Simcenter Amesim to build a cooling system for the battery of electrical vehicles. Simcenter Amesim, well known in the realm of system simulation, is natively causal and Bond-Graph based. It provides also a full-featured Modelica Editor including physical interfaces to connect both worlds "physically", with Terminals. To meet the challenge of ensuring perfect continuity of thermodynamic properties between Simcenter Amesim and Modelica's fluid libraries, a new Modelica media library, named AmeTpfMedia, has been developed. AmeTpfMedia takes advantage of the mechanism used in Simcenter Amesim to calculate fluid properties.

In the following article, the Modelica support in Simcenter Amesim is described as well as the definition of the physical interfaces. Then we will go over the AmeTpfMedia library developed to be fully consistent with Simcenter Amesim's Two Phase Flow library. Finally, the cooling system built as a proof-of-concept is presented and the simulation results are given.

2 Modelica support in Simcenter Amesim

The IMAGINE company, now Siemens Digital Industry Software has released its System Solution tool Simcenter Amesim back in 2012. This simulation platform gives access to a set of libraries of mechanical, electrical, hydraulic, pneumatic, fluid, and hybrid components created with the help of domain experts from both the industrial and the academic worlds. It enables the development of any new mechatronic product without having to write equations and offers numerous facilities for 1D system simulation (Vasiliu et al. 2018).

Among these facilities, Simcenter Amesim offers a full-

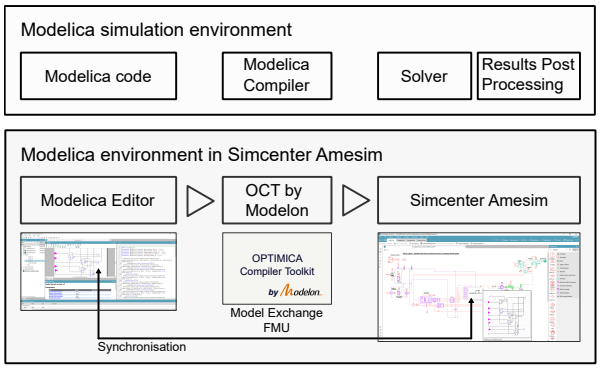

Figure 1. Modelica support and integration in Simcenter Amesim

featured editor dedicated to the Modelica language, as shown in the Figure 1. Since the version 17, the Modelica Editor embeds Modelon's OPTIMICA Compiler Toolkit (OCT), which is today compliant with the Modelica language specification 3.4 (Modelica Association 2017) and supporting both Modelica Standard Library (MSL) 3.2.3 as well as version 4.0.0, except Synchronous Language Elements and State Machines.

For the selected model in the Modelica Editor, the Modelica compiler generates a Model Exchange Functional Mock-up Units (FMU) version 2.0.4 extended with the FMI 3.0 terminals definition. It allows to define a group of variable to ease connecting compatible signals on the system level. The Model Exchange FMU is then treated as a native submodel by Simcenter Amesim, synchronized with the original Modelica code, removing pains that would be introduced due to cosimulation usage. This submodel can be connected to other native submodels and simulated with the internal solver. Thus, Simcenter Amesim can be used as a pure Modelica simulation environment made up by a Modelica Editor, a Modelica compiler, a solver and a bunch of post-processing features, or can be used to mix two modelling approaches to build a heterogeneous model.

3 Heterogeneous model with physical interfaces

In this article, we consider that a heterogeneous model is composed of at least two submodels built using different modeling tools or approaches.

In Simcenter Amesim, all the variables at the ports of the submodels have their causality fixed. Figure 2 illustrates four submodels taken from four different libraries. For example, the wall (c) has two ports where the heat flow rate is defined as an input and the temperature is defined as an output on both ports. Most of the time, several versions of the same submodel are available to modify causality. Such native submodels can only be connected to a Modelica submodel if three conditions are met. The first condition concerns the port variables at the interface, which must be defined as a group of variables. The second condition concerns the causality consistency and last one concerns unit consistency. The following sections describe how to deal with these conditions.

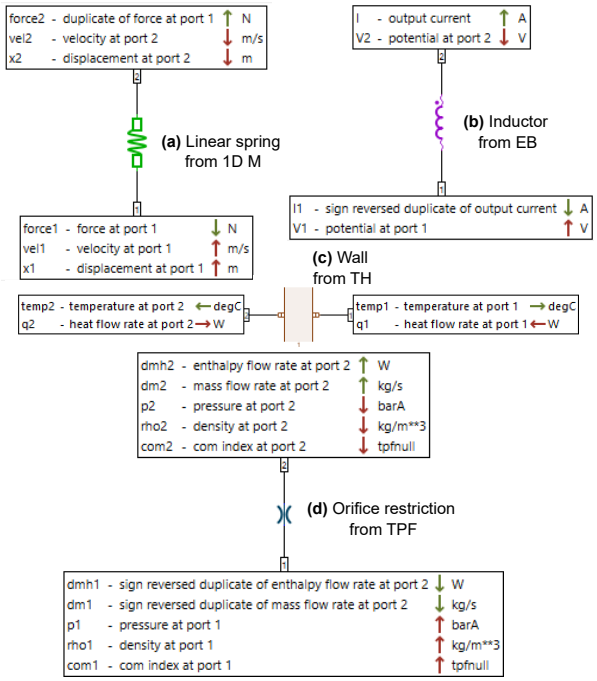

Figure 2. Example of Simcenter Amesim ports with fixed causality. The submodel (a) comes from the 1D Mechanical library, (b) from the Electrical Basics library, (c) from the Thermal library and (d) from the Two Phase Flow library

3.1 Terminals

In order to address new use cases, FMI 3.0 standard introduces the concept of layered standards adding optional features to the FMU, (Bertsch et al. 2023). It includes also an optional mechanism in the `icons/terminalsAndIcons.xml` to define the terminals and their graphical representation, as described in the section 2.4.9 of the specification. In Simcenter Amesim, the terminals definition has been backported to FMI 2.0.4 using the `/extra` directory. It is used to convert a Modelica connector into a physical Simcenter Amesim port.

Assuming that a Modelica connector is coded with terminals requirements, the compilation generates automatically an XML file where the root element is `fmiTerminalAndIcons` with *fmiversion="3.0"* attribute. The children elements are `GraphicalRepresentation` which is ignored in the current implementation and `Terminals` which is a sequence of `Terminal`. Each `Terminal` is described by a name, a mandatory matching rule (plug, bus or sequence) and an optional terminal kind used for the nominal typing. A `Terminal` is a sequence of terminal member variables, identified by their unique name among the list of scalar variables.

To illustrate a typical terminal definition, the Figure 3 shows an example of a XML tree from a compiled Mod-

DOI 10.3384/ecp218703

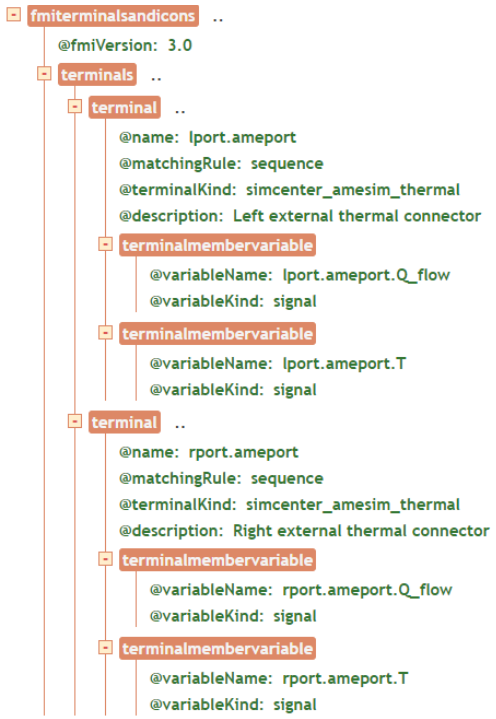

Figure 3. Example of a XML tree with terminals definition

elica submodel packaged into a FMU. The two terminals have a kind defined as `simcenter_amesim_terminals` and a **sequence** matching rule attribute. In Simcenter Amesim, a thermal port is declared with a group of two variables, heat flow rate and temperature, as shown in Figure 2(c). Given that `lport.ameport.Q_flow` and `lport.ameport.T` define a group of scalar variable already existing in Simcenter Amesim with the same causality, the corresponding port is automatically created. Figure 4 shows the external view of the corresponding submodel imported in Simcenter Amesim. Note that the two signal ports `TempOutput1` and `TempOutput2` are also created. But they refer to two other scalar variables with output causality that are not part of a terminal.

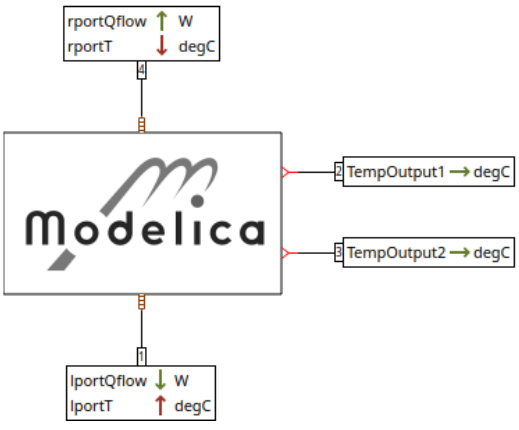

Figure 4. Example of a compiled and imported Modelica submodel using the terminals described in the XML tree

From Modelica point of view, in order to generate in the `modelDescription.xml` a terminal for a group of variables, Modelica compiler requires the following tool vendor annotation:

```
annotation(__simcenter(port(port_type="port
    type name")));
```

In Simcenter Amesim, there are 13 different port types classified per physical domain, listed in the Table 1.

Table 1. List of native port types in Simcenter Amesim

Domain	*Native Port Type*
Mechanical	lshaft, rshaft, rope, mecha 2D
Fluid	hflow, pflow, geocom
Thermal	thermal
Magnetic	magnet
Electrical	elect, elect3p
Chemical	electroch
Signal	signal

3.2 Connectors

The equivalent of a Modelica connector in Simcenter Amesim is a port. From the moment a port is targeted, the rule to build the associated Modelica connector is always the same. The order of the declared variables in the connector must be exactly the same as the order of variables defined in the corresponding port. The same applies to variable causalities and types. And the port type name listed in the Table 1 must be specified in the tool vendor annotation. The following code uses a Modelica connector to generate the thermal port, shown in Figure 4:

```
connector PortTinQout
  output Q_flow(unit="W") "Output heat flow
      ";
  input Real T(unit="degC") "Input
      temperature";
annotation (__Modelon(isTopLevel=true),
    __simcenter(port(port_type="thermal")));
end PortTinQout;
```

As can be seen, order, causalities and units have been set to be consistent with the thermal port targeted as well as the port type name. Knowing these rules, a Modelica submodel can be coded to connect to any of Simcenter Amesim's native physical ports.

3.3 Interfaces

In this context, a Modelica interface is defined as a class where connectors from both worlds are already declared. It provides end-user capability to connect a Modelica library to a Simcenter Amesim's library for the same physical domain. In the Modelica Editor, in addition to the MSL, the library Simcenter Amesim Modelica Library (SAML) is provided. It is a standardized library based on the native submodels including several physical interfaces as illustrated in the Figure 5.

For most used physical domains and associated causalities there is a dedicated interface in the SAML. From

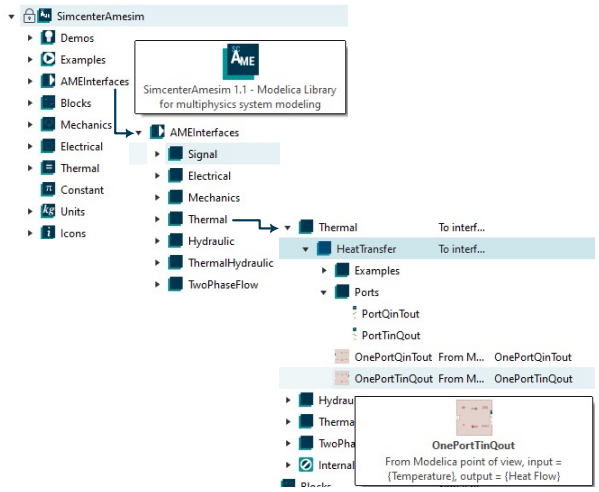

Figure 5. Simcenter Amesim Modelica Library 1.1 tree with the thermal connectors and interfaces

Modelica point of view, the MSL is the reference library of connector definition. For instance, the thermal interfaces in the SAML are built in order to connect any Modelica submodels containing a `HeatPort` connector from the MSL to any Simcenter Amesim submodels coming from the thermal library. In the MSL, the `HeatPort` connector contains the variables T and Q. From Simcenter Amesim point of view, thermal port contains also T and Q but with fixed opposite causalities. Then two causalities and two interfaces can be defined. Figure 6 shows both of them allowing to convert a convection submodel from the MSL dedicated to Simcenter Amesim. As illustrated, the interfaces contain two different connectors, one for Simcenter Amesim and the other to be connected to the convection submodel. Within the interfaces, declared connectors ensure causality consistencies for each variable, and equations ensure units consistency between the two environments.

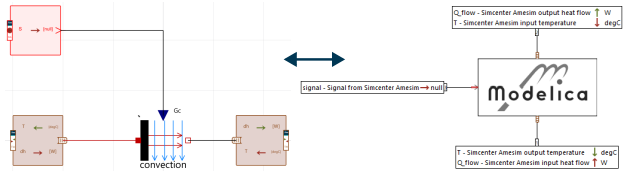

Figure 6. Usage of thermal interfaces to convert a Modelica convection submodel for Simcenter Amesim with the thermal ports

Note that thermal connectors in Figure 6 are not connected to anything, and the compilation is still proceeding correctly. This is due to a second tool vendor annotation telling that connector must be treated as a top-level connector, regardless of the layer in which it has been declared in the model. It allows to simplify the workflow for end-user. A simple drag and drop of the interface into the diagram and a connection with the Modelica submodel is sufficient. The following code is for the interface with heat flow rate as input and temperature as output:

```
model OnePortQinTout "From Modelica point
    of view, input = {Heat Flow}, output =
    {Temperature}"
  SimcenterAmesim.Thermal.Interfaces.
      HeatPort port;
  Ports.PortQinTout ameport;
equation
  port.T = ameport.T + SimcenterAmesim.
      Constant.celsius2kelvin;
  port.Q_flow = -ameport.Q_flow;
end OnePortQinTout;
```

And the thermal connector `ameport` including the two tool vendor annotations, one to treat the connector as a top-level connector and the second for the terminal definition, is coded as follows:

```
connector PortQinTout
  output Real T(unit="degC") "Simcenter
      Amesim output temperature";
  input Units.AMESIUnits.HeatFlowRate
      Q_flow "Simcenter Amesim input heat
      flow";
annotation (__Modelon(isTopLevel=true),
    __simcenter(port(port_type="thermal")))
    ;
end PortQinTout;
```

In this section, terminals, connectors and interfaces have been introduced, showing how to build a thermal interface as an example. The same strategy can be applied for other physical fields like mechanical or electrical and for other connectors than those from the MSL. However, as soon as a transport of a fluid is involved, the interface must also ensure mass and energy balance between both worlds. Such interface is described in the last section of this article where the demonstrator is presented. Finally, in this context, where Simcenter Amesim is the integration and simulation platform, the Modelica part must use the same mechanism than Simcenter Amesim to calculate the fluid properties to avoid physical and numerical discontinuities. This mechanism is introduced with AmeTpfMedia.

4 AmeTpfMedia library

The AmeTpfMedia library has been developed in Modelica for calculation of fluid properties. It uses the same utilities than the Two-Phase Flow (TPF) library and developed for dynamic simulation and design of thermodynamic applications, such as automotive air-conditioning, heat pumps, Rankine cycles... These utilities have been recompiled specifically for AmeTpfMedia and allow to calculate the thermodynamic state properties and their partial derivatives for a set of refrigerants. The description quality of fluid properties depending on the type of equation of state (EoS) used to do the calculation can have a significant impact on the results, performance and robustness of the simulation. With AmeTpfMedia, when a refrigerant is selected, it is possible to find the best compromise for simulation requirements, providing the choice between

DOI
10.3384/ecp218703

Helmholtz, MBWR or Peng-Robinson EoS. Most refrigerants have at least two EoS choices including Helmholtz, and a small proportion have only one. The list of fluids available is presented in the Table 2.

4.1 Architecture

The structure of the library is illustrated in Figure 7. It contains the package AmeTpfMedium extending from PartialTwoPhaseMedium defined in the MSL media package. This strong choice of architecture is motivated by the number of well known libraries in the Modelica community already using the MSL media structure to call the function of fluids, like Buildings (Wetter et al. 2014) or ThermoCycle (Dechesne et al. 2014).

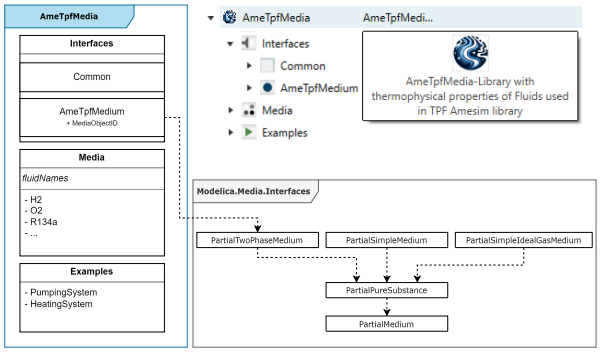

Figure 7. Structure of the AmeTpfMedia library

Inside the AmeTpfMedium package, the class MediaObjectID defines an ExternalObject instantiating the medium, set by an index of fluid named ID, as follows:

```
class MediaObjectID
  extends ExternalObject;
  function constructor
    input Integer ID;
    output MediaObjectID media;
external"C" media =
    create_modelica_media_as_predefined_fluid
    (ID)
    annotation (Include="#include <
        media_public.h>", Library={"
        AmeTpfMedia"});
  end constructor;
  function destructor
    input MediaObjectID media;
external"C" free_modelica_media(media)
    annotation (Include="#include <
    media_public.h>",
         Library={"AmeTpfMedia"});
  end destructor;
end MediaObjectID;
```

The ExternalObject is used as a pointer by all thermodynamic functions contained in the Internal package in order to call directly the compiled resources (headers and compiled objects). For instance, the function calculating the specific enthalpy according to the density and the temperature is coded as follows:

```
function h_dT
  input Density d;
  input Temperature T;
  input MediaObjectID media=mediaID;
  input Integer EoS=EoSInt;
  output SpecificEnthalpy h;
external"C" h =
    modelica_media_compute_h_from_rho_t(
    media,EoSInt,d,T)
    annotation (Include="#include <
        media_properties_from_rho_t_public.
        h>", Library{"AmeTpfMedia"});
end h_dT;
```

These internal functions allow to rebuild one by one the inherited functions from the MSL. The derivatives required for the inversions of temperature and density functions are implemented in Modelica as well as the time derivatives of the enthalpy, density, pressure and entropy to facilitate the numerical inversion.

4.2 Validation

The AmeTpfMedia library has been tested with a set of standard functions calculating the pressure and the specific enthalpy over a range of density and temperature. The utilities used by the AmeTpfMedia library have already been validated in the context of Simcenter Amesim. Nevertheless, to ensure the good integration in the Modelica world, a protocol of test has been defined for three very common fluids, which are Water, CO2, and R134a.

The protocol consists in comparing the results with reputed Modelica libraries of fluid properties: the MSL, the CoolProp library (Casella 2008) and the non-profit version of TilMedia from Clara library (XRG-Simulation GmbH TLK-Thermo GmbH 2023). Figure 8, 9 and 10 compare the results generated from AmeTpfMedia and those from CoolProp, TilMedia and/or MSL. These are results obtained in the form of $Y(T,\rho)$, where Y is the variable of interest, pressure p or specific enthalpy h, evaluated in the domain defined by framing the critical point of each fluid, with n the number of calculated points. To perceive the variations between the libraries, we define the average relative deviation *AvDev* between AmeTpfMedia and the other libraries as follows, where lib can be CoolProp, TilMedia or MSL:

$$AvDev_{lib}(Y) = \sum_{n}(Y_{AmeTpfMedia}/Y_{lib} - 1) * 100/n \quad (1)$$

Regarding the thermodynamic properties of the water calculated by AmeTpfMedia, Figure 8 shows a comparison with the three other libraries. For p and h, there is an average relative difference of 0.5% between AmeTpfMedia and the other libraries. This small difference can be explained by the fact that Simcenter Amesim uses a different standard for the thermodynamic formulation of water.

Regarding the CO2, Figure 9 shows an average relative deviation between AmeTpfMedia and CoolProp of 0.01% and between AmeTpfMedia and TilMedia of 1e-6%. Both are negligible. Note that the non-profit version

Table 2. List of fluids available in AmeTpfMedia

Family	*Fluid usage name*
Common fluids	pH2, H2, oH2, N2, O2, CO2, H2O, H2O2, NH3, Air
Refrigerants	R22, R32, R123, R125, R134a, R13b1, R13i1, R143a, R152a, R227ea R236ea, R236fa, R245fa, R1123, R1224yd(Z), R1234yf, R1234ze(E) R1243zf, R1336mzz(Z), Novec 649, Novec 7000, R404a, R407c R410a, R450a, R452b, R454c, R455a, R507a
Organic compounds	Ethylene, Methane, Ethane, Propane, Butane, Iso-Butane, Pentane Iso-Pentane, Cyclopentane, Heptane, Octanen, Iso-octane Dodecane, Methanol, Ethanol
Noble gas	He, Ne, Ar, Kr, Xe

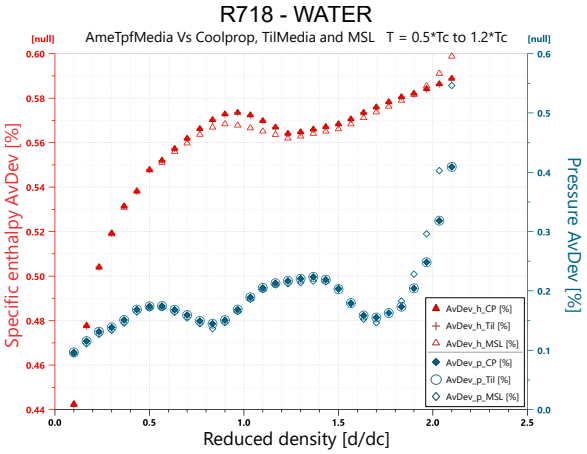

Figure 8. Comparison between AmeTpfMedia, Coolprop, TilMedia and the MSL for the Water

of TilMedia gives only an access to GERG CO2 built using the GERG EoS (Kunz and Wagner 2012) instead of Helmholtz, which is used by CoolProp and AmeTpfMedia. And yet, the biggest difference lies between AmeTpfMedia and Coolprop.

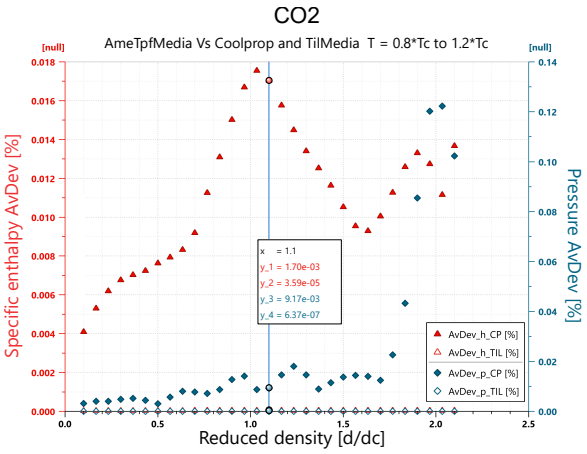

Figure 9. Comparison between AmeTpfMedia, Coolprop and TilMedia for the CO2

Finally, regarding the R134a, Figure 10 shows an average relative deviation of 5e-6% for h and of 1.5e-4% for p, between AmeTpfMedia and CoolProp or the MSL. As a result, the R134a is the fluid with the greatest similarity between the libraries.

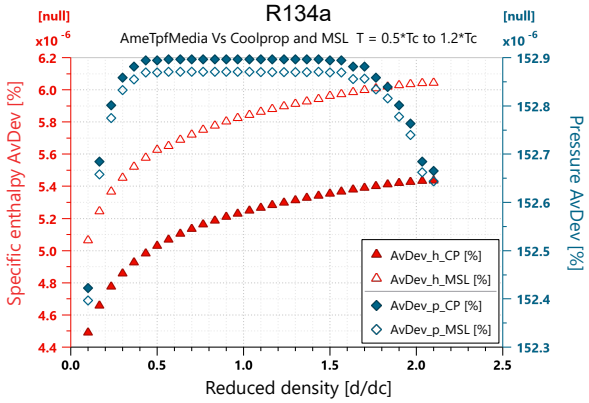

Figure 10. Comparison between AmeTpfMedia, Coolprop and the MSL for the R134a

In this section, thermodynamic properties calculated for three different fluids have been presented. Another article dealing specifically with TPF utilities in Simcenter Amesim would provide more results for more fluids, and address the slight differences observed. Nevertheless, it is considered that AmeTpfMedia reflects the expected behavior and the transition of TPF utilities to Modelica is validated.

4.3 Performance and Robustness

Performance and robustness are key when it comes to accurately calculating fluid properties for thermodynamic cycle simulation. This section introduces a benchmark consisting in simulating on the same environment and the Simcenter Amesim's solver an evaporator model taken from the ThermoCycle library. Water and carbon dioxide are chosen as refrigerants and CPU times of each library are compared. The aim is not to make a general statement on which library is the best performing. This would require a much larger number of tests with a wide selection of models and fluids. This is a qualitative reference to see

DOI 10.3384/ecp218703

if AmeTpfMedia performs comparably to other reputable libraries.

The model used for the test bench coming from ThermoCycle is named `Hx1DConst`. This is a discretized counter-current heat exchanger in which one of the two fluid has a constant heat capacity. The other fluid (Water or carbon dioxide) is described at each cell of the tube, where enthalpy, density, pressure and vapor quality is computed. The heat exchanger is discretized into 30 cells and the start values chosen are exactly the same for a selected fluid. The boundary conditions are defined in order to evaporate the selected fluid.

With regard to the water, as can be seen in Figure 11, CPU times of libraries using external objects for calculation are fairly similar, with AmeTpfMedia slightly ahead. As expected, the MSL gives the best CPU time. Indeed, as described in the MSL documentation, the water was explicitly designed to work well in dynamic simulations with a high focus on the performance. In the second graph, a comparison of the cooling power can be found. The results show a relative difference of 0.2% between AmeTpfMedia and the other libraries, which is consistent with the deviation observed in Figure 8.

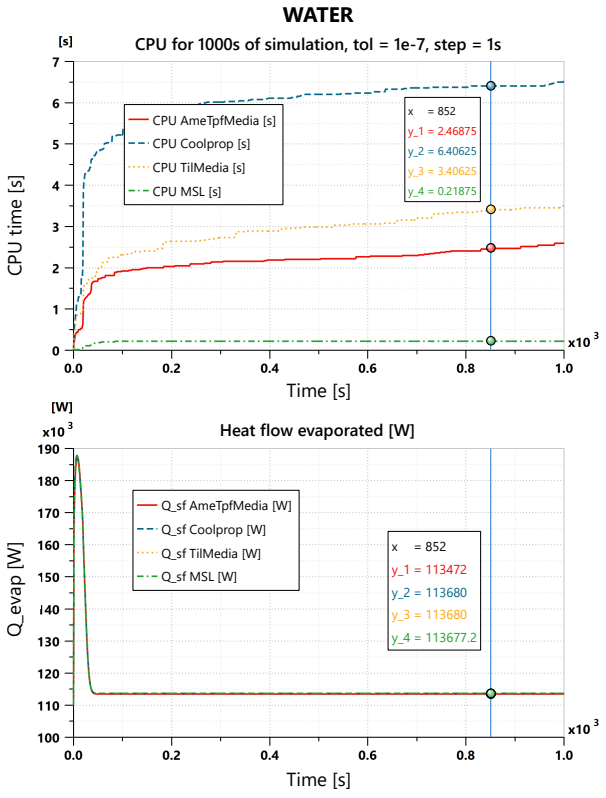

Figure 11. Comparison of CPU time and cooling power with water as working fluid

For carbon dioxide, as shown in Figure 11, AmeTpfMedia and TilMedia have similar CPU times, while CoolProp is 3 to 5 times slower. TilMedia is slightly ahead probably due to the GERG EoS used for the CO2. As for the cooling power, the result shows negligible differences.

During the benchmark, no significant difference was observed concerning the robustness. The libraries behaved in the same way at each simulation.

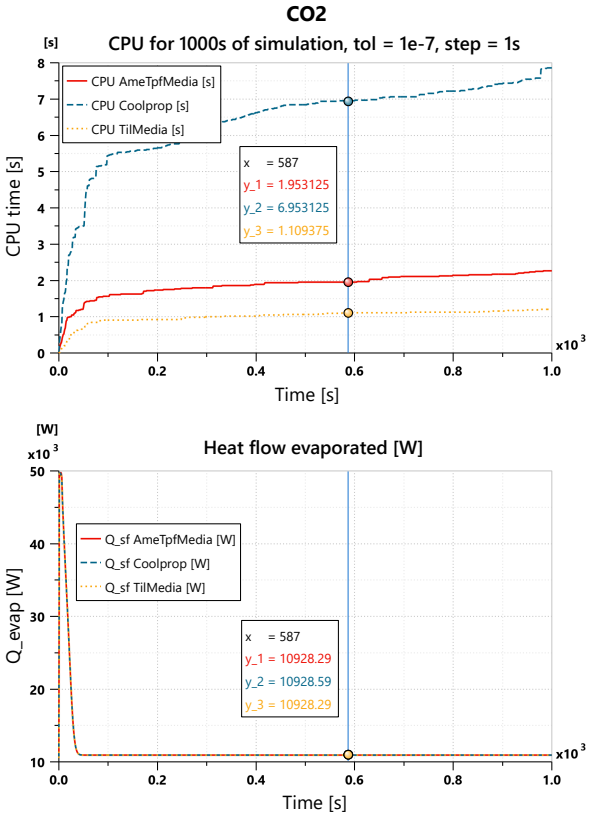

Figure 12. Comparison of CPU time and cooling power with carbon dioxide as working fluid

5 Use case: heterogeneous cooling system

Imagine two teams tasked with modeling a complex system like battery thermal management. One team employs Simcenter Amesim, while the other develops in-house submodels using the Modelica language. Nowadays, this scenario is becoming increasingly common, particularly among large industrial groups with multiple R&D departments. The following demonstrator aims to answer this need.

5.1 Description

The first team has developed the complete system in Simcenter Amesim, with the exception of the compressor, condenser and valve, which were developed by the Modelica team. Thanks to the Terminals and AmeTpfMedia, it becomes possible to integrate each development made by each team to build the full system presented in the Figure 13. As can be seen, the system consists of the charger, the battery in purple, the coolant system in orange, the refrigerant system in blue, part of which is made in Modelica, and the control in red.

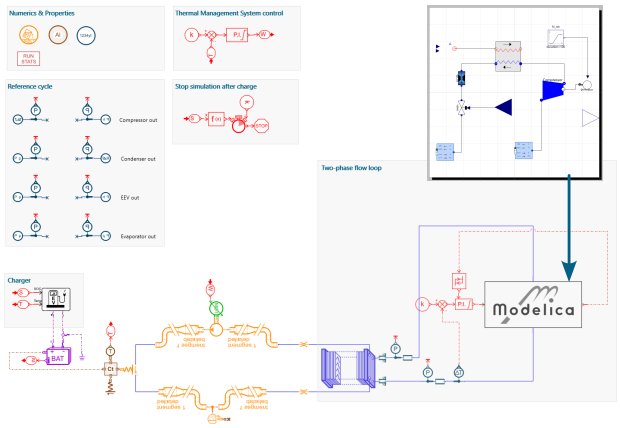

Figure 13. Heterogeneous chiller loop design for battery thermal management

For this use case, the focus is on the design of the cooling loop, composed of an evaporator from Simcenter Amesim and a compressor, condenser and expansion valve from Modelica's ThermoCycle library. The evaporator is a discretized brazed plate heat exchanger with 5 cells. The condenser from ThermoCycle is a discretized heat exchanger with 6 cells. The required cooling power is 7 kW. The evaporation temperature is set at 5°C with a superheat of 5°C. The condensation temperature is set at 55°C with a subcooling target of 7.5°C. Finally, the working fluid is R1234yf.

5.2 TPF physical interface

At evaporator boundaries, the causalities for both ports are defined as shown in the Figure 14(a). These boundaries impose the causality to the Modelica submodel. The Figure 14(b) is a representation of the Modelica TPF interface where pressure and density are given by Simcenter Amesim and specific enthalpy and mass flow are given by Modelica. The Modelica part built with ThermoCycle's submodels use the MSL connectors for the fluid. Thus, the TPF interface must be defined with a MSL fluid connector and a TPF connector.

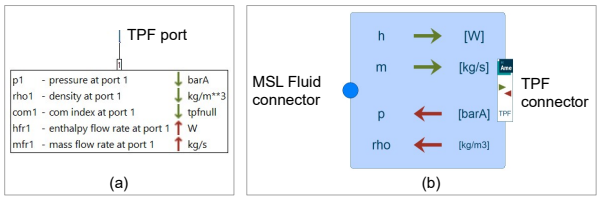

Figure 14. TPF port definition with a fixed causality. (a) Represents external TPF ports and (b) represents the corresponding TPF interface in the Modelica world

The TPF connector is coded as follows:

```
connector Portpinmout "p,rho in / m,Q
    out"
output SimcenterAmesim.Units.AMESIUnits.
    HeatFlowRate Q_flow
  "Enthalpy flow rate";
output SimcenterAmesim.Units.AMESIUnits.
    MassFlowRate m_flow "Mass flow rate";
input AmeTpfMedia.AMEUnits.
    AbsolutePressure_bar p "Pressure";
input SimcenterAmesim.Units.AMESIUnits.
    Density rho "Density";
input Real ComId(unit="tpfnull") "Com
    index";
annotation (
  __Modelon(isTopLevel=true),
  __simcenter(port(port_type="hflow")));
end Portpinmout;
```

The causalities are fixed in the good order, as well as the units and the annotations with the port type name related to the fluid domain. Note that the ComId is a communication variable specifically used in Simcenter Amesim context. This variable avoids redundant calculations and evaluates the total volume of a system by counting the number of capacitive (volume). In this demonstrator, the Modelica part receives this variable and therefore does not interfere with Simcenter Amesim.

The interface between the Modelica fluid connector and the TPF connector is coded as follows:

```
model OnePortpinmout "(R) TPF Interface"
  // Medium package
  replaceable package Medium = AmeTpfMedia.
      Media.partialMedium "Medium model";
    "Mass flow rate";
  // Connectors
  Modelica.Fluid.Interfaces.FluidPort_a
      fluidport(
    redeclare package Medium = Medium,
    C_outflow=fill(1/Medium.nC, Medium.nC),
    Xi_outflow=fill(1/Medium.nX, Medium.nX
        - 1));
  SimcenterAmesim.TPF.Interfaces.Ports.
      Portpinmout ameport(
    p(start=1),
    rho(start=500));
  // Medium state
  Medium.ThermodynamicState state=Medium.
      setState_pdX(ameport.p*1e5, ameport.
      rho);
equation
  fluidport.p = ameport.p*1e5;
  ameport.m_flow - fluidport.m_flow = 0;
  if ameport.m_flow >= 0 then
    ameport.Q_flow = ameport.m_flow*
        inStream(fluidport.h_outflow);
  else
    ameport.Q_flow = ameport.m_flow*state.h
        ;
  end if;
  state.h = fluidport.h_outflow;
  fluidport.Xi_outflow = inStream(fluidport
      .Xi_outflow);
  fluidport.C_outflow = inStream(fluidport.
      C_outflow);
end OnePortpinmout;
```

This TPF interface is made up of a replaceable package for defining the fluid, the required connectors, and a pressure- and density-dependent state functions (inputs from Simcenter Amesim). It contains also the equations

ensuring the unit consistency, the mass and energy balance and the sign consistency taking into account the Modelica `flow` and `stream` definition.

With such interface, the end-user only needs to drag and drop this class to the diagram, define the fluid and connect it to the the Modelica models as shown in the Figure 15.

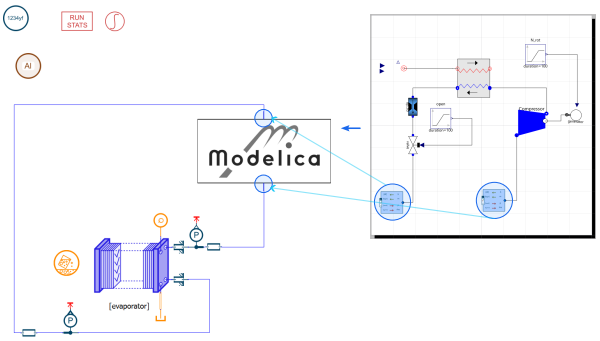

Figure 15. Heterogeneous cooling system with TPF evaporator, TPF Modelica interfaces and ThermoCycle submodels. The R1234yf is set in both worlds

5.3 Results

All submodels have been designed step by step to match the pre-design cycle calculated on the basis of the requirements listed in the descriptive section. The heterogeneous model was compared with the original homogeneous model built using only Simcenter Amesim's native submodels. Simulation time is 1000s with a tolerance of 1e-7 for both models. As shown in Figure 16, some differences in dynamics can be observed, as well as in the starting points. This is acceptable given that the compressor, the condenser, and the expansion valve found in the Modelica ThermoCycle library are not defined and built like the Simcenter Amesim's submodels replaced in this use case. Looking at the steady state, the cooling power of the evaporator sticks well to the requirement of 7 kW. The mass flow rate, pressures, and specific enthalpies are very similar in both models and are also aligned with the requirements. These observations validate the proof-of-concept that combines two modeling paradigms to build a closed-loop cooling system with its working fluid.

6 Discussion and Outlooks

In this use case, we intentionally selected the causality in order to obtain the ComId variable from Simcenter Amesim, rather than the other way around. This decision was made because our current OCT integration lacks internal communication to ensure a consistent value of the ComId from the Modelica's perspective. However, we can propose a workaround by introducing a small volume, such as a pipe, in the Simcenter Amesim component before the connection. This will reverse the causality and allow us to achieve the same conditions as demonstrated.

Furthermore, it's important to note that the connections between Modelica and Simcenter Amesim in our current

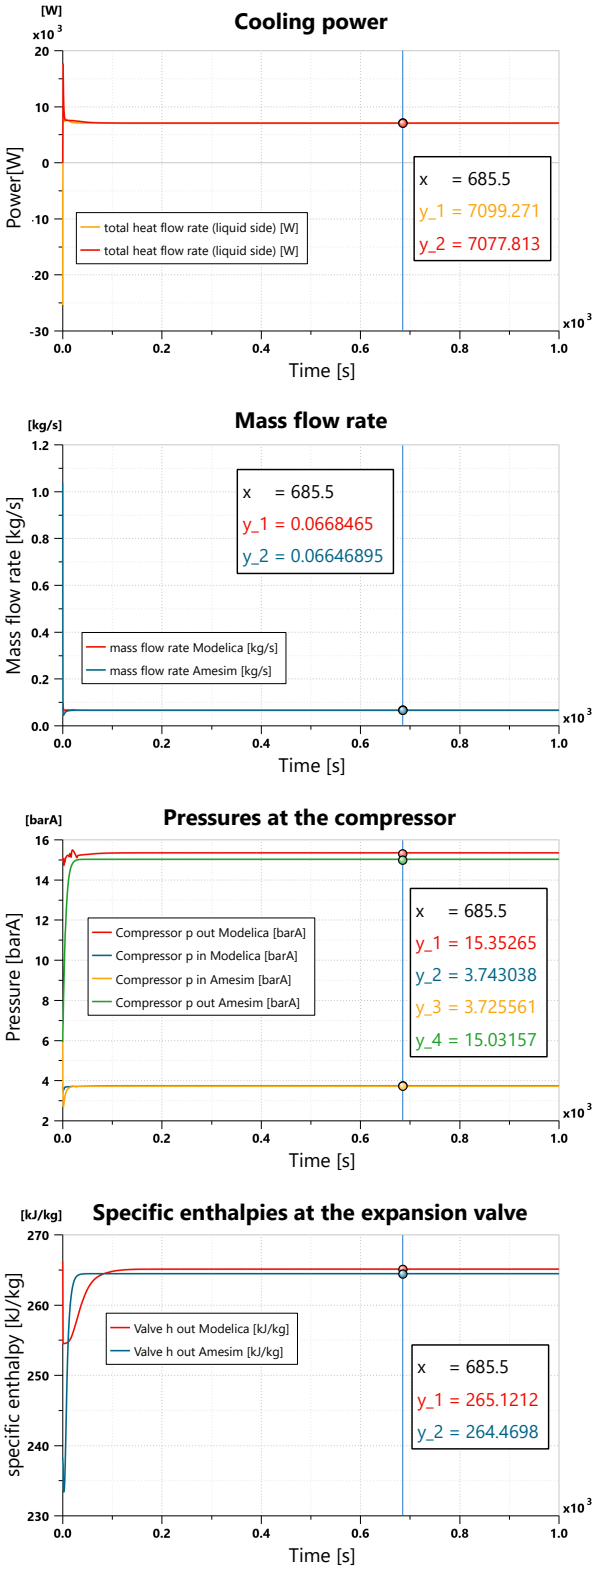

Figure 16. Comparison of simulation results between a homogeneous and a heterogeneous cooling system

demonstration are purely physical. Unfortunately, there is no capability to transmit information from Simcenter Amesim to an inner class in the Modelica world. There is currently no possibility to exchange the volume of the

system or the mass of the refrigerant between the two worlds, which could potentially impact the initialization process or certain internal variables, such as total pressure loss. To address this limitation, a workaround is to manually incorporate the correct mass, volume, or pressure loss values, calculated or fixed, in each world. However, this workaround assumes that the selected or developed Modelica library takes these factors into consideration. As a suggestion for future work, it would be beneficial to explore methods of communicating information outside the FMI standard to the compiler.

Another important milestone that has been identified pertains to AmeTpfMedia. Currently, the library only includes methods for calculating properties of a single fluid. However, TPF utilities already have the capability to calculate properties of fluid mixtures. Therefore, the next step would involve adding functionalities specifically dedicated to fluid mixtures, allowing for configuration of the number of fluids and their respective mass fractions.

7 Conclusions

This paper presented how the FMI terminals and the library AmeTpfMedia offer a new way to build heterogeneous closed loop fluid systems in Simcenter Amesim. This new solution meets needs coming from the industry where Simcenter Amesim and Modelica are most often used in separate departments. It can

A series of test cases demonstrated that AmeTpfMedia is well suited to the simulation of fluid systems, thanks to its accuracy and performance. Its architecture inherited from the MSL saves a lot of time when it comes to use open-source libraries also compatible with the MSL.

Finally, by following the steps described in the article, it becomes possible to recreate manually a Modelica physical interface to connect Simcenter Amesim to an in-house connector.

Abstract

New York State (NYS) faces significant challenges in meeting the Climate Act's bold goals of 70% renewable energy generation by 2030 and total decarbonization of the electric grid by 2040. Extensive simulations are required to assess the impact of numerous inverter-based resources (IBRs) deployed to the large-scale NYS power grid, aiming to evaluate their dynamic behavior and mitigate any negative interactions with their control schemes. However, the modeling efforts required are huge and the computational burden of large-scale simulations is extensive, and often limited by the capabilities of domain-specific tools. This work addresses these limitations by developing a Functional Mock-up Unit (FMU) of Grid-Forming (GFM) Inverters for IBR control and integrating them with an electromechanical phasor-domain power system solver. The proposed FMU facilitates the simulation and parametric studies needed to analyze large-scale IBR usage with significantly improved manual modeling and computational efforts. The paper details the process of developing and FMU model for GFM IBRs, including all relevant control loops implemented in the Modelica language and FMU integrated in OPAL-RT's ePHASORSIM^{TM} software. Our FMU models are used to successfully deploy and study the impacts of up to $6,200+$ MVA from IBRs on the 5000-bus NYS transmission system.

Keywords: Power Grid, Power Systems, Droop-based Control, Grid Forming Inverter, Inverter-based Resource, Modelica, Functional Mock-up Unit

1 Introduction

In accordance with the NYS Climate Leadership and Community Protection Act, 70% of New York State's electricity must be derived from renewable energy systems (RES) by 2030 (Senate 2023). Grid-forming (GFM) inverter-based technology stands out as a promising solution to integrate RES that are interfaced with the NYS grid via power electronics-based inverters, including wind, PV solar, and fuel cells. This is due to the ability of GFM control to independently provide voltage and frequency support to the grid with fault ride-through capabilities (Du et al. 2019). Comprehensive simulation studies are essential to evaluate the impacts of IBRs on the future NYS grid. However, modeling and simulating a large power system with GFM IBRs deployed at scale introduces substantial challenges including modeling efforts, interfacing resources, and computational requirements.

To address these challenges, this paper presents the development of a complete IBR model with a droop-based GFM control as a Functional Mock-up Unit (FMU). An FMU is a prepackaged, standardized container of user-defined models that adheres to the Functional Mock-up Interface (FMI) standard. The FMI standard is a free tool-independent standard that defines *"a container and an interface to exchange dynamic simulation models using a combination of* `.xml` *files, binaries and C code" (Modelica Association 2025).*

The main advantage of developing IBR models in Modelica is that the models can be re-utilized in different simulation platforms by exporting them as an FMU. This provides end-users with full control over model parameters and IBR control modes, making their reuse in simulation highly scalable and efficient. In addition, FMUs enhances interoperability between different simulation tools (Luigi Vanfretti, Li, et al. 2013). Common industry tools such as PSS/E, PSCAD, EMTP and PowerFactory have different ways of defining models and data, making it difficult to share them between tools (Laera et al. 2022). In contrast, using FMUs offers a *"build once, deploy anywhere"* advantage, allowing models to be easily shared and reused across different simulation platforms without the need for extensive reconfiguration. This minimizes dependencies to the C compiler and the Modelica tool (Luigi Vanfretti, Laughman, and Chakrabarty 2024). Some of the power system simulation tools that currently support FMUs include ePHASORSIM, EMTP, Pandapower, and Powerfactory. Users can also create custom models and interface them as FMUs when existing native software libraries do not offer the required models. Flexibility is key when performing large-scale power system simulation and assessing the impact of integrating IBRs, as required in NYS grid studies, and FMUs offer such advantage.

The FMU developed for the GFM IBR used in this paper is implemented in the Modelica language. Modelica is

an open-access standard and a free, object-oriented mathematical modeling language that is generally used to describe large-scale physical systems (Fritzson and Engelson 1998) and build control applications that interact with their environment (Thiele et al. 2017; Hellerer, Bellmann, and Schlegel 2014). Modelica supports component-based modeling and allows one to mathematically describe a model using differential, algebraic, and discrete equations. In addition, the Modelica Standard Library provides a plethora of components that can be reused, for example, as done in this paper to build several control loops of the GFM IBR. Using object-oriented modeling constructs, such as inheritance (Fachini, Bhattacharjee, et al. 2023), the GFM inverter model is created hierarchically. Beginning with a simple voltage source, we progressively build a controllable voltage source that is the fundamental backbone of the GFM inverter model. The generated FMU is set up to be independently tested and verified inside a Modelica-compliant tool, Dymola (Brück et al. 2002), prior to external deployment. This is one of the main advantages of using the Modelica language and Dymola, which allows to test each of the individual component of the model in isolation, a feature currently not supported by power system simulation software (Laera et al. 2022).

1.1 Literature Review

The Modelica language has been widely used for various power system applications. One notable development is the Open Instance Power System Library (OpenIPSL) (L. Vanfretti et al. 2016; Baudette et al. 2018; de Castro et al. 2023) which has power system component models written in the Modelica language for power system dynamic studies, such as phasor time-domain simulations, while allowing one to extend the modeling scope of conventional power system simulators. The authors in (Luigi Vanfretti, Mukherjee, et al. 2019; Gomez et al. 2018) develop an automatic re-synchronization controller for islanded networks within a multi-domain gas turbine and power system model using Modelica. Specifically, they used Modelica libraries such as ThermoPower (Casella and Leva 2005) to model the thermomechanical dynamics of the gas turbine and OpenIPSL for the components of the power system. The authors in (Mukherjee and Luigi Vanfretti 2018) implemented a frequency controller in Modelica for island operation in power distribution networks. This work integrated multiple Modelica blocks that include a synchronous generator, a gas turbine model, and an excitation system, Modelica noise library for stochastic load modeling and zero-order hold, and `fixedDelay` blocks for PMU reporting rates and delays.

Modelica breaks through the limits of conventional power system simulators. It allows one to conduct specialized studies that usually need various tools or separate programs for different analyses. This is beneficial, for example, in studies related to the stability of island power systems, such as those presented in (Winkler 2018). Here, different models of an island power are connected through a single transmission line to the Icelandic power grid, and their stability is analyzed. The entire transmission and generator models were built in Modelica using the OpenIPSL library, and multiple scenarios are studied for cases where connection to the national grid is lost. Another example in (Segerstrom et al. 2023) develops a Modelica-based approach to analyze subsynchronous oscillations for a lumped mass torsional shaft model with 25 masses. The Modelica implementation was shown to have two unique advantages. In addition to including shaft torsional dynamics, turbine, boiler, and governor dynamics were taken into account using components from OpenIPSL. In addition, the authors emphasize that the `Modelica_LinearSystems2` library (Baur, Otter, and Thiele 2009) allows the analysis of modal-based eigenvalues to be performed directly, eliminating the need to develop a separate model for linear analysis or the use of additional tools for this purpose (Nikolaev et al. 2020).

Microgrid modeling and simulation often exclude phasor simulations, yet they offer benefits by being computationally efficient, as they simplify the switching behavior of power electronics components. For example, the authors of (Fachini, Bhattacharjee, et al. 2023; Fachini, Pigott, et al. 2023; Fachini, Bogodorova, et al. 2024) have implemented a microgrid model using Modelica standard libraries and the OpenIPSL library (Fachini, Bhattacharjee, et al. 2023; Fachini, Pigott, et al. 2023). In (Fachini, Bhattacharjee, et al. 2023), the microgrid was developed with two combustion turbo generators and four steam turbo generators using OpenIPSL machine, prime mover, and control system models, and analyses were carried out to study contingency and modal analysis. This study was extended in (Fachini, Pigott, et al. 2023), where distributed energy resources such as PV were integrated, and fault studies were carried out. These microgrid models were also extended to perform Model Predictive Control (MPC) in (Fachini, Bogodorova, et al. 2024), where the linearized model was used to obtain the MPC solution, and time-domain simulations were performed to apply the MPC actions for safe island operation and re-synchronization.

Developing power system models with Modelica provides additional benefits brought through the FMI ecosystem of tools for new and emerging needs. An example is the `ModelicaGridData` tool which was developed and interfaced with OpenModelica and/or Dymola through their respective Python APIs to generate large data sets of different operating conditions and disturbances, which were then used to train machine learning-based stability assessment approaches (Dorado-Rojas et al. 2023). Another example in (Castro et al. 2022) illustrates how power system models built using the OpenIPSL library can be exported as FMUs to be tested on real-time simulators such as dSPACE. Other power system applications using Modelica include control coordination for HVAC/HVDC power systems (Bakhos et al. 2017; Babaeifar, Barsali, and Ceraolo 2023), implementing and validating variable-speed drive-based induction mo-

DOI 10.3384/ecp218713

tor models (Fachini, Castro, et al. 2024), building energy simulation (Luigi Vanfretti, Laughman, and Chakrabarty 2024), and special protection schemes (Jakobsen et al. 2022).

Beyond power systems, Modelica has proven effective and extensively used in other domains such as thermofluid systems (Steinmann, Herold, and Schirmer 2024), aerospace (Reiner 2022), robotics and mechatronics (Reiser and Reiner 2023), and other industrial applications (Weber, Cartignij, and Zimmer 2023).

1.2 Contributions and Paper Organization

The three specific requirements of this study include: (a) the development of GFM inverter models suitable for large-scale power system simulation, (b) parametrization of GFM inverters, and (c) minimization of both manual and computational effort required for deployment and parameterization. This paper makes the following novel contributions to address the requirements:

1. Provides a guideline for modeling droop-controlled GFM IBRs using Modelica.

2. Develops a systematic approach to validate various subsystems of the GFM IBR model inside Modelica prior to full-scale deployment.

3. Develop interfaces to generate FMUs for the GFM inverter for integration with a specific power system simulator.

4. Discusses the benefits of using FMUs for large-scale power system simulation, such as 'easy-to-build' and 'easy-to-manage' advantages that involve minimal manual intervention and improved computational performance.

5. Examining scaling up of GFM IBR deployment via FMU across the New York State 5000-bus power grid.

The remainder of this paper is organized as follows: Section 2 presents the overview of the Modelica GFM library, Section 3 discusses the development of the GFM inverter model in Dymola, followed by FMU generation in Section 4 and interfacing with OPAL-RT's ePHASORSIM in Section 5. Results from simulation studies are discussed in Section 6 followed by the conclusions from this work in Section 7.

2 Modelica GFM Library Overview

This section presents the GFM IBR library in detail, including various dependencies, packages, and subpackages. In addition, it describes how the object-oriented approach is utilized to construct the GFM IBR model.

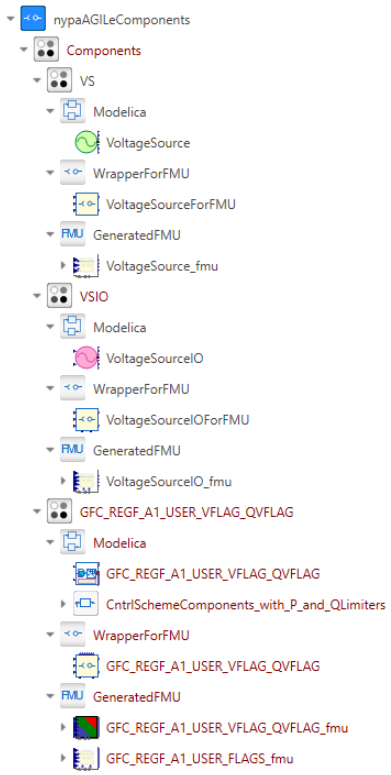

Figure 1. GFM library organization in Dymola

2.1 Organization of GFM Inverter Library

The GFM inverter components are built in the widely popular and proprietary Modelica-compliant language tool called Dymola (Brück et al. 2002). Dymola offers an intuitive graphical user interface with features that allow users to easily navigate built-in libraries and organize their own user-defined models. The GFM IBR library, called `nypaAGILeComponents`, needs to be combined with other Modelica libraries. These include two of Opal-RT's Modelica libraries, the `Opal_RT` [1], a proprietary library that uses the `Opal_RT` library to build power plant sub-systems called `GenUnit`, the Modelica Standard Library, and OpenIPSL. A snapshot of the `nypaAGILeComponents` library where the GFM inverter is built is shown in Figure 1.

There are three main components: (a) voltage source (VS), (b) controllable voltage source with input/output (VSIO), and (c) GFM control model REGFM_A1 (Du 2023). The library is organized reflecting the incremental manner in which components were developed and added. Each component has (a) the Modelica model, (b) an FMU wrapper, and (c) the generated FMU. The wrapper is a Modelica block that encapsulates the Modelica model and causalizes it when the FMU is generated. It contains the mandatory connectors, interfaces and parameters required by ePHASORSIM (described later in Section 4). In addition, each specific wrapper includes an additional set

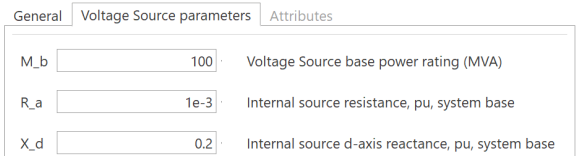

Figure 3. Simple voltage source parameters in Dymola

of parameters that the user can modify using the external tools, e.g., to select the control mode of the GFM inverter and parameterize it. The 'generated FMU' is a Modelica model that contains within the generated FMU the appropriate interfaces for use within the Modelica tool.

2.2 Model Building through Inheritance

Using inheritance, hierarchical and reusable component models were created for GFM modeling in Dymola. Each new component (such as the IBR model) inherits properties and behaviors from existing ones (such as the voltage source). This approach simplifies model development and maintenance by allowing modifications at higher levels of the hierarchy to propagate automatically to derived models. For example, the voltage source (VS) inside the GFM IBR extends from a "VS Droop model" that provides the required "measurement" outputs for the GFM controls. This component itself extends a simple VS whose voltage can be specified by external inputs, are applied to an internal impedance and couples with an acasual connector. An example of such inheritance is given through the statement: `extends VSIO.Modelica.VoltageSourceIO VS();`.

3 Droop-based GFM Components

The GFM inverter operates as a controllable VS behind a coupling reactance (Du et al. 2019). To understand the GFM inverter modeling in Dymola, we start with the design and validation of a simple VS, which forms the basis for the controllable VS that is needed for the GFM model. The controllable VS is followed by two droop-based control architectures (P-f and Q-V), overload limiters and a fault current limiter, as described below.

3.1 Simple Voltage Source

Consider a simple VS with an internal impedance of $R_a + jX_d$ connected to a bus shown in Figure 2. The objective is to find the internal voltage $E\angle\delta_E$ of the source from the active and reactive power (P and Q) measurements at the Gen1 terminal bus. The terminal voltage is denoted as $V\angle\delta_V = V_r + jV_i$. The current equation is given as:

$$I^* = \frac{P+jQ}{V_r+jV_i} = \frac{PV_r - jPVi + jQV_r + QV_i}{V_r^2+V_i^2} \tag{1}$$

The real part of the current is:

$$\Re\{I^*\} = I_r = \frac{PV_r + QV_i}{V_r^2+V_i^2} \tag{2}$$

The imaginary part of the current is:

$$\Im\{I^*\} = I_i = \frac{PVi - jQV}{V_r^2+V_i^2} \tag{3}$$

With internal source impedance of $R_a + jX_d$, the internal voltage ($E = E_{mag}\angle E_\delta$) is given as:

$$E = (I_r + jI_i)(R_a + jX_d) + (V_r + jV_i) \tag{4}$$

The real part of the internal voltage is:

$$\Re\{E\} = E_{real} = V_r - I_iX_d + I_rR_a \tag{5}$$

The imaginary part of the internal voltage is:

$$\Im\{E\} = E_{imag} = V_i + I_iR_a + I_rX_d \tag{6}$$

An excerpt of the VS model with parameters such as base and internal impedance is shown in Figure 3. The VS is implemented in Modelica, as shown in Listing 1. The terminal voltage values are interfaced with the mandatory (required by ePHASORSIM) connector of the `Opal_RT` library, `Powerpin (PwPin)`, through `p.vr` and `p.vi`. Details on PwPin and interfacing can be found later in Section 4.4.

3.1.1 VS Parameter Initialization

Using the VS parameters shown in Figure 4, the component is initialized as shown in the Listing 2. Note that we explicitly define variables with `start` values for initialization not only to provide a good starting guess value for the numerical solvers when simulating from different starting steady-state operating conditions, but also because these values need to be modified when the model is exported as an FMU to be used in a power system simulator.

Listing 1. Snippet of the Internal Voltage Source Equations

```

```

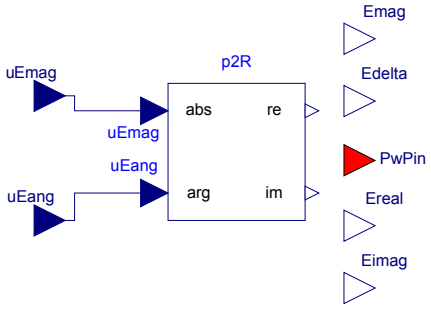

Figure 5. Controllable voltage source with two inputs

3.2 Controllable Voltage Source

The controllable VS is developed in Dymola based on the equations of the simple VS given in Equations (1) - (6). The controllable VS has two inputs `uEmag` and `uEang`, as shown in Figure 5, to vary the voltage magnitude and angle of the VS, respectively. To increase flexibility and facilitate testing, the input to the controllable voltage source can be provided from two sources: (a) Case 1: inject a voltage phasor to define the internal voltage of the source from an external tool (e.g., a power system simulator like ePHASOSRSIM), and (b) Case 2: inject a signal that is a deviation from the initial value of E0 and delta0 for internal testing. These two cases are shown in Listing 3.

Listing 3. Internal equations for controllable VS

```
if Case 1 then "input from external tool"
    E = uEmag;
    delta = uEang;
    Er = p2R.y_re "Real part of E";
    Ei = p2R.y_im "Imaginary part of E";
else "deviation from initial value"
    E = E0 + uEmag;
    delta = delta0;
    Er = Er0 + p2R.y_re;
    Ei = Ei0 + p2R.y_im;
```

3.3 Droop-based GFM Inverter Model

The controllable VS is used as a basic building block to build the GFM IBR model. Similarly to the controllable VS in Figure 5, the GFM inverter model has two inputs: `uEmag` and `uEang`. The input `uEang` that controls the voltage angle is determined by the P-f control loop, and `uEmag` that controls the voltage magnitude is determined by the Q-V control loop. The complete GFM IBR model, along with its control scheme, is shown in Figure 6.

3.3.1 Active Power-Frequency Droop-based Control

The active power-frequency (or P-f droop) droop-based control adjusts the output frequency of the inverter in response to changes in active power output. With $E\angle\delta_E$ as

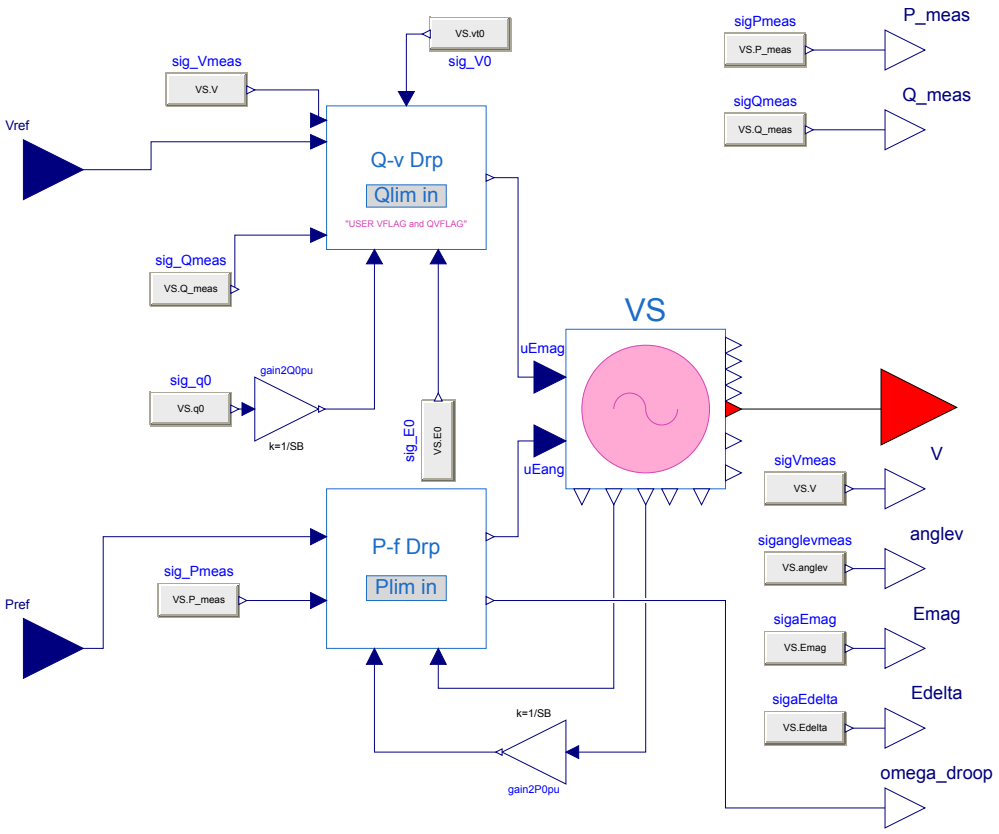

Figure 6. GFM Inverter Dymola Model Block Diagram

the internal voltage phasor and $V\angle\delta_v$ as the terminal voltage phasor, the active power output of the inverter P can be written as (Du 2023),

$$P \approx \frac{EV}{X_L} sin(\delta_E - \delta_v) \approx \frac{EV}{X_L}(\delta_E - \delta_v) \tag{7}$$

When a setpoint change or a disturbance causes the inverter active power to increase, the P-f droop-based control reduces the angular frequency ω of the internal voltage to reduce the inverter power output (Rocabert et al. 2012), which is modeled as a change in δ_E (Du 2023). The P-f droop-based control also ensures that multiple GFM inverters share power relative to their active power capacities under disturbances. The overall P-f droop-based control architecture is shown in 7, and the detailed P-f droop-based control loop is shown in Figure 8. The P-f droop loop takes the error between the reference active power `Pref` and the measured active power `Pfilt` (after passing through a low pass filter) as input, and provides the internal voltage phase angle and angular frequency of the VS as output. There is an auxillary input signal from the output power limiter block that prevents the active power output of the inverter from exceeding its limits. Note that the integrator in the control loop is initialized with the value `delta0` as discussed in Section 3.1.1 (see line 35 in Listing 2).

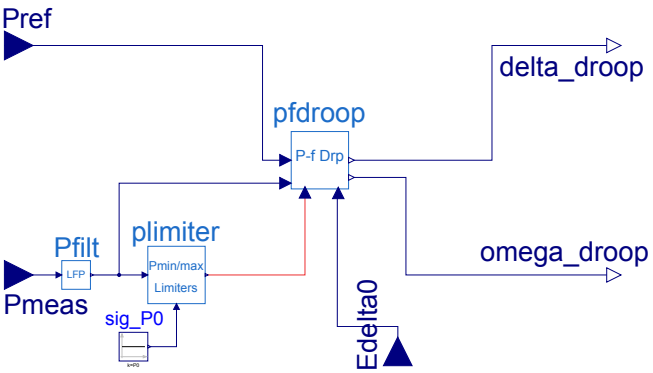

Figure 7. P-f Droop-based Control Architecture

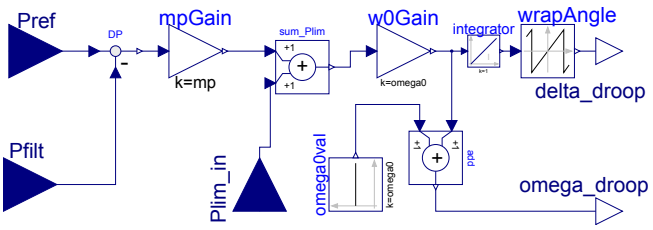

Figure 8. P-f Droop-based Control Function

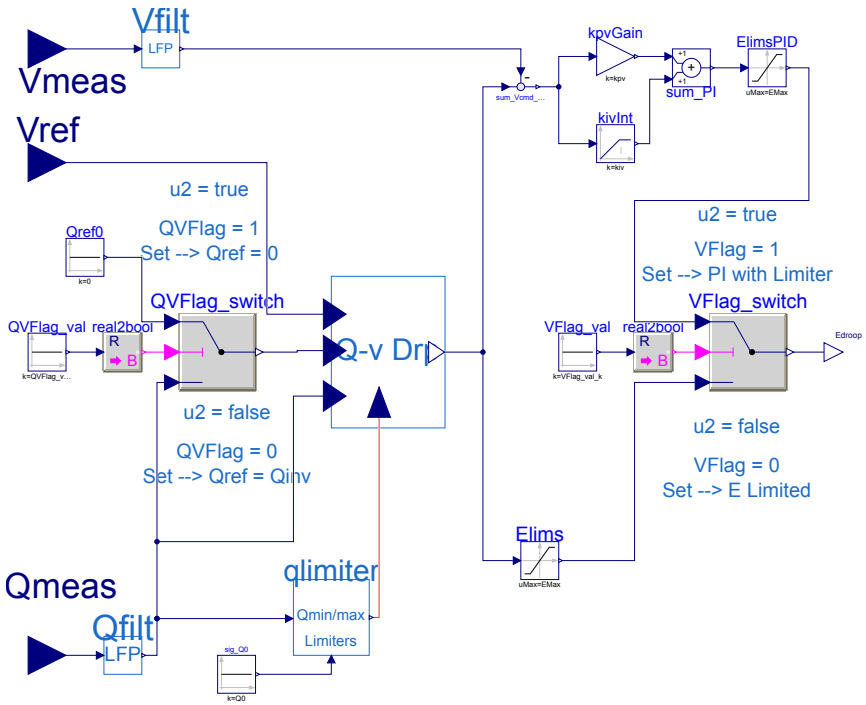

Figure 9. Q-V droop-based control architecture

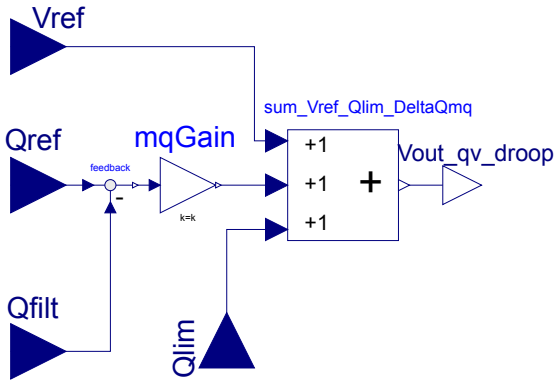

Figure 10. Q-V Droop-based Control Function

3.3.2 Reactive Power-Voltage Droop-based Control

The reactive power-voltage (or the Q-V) droop-based control adjusts the inverter reactive power output in response to changes in the voltage at its terminals. The reactive power output of the inverter can be written as (Du 2023),

$$Q \approx \frac{E^2 - EV\cos(\delta_E - \delta_v)}{X_L} \approx \frac{E(E-V)}{X_L} \tag{8}$$

When there is a step change in voltage setpoint or an event disturbs the terminal voltage, the Q-V droop-based control manipulates the magnitude of the internal voltage of the inverter to adjust the reactive power output accordingly. The Q-V droop has two voltage control modes; it can either regulate: (a) the internal voltage, $E\angle\delta_E$, or (b) terminal voltage, $V\angle\delta_V$, which is determined by the setting of `VFlag`. In addition, the Q-V droop has two reactive power control modes that are set by `QVFlag`, which can be set to represent the plant controller strategy of adjusting either the reactive power or voltage setpoint. When multiple GFM inverters are connected to the grid in parallel, the Q-V droop-based control prevents the circulation of the reactive power.

The input/output and control blocks of the Q-V droop scheme are shown in Figure 9. The Q-V droop model takes as input the reference voltage, the measured reactive power (after passing through the low-pass filter) and two flags, `VFlag` and `QVFlag`, and provides the internal voltage magnitude as output, as shown in Figure 10. In addition, the auxiliary signal from the output power limiter block prevents the reactive power output of the inverter from exceeding the converter's limits. Note that the integrator in the control loop is initialized with the value `v_0` as discussed in Section 3.1.1 (see line 9 in Listing 2).

3.4 Overload Limiters

For both control loops, there are corresponding maximum and minimum MW and MVAR limits to prevent the inverter from exceeding rated capacities. The block diagram for the limiters are shown in Figure 11 and Figure 12.

3.5 Fault Current Limiting Function

When there is a short-circuit and fault currents are very high (exceeding inverter rated current I_{maxF}), the GFM internal voltage $E\angle\delta_E$ will be calculated based on the inverter terminal voltage $V\angle\delta_v$, coupling reactance X_L and current phasor $I_{maxF}\angle\phi_{lim}$, which represents the limited current. The GFM internal voltage under fault conditions is given as:

$$E\angle\delta_E = V\angle\delta_v + jX_L I_{maxF}\angle\phi_{lim}. \tag{9}$$

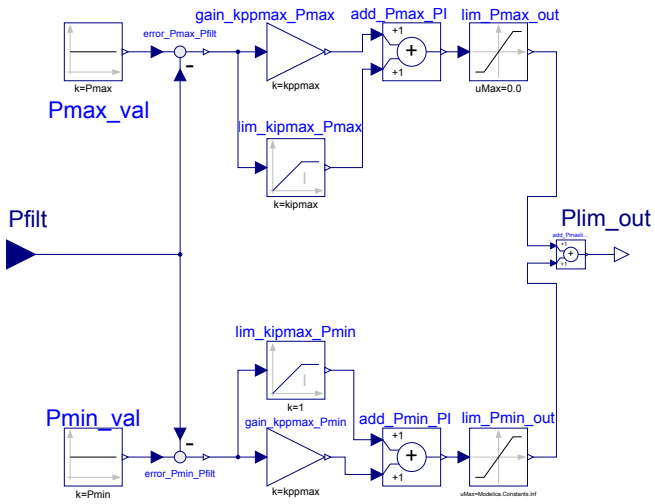

Figure 11. MW Limiter

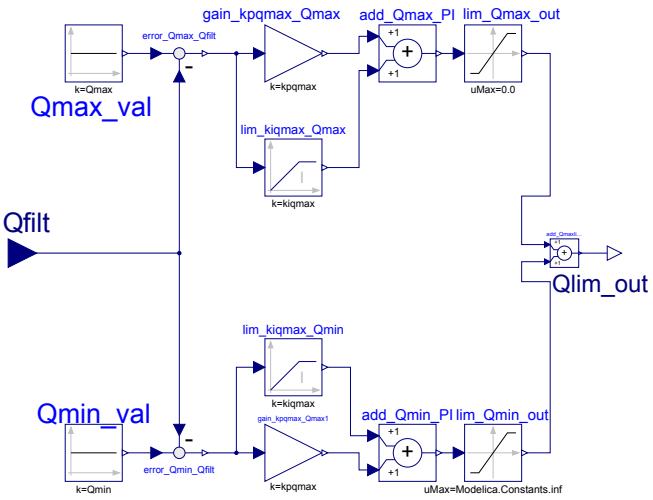

Figure 12. MVAR limiter

Due to space limitations, block diagrams for current limiters are not shown in this paper.

4 FMU Generation

In this section, we briefly discuss how Modelica model is setup to generate an FMU.

4.1 System Dependencies

To generate FMUs using Dymola, compatible with Windows and Linux (required by the ePHASORSIM simulator from Opal-RT), the following dependencies are necessary: Windows 10 or later versions, a suitable compiler for C++ (such as Visual Studio 2019 with the 'Desktop development with C++' workload enabled), and Windows Subsystem for Linux (WSL) 2 with Linux kernel update package.

4.2 Windows Subsystem for Linux (WSL)

The cross-compilation feature available in Dymola allows Dymola to compile models to be used on a Linux target. This is done through WSL, which enables a Linux system to run inside a Windows machine using WSL. FMUs generated with this feature can be executed by software tools native to Windows and Linux-based operating systems (OS). This is because the generated FMU will have specific target binaries for each of those OSs. ePHASORSIM crucially needs this feature since it relies on Windows for offline and Linux for real-time simulations.

4.3 FMU with and without Source Codes

FMUs can be generated with or without the C source code. With Dymola, this capability depends on whether or not the user has a license that enables code export. Regardless, both options are useful, since a user with a local "vanilla" Dymola license could regenerate the FMUs and execute off-line local simulations. Export of source code is only required when running the ePHASORSIM in real time. For FMUs without source code, the FMU package contains only the compiled binaries of the model, not the C source code used to build the binary (.dll or .so). With the source code export, users can recompile the FMU's code, offering greater flexibility.

ePHASORSIM has specific requirements for the FMUs it receives from Dymola, for example, it requires that internal variables of the FMU can be accessed, which is enabled in Dymola with the flag `Advanced.FMI.BlackBoxModelDescription := flase`. In this paper, we create the `FMUExportUtilities` feature that allows to create FMUs both with and without source code with the required flags for import in ePHASORSIM. Figure 13 shows the GUI of the function call used to generate the FMU with/without source code. Listing 4 shows the flags necessary to generate the FMU with source code from Dymola while taking into account the requirement of the availability of the source code generation license for code export. Note that OPAL-RT ePHASORSIM currently supports FMI version 1. While three types of interfaces are defined in FMI standard, we are interested in the FMI for Model Exchange (ME). ME implements only the model and not the required solution. It exposes the differential equations to an external solver that imports the model and performs numerical integration.

4.4 Testing of Models and FMUs in Dymola

The models and FMUs generated by Dymola are tested within the Dymola interface before interfacing with ePHASORSIM. In this section, we demonstrate both (a) testing the Modelica model within a power system model and (b) testing the FMU in Dymola within a power system model.

The GFM inverter model is tested within a power system modeled using OpenIPSL. A Single Machine Infinite Bus (SMIB) system with one load is extended from the OpenIPSL library using `extends OpenIPSL.Tests.BaseClasses.SMIB(SysData(fn=60), pwFault(R = 1e-6, X = 1e-3, t1 = 32.0, t2 = 32.15))` with a fault duration of 0.15 s. The setup is shown in Figure 14.

To connect the GFM model with the OpenIPSL SMIB within Dymola, the `Powerpin (PwPin)` connector is used by instantiating it from the `OPAL_RT` class `OpalRT.NonElectrical.Connector.PwPin`. The `PwPin` is required by ePHASORSIM, as when the FMUs are loaded, ePHASORSIM will determine if `PwPin` has been used or not. This is done by the software to force conformance to its internal numerical solver interface. The `PwPin` has two flow variables (`ir` and `ii`) and two potential variables (vr and vi). The implementation of `PwPin` is given in Listing 5.

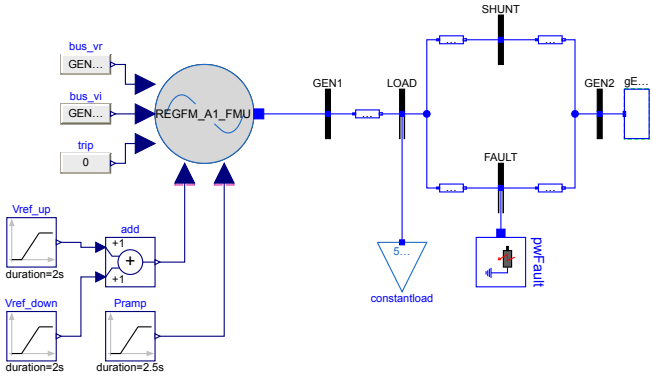

Figure 15. Testing GFM FMU in Dymola within a power system model built using OpenIPSL.

Listing 5. `PwPin` Connector from `Opal_RT`'s library

```
connector PwPin
    Real vr "real part of the voltage";
    Real vi "imaginary part of the voltage";
    flow Real ir "real part of the current";
    flow Real ii "imaginary part of the current"
        ;
end PwPin;
```

To interface the GFM model developed according to ePHASORSIM's requirements (with `PwPin`) with electrical components from the OpenIPSL library inside Dymola, an additional connector is required. In this connector, the variables of `PwPin` (instantiated as `pwPinA`) are assigned to the corresponding variables of the OpenIPSL electrical connector (instantiated as `pwPinB`). The interface between the power pins of both libraries is shown in Listing 6. This setup is used to test all models and submodels inside Dymola.

Listing 6. Code Excerpt of the Connector Interfacing the `Opal_RT` and OpenIPSL Libraries

```
model Opal2OpenIPSL "Interface between power
    pins of both libraries"
equation
  pwPinB.vr = pwPinA.vr;
  pwPinB.vi = pwPinA.vi;
  pwPinB.ir = pwPinA.ir;
  pwPinB.ii = pwPinA.ii;
end Opal2OpenIPSL;
```

The generated FMU model is also tested within a power system modeled in Dymola. A similar setup is shown in Figure 15.

Note that the `nypaAGILecomponents` library was developed and tested with Dymola 2024X and compatibility with other Modelica-compliant tools has not been verified. Meanwhile, the Opal-RT library is compatible with both `OpenModelica` and Dymola, while the `OpenIPSL` is compatible with Dymola, OpenModelica, Modelon Impact, and Wolfram SystemModeler.

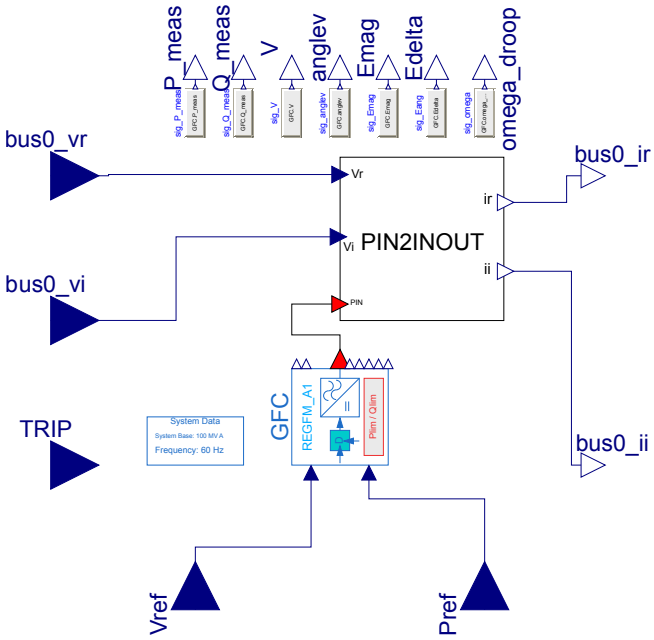

Figure 16. Wrapped GFM Model with Required Interfaces by ePHASORSIM for Export as FMU

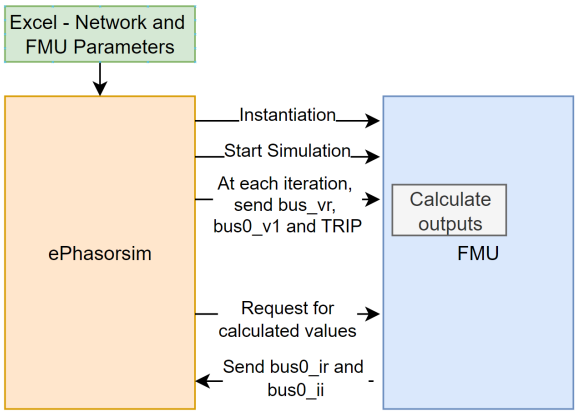

Figure 17. Flowchart of communication between OPAL-RT ePHASORSIM and FMU

5 Interfacing FMUs with ePHASORSIM

5.1 FMU - ePHASORSIM `PIN2INOUT` Interface

To interface the FMU with ePHASORSIM, an FMU wrapper is created. As discussed in Section 2.1, the wrapper includes the mandatory connectors, interfaces, and parameters required by ePHASORSIM and the set of parameters that the user can modify using external tools. The FMU wrapper is shown in Figure 16.

A `PIN2INOUT` block is required by ePHASORSIM to be used as an interface with FMU, which enforces the input (voltage) and generates (current) outputs as expected by ePHASORSIM. OPAL-RT's ePHASORSIM requires the mandatory `PwPin`. The block `PIN2INOUT` converts the acasual `PwPin` variables to casualized signals, defining the voltages as inputs and currents as output with the current flow direction required by ePHASORSIM. Listing 7 an excerpt of the `PIN2INOUT` block source code.

Listing 7. Excerpt of the `PIN2INOUT` block

```
block PIN2INOUT
equation
  p.ir = -ir;
  p.ii = -ii;
  p.vr = vr;
  p.vi = vi;
end PIN2INOUT;
```

5.2 Data Exchange between ePHASORSIM and FMU

Figure 17 shows the data exchange between OPAL-RT ePHASORSIM and the FMU generated from Dymola. In ePHASORSIM, all parameters for a power system model are defined in an Excel file. Once ePHASORSIM reads the network and FMU parameters from the Excel file, it instantiates the FMU and passes the parameter data to it. ePHASORSIM uses a fixed time-step solve, hence, at each simulation step, it sends the terminal bus voltage real and imaginary values, `bus0_vr` and `bus0_vi`, and any inputs defined in the wrapper to the FMU. The FMU equations are evaluated with the received values, and the results are sent back to ePHASORSIM in the form of real and imaginary current injection values `bus0_ir` and `bus0_ii`, and any of the output values included in the FMU wrapper. ePHASORSIM then solves for all variables within its internal models and assembles the overall network solution.

6 Simulation Results

6.1 Controllable Voltage Source

As discussed in Section 4.4, the models are interfaced to the OpenIPSL SMIB for testing within the Dymola environment. Testing within Dymola itself offers the advantage of efficient debugging, validation, and iterative development of models and FMUs without the need for external tools. The setup for testing the controllable VS is shown in Figure 18.

Figure 19 shows the responses of the internal magnitude and angle of the controllable voltage source to the ramp functions within Dymola. For `Emag`, the ramp was activated at 4 s., changing the value from 1.01439 p.u. to 1.03439 p.u. within 1 s. For `Eang`, the ramp was activated at 6s changing the value from 0.149386 rad to −0.243364 rad within 3 s. Meanwhile, Figure 20 shows the response of the active and reactive power, P and Q. It becomes apparent from the plot how a change in the internal voltage source δ_E has a direct impact on P according to Equation (7), while changes in E have a direct impact on Q as per Equation (8).

6.2 Implementation of GFM inverter FMU on NYS Transmission

GFM IBRs, modeled as FMU, were integrated into the NYS 5000-bus, 800-machine transmission system in ePHASORSIM. In addition to the GFM components, models of synchronous generators (SG), exciters, turbines, wind generators, and power system stabilizers, developed using Modelica language and exported as FMU, were interfaced with ePHASORSIM. A total of 9 GFM IBR with 6,272.5 MVA capacity was configured to substitute traditional generators within the NYS transmission system. The impact on the transient stability was analyzed under different conditions, such as changes in GFM active power and voltage setpoints. For example, Figure 21 shows the response of when the MW set-point on one IBR increased from 187.46 MW to 300 MW. Figure 22 shows the response of the IBRs when the voltage setpoint on target bus was changed from 1.019 p.u. to 1.017 p.u. This demonstrates that the FMU generated from Dymola is successfully integrated with a large-scale power system, highlighting the approach that is easy to deploy, scalable, and computationally efficient.

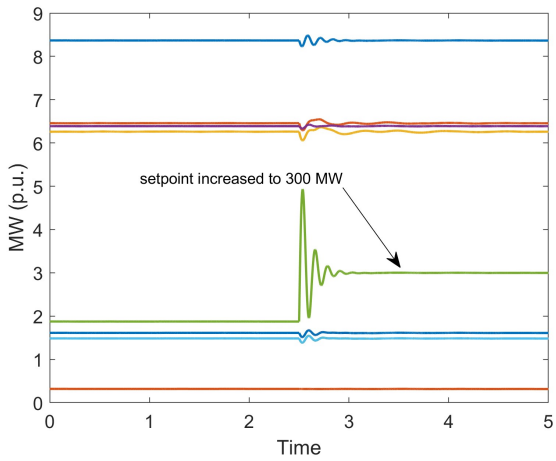

Figure 21. GFM response to changes in MW setpoint in OPAL-RT ePHASORSIM

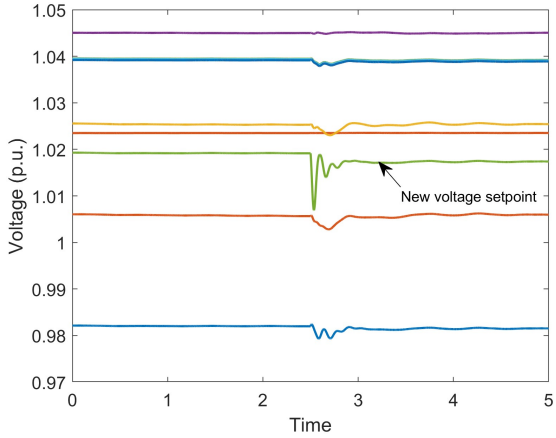

Figure 22. GFM response to changes in voltage setpoint in OPAL-RT ePHASORSIM

Table 1. Comparison between Simulink-Based and FMU-Based GFM IBR Deployment in ePHASORSIM

Aspect	**Simulink-Based Deployment**	**FMU-Based Deployment**
Controller Integration	Manual copy-paste of droop-based GFM controller block each time	Controller is pre-embedded in FMU; no need for repetition
Signal Wiring	Manual setup for each new GFM (all inputs/outputs to/from solver)	Minimal signal mapping (e.g., `Pset`, `Vset`) required
Model Scalability	Tedious and error-prone with more GFMs	Easily scalable to large numbers of GFMs (e.g., hundreds)
Transformer Setup	Details must be manually specified in Transformer sheet	Can be included directly in FMU or in the additional FMU-named sheet
Error Probability	High, especially with manual wiring and naming	Lower, due to fewer steps and more automation
Time Efficiency	Time-consuming due to repetitive steps and complex wiring	Very time-efficient and streamlined for high GFM penetration
Maintenance & Debugging	Difficult to trace and fix due to signal complexity	Easier maintenance

One significant advantage observed during the development process was the ease and efficiency of deploying FMUs with ePHASORSIM compared to using MATLAB/SIMULINK to build and deploy IBRs manually. A detailed comparison of both approaches is given in Table 1. These demonstrate that FMUs are the ideal candidates for efficient and scalable simulation.

7 Conclusion

This paper demonstrates the advantage of developing and deploying FMUs for large-scale power system simulations. A grid-forming inverter model was developed in Modelica with Dymola and integrated as an FMU with OPAL-RT's ePHASORSIM simulator to evaluate the impact of widespread renewable energy integration on the NYS transmission system. The development of the GFM FMU inverter was made easier through the object-oriented modeling features of Modelica. First, a generic voltage source model was implemented which was then extended to create a controllable voltage source and was further extended to develop the GFM-controlled inverter. With a 'build-once deploy-anywhere' approach, this paper shows that FMU offers significant time savings in modeling, debugging, and parametrization compared to other power system simulation approaches. The FMUs were tested inside Dymola and integrated with the NYS 5000−bus system in ePHASORSIM. In future, we will extend our work by (a) building FMU models for the virtual synchronous machine GFM model, (b) exploring FMU interoperability by deploying FMUs on different power system simulation tools and (c) investigating the impact of IBR parameter uncertainties on overall system stability.

Abstract

Steam power systems, as one of the critical power systems in industrial applications, require rigorous design and verification processes. Model-Based Systems Engineering (MBSE) provides a structured approach to decomposing system architecture from top to bottom and enabling multi-disciplinary collaborative design, ensuring precise requirement management and efficient design processes. To accelerate the iterative design and verification of steam power systems, this paper employs the SysML language to conduct requirement, functional, structural, and parametric analyses, thereby completing the system architecture design. The seamless transformation from system design architecture to system simulation architecture is achieved based on the SysML-to-Modelica tool. Additionally, Modelica simulation technology is utilized to construct simulation models and perform dynamic scenario analyses of the system. Innovatively, this paper proposes a closed-loop technical approach for steam power system design, simulation, and verification, which effectively optimizes system design and improves the efficiency of both design and verification processes.

Keywords: MBSE, Steam Power System, SysML, Modelica

1 Introduction

With the rapid advancement of industrial technology, the complexity of engineering systems has increased dramatically, and traditional systems engineering (TSE) is increasingly showing limitations in addressing the design and verification of complex systems. Meanwhile, the rapid development of information technology centered on modeling has provided new solutions for systems engineering. Driven by requirements and technology, the International Council on Systems Engineering (INCOSE) officially proposed Model-Based Systems Engineering (MBSE) in its Vision 2020 for Systems Engineering in 2007, clarifying the trend of future methodological and technological evolution in systems engineering toward MBSE. As the application of modeling methods in engineering activities, MBSE spans the entire process from top-level conceptual design to physical implementation, relying on interdisciplinary expertise to unify the expression of complex system development methods, thereby promoting interdisciplinary integration and the implementation of large-scale complex systems.

Currently, MBSE is widely applied in the design of complex large systems, particularly in the fields of aeronautics, astronautics, and shipbuilding, where significant achievements have been made. Overseas research institutions have deeply explored the foundational theories and modeling mechanisms of MBSE and conducted application studies. For example, in 2009, the U.S. National Aeronautics and Space Administration (NASA) applied MBSE to evaluate the practicality of new technologies, construct test and evaluation architecture configurations, and develop mission operation concepts[1]. The U.S. Navy has applied MBSE to the configuration management of hardware and software in submarine combat systems, achieving parallel management of internal and external interfaces in the Submarine Warfare Federated Tactical Systems (SWFTS), which includes over 20 projects, 35 subsystems, and 50,000 model elements[2]. In China, the China Shipbuilding Systems Engineering Research Institute, addressing the high complexity and strong integration of ship systems, adopted MBSE methods in the development of shipborne electronic countermeasure systems, successfully resolving design challenges associated with traditional systems engineering[3].

However, despite significant achievements in complex system design, MBSE still faces the following challenges in the specific domain of ship steam power systems: 1) The limitations of traditional systems engineering methods in complex system design, which struggle to effectively address the complexity of multi-disciplinary coupling and requirement management; 2) The potential of MBSE in ship steam power systems has not been fully realized, particularly in the systematic solutions for multi-disciplinary modeling and simulation verification; 3) Existing methods fail to comprehensively cover system performance and reliability assessments

during design verification and optimization, leading to long development cycles and high costs.

This paper focuses on ship steam power systems and employs MBSE methods based on SysML and Modelica languages. Using SysML, it establishes models for requirements, functions, architecture, and parameters, completing stakeholder analysis, requirement analysis, functional analysis, structural analysis, and parametric analysis. Modelica is used to build system simulation models to verify system requirement indicators and validate functional logic. This approach integrates forward design processes with bottom-up design and simulation, driving debugging simulation, co-simulation, system verification, and process validation. By exposing design issues early, this method reduces the number of product development iterations, lowers costs, shortens development cycles, and improves the efficiency of complex system design and development. This study provides a systematic solution for the efficient design and verification of ship steam power systems and promotes the application and development of MBSE in complex ship power systems.

2 System design method

2.1 Steam Power System Architecture Design

Steam power systems[4] use thermal energy as the driving force to convert water into high-temperature, high-pressure steam. This steam is then transformed into mechanical energy through turbines and other mechanical components, which drives generators to produce electricity. The system includes functions such as steam generation and transportation, steam condensation, exhaust steam transportation, equipment cooling, equipment lubrication, and steam sealing and extraction. These functions correspond to subsystems such as the steam system, condensate system, exhaust steam system, cooling water system, lubricating oil system, and steam sealing and extraction system. The subsystems interact through thermodynamic equipment. For example, turbines convert high-temperature, high-pressure steam from the steam system into mechanical energy and exhaust steam, which is transported by the exhaust steam system to the condenser. The lubricating oil cooler facilitates heat exchange between the cooling water system and the lubricating oil system, ensuring proper cooling of the lubricating oil. The logical interactions between subsystems in steam power systems are complex, involving a large number of components and design considerations spanning multiple disciplines, including thermodynamics, mechanical design, fluid mechanics, and control systems.

In recent years, traditional document-based methods[5] have shown the following limitations in complex system design: 1) Complex document management, making it difficult to track requirement changes and design iterations; 2) Lack of visualization and structured expression, making it challenging to clearly describe the logical relationships of complex systems; 3) Dispersed design processes, hindering multi-disciplinary collaborative design; 4) Low efficiency in verification and optimization, making it difficult to identify potential issues early, leading to long development cycles and high costs. Due to their lack of flexibility and reusability, traditional document-based design methods are gradually being replaced by model-based systems engineering (MBSE) approaches. Driven by advancements in computer and software technologies, MBSE has been widely applied in system modeling and design. This paper combines SysML language and Modelica simulation technology to achieve design and verification of steam power systems, optimizing system design management. The SysML models were constructed using SysBuilder software developed by Suzhou Tongyuan Soft Control Information Technology Co., Ltd. This tool serves as a system architecture design environment for complex engineering systems, adhering to the SysML specification. By taking user requirements as inputs, SysBuilder employs graphical, structured, and object-oriented methodologies to comprehensively support system development phases, including requirement modeling, functional analysis, architectural design, and verification/validation processes.

The three key elements of MBSE forward design are: modeling tools, modeling languages, and methodology. Among these, methodology, as the core of system architecture design, is the most critical. Based on the traditional MBSE framework (Requirements, Behavior, Structure, Parameters) and combined with the multi - level complex structural characteristics of the steam power system, this paper develops a matrix - based system architecture design method. (as shown in Figure 1). The entire design process is decomposed into three levels: system, subsystem, and equipment, with specific design content divided into four parts: requirements, behavior/function, structure, and parameters.

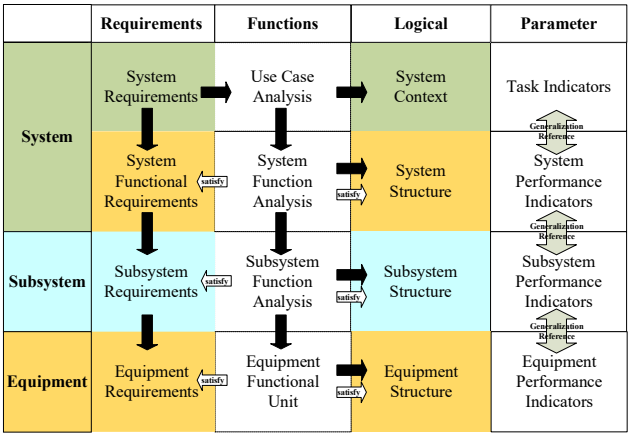

Figure 1. Matrix methodology for steam power system architecture design.

The architecture design of a steam power system starts from the overall requirements articulated by stakeholders

DOI 10.3384/ecp218727

and can be divided into two parts as inputs to guide the design: one part is functional requirements that describe the system's functionalities, while the other part is non-functional requirements that describe system performance constraints. Functional requirements are translated into the system's external capabilities, states or behaviors, while non-functional requirements are transformed into constrained indicators used for checking and validating system performance. Based on these principles, the functional activities and hierarchical structure of the system level (steam power system), subsystem level (steam system, condensate system, cooling water system, low-pressure steam system, sealing and extraction system, lubrication system) and equipment level (turbine, feedwater pump, condenser, vacuum pump, oil cooler, deaerator, etc.) are analyzed. Requirements are traced throughout the process to ensure that the overall requirements articulated by stakeholders are fully covered, and performance indicators are decomposed and verified through layers of indicators assignment and calculation as design constraints. As shown in Figure 1, black one-way arrows illustrate the process flow of system design, white single-direction arrows represent tracing and verification of requirements, and green two-way arrows represent decomposition and validation of performance indicators.

Based on the steam power system architecture design methodology described above and using the SysML modeling language, this paper models the steam power system using the MWORKS system architecture design software. As shown in Figure 2, this is the logical architecture of the steam power system, which reflects the main components of the steam power system and the logical interactions between them. The differently colored lines represent different object flows.

Further analysis of the system hierarchy architecture, each subsystem and equipment are designed until meeting the requirements of the model granularity. As shown in Figure 5, this is the subsystem architecture of the steam power system, including the cooling water system, lubrication system, low-pressure steam system, sealing and extraction system, steam system, and condensate system. Finally, each equipment and subsystem are simplified and assembled from bottom to top to obtain the overall architecture of the steam power system.

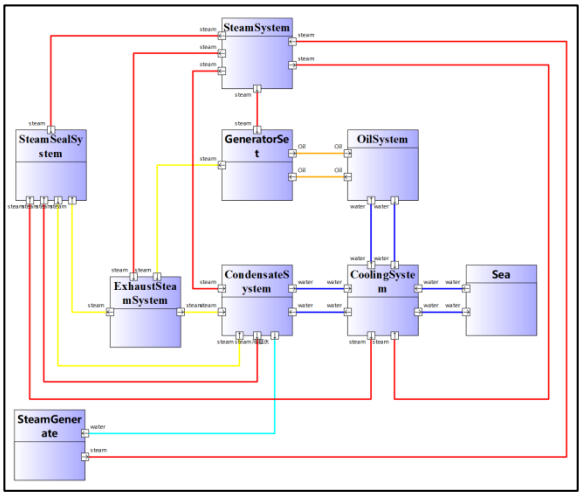

Figure 2. Steam power system architecture

Building upon the steam power system architecture, this study employs the automated SysML-to-Modelica conversion interface within the MWORKS platform to transform architectural models into simulation-ready models. This conversion mechanism operates on the principle of XMI (XML Metadata Interchange)-based model-to-library mapping. Specifically, it parses XMI files generated from SysML to extract critical metadata, including:

- Model organizational hierarchy (XMI, Model, Package)
- Component definitions (ownedAttribute)
- Interface connections (ownedConnector, End)
- Inter-object relational topology

The process extends SysPhs semantics to comprehensively convert parametric constraints, connection dependencies, and governing equations embedded in the design model. Through a GUI-driven workflow, engineers can:

- Select framework templates for physical model encapsulation
- Configure mapping rulesets (type matching, interface binding)
- Generate executable Modelica standalone models or reusable component libraries

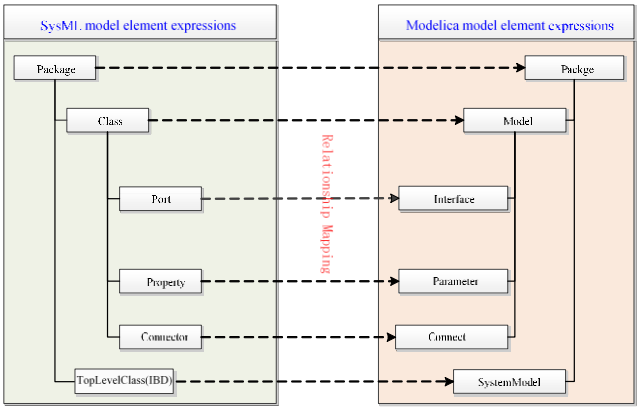

Figure 3 Mapping relationship between SysML model and Modelica model

The platform further provides co-simulation capabilities for iterative debugging and validation of converted models, ensuring behavioral consistency with original architectural specifications[6]. As shown in Figure 4, this is the architecture of the steam power system simulation model.

2.2 Steam Power System Simulation Model Implementation

Modelica is a multi-domain physical system modeling language that uses non-causal and declarative modeling techniques and supports almost all engineering disciplines. The language follows object-oriented programming principles and employs a hierarchical mechanism, component connection mechanism, and inheritance mechanism for model construction, thus simplifying the complexity of the model structure. Unlike Simulink modeling, where mathematical models need to be derived as definite causal relationships with fixed data flow directions, Modelica defines the behavior of variables through equations without artificial division of equation-solving directions. The solver solves unknown variables based on the given conditions. The language models the real physical topology of the system and the component view has a similar structure hierarchy and layout as the real system. Its built-in Modelica standard library includes basic component models in multiple domains, such as mechanical, electrical, hydraulic, thermal, and control, enabling comprehensive performance analysis and evaluation of modern complex engineering systems[7].

Currently, Suzhou Tongyuan Soft-Control Information Technology Co., Ltd. have jointly launched the MWORKS.Sysplorer platform based on the Modelica language for system modeling and simulation. The platform is a modeling and simulation environment for multi-domain industrial products. It fully supports the unified multi-domain modeling standard Modelica. It organizes models hierarchically based on the actual physical topology of products. It also supports various visual modeling methods, including physical, block diagram, and state machine modeling. Sysplorer offers embedded code generation, and supports the integration of design, simulation, and optimization. It is internationally recognized as advanced general-purpose software for system modeling and simulation. For this research, the MWORKS.Sysplorer platform based on the Modelica language is adopted for the construction of the steam system simulation model.

2.2.1 Component Model Construction

Based on the steam power system architecture, a steam power system simulation model library is constructed using the Modelica multi-domain unified modeling specification. The steam power system mainly includes equipment such as steam turbines, condenser, pumps, and valves. Below are the physical principles of some of the main components and equipment models.

a) Steam turbine

The main function of a steam turbine model is to calculate the power output generated by high-temperature and high-pressure steam through expansion. In this article, a mathematical model of the steam turbine is established based on the Rankine cycle formula[8]. The steam flow rate at the outlet of the steam turbine is given by:

$$\frac{G_E}{G_{E0}} = \sqrt{\frac{p_E^2 - p_L^2}{p_{E0}^2 - p_{L0}^2}} \sqrt{\frac{T_{E0}}{T_E}} \tag{1}$$

Steam outlet specific enthalpy:

$$h_L = h_E - \Delta h_i \eta_i \tag{2}$$

Turbine power:

$$P_t = G_E(h_E - h_L) \tag{3}$$

Among them, G_{E0} represents the rated steam flow rate, p_{E0} represents the rated steam inlet pressure, T_{E0} represents the rated steam inlet temperature, p_{L0} represents the rated steam outlet pressure, p_L represents the actual steam outlet pressure.

b) Condenser

The condenser is a common multi-inlet shell and tube heat exchanger in the thermal system. The cooling water flows through the pipe side by the circulating pump, and the steam passes over the outside of the tube in the shell side for condensation and heat release. The heat is transferred to the cooling water through the tube wall, and the lower temperature cooling water keeps the condenser high vacuum through continuous circulation.

Shell side steam mass conservation equation：

$$\frac{d\mathrm{m}_g}{dt} = \mathrm{q}_{m,in} + \sum q_{m,in}^{OT} + q_{m,HW} - q_{m,p} - q_{m,con} \quad (4)$$

In this equation, m_g represents the steam mass within the condenser, $q_{m,in}$ denotes the steam mass flow rate of exhaust steam from the turbine , $q_{m,HW}$ indicates the steam mass flow rate entering the steam space through the heat well , $q_{m,p}$ is the steam mass flow rate extracted by the extraction steam trap, $q_{m,con}$ refers to the condensate flow rate at the steam space outlet of the condenser.

Shell side steam energy conservation equation:

$$\frac{d(\mathrm{m}_g h_g)}{dt} = q_{m,in}h_{in} + \sum (q_{m,in}^{OT} h_{in}^{OT}) - q_{m,p}h_p - q_{m,con}h_{con} \quad (5)$$

Here, h_g denotes the enthalpy of steam in the condenser, h_{in} represents the enthalpy of exhaust steam from the turbine, h_p indicates the extracted steam enthalpy from the extraction steam trap, h_{con} is the enthalpy of condensate at the steam space outlet of the condenser.

Tube side thermal balance equation：

$$Q = KA\Delta T_m = q_{m,W}(h_{W,L} - h_{W,\mathrm{E}}) = q_{m,G}(h_G - h_C) \quad (6)$$

Where Q represents condensation heat transfer, K denotes the total heat transfer coefficient , A is the condensation heat transfer area, ΔT_m is the logarithmic mean temperature difference, q_m is the cooling water flow rate, $q_{m,G}$ is the exhaust steam flow rate, $h_{W,E}$ is the specific enthalpy of cooling water at inlet , $h_{W,L}$ is the outlet temperature of cooling water, h_G is the specific enthalpy of exhaust steam and h_C is the specific enthalpy of condensate.

The overall heat transfer coefficient K is calculated as：

$$K = 794 \times 4186/3600\beta\sqrt{v_W} \cdot \sqrt[4]{\frac{T_{W,L} + T_{W,E}}{2}} + 17.8 \quad (7)$$

Where β is the fouling coefficient, v_W is the cooling water flow velocity, $T_{W,L}$ is the inlet temperature of cooling water, and $T_{W,E}$ is the outlet temperature of cooling water .

c) Centrifugal pump

The pump model is used to convert mechanical energy into fluid kinetic and potential energy, thereby increasing fluid pressure. Pressure of centrifugal pump:

$$\frac{H}{H_0} = \left(\frac{n}{n_0}\right)^2 \quad (8)$$

Centrifugal pump mass flow rate:

$$\frac{q_{m,z}}{q_{m,0}} = \frac{q_m}{q_{m,0}} \cdot \frac{n_0}{n} \quad (9)$$

Centrifugal pump powe:

$$\frac{q_{m,z}}{q_{m,0}} = \frac{q_m}{q_{m,0}} \cdot \frac{n_0}{n} \quad (10)$$

Centrifugal pump powe:

$$P_p = \frac{\Delta p_p q_{mp}}{\rho \eta_p} \quad (11)$$

$$\Delta p_p = p_L - p_E = H \quad (12)$$

Outlet temperature of centrifugal pump:

$$T_L - T_E = \frac{(1-\eta_0)}{\eta_0} \cdot \frac{H_0}{\rho C_p} \quad (13)$$

Centrifugal pump torque:

$$\tau_p = \frac{30P_p}{\pi n} \quad (14)$$

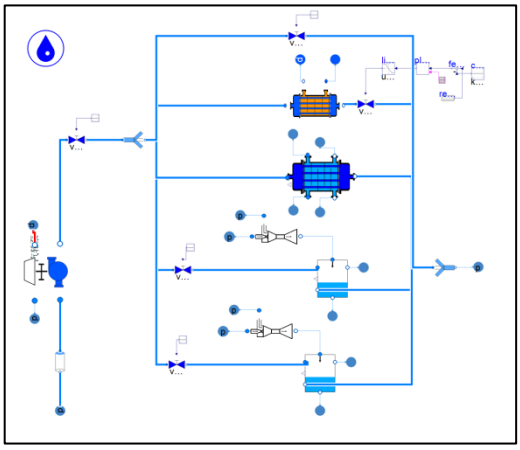
Among them, H is the actual pressure head, H_0 is the design point pressure head, q_m is the actual flow rate, q_{m0} is the design point flow rate, q_{mz} is the flow rate converted from the actual flow rate to the design point speed, n is the actual speed, n_0 is the design point speed.

d) Steam regulating valve

Steam control valve is used to control the steam flow rate entering the steam turbine, thereby controlling the output power of the steam turbine[9]. Assuming that the steam flows adiabatically and isoentropically in the valve, only the flow rate produced by the pressure difference between the inlet and outlet is considered. The momentum equation is:

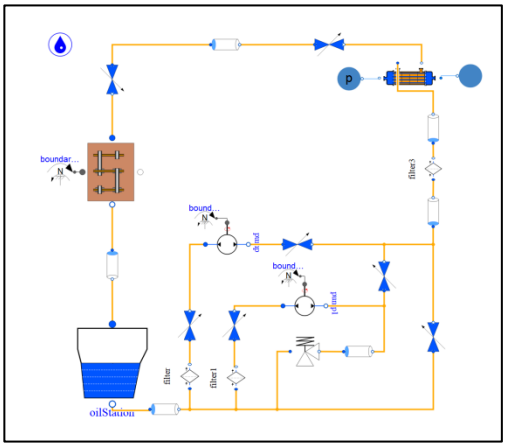
$$q_{m_E} = k_{m_x} k_v \left(1 - 0.367\frac{X}{X_{cr}}\right)\sqrt{\rho_E p_E X} \quad (15)$$

$$X_{cr} = 1 - \left(\frac{2}{K+1}\right)^{\frac{K}{K-1}} \quad (16)$$



$$k_{mx} = \sqrt{\frac{2KA_{max}^2}{K+1}} \quad (17)$$

q_{m_E} is the steam mass flow, ρ_E is the inlet steam density, p_E is the inlet steam pressure,X is the valve pressure loss ratio, X_{cr} is the critical pressure loss ratio, K is the heat capacity ratio, k_{mx} is the valve characteristic correction coefficient, and A_{max} and is the maximum opening flow area of the valve.



2.2.2 System Model Construction

Based on the general model library of steam power systems, equipment, subsystem, and system models are built from bottom to top according to the system design architecture. Figure 6 shows the sub-system simulation model of the steam power system. The cooling water system includes a lubricating oil temperature control module, and the condensate system includes a condenser water level control module.

(f) Condensate System

Figure 6 Simulation model of steam power system subsystem

After completing the construction of subsystem simulation models, they are connected according to the interface relationships between the subsystems of the steam power system based on its logical architecture. Finally, the steam power system simulation model is obtained (shown in Figure 7). The steam power system consists of a steam system, condensate system, low-pressure steam system, cooling water system, seal system and lubrication oil system. Its main equipment includes steam turbine, boiler feed pump, condenser, condensate pump, ejector, deaerator, lubricating oil cooler, lubricating oil pump, valves, and pipeline accessories. The control logic in the system includes condenser water level control and lubrication oil temperature control.

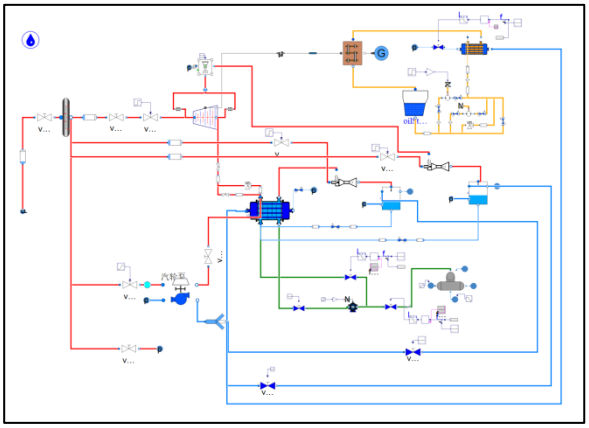

Figure 7 Simulation model of steam power system

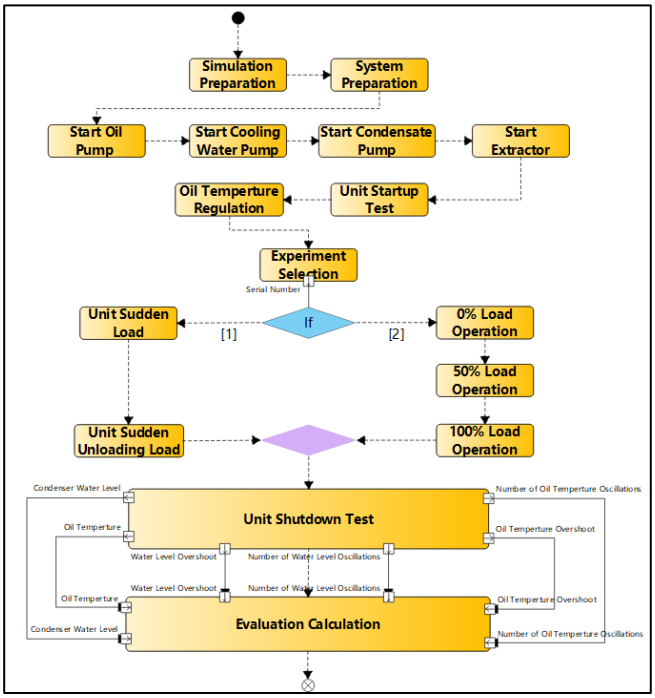
3 System dynamic scene analysis and indicator validation

3.1 Dynamic scene analysis

In order to describe the dynamic scene of a steam power system, you can select the functional activity model in SysML language from the steam power system architecture design model library. By defining the dynamic operational scene of the steam power system, an activity diagram can be formed that can be used for simulation and verification. This achieves the integration of system architecture design and simulation verification.

In the activity diagram that describes the dynamic scene of the steam power system, functional activities are used to express the control behavior of the simulation model, such as the "start lubrication pump" functional activity. Based on the programming of the "start lubrication pump" behavior through architecture design software functionality, a design and simulation integrated script is defined, and a joint simulation interface for creating simulation models is established. Through UDP communication, the instruction signals for starting/stopping the "lubrication pump" device in the control simulation model are sent to the system simulation model, thus achieving dynamic verification of the steam power system operating scenario based on the simulation model. Figure 8 shows the activity diagram of the dynamic scene of the steam power system. In the activity diagram, functional activities for the steam power system are defined, including simulation preparation, system backup, start lubrication pump, start cooling water pump, start condensate pump, start air extractor, unit start-up test, lubrication temperature regulation, and test selection. The activities are connected by control flows according to the execution logic of the steam power system (represented by dashed lines with arrows in Figure 8), and the arrows indicate the sequence of activity execution.

Meanwhile, the steam power system simulation model needs to set corresponding control interfaces and



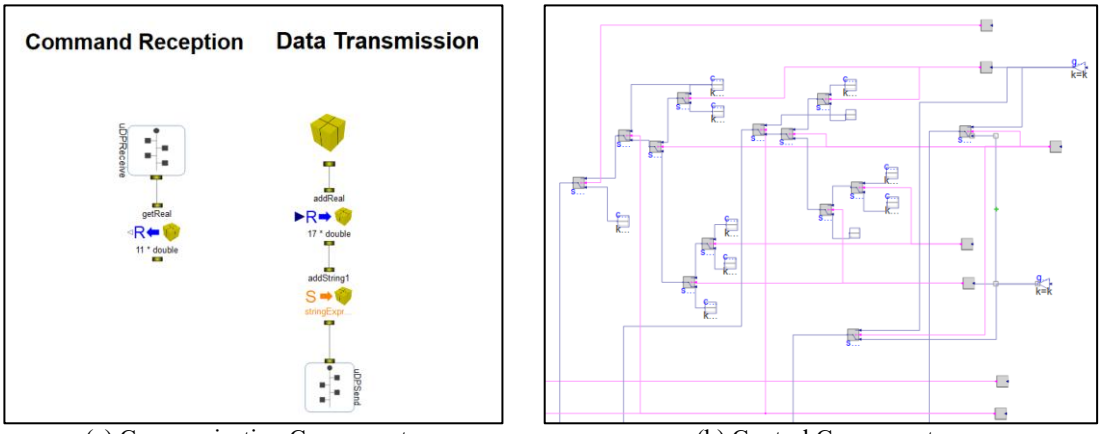


Figure 8 Steam Power System Dynamic Scene Activity Diagram

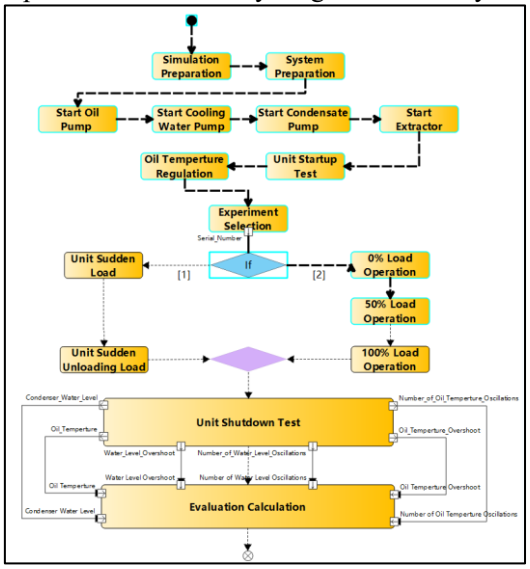
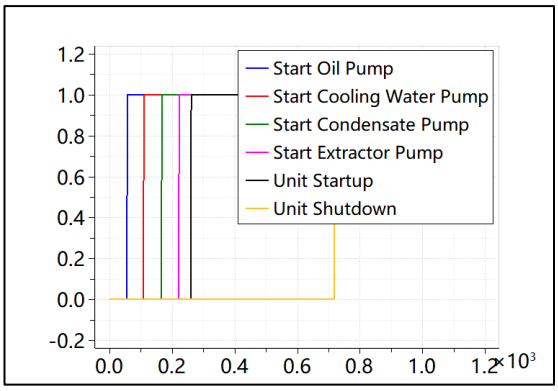
strategies to meet the evolving activity flow of the system's dynamic scene. Therefore, based on the previously constructed steam power system simulation model, a simulation model control module needs to be further established. The control instructions corresponding to different functional activities and the activity transition conditions are received and sent through the UDP communication component. When the activity diagram starts the simulation, the activity nodes execute according to the control flow of the activity diagram. Different activity nodes send different operation instructions to the simulation model. The simulation model feeds back the calculation results of the key parameters of the model to the activity diagram in real time. After the calculation parameters of the simulation model meet the transfer conditions of the corresponding activity, the activity diagram executes the next activity node. Figure 9 shows the communication component and control module of the system simulation model. The communication component is used to receive the control instructions in the activity diagram and the feedback signals of completed activities. The control module passes the control instructions received by the communication component to the corresponding component or device of the simulation model to achieve a dynamically simulated system based on the activity diagram.



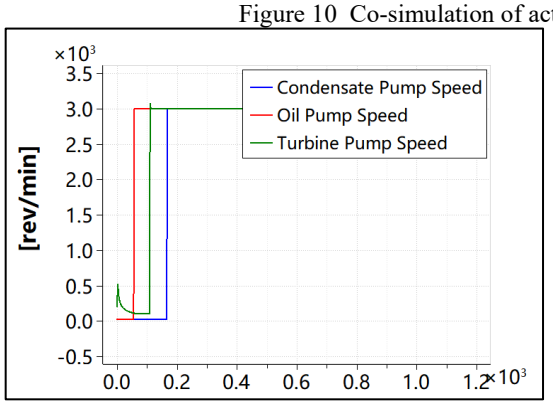
DOI 10.3384/ecp218727

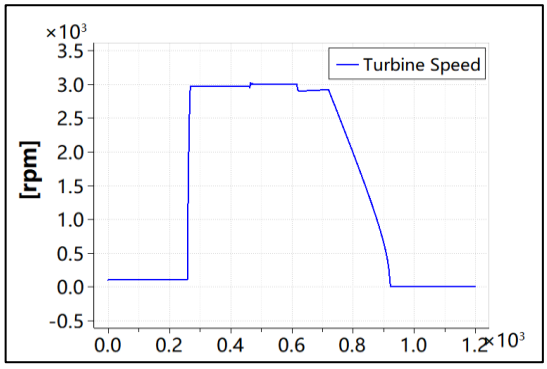


(a) Communication Components (b) Control Components

Figure 9 Communication component and control module of system simulation model

After debugging the communication and control module of the simulation model according to the execution logic of the system's dynamic scene activity diagram, the simulation calculation of the activity diagram can be performed. Figure 10 shows the schematic diagram of the activity execution status in the joint simulation process of the activity diagram and the system model, and the status of the system model instruction receiving. In the activity diagram, the current activity in the execution state is highlighted by the activity model. At the same time, when the corresponding control instructions are received by the system simulation model, the curve value of the corresponding instruction changes to 1.





(a) Activity Diagram Simulation

(b) Command Reception

Figure 10 Co-simulation of activity diagram and system model

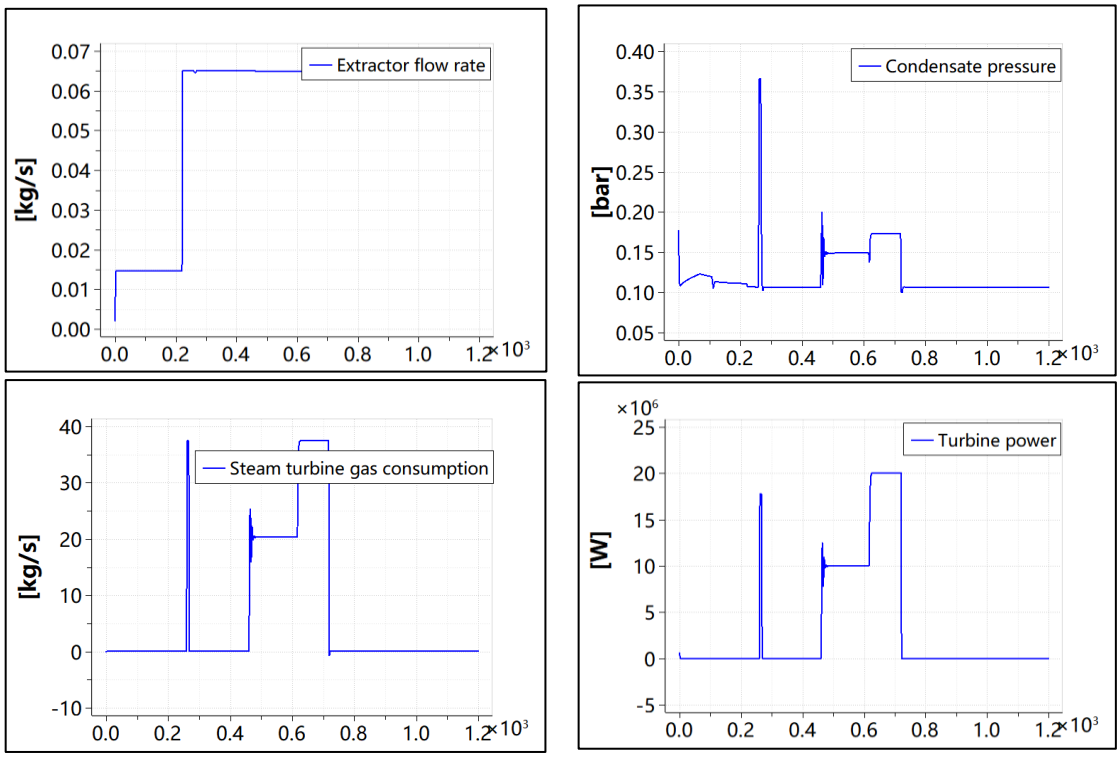


Figure 11 Key equipment parameters of the system simulation mode

Figure 11 shows the critical equipment parameter curves of the system simulation model, which primarily include the "lubricating oil pump speed," "condensate pump speed," "turbine circulation pump speed," "turbine speed," "exhauster extraction flow rate," and "condenser pressure." These curves are analyzed in comparison with the control command changes shown in Figure 10.

When the simulation model's "lubricating oil pump" receives the "start lubricating oil pump" command from the activity diagram, the lubricating oil pump speed rapidly increases to 3000 r/min. Similarly, at approximately 275 seconds, the "turbine unit" receives a "start-up" signal, causing the steam control valve to open and the steam flow to surge instantly. The turbine speed rapidly increases from a low standby speed to 3000 r/min. After the speed stabilizes, the valve is throttled to maintain 3000 r/min. During the start-up phase, the sudden increase in steam flow causes the condenser pressure to rise briefly before quickly decreasing.

At approximately 750 seconds, the "turbine unit" receives a "shut-down" signal, and the steam control valve closes. The steam flow into the condenser drops rapidly, leading to a decrease in condenser pressure. The turbine speed gradually decreases from the rated speed to 0 r/min.

3.2 System indicator validation

In the previous section, the steam power system simulation model executed dynamic calculations in sequence according to the activity diagram scenarios, accurately obtaining dynamic operating parameters for the system and equipment. These state parameters are fed back to the system architecture design software via UDP communication components, enabling comprehensive verification and validation of the system architecture design performance metrics.

This paper uses the verification of performance metrics for condenser water level and lubricating oil temperature control in the steam power system as an example. The steam system imposes strict performance requirements on water level control in the condensate system and lubricating oil temperature control in the lubricating oil system, specifically regarding overshoot and oscillation count. During dynamic operation, these parameters must meet the limits for overshoot and oscillation count. As shown in Figure 12, the overall performance metrics for the control system specify a maximum condenser pressure of 1 bar, with a maximum allowable oscillation count of 5 for water level; for lubricating oil temperature control, the maximum allowable overshoot is 0.3, and the maximum allowable oscillation count is also 5.

需求属性

参数名称	值	单位

Figure 12 Control system performance indicators

As shown in Figure 13, the curves represent the computed performance metrics of the simulation model.

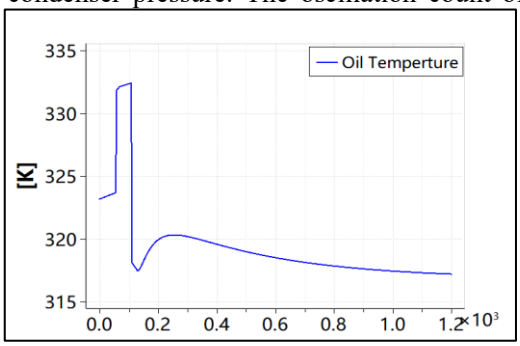

Figure 13(a-c) show the lubricating oil temperature variation curve, the oscillation count of lubricating oil temperature, and the overshoot of lubricating oil temperature. The oscillation count refers to the number of times the temperature crosses the target value under control regulation, totaling 2 times, while the overshoot is

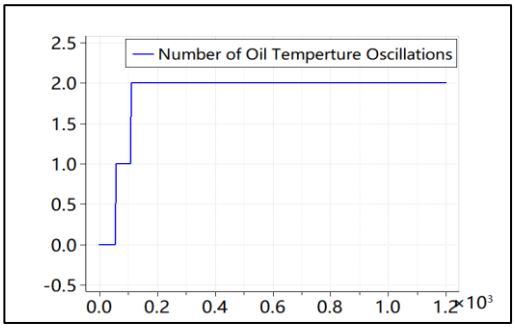
DOI
10.3384/ecp218727



the percentage by which the maximum actual temperature exceeds the target, at 0.054%.

Figure 13(d-f) depict the oscillation count of the condenser water level, the condenser pressure, and the maximum condenser pressure. The oscillation count of the water level is the number of times it crosses the target value under control regulation, totaling 3 times.

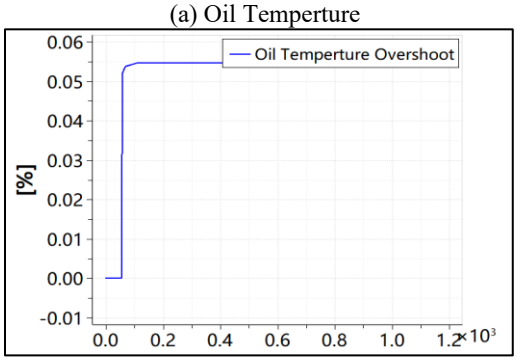


Figure 13(g) shows the state parameters received by the system architecture design software from the simulation model's feedback.

(g) Fedback Data of Simulation Model

Figure 13 Calculated parameters of the control system

To further validate whether the system performance metrics are met and determine the feasibility of the system architecture design, metric constraints can be established based on the overall performance metrics from the requirements model and the state parameters returned by the simulation calculations. Figure 14 illustrates the performance metric validation process. Figure 14(a) shows the constraint relationship between the performance metrics and the state parameters. Here, the actual maximum overshoot of the lubricating oil temperature is calculated and assigned to the constraint model value property. Figure 14(b) presents the results of all metric constraint validations. A metric constraint value of 1 indicates that the performance metric is satisfied. As shown in the figure, the actual maximum overshoot of the lubricating oil temperature (0.054%) is less than the metric value (30%), the actual oscillation count of the lubricating oil temperature (2 times) is less than the metric value (5 times), the actual maximum pressure of the condenser (0.366 bar) is less than the metric value (1 bar),

and the actual oscillation count of the condenser water level (3 times) is less than the metric value (5 times). All performance metrics are thus satisfied.

4 Conclusion

Based on the model-based systems engineering approach, this paper has completed the architecture design and system simulation verification of a steam power system, realizing a closed-loop process of design-simulation-verification. The conclusions are as follows:

1) The paper innovatively proposes a closed-loop technical approach integrating steam power system design, simulation, and verification. This approach combines system design with simulation verification, overcoming the limitations of traditional separation and boosting design efficiency. Relying on Modelica's powerful functions for precise modeling and efficient simulation, it quickly identifies design issues, optimizes designs early, reduces iterations, cuts costs, and shortens development cycles, offering a new method for complex system design.
2) Based on the architectural model, this approach enables seamless transformation from system design architecture to system simulation architecture. By applying well-defined mapping rules, it accurately converts elements such as composition, interface, and connection relationships from SysML architectural models to Modelica simulation model architecture. This ensures consistency between design and simulation architectures in terms of interfaces and parameter passing. The process not only integrates design and simulation but also leverages Modelica's power in multi-domain physical system modeling, facilitating a smooth transition from conceptual design to performance verification.
3) Dynamic scenario simulation and verification of the steam power system are done via combined simulation of activity diagrams and system models. Using Modelica simulation technology with SysML-defined dynamic activity diagrams, it achieves precise dynamic simulation of the system's operation. This combined simulation not only reproduces the dynamic process but also provides reliable real-time state parameter feedback for performance metric verification, enhancing the closed-loop system of steam power system design, simulation, and verification.

Abstract

Significant opportunities exist to preserve and reuse simulation and analytical models and data. Based on the capabilities developed by the Modelica Association (MA), LOTAR International, and other contributing tool developers, multiple engineering and manufacturing industries can compile extensive archives of reusable and interoperable performance, behavior and integrated product information. Through the development and implementation of a preservation plan, the use of compliant off-the shelf software applications, and packaging using compatible data standards, a repository of analytical interactions, simulations and functional prototypes can be archived, maintained, and resourced by future users. The scope of this paper is the exploration of alternative data standards that might support LOTAR requirements. This paper identifies progress made since the publication of (Coïc 2021, Coïc 2023) with respect to maturity of the "Long Term Archiving and Retrieval" (LOTAR) draft standards – ASD-STAN 9300 series, (ASD-STAN, 2025) and accompanying prototype implementations. There has also been significant progress by the Modelica Association with the introduction of layered standards in new versions of the FMI and SSP standards (Modelica Association 2024-11., Modelica Association 2024-12). The soon to be released layered standard SSP Traceability (Modelica Association 2025-04) provides mechanisms to document and preserve relevant metadata for model archiving in support of LOTAR. The FMI layered standard FMI-LS-Ref standardizes parameter sets and reference results, which are an important subset of the LOTAR International requirements.

Keywords: Model reuse, SSP, FMI, LOTAR, Traceability, Modelica

1. Introduction

Model-Based Systems Engineering (MBSE) has become the de facto standard for developing complex systems, where models are first-class members of the engineering process. Rather than relying on documents, MBSE encourages the use of descriptive and analytical models to support key lifecycle activities such as requirements definition, design, analysis, and verification. This model-centric approach is critical to enabling the Digital Thread—a connected and consistent flow of engineering information that supports collaboration across disciplines and lifecycle phases.

As digital engineering practices mature, simulations are essential to representing, verifying and validating complex Cyber-Physical Systems (CPSs). Analytical simulations capture domain-specific behaviors and performance characteristics. However, while these simulations are widely used during a product's development and manufacture, they are not commonly preserved in a reusable or interoperable format. Traditional Product Lifecycle Management (PLM) tools focus on managing static artifacts, configurations, and project milestones. However, they usually lack the features needed to manage alternative formats, expose and supplement metadata or maintain contextual links and dependencies needed for reuse across different lifecycle stages and related projects.

Recently, engineering has seen the definition of different metamodels that express the configuration and relevant information needed to share, exchange and execute analytical models. The Digital Data Package, DDP (Prostep ivip 2024) provides a structured container to bundle models, input/output data, documentation, and related metadata. This packaging approach enables traceability, validation, and long-term reuse across lifecycle phases. The analytical models contained in a DDP are further enhanced by using the Model Identify

Card, MIC-Core**,** (IRT SystemX 2020). The relationships with other models can be further elaborated by the ISO 1030-243 standard, known as AP 243, (ISO 2021) which serves as a formal metadata structure to capture the key characteristics of a model; such as its purpose, inputs, outputs, assumptions, limitations, and applicable domains. The AP 243 - MOSSEC standard defines a metamodel "*enabling the sharing and exchange of Modelling and Simulation contextual metadata"*. It acts as a technical "passport" for models, supporting collaboration and enhanced content identification, empowering engineers to assess a model's fitness for use without deep inspection of its internals. Note that the SRMD metadata format (Modelica Association 2025-3), defined in the SSP Traceability draft standard (Modelica Association 2025-1), can efficiently store metadata information from MIC-Core, MOSSEC, or any of the various other model metadata specifications currently in use.

1.1 LOTAR MBSE Standards - Overview

All forthcoming LOTAR MBSE standards are still in a draft format or under review for approval. It is, however, useful to present their overall structure here.

- **Part 500**: Fundamentals and Concepts for long term archiving and retrieval of Model-Based Systems Engineering information.
- **Part 510**: Long term archiving and retrieval of Requirements, and their management schema, as text, graphics, tables, models, or "parameter based" information.
- **Part 515**: Long term archiving and retrieval of Validation and Verification "text based" and "parameter based" information (expanding Part 510).
- **Part 520**: Long term archiving and retrieval of system or component level analytical behavior models described by specification or executable code, containing differential, algebraic and discrete equations. Includes causal or acausal models not addressed by the Part 600 series.
- **Part 530**: Long term archiving and retrieval of models that use system architecture descriptions and architecture description languages (ADLs) specified by ISO 42010/SAE AS5506 [9].
- **Part 540:** Long term archiving and retrieval of data and models specifying the Logical Bill of Materials (LBOM) (Design implementation requirements).
- **Part 550**: Long term archiving and retrieval of models or features describing digital or relational links. Methods for specifying highly integrated and interrelated models and elements across numerous software tool applications.

In preparation of defining, demonstrating, and publishing future preservation process standards, the LOTAR Model Based Systems Engineering Workgroup (LOTAR MBSE 2025) has introduced the application of the P510 and P515 metamodel (see above). Draft schemata are also available for P520 and P550, as well as a common core schema. The current state of Systems Engineering in virtual environments emphasizes the increasing need for early verification and validation of system specifications, often described as the stakeholder, functional, and technical requirements, and the necessity for configuration management and traceability of all related design data. The preservation of this information will be described in the P515 process standard and will be supported by preserving the data traceability features utilizing the P550 standard for linking information. As systems become more complex and interconnected, ensuring that specifications align with both system behavior and stakeholder needs throughout the development lifecycle represents a cornerstone of the MBSE process. This paradigm shift highlights the importance of good practices for model-based approaches that can facilitate the continuous tracking and validation of requirements, their allocation to design features, and model specific test results, ensuring that every decision and change is captured and verifiable at all stages of the system's lifecycle. Note that the ISO 26262-Standard (ISO 2028) for automotive functional safety has very similar traceability requirements and often needs the same type of behavioral models for verification and validation.

In this paper, we introduce the modeling practices and specifications needed to preserve and reuse analytical simulations effectively. This includes defining standard ways to document simulation intent, manage contextual metadata, and ensure consistency across tools and formats. By formalizing these aspects, we can move toward an executable and dynamic engineering environment, where simulations are not isolated efforts but integrated assets within a sustainable and reusable digital ecosystem.

Note the significant overlap of these purposes with finished and ongoing standardization efforts and process practices within the Modelica Association:

- **Part 515**: Part 515 aims at formalizing the informal process that is currently used by the Modelica Library project of verification and validation of the Modelica Standard Library. Similar methods are also used by commercial Modelica vendors. The ongoing effort of standardizing the capture of modeling results and parameter sets in FMI-LS-REF covers the same end user needs. In the ongoing prototype work, the proposed P515 schema was merged with the draft FMI-LS-REF schema for demonstration purposes, but developing the framework for a common schema would be preferable.
- **Part 520**: Part 520 addresses the core topics of Modelica Association standards, notably the behavior and simulation models. Both Modelica and

DOI 10.3384/ecp218741

FMI generally cover the P520 model type referenced here. However, the potential future role of the SSP-standard will need to be evaluated. Until recently, the P520 has focused on FMI mostly due to the much broader adoption of FMI by the software tool vendors. Also note, to avoid repeated translations, that the long-term preservation benefits represented by the LOTAR process are potentially easier to achieve with native Modelica models than with proprietary code repackaged into reusable FMUs. Nevertheless, using FMI as a preservation format will still accommodate many of the models developed using software applications that are alternatives to Modelica.

- **Part 530**: Through the use of Modelica components and acausal connectors, the SSP-standard utilizes a different philosophy than the ISO/SAE ADLs and is potentially useful as a substitute representation of a logical or functional design architecture. An execution oriented SSP system model would be easier to verify. Taking this view, the combination of Part 530 and Part 520 form a similar hierarchical and practical relationship as the SSP and FMI standards.
- **Part 550**: Combining the functionality of the SSP container format with the features of SSP Traceability exposes many of the characteristics defined by the P550 process. Together, they establish and specify the need for relational links between the models and their internal artefacts. They are both successful at formalizing the model integration results and providing auditable evidence of design traceability.

It therefore seems obvious that the Modelica Association and the LOTAR MBSE working group would recognize the significant benefits of developing a closer collaboration relationship. With the Modelica Association's focus on data standards, and LOTAR MBSE's focus on process standards, there is an obvious synergy and mutual benefits.

2. The Benefits of Preservation

Data preservation should be a leading consideration for all engineering models, and preservation planning should be a leading activity in all modeling endeavors. While the specific advantages of digital data preservation vary by industry, maintaining an engineering data archive offers broad benefits to any engineering enterprise or effort. The obvious renumerations include: the documentation of design decisions, permitting flexibility in the contributions of future personnel, historical evidence of process management, and sustaining the traceability of interrelated data from all applicable domains. Other practical but important factors include facilitating warranty investigations, product maintenance planning, a design history to address potential part obsolescence, and support for future modifications and enhancements.

A concise preservation plan typically includes the following elements: a repository with configuration management and robust data search capabilities; use of modeling techniques that promote data interoperability and integration; tools or processes to expose and capture model metadata; generation of summary model reports for future results verification; and the establishment of traceable links to source the original technical requirements and any reference data.

2.1 Preservation Process

Preservation begins with the formulation of a data preservation plan that identifies the model types, dependencies, applicable standards, and intended future uses. Archiving is performed at defined maturity milestones—such as design reviews or configuration releases—capturing fully verified and consistent data packages known as configured baselines.

Each archived package targeted for preservation includes a Model Manifest, which documents the model's structure, purpose, and metadata; and a Model Report, which records the model's execution, results, and verification and validation (V&V) evidence. Verification ensures the technical completeness and integrity of the archived data, while validation confirms that the model meets its intended purpose, and viability after storage and subsequent retrieval. To facilitate interoperability and futureproofing, data is translated into a standardized neutral format, such as those defined by STEP protocols.

As prescribed by formal Systems Engineering standards, all archived models must maintain clear traceability to their source requirements, design rationales, and validation artifacts. The preservation infrastructure itself must support robust search functions, metadata management, and integrity checks to ensure that the data remains unaltered and usable. This paper has already identified the key metadata standards, MIC-Core and

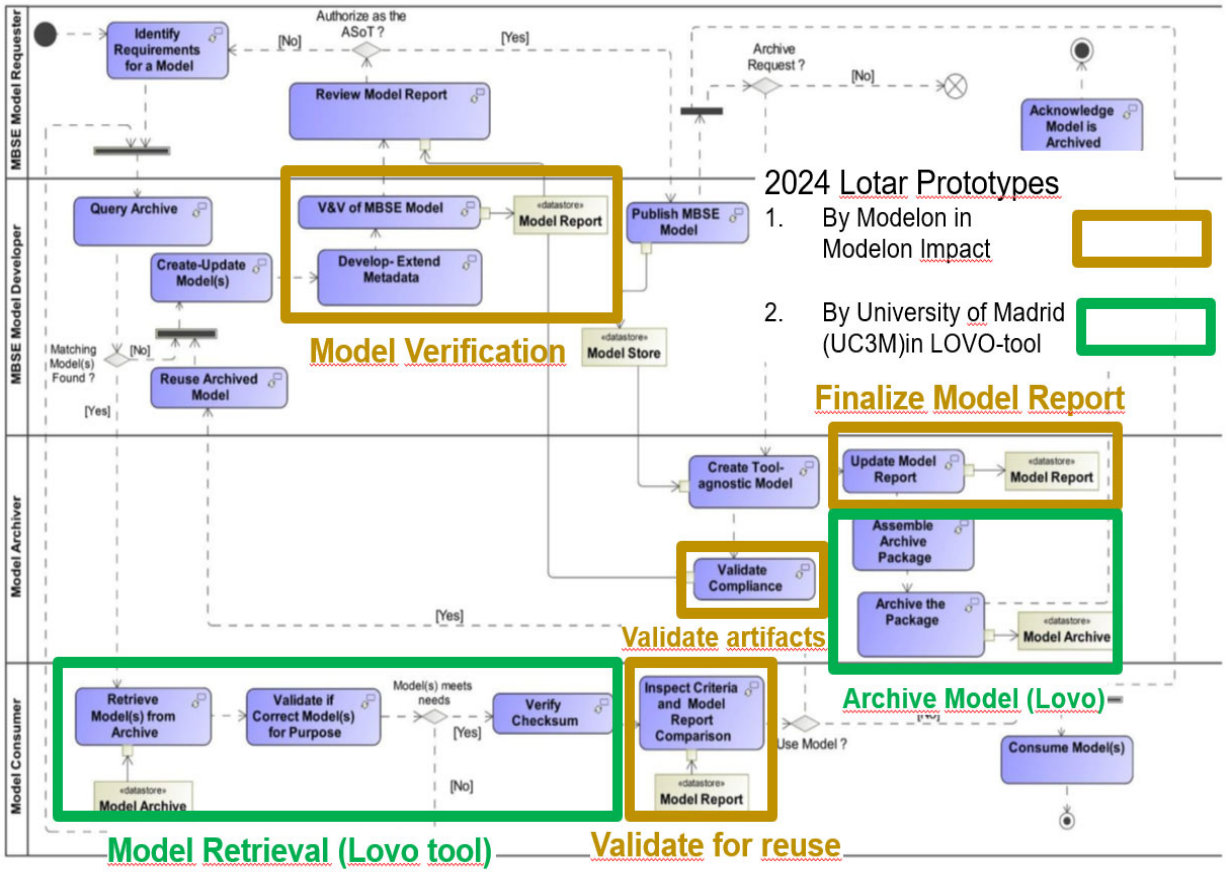

Figure 1: The LOTAR MBSE process flow with role-based swim lanes (Coïc et al, 2023).

MoSSEC, and the DDP as a packaging mechanism. The LOTAR standards identify a packaging framework, as described by the OAIS standard (ISO 2012), that compliments and formalizes the DDP.

The LOTAR preservation process, showing swim lanes for different enterprise roles for both the archival and retrieval process is depicted in Figure 1.

3. Types of Standards

The LOTAR domain specific Parts, previously defined as the P510, P515, P520, and P550 standards, are process standards that rely on widely available and robust data modeling standards. Data modeling standards support data interoperability between multiple brands of tools and users. They can also support translations into neutral or alternative formats. Data Modeling standards support model preservation if subsequent versions maintain compatibility through future software tool revision cycles. Some of the best examples of modeling standards are produced and maintained by the Modelica Association. Other notable modeling process standards for modeling and simulation are by NASA, (NASA 2024, NASA 2019).

3.1 Data Modeling Standards

The Functional Mock-up Interface (FMI) facilitates the exchange of simulation and analytical models, while System Structure and Parameterization (SSP) supports system assembly. Recent updates made them more appropriate for LOTAR purposes than they were originally, and the introduction of "Layered Standards" supports the concept and implementation of LOTAR even better. Two layered standards under development by their respective FMI and SSP projects stand out in how much they align with LOTAR needs:

- The SSP Traceability standard (to be released shortly) supporting model and process traceability; and the
- FMI-LS-REF standard that aims to add a standardized way to include simulation experiment definitions, multiple parameters sets and simulation result files to an FMU.

Together they will further enable the identification and management of metadata and traceability features in both FMUs and SSP containers.

DOI 10.3384/ecp218741

3.2 The Behavioral Model Results Report

During 2024, major progress was made to implement and test a prototype that enhances the Part 515 verification and validation process. The deliverables developed by Modelon AB included python code and a draft xsd-schema. This expanded earlier efforts to prototype the Part 520 process and integrate the Part 550 linking mechanisms directly into a Modelica model (Coïc et al. 2021, Coïc et al. 2023). The 2024 prototype added detailed checks on the completeness and correctness of all available FMU and SSP assets, as well as the model verification capability. The process break-through evolved by formalizing the existing infrastructure, used by the Modelica Association and modeling community, that automates the regression testing of behavioral models. Unfortunately, even with more than a decade of experience in automated model verification, the Modelica Association has never agreed on formalizing the definition of solver types and terminology, which are necessary for quantitative verification of simulation models. In addition to other features, the Part 515 xsd-schema formalizes the following elements of model verification:

- The link to the model to which it applies
- The required test cases
- The context of the test case
- The actual scenarios used
- The experiment definition, such as solver type, tolerances, start and stop times, and number of result points that should be stored
- The referenced variables
- Verification tolerances in the x and y direction
- Boundary conditions
- Modified parameters
- Links to the reference result files

This is a superset of the information currently envisioned for the FMI-ls-ref layered standard. The intention of the FMI-ls-ref standard was to enable a so called “smoke test” for exchanging FMUs, whereas the needs for verifying archived models for design reuse requires precisely quantified tolerances. Nevertheless, the development, agreement and utilization of a basic verification infrastructure as a layered standard to FMI would simplify future adoption.

The SSP Traceability standard by the MA provides a modular data standard that enables an in-depth and customized metadata definition. It does, without additions, not provide the precise definitions that are needed for long term archival.

4. Encoding Metadata

The LOTAR Working group’s standards include encoding the processes steps and defining the necessary metadata to enable reuse of models after potentially long periods of archive storage. In parallel to the LOTAR developments, the German national research project SET level (Otter et al. 2022, Setlevel 2023) initially developed what has become the SSP Traceability standard. As enhancements to the product development process, SET Level starts with defining the “Credible Decision Process” and the “Credible Simulation Process” (CSP). It also established a metadata format in support of SSP Traceability. It evaluates the credibility of the process by documenting the steps and linking and integrating all required artifacts. While the purpose for collecting and integrating the metadata is different, there are a lot of commonalities. SSP Traceability (MA 2025-1) has been defined as a feature that facilitates a large degree of process variation. An observer’s ability to understand the model’s purpose and then generate identical results at different times is common to both efforts. SSP Traceability is designed to capture metadata throughout the entire design process, whereas for LOTAR only the final maturity status must be set before an archiving decision is considered. However, model preservation for a longer period likely requires additional metadata that might not be needed for a shorter lifecycle. In any case, with the recently added ability to add “layered standards” in a compatible way to MA standards, the LOTAR MBSE standards could be built as a layered standard on top of SSP Traceability. The integration of this additional capability could simplify the implementation and future adoption.

The SSP Traceability standard contains several separate namespaces and parts, which don’t map 1:1 to the LOTAR specification, but would still make it possible to cover LOTAR’s intended results. The main elements of SSP Traceability are (MA 2025-1):

- **Decision Task Meta Data (DTMD)** is an XML format representing process-relevant information, as defined by the Credible Decision Process, with a file extension ending in dtmd.
- **Simulation Task Meta Data (STMD)** is an XML format representing process-relevant information, as defined by the Credible Simulation Process, with a file extension ending in stmd.
- **Simulation Resource Meta Data (SRMD)** is an XML format representing metadata for resources, with file extension ending in srmd.

Note that according to the SSP standard these metadata files can also be embedded in FMU files, not only in the SSP packaged files.

To use recurring description elements consistently, they must be defined separately from the three XML Schemas

above. As a result, these description elements are also available in the DTMD, STMD and SRMD XML Schema. The XML Schema for common content is named **Simulation Traceability Common (STC)** XML Schema representing recurring description elements of the other three XML Schemas. An important concept of SSP Traceability is the Glue Particle approach:

- The **Glue Particle Approach** is a concept for packaging data and the file-based transfer of process-relevant information and resources from a Credible Decision Process or a Credible Simulation Process.
- A **Glue Particle** is a package of process-relevant information and resources from a Credible Decision Process or a Credible Simulation Process. The form in which this bundle exists, e.g. whether it is stored as a file or in a database or a specific data format, is not specified.
- A **Glue Particle file** is a Glue Particle that is in a file-based representation and can therefore be transferred between tools or organizational units such as people, departments, or companies.
- File-based resources linked by or to a Glue Particle file should be exchanged with the Glue Particle file itself to take full advantage of the Glue Particle transfer.

SSP Traceability reuses the W3C XLink language (XLink 2012) for data element linking, whereas the P550 draft schema uses a simple URI schema that differentiates between local and global links. Both linking schemata have the same goal: to provide the "Authoritative Source of Truth" (ASoT) by creating traceable links between requirements, needs, and the artifacts to be verified or validated.

Part 520 metadata provide a set of classifications describing the model's pedigree and usage. The same classifications could equally be expressed with the ClassificationEntry elements in the STC schema. Some of the Part 520 data elements map more clearly with elements in the STMD schema, such as the Integration_Process_Type.

The Part 515 schema focusses on the data needed to verify the model results after retrieval from an archive. The data may be different than what was used to verify the original analysis requirements and results. As mentioned earlier, this is similar to the current draft fmi-ls-ref specification but with additional considerations. STMD on the other hand focuses on the entire verification process of the original model. Undoubtedly, STMD data would be of great use for an engineer trying to reuse a model after it spent a decade or more being buried in an evolving archive.

Prototypes for creating and validating the P515 and P520 LOTAR MBSE archiving process were implemented in the Modelon Impact software application to demonstrate that they can easily be accomplished and repeated using Modelica-based tools.

5. Representing Analytical Models

Utilization of the Modelica language satisfies many of the needs of the P520 process, but in today's environment the majority of models are developed using proprietary tools. However, most of these tools now support the export of models as Functional Mock-up Units (FMUs). In principle, text-based language models have fewer intricate implicit dependencies on details of the execution environment such as Application Binary Interfaces (ABIs) and dynamically linked libraries (sometimes referred to as "dll-hell"), which doesn't go to the full depth of the second problem, major revisions of the underlying operating system. The volume of metadata needed to define, let alone guarantee, a compatible execution environment is quite high. However, the containerization of computational resources has at least made it easier to recreate the original settings, but preservation planners must still account for open-source or proprietary operating systems, plus any additional system libraries and software platforms. A partial remedy to the execution environment lifecycle is to use "source-code FMUs", but they are not supported by many tools. The detailed "Build Configurations" available in FMI 3.0 will improve portability, ease of use, and expand the archiving alternatives. There are further improvements in FMI 3.0 that "sharpen" the semantic precision of models and therefore accommodate the packaging of more sophisticated simulations of integrated systems and controls. The most relevant features here are:

- Clocks
- Transition events in co-simulation FMUs
- Interface provisions for scheduled executions
- New data types, including binary data
- Methods to manage the build configuration
- A new implementer's guide to improve the user's interpretation of the standard.

In earlier work prototyping the P550 concepts (Coïc et al 2023), Modelica records were used to embed interactive traceability links to elements (e.g., requirements parts, attributes) directly in the Modelica code. They were modelled as Strings in a traceability record. Now that the Modelica Association has exposed the SSP Traceability standard (current status - release candidate, but several commercial tools appear to be early adopters), it seems reasonable to tag elements with a Modelica Resource, enabling a standardized annotation link to point to the

DOI 10.3384/ecp218741

required resources. Such resources can even be embedded in the SSP.

6. Model archive and retrieval: verification and traceability

As discussed previously, preservation of engineering artifacts is a critical capability for organizations seeking to enable long-term traceability, reuse, and maintain compliance in complex system development. The preservation process is not limited to mere storage. As illustrated in Figure 1, data preservation requires a robust workflow for model identification, verification, archival, and retrieval. Combining these steps ensures the integrity and accessibility of engineering data over time. In this section, we briefly describe significant process enhancements to the archive and retrieval of engineering artifacts by leveraging metadata verification, packaging standards, and knowledge graphs for queries and model identification.

1) The archival process starts with the verification of a **metapackage** described through an instance of the P550 schema. This metapackage-information serves as the entry point for validating the consistency of the engineering artifacts to be preserved. Each metapackage comprises references to one or more subpackages (e.g., P510, P515, P520), each associated with a manifest and a corresponding engineering artifact. Before indexing any package into an archive, two levels of verification are required:
   - **Traceability level**: the archival process must ensure that all traceability links between the engineering artifacts actually exist and are all accessible. This includes validating cross-references between requirements, models (logical and physical), and model elements.
   - **Artifact level**: the content of each artifact must also be correct in terms of data formats. For instance, artifacts of type **P510** (e.g., requirements) must comply with the ReqIF standard. Artifacts of type **P520** (e.g., physical/analytical models) must be executable with the associated FMI components and produce the results specified in the manifest and model report. In general, each manifest must declare a valid checksum and timestamp to verify content immutability.

   Once these two aspects are verified, packages can be stored in the archive. The process supports updating the manifest metadata as necessary to reflect any corrective or clarification changes. This guarantees the long-term preservation of both the engineering artifact and its descriptive. context
2) The retrieval process for preserved engineering artifacts follows a similar set of checking actions. Given a package is contained in an archive, the system starts from a P550 instance and traverses all associated subpackages recursively. Each subpackage is unpacked, and its manifest is opened and validated using the same rules as in the archival phase. If the type of artifact is known (P510, P515, P520, etc.), the appropriate toolchain is invoked to:
   - Parse the manifest and validate schema conformance.
   - Check that the artifact's format (e.g. ReqIF, FMI) is as expected.
   - Run simulations or syntax checks as needed to validate behavior or structure with an external tool.

Once verified, both metadata and artifact data can be exposed for further processing, modification, search, or visualization.

6.1 Knowledge Graphs and Search Queries

While the verification process ensures and maintains model integrity, precision identification, suitability and selection of engineering artifacts requires more powerful query and exploration capabilities. To address this, we implemented a semantic layer on top of the archive based on knowledge graph representations. Two strategies were implemented: 1) a Label Property Graph (LPG) using Neo4j Desktop 1.5.9 and 2) an RDF Graph using Apache Fuseki 5.2.0**.** These representations were derived directly from the XML-based manifests using the following transformation rules:

1) XML to Label Property Graph transformation.
   - Each XML element becomes a **node** with a unique identifier and a type-classification derived from the element's type in the XML Schema.
   - Attributes of elements are mapped to their respective node properties (e.g. attribute_name:attribute_value).
   - Hierarchical relationships are transformed into directed edges between nodes, named as `has_<element_name>`. For simple (literal) child elements, values can also be modelled as node *properties* of the parent node rather than separate nodes to avoid too many edges.
2) XML to RDF. The second approach makes a representation of the XML content in RDF (an OWL/RDFS ontology was previously created to derive all XML Schema definitions as classes and properties):
   - Each XML element is an instance of an RDF resource, where the resource type corresponds to an XML Schema Complex Type represented as a class.
   - For each element, a triple is created linking it to its parent using a property named `has_<element_name>`, and then typed either as

an ObjectProperty, AnnotationProperty or DatatypeProperty depending on its origination and whether the value is complex or literal (user defined or from a pre-defined dictionary of terms).

- Every resource is annotated with a rdfs:label to ensure a human-readable identifier.

3) As illustrated in Figure 2, a graph structure enables the integration of the model manifests and the opportunity to perform traversal-based queries using languages such as SPARQL or Cypher. Through the use of queries engineers can explore model features, data relationships, or perform consistency checks. A sample of query results is depicted in Figure 3. A query example, "***Find all scenarios that have a verification credibility level 'Low'***" is defined using SPARQL in Figure 4.

The engineering artifacts and sample data used for these examples are hosted in the Stratoliner Project (MBE-Demonstrator-RM 2024). The sample source models and manifests included a text-based technical requirements specification in a ReqIF model format, and two FMUs depicting the airplane's alerion actuators. All of the verification and traceability capabilities presented in this section are implemented within the LOVO (LOtar Validation tOols) framework, included in the Stratoliner Project. LOVO will be released under license in a common Python package repository by the authors in 2025.

7. Summary

Significant progress has been made in defining the fundamental parts of the LOTAR MBSE archiving process. This includes multiple tool prototypes to develop and demonstrate feasibility, code to automate many of the process steps, and to-be-released process documentation to standardize the procedures. Many of the techniques necessary for a proper archival and retrieval process are currently un-documented "best practices" developed by experienced simulation experts. But these process advances are usually implemented as an ad-hoc methodology, and with inconsistent technologies across different companies. The LOTAR MBSE schemata formalize these practices and thereby facilitates their eventual integration into familiar off-the-shelf tools.

The initiatives for the SSP Traceability standard, primarily motivated by the needs of the automotive industry, and the aerospace driven LOTAR MBSE standards, were developed in parallel at about the same time. Both industries have similar needs for data traceability and model interoperability. It is therefore assumed that increased coordination and dialog between the respective representative organizations will encourage and accelerate their adoption by the software tool vendors. Although the current Standards produced by the Modelica Association have significantly enhanced the LOTAR process options, multiple challenges remain. The Modelica Language should include the prescriptive identification of the common metadata elements. If the SSP Traceability standard could also apply to FMU containers, and the source analytical models, traceability would be significantly improved. The true advantage would be integration within the Modelica language.

The LOTAR MBSE standard originally was designed to use only the FMI standard, but the extension to SSP is a logical step. Unfortunately, industry's adoption of SSP is lagging behind FMI. The metadata that extends to the SSP container will be slightly different and needs its own unique set of system level classes. Many of the metadata elements could be captured automatically by the original modeling and simulation applications and automatically reproduced in the XML-files used for model integration and traceability. When exported and exposed to the repository, the model metadata would support queries across the LOTAR MBSE preservation archives.

Layered standards, such as SSP Traceability, are quite new in the Modelica community. They offer significant opportunities for LOTAR-type initiatives to satisfy their specific process needs on top of the well-established standards of the Modelica Association (MA) (e.g. FMI and SSP). However, basic instructions and knowledge of how to specify them are not generally available. A published guide about how to develop and coordinate layered standards by the MA would notably improve their adoption. Layered standards, if designed and used correctly, will make implementation of related data standards much easier and facilitate their widespread use.

8. Acknowledgements

This work has been supported by the yearly project prototypes (2022, 2023, and 2024) developed under the sponsorship of LOTAR International, a consortium of industry volunteers sponsored by PDES, Inc. In the United States, and prostep ivip in Europe, with publication services provided by the Aerospace Industries Association (AIA) in the U.S. and the Aerospace and Defense Industries Association of Europe for Standardization (ASD-STAN) both under the supervision of the International Aerospace Quality Group (IAQG).

The authors would also like to thank:

Abstract

In the realm of model verification, ensuring traceability and repeatability is paramount for achieving Modeling & Simulation (M&S) credibility and development efficiently. This paper explores challenges and solutions for expressing complex model Verification & Validation (V&V) workflows that ensures readability while still enables automation, parallelization and advanced customization of verification activities. This paper contributes a practical solution that is evaluated through a detailed implementation within an in-house developed multi-purpose automation and Verification & Validation (V&V) framework.

Keywords: Model Verification, Machine-Interoperable Traceability, Workflow Automation, Model-driven Engineering, Simulation Credibility, Verification and Validation

1 Introduction

To quote Balci and Ormsby (2000): “any use of a model in a context where it can not be proved to be credible is by definition not credible”. Credibility is, to say the least, a broad concept involving many aspects of model development and use (*Standard for models and simulations* 2024). As systems and models become larger and more complex (Ahmed, Shah, and Umar 2016), so does the need to establish model credibility (Arthur et al. 1999). Where previously a few verification scenarios were executed and verified manually (Arthur et al. 1999), there is now a move towards extensive model exploration (Bouskela et al. 2023) with increasingly complex, multistep verification activities being implemented (Rosenlund et al. 2024).

In several ongoing industrial research projects, there is a large focus on traceability and frameworks such as System Structure and Parameterization (SSP) Traceability and the Credible Simulation Process (Ahmann et al. 2022). Where traceability of verification activities was previously based on manual documentation, as verification activities increase in size and complexity, this approach is no longer plausible (Arthur et al. 1999). The growing number of experiments increases the need to automate the verification process to maintain development efficiency. And just as in research, one of the core pillars for motivating trust in results is the reproducibility of experiments (Dalle 2012), where traceability of data, both regarding the conducted activity and its results, enables decisions to be taken on "known knowns" and "known unknowns" (Nallaperumal and Krishnan 2013).

To address these needs, the primary research question is formulated as follows:

> **Research question**
>
> How can automated model verification be conducted in a manner that is both traceable, repeatable and comprehensible?

Our proposal couples a lightweight workflow schema based on the Extensible Markup Language (XML) with Git-based change management to satisfy both repeatability and traceability (Figure 1). Because every transformation and activity are explicit in the workflow and intermediate artifacts are version-controlled, stakeholders can audit exactly how a simulation result was obtained. In proposing a schema for representing complex model verification workflows, we build upon insights from existing solutions used in automated data processing while adhering to requirements specific to model verification. Furthermore, evaluation of existing change management methods seek to enhance traceability throughout the verification process; potentially leveraging a mature ecosystem for data management.

To enable close collaboration between industry and academia, the established method denoted as "Industry-as-laboratory" by Potts (1993) was utilized. A number of use cases, established from industrial needs, were used for evaluation of different model verification and exploration

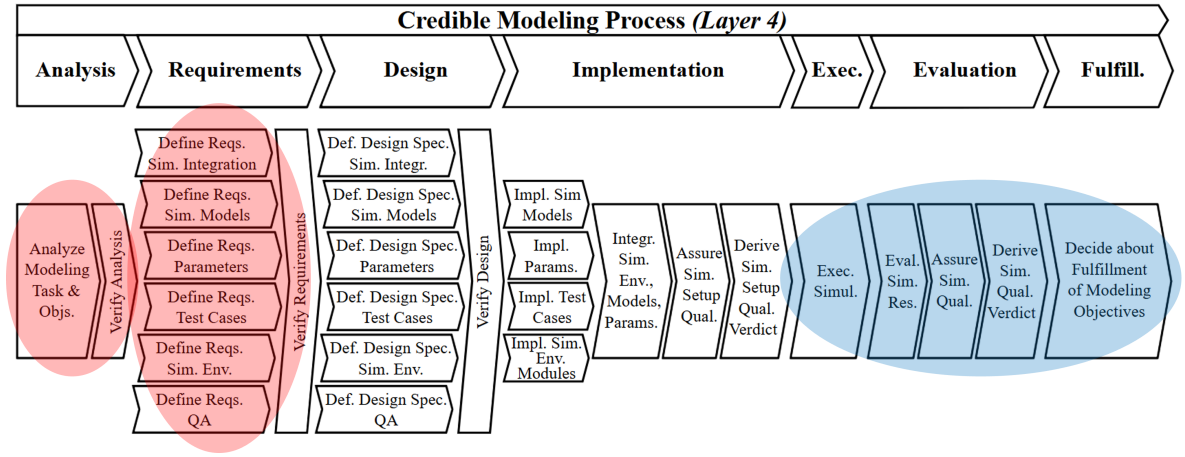

Figure 1. Visualization of the Credible Modeling Process Layer of the Credible Simulation Process Framework (Modelica Association 2022). The red areas showing the verification design phase and the blue area the verification execution phase

scenarios in an in-house automation and testing framework. The focus is here on verification, but the solution can equally well be applied to validation, e.g. as described in (Hällqvist 2023). Looking ahead, our findings offer promising avenues for further refinement and extension in future research, addressing ongoing challenges and exploring new opportunities in model management and V&V.

Contributions This study contributes to the advancement of model V&V through the integration of both novel and established solutions, aiming to promote greater transparency in the process. This by introducing a traceable and repeatable workflow representation—as a simple XML schema—that promotes readability and enabling automation.

The work is demonstrated within an in-house V&V automation framework, integrating established version control methods within model archives. It explores aligning model change management with existing software practices and the SSP Traceability framework, offering a scalable approach to managing changes and enhancing traceability and automation both during and after initial model development.

2 Theoretical Background

This section introduces the key frameworks and concepts that support the development and traceability of simulation models. These include the Credible Simulation Process Framework, version control systems, automated verification and validation mechanisms, and data pipeline architectures. Together, they form the basis for ensuring model credibility, enabling traceable workflows, and supporting scalable, reusable simulation practices.

Credible Simulation Process Framework and SSP Traceability To ensure that design decisions are based on credible data, SSP Traceability (which acts as an enabler of the Credible Simulation Process) was developed. This research focuses on a set of activities that are part of the Credible Modeling Process layer within the Credible Simulation Process. As illustrated in Figure 1, the Credible Modeling Process is largely analogous to the model development and delivery process used at Saab Aeronautics (Andersson and Carlsson 2012). The activities highlighted in blue in Figure 1 are addressed in this work, while those marked in red provide essential artifacts that serve as prerequisites for the activities under focus. A subset of these artifacts is discussed in (Rosenlund et al. 2024).

The Credible Simulation Process Framework allows the tracking of modeling activities, digital artifacts, and decisions to provide a solid foundation for model credibility assessment tasks. It provides the means of documenting data related to simulation tasks in a transparent and comprehensive manner (Modelica Association 2022). The related metadata is stored alongside the model using mechanisms implemented in SSP for coupling metadata related to the model within the same container. It employs various specialized metadata formats, such as Simulation Task Meta Data (STMD) for tracing tasks and Simulation Resource Meta Data (SRMD) for resource data.

DOI 10.3384/ecp218751

Version Control System Extensive usage of Version Control System (VCS) is employed by software companies to maintain collaboration and manage evolving products (Khleel and Nehéz 2020). They are used to storing code, documentation, and related artifacts in a traceable manner, where each change is accompanied by metadata detailing its relationship to other versions, the date, and the author (Khleel and Nehéz 2020). A transition from Centralized Version Control System (CVCS), such as Apache Subversion (SVN), to Decentralized Version Control System (DVCS), e.g. Git, is in progress (Muşlu et al. 2014), largely to enable more fine-grained control during development. The key benefit, in our context, of this transition is that it enables using VCS for tracking model changes even when the model is packaged within archives, as is the case for Functional Mock-up Interface (FMI) and SSP.

Verification and Validation Automation Framework An internal automation framework for model verification and validation, which supports extensive model exploration—the term here referring to the activity of subjecting the model to multiple scenarios while its behavior is checked against requirements or validated against test data (Hällqvist 2023)—serves as an application playground for this research. Model exploration in this context serves to strengthen model credibility thus enabling efficient and large scale model development, model-based decision-making in any life-cycle phase, and improve anomaly detection in model or physical product. The framework provides mechanisms for documenting both model and simulator Operational Domains (ODs) and Domains of Validation (DoVs)[1]. The DoV are all operating conditions where the model has been tested, including outcomes of verification or validation activities, and it serves as a foundation for assessing various aspects of the model's *credibility* (*Standard for models and simulations* 2024). In contrast the OD (or *applicability domain*) defines where the model can be used in regard to a set of requirements, including acceptance criteria, that reflect the model's intended use. A result of this is that the OD will always be a subset of the DoV, since requirement fulfillment outside the DoV is per definition unknown. More detailed descriptions of mode ODs and DoVs can be found in the literature, see for example Oberkampf and Roy (Oberkampf and Roy 2014) and Beisbart et al. (Beisbart and Saam 2019). Establishing both ODs and DoVs is crucial for ensuring the appropriate and credible application of a model, promoting traceability with respect to verification activities and facilitating model reuse by clearly communicating model limitations (Rosenlund et al. 2024).

Data Pipeline / Workflow Frameworks A data pipeline—or workflow—is based upon the architectural pattern **pipes and filters**, in this case more specifically the **tee and join** variant, where filters correspond to activities and pipes to the chaining of these activities (Buschmann et al. 1996). In short, pipes are a set of activities arranged in a specific order, where inputs and outputs are connected between the activities, often creating a Directed acyclic graph (DAG). The pattern's main advantage, when constructing verification workflows, is that "changes should be possible by exchanging processing steps or by recombination of steps, even by users" (Buschmann et al. 1996). The pattern also provides determinism regarding execution order and data flows; from the activity Directed acyclic graph (DAG), parallelization opportunities can be identified. Due to the often computationally expensive operations related to running simulations, this can result in considerable performance gains.

There are a number of existing software solutions that employ this pattern in various forms; two examples of more specialized solutions are **Jenkins** (*Jenkins (software)* 2025), for setting up build flows, and **dask** (*Dask (software)* 2025) for data processing and computation workflows. These solutions employ various methods for expressing workflows, using specific Domain-specific languages (DSLs), general programming languages such as python or existing data storage solutions such as JavaScript Object Notation (JSON) or XML.

3 Methodology

The methodology adopted in this work was driven by the need to define a verification workflow representation that could balance traceability, repeatability, readability, and automation possibilities. The foundation of the implementation lies in a set of verification activities that must be supported, as well as in the coupled requirements governing the verification process. The activities and requirements, collected from verification engineers, are in several cases supported by other sources to strengthen their validity (Cederbladh, Cicchetti, and Suryadevara 2024; Andersson and Carlsson 2012). The resulting methodology is presented in

[1] Or Domain of Verification

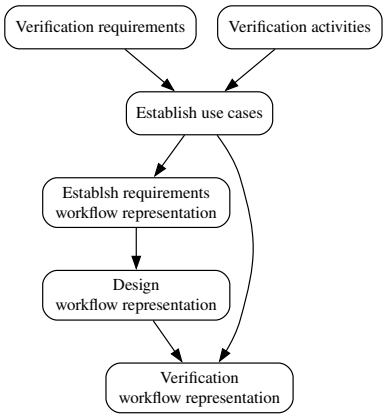

Figure 2. The research process employed

Figure 2, which illustrates the research and development process: starting with the collection of key verification activities and requirements, moving toward well-defined use cases, and culminating in a fully specified, validated workflow.

Requirements

- **Traceability** - Create traceability regarding verification activities and its results, striving for alignment against SSP Traceability
- **Repeatability** - Repeatability of simulation results, this implies that any operation must be deterministic
- **Automation** - The workflow needs to be automated to streamline development and enable effective regression testing
- **Human and machine-readable** - To facilitate both manual design and verification together with a high level of automation, any workflow representation must be both human understandable and machine-readable
- **Customization** - To enable reuse of similar operations between models
- **Resource utilization** - Computationally expensive operations require parallelization to ensure a quick feedback loop during V&V and development

Verification activities

- **Custom activity** - Easy implementation of verification activities
- **Activity comparison** - Compare the outcome of different activities, including simulation results for different scenarios or parameter sets
- **Result aggregation** - Allow aggregation of results

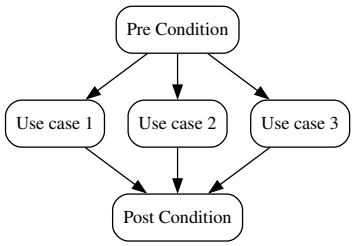

Figure 3. Multiple use cases sharing a common pre and post conditions

Table 1. Mapping between verification activity and use cases

	UC1	UC2	UC3
Activity Comparison	x		
Result aggregation	x	x	
Model Exploration		x	x
Design Optimization			x
Design of Experiments			x

- **Model exploration** - Enable methods of model exploration to evaluate different scenarios or parameter sets
- **Design optimization** - Provide means of using iterative optimization methods such as Bayesian or evolutionary algorithms
- **Design of experiments** - Evaluate what experiments would provide the most value in regard to what we currently know, often implicitly fulfilled by **Design optimization** since this is the first step when using iterative optimization methods

3.1 Use case

Several different use cases were formulated to capture the functionality needed to support the verification activities while fulfilling the defined requirements. Due to the broad nature of the activities, creating multiple smaller use cases enables a better coverage of the activities while also enabling a tighter connection to the final verification, see Figure 3. A mapping between the verification activities and use cases is in Table 1 ensures coverage.

Pre Condition The cases start with a model and a need to verify, validate or optimize certain aspects of the model or system.; they all begin with the establishment of the verification workflow representation itself where all activities are defined and it is decided what additional artifacts are to be saved for traceability. This representation is stored within the model archive for traceability and enabling repeatability, in alignment with SSP Traceability.

DOI 10.3384/ecp218751

Post Condition The tasks all have a final activity where the additional traceable artifacts relating to the verification are packaged within the model (FMI) or system (SSP) container, this to enable a strong traceability connection between the verification activity and data to the model. The post condition states that there should be a containerized model that can be utilized and simulated.

3.1.1 Application Use Case 1

Description The first use case is designed to evaluate multiple product designs over a number of test scenarios. A real world example may be when evaluating different pipe sizes in a system during different load conditions. The process begins by establishing what test scenarios are to be evaluated. For each test scenario, multiple model variants are created and simulated, and the results are subsequently compared. Since all simulation variants are independent of one another, they can be executed in parallel.

Scenario

1. Load existing scenarios from a file, store the scenarios or its location
2. Create the different design variants, store meta data of the design variations
3. Simulate the different variants in parallel
4. Collect and compare the Quantities of Interest (QoIs), store the results associated with the QoIs

3.1.2 Application Use Case 2

Description The second use case is designed to evaluate different behaviors of a model, this by creating multiple combinations of input stimuli and evaluating the results. This is often applicable as verification after model adjustments or prior to deployment to verify that the model is fully functioning. May involve using a number of preset scenarios or creating randomized permutations of scenarios based on methods such as Monte Carlo, then evaluate the resulting behavior in regard to one or multiple requirements and finally generate a OD that corresponds to the fulfillment of that requirement. Just as in the first case, the generated scenarios are not dependent on each other and all can be executed in parallel. To fulfill the requirement of repeatability, any randomization based method must either store the full scenario or metadata enabling recreation of the full scenario. Metadata could for example include reference to the software used for scenario generation, randomization method and/or seed.

Scenario

1. Create the different scenario variants, store meta data regarding the scenarios
2. Simulate the different variants in parallel
3. Collect the QoIs, evaluate and aggregate the fulfillment of the requirement against the DoV as an OD, store the resulting OD using Simulation Task Meta Data (STMD)

3.1.3 Application Use Case 3

Description In the third case, the goal is to find the optimal design of a geometry under some predefined constraints by using Bayesian methods for optimization, where the outputs of previous simulation are used to find better sampling positions. May be applicable in cases were complex interactions between models make optimization challenging, for example in optimizing cooling capabilities in relation to usage scenarios. Using iterative methods creates difficulties when it comes to determinism and repeatability of results. Synchronous batch-sequential methods have previously been employed in other areas using Bayesian search methods (Tran et al. 2022). In these the simulations are grouped in batches and when a batch is completed the next one is allowed to start. This allows each batch to utilize the outcome of previous batches to calculate new sampling positions while ensuring determinism. The main downside of this method is that it is often less effective than using methods that do not take batching into consideration, since the variance of the model simulation time can greatly influence the utilization ratio of the computational resource.

Scenario

1. Store the optimization algorithms and corresponding parameters, variables and, if applicable, randomization seed
2. Create the batch of design variants to evaluate based upon known information, store meta data of the design variations
3. Simulate the batch in parallel
4. Collect the QoIs and evaluate if the design goal is fulfilled, if not return to Item 2
5. Store the parameter set of the final design

3.2 Requirements of Workflow Representation

The workflow representation is to provide clarity as to what, and in which order, any verification

activity is to be executed. It should help maintain a clear trail of artifacts, enabling determinism, traceability and repeatability. To enable complex scenarios, it should support nested workflows, where sub-workflows have a clear connection to parent activities. Moreover, it should enable the execution of independent tasks concurrently, whether locally or in a distributed environment such as High Performance Computing (HPC), to optimize resource usage and efficiency.

The representation should have the ability to encapsulate common verification actions, such as simulation runs or result comparisons, into reusable components, to reduce code duplication, enhance maintainability, and lower the risk of human errors. To further enhance the possibility for re-use of components, it should possess the capacity for easy customization of activities, such as test conditions, parameter sweeps, and simulation scenarios. The workflow should also enable adaptation to intermediate results by using conditional rules that change the next steps based on factors like missing artifacts or whether goals were met. Finally, it should allow for comments, fostering clarity and collaboration by documenting the purpose and logic of each part of the workflow.

3.3 Design of Workflow Representation

We identified existing solutions for representing verification workflows and considered established domain-specific languages and workflow engines, such as Jenkins, Dask, Nextflow, Prefect, Luigi, Airflow, and Snakemake. While these tools offer advanced parallelization and dependency management features, our analysis came to the conclusion that their complexity and overhead often exceeded what was necessary for this scope.

Instead, we landed in a simplified Application Programming Interface (API) to express these tasks and dependencies. This approach maintained the option to layer on more sophisticated workflow management tools in the future, should complexity or scalability demands increase. Once the interface was established, the next decision was how to represent the workflows themselves: using an existing General-purpose language (GPL), such as python or develop a custom Domain-specific language (DSL) in the form of existing markup languages such as xml or json. Using a GPL offers the benefit of leveraging a mature ecosystem with readily available tools. However, it also requires that users are proficient in the chosen language and capable of effectively make use of existing tools. To keep complexity down and simplify access, both to users and potential no code/low code applications, the solution landed on limiting supported features though the utilization of an existing markup language. But to cater the more advanced users, it was also made possible to exploit the API directly as showcased in the Appendix under Listing 10 in cases where access and readability to non developers is deemed less important.

Selection of markup language began by evaluating common existing key-value pair data formats, including YAML Ain't Markup Language (YAML), JSON, Tom's Obvious, Minimal Language (TOML) and XML to determine how they fit the requirements. The final selection of XML was guided by three main considerations. First, the chosen format had to be easily interpretable and editable by engineers, ensuring that the workflow could be understood, maintained, and customized without invoking a specialized programming knowledge. Second, the storage solution needed to supply flexibility and be extensible to support a diverse range of verification tasks, including dependency management, parameterization, and dynamic adaptations. Third, we prioritized easy to use parsing possibilities and schema validation capabilities, all of which contributed to improved maintainability and scalability. Fourth, the selected solution should enable interoperability with traceability frameworks sush as SSP Traceability. To ensure that the verification workflow remains accessible and robust, we imposed guidelines on the structure and complexity of the XML files. Using standardized field naming conventions, encouraging descriptive comments and employing schema validation provides immediate feedback and clarity on correctness.

3.4 Version Control

To enable traceability of the evolving model and not just the final version, VCS—specifically Git—was integrated into existing model packaging formats such as FMI/SSP archives. In this use case, version control and packaging standards serve **orthogonal purposes**. The solution does not change the internal structure of the archive, it merely adds data for tracking changes. The combination a symbiosis; embedding a repository inside an archive enables tracking changes, ensures reproducibility, and allows auditing of the lineage of verification tasks. This approach used familiar version control mechanics, enabling seamless collaboration, comparison of different versions, and

DOI
10.3384/ecp218751

storage of historical results for review.

3.5 Verification of Workflow Representation

Finally, the methodology was verified through tests that confirmed its ability to meet the stated requirements. The approach was stress-tested by scaling the number and complexity of verification scenarios according to the use cases, with observations showing stable performance, clear error-handling mechanisms, and effective parallelization strategies. These tests also examined the impact of version control integration on model archive size and complexity.

4 Results

The solution consists of two distinct parts: first, the markup schema for defining the verification workflow, allowing for easy customization and repeatability of verification activities, its inherent portability making it optimal for providing traceability by integration into FMI or SSP archives; and second, a python function library—contained within the in-house V&V automation framework—defining the verification activities, providing a static point that multiple workflows can operate against.

4.1 Resulting Workflow Representation

The structure and attributes of the resulting XML schema are described in this section along with the connection to the initial requirements.

Action Starting with the smallest artifact of the schema, the link to the automation framework library of predefined functions. It specifies a named reference inside the library, any additional fields within the scope are custom parameters that will be passed to the library function as seen in Listing 1. A function together with its parameters effectively creates templates for simplified re-use to reduce code duplication and maintenance overhead. Instead of rewriting actions for similar tasks, engineers can adapt templates by altering a few parameter values, making the verification process more flexible, modular, and cost-effective.

Listing 1. Activity example

```
<action function="simulation">
    <parameter_1 value="f"/>
</action>
```

Grouping mechanisms Due to the often computationally expensive operations involved in executing simulations, the speed-up factor of parallelizing very slow activities—such as simulations—can often be close to optimal since any overhead will almost always be much smaller than the actual simulation. Therefore, enabling parallelization is essential for scalability, where multiple simulations should be processed simultaneously. To facilitate this, two different grouping types were introduced: **sequential** (Listing 2) and **parallel** (Listing 3). These grouping types enable clustering of activities, the former defining a dependency chain of execution in sequential order and the latter that all activities within the group are independent and could be executed individually.

Listing 2. Sequential example, creating a sequential dependency chain between the actions, forcing execution in a specific order

```
<sequential>
    <action function="action_1"/>
    <! -- potential additional actions -->
</sequential>
```

Listing 3. Parallel example, all actions can be invoked independently of each other

```
<parallel>
    <action function="action_1"/>
    <! -- potential additional actions -->
</parallel>
```

Structure The overall structure is based on two main principles. First, a hierarchical structure that enables nested grouping operations, allowing for complex scenarios while maintaining coherence and clarity (see Listing 5). The second principle is dynamic adaptation, which allows any action to change or add actions downstream.

Dynamic adaptation has two main objectives, the first being to facilitate adaptation to unknown factors. For example, an action that searches for scenarios in a folder has no way to know how many, or what kind of, scenarios it will find before execution. To enable this, the action, after finding the scenarios, will make adjustments to downstream actions to reflect the new information, Listing 5 showcases a workflow that corresponds to this scenario, simulating and verifying results for each input data file it finds in a directory at runtime, the definition of the function called shown in Listing 4. The second objective of dynamic adaptation is to enable the workflow to take into account intermediate results such as failures or fulfillment of conditions and automatically branch to alternative paths. This adaptability is often connected to handling iterative tasks where the number of iterations may not be known beforehand.

Listing 4. Python signature of `find_files`

```
def find_files(path: str,
               pattern: str = "*.csv") ->
                   list[Node]:
    """Creates corresponding nodes to
        availible files that match *pattern
        * under *path*."""
```

Listing 5. Dynamic adaptation, adapting to the number of files found

```
<sequential>
  <action function="find_files">
    <path value="file_storage/"/>
  </action>
  <sequential>
    <action function="simulate"/>
    <action function="evaluate_results"/>
  </sequential>
</sequential>
```

Combining these two principles enable the building of almost any workflow, including generating scenarios and design variations, comparing results, and executing different actions depending on the outcome, all while maintaining the readability of both simple and complex workflows. In the end, the basis for enabling these requirements, while keeping the representation compact and understandable, was to outsource much of the complexity to the automation framework's function library; this by creating helper functions for advanced use cases. The ability to construct templates of common verification scenarios also creates reusability opportunities and limits code duplication between workflows.

Global parameters Outside the scope of the workflow, it is possible to place **global parameters**, as seen in Listing 6. Any number of global parameters can be created, and they will be propagated to all functions, this to enable some common understanding of context without explicitly feeding the parameters, for example model location, to each action. As seen in Listing 6, the top workflow definition consist of a single sequential or parallel grouping.

Listing 6. Workflow example

```
<VerificationWorkflow>
    <model value="./model_1"/>
    <sequential>...</sequential>
</VerificationWorkflow>
```

Limitations The order of execution is strictly downstream, meaning that each action can only be executed once in a specified sequence. This results in that an action should not create a downstream dependency to any action that is upstream. Data, on the other hand, can only be accessed upstream where a dependency exists to ensure a deterministic result. Figure 4 showcases how requirements regarding execution order, parallelization opportunities and data access relate.

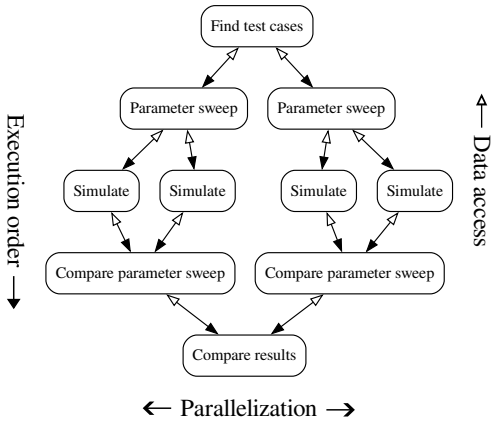

Figure 4. Showcasing execution order, parallelization possibilities and data flow

To mitigate some complexities related to merging branches executed in parallel, there is a defined limit to the change scope for dynamic adaptations. An action may only adjust actions or groups that are within its own grouping scope. For example, in Listing 7, **outer_action_1** can alter everything downstream, including the inner actions. However, when moving into the inner scope, the **inner_action_1** can only alter actions downstream within its grouping scope, more specifically **inner_action_2**.

Listing 7. Dynamic adaptation scope

```
<sequential>
    <action function="outer_action_1"/>
    <sequential>
        <action function="inner_action_1"/>
        <action function="inner_action_2"/>
    </sequential>
    <action function="outer_action_2"/>
</sequential>
```

4.2 Implementation

The V&V framework parses the workflow representation and constructs a corresponding Directed acyclic graph (DAG). Any actions grouped by a clustering mechanism are enclosed by start and end nodes to facilitate simpler graph manipulations. This design is chosen for the same reason that most programming languages use notations such as {} or tabs to clarify the beginning and end

DOI 10.3384/ecp218751

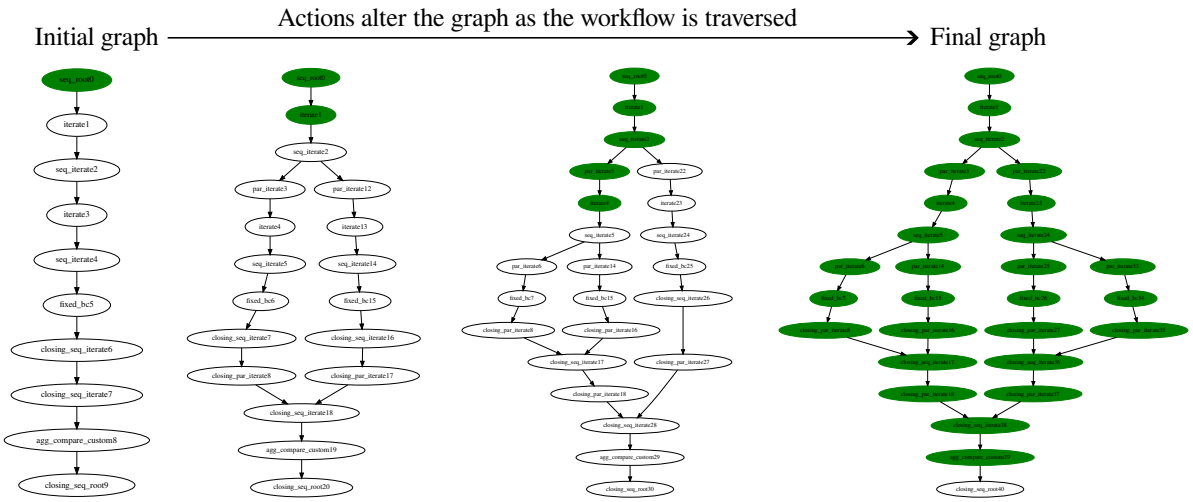

Figure 5. Graph adaptation during execution for use case 1. Filled node marks completed actions

of constructs. Although the start of a construct can often be inferred from context, it is often challenging to distinguish where the construct ends without a closing notation.

After finding the starting node, the application begins traversing the DAG downstream, morphing the graph as the actions execute, see Figure 5 for a description of how the graph alters after that actions are processed. To enable this, the full DAG is passed to each action for modification and when returned, it is merged back into the original DAG before continuing execution. The graph corresponding to use case 1 is showcased in Figure 5; the traceable artifacts of the activity and workflow representation are described as SSP Traceability artifacts in the Appendix, see Listing 8 and Listing 9.

4.3 Version Control

By integrating version control systems within model archives, each verification activity and its results could be linked to specific model versions, parameters, and configurations, thereby creating a comprehensive audit trail, see Figure 6 for a visualization of the concept. This enhanced traceability facilitated root-cause analysis in cases where discrepancies arose and provided a robust foundation for conducting credible and reproducible verification processes. But despite these successes, some limitations surfaced. Handling large binary artifacts within the version control system was challenging, inflating repository sizes and complicating storage. Future improvements might involve adopting specialized large file storage solutions or more effective strategies.

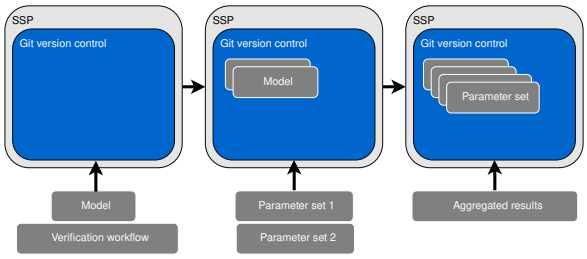

Figure 6. Showcasing the version control methodology, each step a snapshot in time enabling traceability of model creation and alterations

4.4 Verification

When applied to the use cases, the workflow consistently produced traceable and reproducible verification results. Stakeholders perceived the enhanced traceability as increasing the trustworthiness of verification outcomes. Preliminary evaluations suggested that the new workflow format offered clearer logic navigation and easier interpretation than previous solutions. The workflow representation was perceived to minimize the need for code duplication between projects. Additionally, the options for using templates for common functions to further simplify the workflow design are promising and warrant further evaluation.

5 Discussion

Workflow representation By comparing the verification method to established practices highlights some improvements. Traditional methods, such as the *Saab Aeronautics Handbook for Development of Simulation Models* (Andersson and Carlsson 2012), often rely on non machine readable, document-centric tracking, which may be error-prone and sometimes difficult to maintain. By consolidating workflow definitions and

model data into a consistent, machine-readable form, the proposed approach reduces human error, enhances discoverability, and aligns well with growing industry trends toward continuous integration and continuous delivery.

The function library contained within the automation framework offloads much of the complexity from the workflow representation and direct manipulation of the DAG, enabling a simpler representation of the workflow. Offering fine-grained control via arguments or flags enabled teams to adapt the workflow to various conditions without creating entirely new test definitions. However, this raises questions whether it might sometimes be too simplistic. For example, in Listing 5, it is not possible to determine how the function **find_files** will alter the downstream actions by only looking at the representation. This places requirements on the function library to provide clarity regarding what functions do and how they affect the workflow; Underscoring the need for intuitive defaults, comprehensive documentation, and clear guidance to ensure broad and consistent user adoption. It is identified that a possible mitigative action is to foster collaboration best practices regarding workflow adaptations among users.

During the design, the discussion rose early to include the possibility to let workflow designers work directly in python, skipping the markup schema. In some cases one is preferred, in others not. It almost always comes back to how to enable easy access for all stakeholders, not only developers, to the verification workflows. We identified that XML would align more closely with standards such as SSP and FMI but may in some cases be quite explicit provide less readability for use cases such as this. If a port to some other format would be deemed necessary in the future, XML is highly convertible into almost any other key-value pair format.

Implementation By breaking large verification tasks into parallel segments, total execution time was reduced; however, coordinating these tasks introduced new challenges in synchronizing data states and results. Many of these challenges relate to how branches should be merged; for example, how to handle situations where two branches have made different changes to future common activities. To cope with this, it was necessary to place restrictions on how dynamic adaptation functions in order to mitigate some complex cases. Prohibiting feedback loops in the graph is one such restriction that minimizes the chance of overwriting artifacts at consecutive invocations. Disallowing loops does lead to some complexity when taking iterative workflows into account, and creative workarounds are sometimes needed to achieve certain complex cases. For example, in iterative workflows to achieve conditional effects the solution could be to copy the desired actions to the end when a condition is triggered, thus creating the next iteration.

The chosen implementation solution for parallelization has created a high level of complexity when coupled to the ability for dynamic adaptation of the graph. The design decision not to use a central graph handler to orchestrate the parallelization, but to let parallel threads traverse the graph independently of each other, enables a very high degree of parallelization. In hindsight, most likely unnecessarily high since any simulation activities will be magnitudes slower, a clear case of premature optimization. The implication of the design is that each parallel branch has its own notion of the DAG. Without a central authority, the branches must negotiate the new notion of truth before continuing when merging branches.

Traceability The intention originally was to utilize Simulation Resource Meta Data (SRMD) for storing and the resulting workflow definition. After delving deeper into the definition of SSP Traceability, it was later adjusted to utilizing an external resource together with STMD. Both SRMD and STMD are connected to the **Credible simulation process**, but more fitting would be to have a stronger connection to the **credible modeling process** by utilizing Modeling Task Meta Data (MTMD). But at the moment this is not included into the released version of the standard and the content between the metadata formats are in large interchangeable, thus the choice went to using the released STMD

Embedding version control systems directly within the model archives offers a transparent, maintainable history that aligned well with established practices such as FMI/SSP. The resulting benefits, including easier reproduction of results, better understanding of model evolution, and stronger stakeholder confidence, generally outweighed the overhead and complexity of managing multiple branches, commits, and binary data within a repos-

DOI
10.3384/ecp218751

itory. Data management and storage considerations emerged as another critical aspect of the solution. Storing binary artifacts within version control systems allowed for a single source of truth and integrated traceability, but also increased repository sizes, potentially affecting performance and long-term maintainability. Strategies like introducing binary files early, employing artifact repositories or Git LFS, and limiting unnecessary duplication can mitigate these issues. Nonetheless, as verification activities scale up, organizations will need to carefully balance repository complexity against the benefits of having all artifacts co-located and tracked within the same environment.

6 Conclusion

This work has presented a method for managing model verification activities that meet the stated research objective of achieving traceability and repeatability in verification workflows, while ensuring readability and enabling automation. By preserving the complete history of verification activities, providing a transparent and evidence-based record that in the end supports more informed decision-making during and after development. Binding verification logic closely to model versions, harnessing parallel execution, and embracing dynamic adaptation, the approach supports more rigorous and scalable verification scenarios. By integrating traceable verification workflows with version control embedded into model archives, the approach provides a platform for managing complex and evolving verification processes.

The Modelica association standards FMI, SSP, and SSP Traceability serve as key enablers to the presented work. Relying on such standards allow the presented functionality to interplay, through portable and stand-alone simulation packages, with similar functionality provided in both open source and commercial tools, such as Dymola (Bruck 2023). Work to initiate this described interplay between testing frameworks and development tools has been initiated in the OpenSCALING project and at Saab through, for example, the work of Matstoms (Matstoms 2025). Matstoms realizes SSP Traceability, and automation, in an existing regression testing framework including model development tools in the loop, particularly Dymola, OpenModelica (Mengist et al. 2015), and easySSP (exxellent Solutions 2025).

The positive reception, strong performance gains, and improved user experience provide a solid foundation for ongoing refinements and broader integration into current software development practices, continuous integration processes, and simulation ecosystems that use standards such as FMI or SSP. As best practices and tools continue to evolve, integrated, traceable, and machine-readable verification workflows are likely to continue evolving and becoming more mature, in the end benefiting a wide range of simulation and modeling applications.

Acknowledgments

This research was conducted within the scope of the Advanced digitization ERATO projects as well as the ITEA4 OpenSCALING project, funded by Vinnova and Saab AB. The authors would also like to thank Dan Louthander for his work with the in-house verification framework.

Integration of Geometric Tolerance Analysis in System Simulations via Functional Mock-up Units

Abstract

This paper presents a concept for integrating geometric tolerance analysis into system simulations using Functional Mock-up Units (FMUs). While various methods and tools for tolerance analysis exist in the mechanical domain, there is currently no standardized or widely established approach for their integration into multi-domain system simulation. This work proposes a structured FMU interface based on the Functional Mock-up Interface (FMI) standard, enabling a modular and reusable representation of tolerance behaviour. The concept is demonstrated in a case study, in which an FMU for static tolerance calculation was implemented and successfully verified against a commercial analysis tool. Furthermore, the use of the FMU with FMUGym illustrates the potential of the FMI ecosystem to flexibly combine tolerance models with other simulation environments and analysis methods. The results demonstrate that FMUs can provide a suitable and tool-independent interface for integrating geometrical tolerance effects into system-level simulations and model-based engineering processes.

Keywords: geometric tolerances, ISO GPS, tolerance analysis, MBSE, system simulation, Functional Mock-up Interface

1 Introduction

Geometrical tolerances of mechanical parts, in particular shape and position tolerances, play a central role in the precise definition of technical systems. They are defined by the geometric product specifications (GPS). Although there are already numerous simulation approaches for these tolerances in the mechanical domain, there is a lack of standardised approaches for integrating them into multi-domain simulations which are used for Model Based System Engineering (MBSE). The aim of this work is therefore to investigate a possible solution to enable the integration of geometrical tolerances for such simulations and to evaluate Functional Mock-up Units (FMU) (Blochwitz et al. 2011) as a possible interface. FMUs could serve as the connection between commercial Computer-Aided Tolerance (CAT) management programs or other analysis models and the system simulation, as shown conceptually in Figure 1.

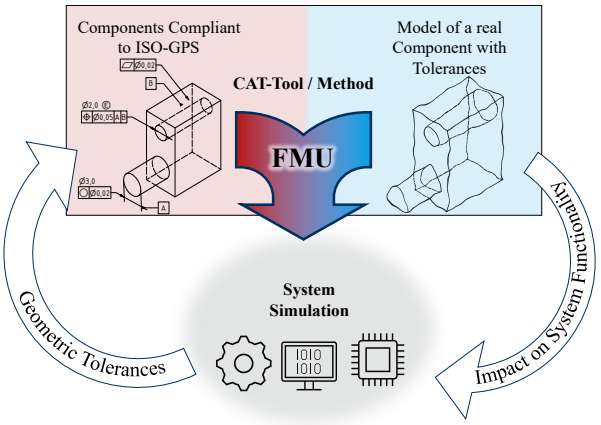

Figure 1. Our concept for the integration of geometric tolerance simulations into the product development process with system simulation via FMUs, influenced by ISO-GPS (red) and the modelling method used (blue).

Several challenges show the necessity of such an approach. Firstly, CAT with commercial tools is often regarded as a black box by the user, as the underlying methods are not accessible in detail (Kosec, Skec, and Miler 2020). This makes it difficult to adapt the models to new applications under changed boundary conditions. In addition, there is still no standardised methodology for setting up mechanical tolerance simulations, which impairs the comparability and reproducibility of results (Morse et al. 2018). The usability of existing scientific solutions also poses a problem, as many approaches are either too complex, not accurate enough for certain problems or not sufficiently user-friendly (Walter et al. 2021). There are also approaches from the field of MBSE to solve geometric problems using library elements (Moers et al. 2025). However, these are much less flexible and less precise than tolerance simulations that are specifically tailored to the problem of mechanical part geometry.

Precise tolerance simulation requires expert knowledge and a deep understanding of the respective domain (Ramnath et al. 2018). Modularisation of the modelling task therefore appears to be a promising approach to reduce complexity and facilitate access for users.

This work focuses on the simulation of rigid mechanical assemblies, with the aim of enabling static tolerance

analysis in the context of system simulation - similar to existing commercial tools such as *CETOL*, *MECAmaster*, or *3DCS*. While dynamic and transient simulations of tolerances have been addressed in initial research (Husch and Walter 2024), this paper deliberately focuses on static scenarios as a first step. Future extensions could build on these results to support more complex, dynamic applications.

The main contributions of this paper are:

- An analysis of the state of the art in tolerance simulation methods, with a focus on their interfaces and applicability within system simulation.
- The introduction of a new FMU-based concept for transferring specialised tolerance analysis methods to system-level simulations, demonstrated through a case study.
- The demonstration of additional use cases for FMUs within the FMI ecosystem, illustrated by performing a Monte Carlo simulation using the FMUGym toolbox.

2 Related Work and Methods

In order to effectively implement a mechanical tolerance model, it is essential to first consider both the standards and regulations that define geometric specifications, as well as the scientific methods used to simulate and analyse them. The relevant aspects of FMUs in relation to this application are important as well and thus, are also summarized below.

2.1 Mechanical Tolerance Analysis

Mechanical tolerance simulation in this paper's context specifically refers to the simulation of geometric deviations in components arising from their dimensions (size), shape (form), orientation, position (location), profile, and run-out in relation to one another. The underlying standard is the ISO-GPS system (ISO International Organization for Standardization 2011). The unique aspect here is that these tolerances go beyond pure scalar dimensions and therefore require special calculation methods for linking several tolerances.

Before the established analysis models are presented, two terms that are equally relevant for all of the methods need to be explained:

- *Functional Requirement (FR):* This is sometimes also referred to as a functional condition and describes the geometric entity that is relevant for the correct function of the assembly in the technical application and has to stay inside of certain limits. Depending on the calculation method used, this describes either a scalar (a distance) or the three-dimensional boundary of a resulting position in space. Defining this condition is the task of the user for all available methods. There are approaches for systematically or even automatically determining this condition, which can be used when solving specific tasks (Anselmetti 2006). FRs still have to be interpreted afterwards. Frequent target variables are, for example, the clearance of a fit or the misalignment in an assembly. The FR is an edge in the contact graph.
- *Contact Graph:* Or assembly graph is used to model the network of mating contacts and constraints between features in an assembly. This graph defines the relationships that form the tolerance chains - the paths through which individual part variations accumulate to affect a functional requirement. In commercial CAT software, the contact graph can be derived from the 3D CAD model, sometimes with the help of additional user input. For manual analyses according to the methods presented below, it must be created by the user, for which systematics are suggested in the literature (Haghighi et al. 2014).

The following paragraphs describe six analysis methods as well as groupings of tolerance models with their primary literature sources. There exist various modifications of most of the methods, for which numerous reviews (Hallmann, Schleich, and Wartzack 2020; Chen et al. 2014; Cao, Liu, and Yang 2018; Shah et al. 2007; Shen et al. 2005) provide a good overview. A summary of the most relevant aspects can be found in Table 1.

Vector Loop
(Chase et al. 1996)
The Vector Loop method models assemblies as closed kinematic loops, using vectors to represent nominal dimensions and constraints for mating conditions between parts. Tolerances are represented by small adjustments at the joints. Nominal dimensions, tolerance values, and assembly constraints are required as inputs. The calculated result is a point to point distance, which is interpreted as the FR. The method is able to calculate worst-case as well as statistical results with consideration of input-distributions. It can handle serial tolerance chains well but is not capable to represent complex, parallel tolerance chains in its basic form due to its limited ability to model intricate geometric interactions.

Matrix TTRS
(Desrochers and Riviere 1997)
The Matrix TTRS (Technologically and Topologically Related Surfaces) method uses homogeneous transformation matrices to model tolerances as small permissible displacements. It requires the nominal geometry, tolerance zone constraints, and assembly connections. The output is a range of variation in a critical assembly dimension based on solving inequality constraints. This represents the worst case calculation. It can theoretically handle complex parallel tolerance chains, but solving large constraint sets is computationally expensive, making it impractical for very detailed assemblies.

DOI
10.3384/ecp218765

Table 1. Overview of tolerance analysis models with their relevant characteristics.

Method / Model	*Result*	*Tolerance Representation and Calculation*	*Comment*
Vector Loop	distance, point to point	solution for joint conditions, concatenation of linearized transformation matrices	point based method (not well suited to represent form deviations), no parallel chain calculations
Matrix TTRS	distance, point to point	TTRS with non-linear constraint inequalitys	point based method, statistics only from Monte Carlo
Jacobian Torsor	interval of FRs position and rotation (6D)	multiplication of jacobian matrix with SDT (interval arithemtic)	partly represents form tolerances, handles certain parallel chains
Deviation-Domain	boundaries of tolerance zone in deviation space (6D)	coordinate transformation and polytope calculation	good compatibility with ISO-GPS, complicated implementation
Parametric Variation & Skin Model Shape	one or multiple measurements with statistic distribution	variation of parameters and 3D-contact solving with solids or mesh bodies	requires a sophisticated solution to solve the 3D contact problems

Jacobian Torsor
(Desrochers, Ghie, and Laperrie‘re 2003)
The Jacobian Torsor method combines Jacobian matrix transformations with Small Displacement Torsors (SDTs) to represent tolerances in six degrees of freedom. It requires assembly constraints, SDT representations of tolerances, and a functional requirement definition. The output is the variation range of a key dimension, computed using interval algebra. It handles complex and to some extent also parallel tolerance chains, making it usable for larger assemblies while maintaining computational efficiency.

Deviation Domain Methods
(T-Map (Davidson, Mujezinovic, and Shah 2002) and Polytope (Homri, Teissandier, and Ballu 2015))
The methods working in the Deviation Domain explicitly compute the geometric region of variation using operations on the tolerance space, which represents the possible translation and rotation of a feature (6D). The required input includes tolerance zones, assembly constraints, and mating feature definitions. The output is a geometric volume of possible variations, enabling worst-case and statistical analysis. It can theoretically handle parallel tolerance chains but suffers from exponential computational complexity, making it suitable for small critical assemblies rather than large systems.

Parametric Variation
(Gupta and Turner 1993)
The Parametric Variation method applies Monte Carlo simulation to a parametric CAD or analytical model, varying dimensions based on statistical distributions. It requires a parametrised assembly model, tolerance distributions, and assembly constraints. The output is a probabilistic distribution of functional variation. It can handle complex and parallel tolerance chains within the limits of the used geometric contact solver (for parametric CAD) but may require thousands of runs, making it computationally expensive.

Skin Model Shape
(Schleich et al. 2016)
The Skin Model Shape method (SMS) simulates tolerance effects by generating randomized part surfaces, assembling them virtually, and measuring the outcome. It requires a detailed CAD model, tolerance distributions, and assembly constraints. The output is a statistical distribution of assembly variations, considering realistic form deviations. It can handle complex and parallel tolerance chains, but the computational burden is extremely high, making it impractical for routine design work but useful for high-precision simulations. It can be considered a further development of the parametric variation approach.

All analysis methods have in common that they take information from both the nominal geometry (3D model) and the defined tolerances as input - including positions, interactions according to the contact graph, tolerance types and tolerance zone widths. The output is an FR in one or more dimensions, either as a scalar value or as a value range.

2.2 FMU

An FMU is a self-contained executable file that facilitates integration and simulation within various development environments that adhere to the FMI standard (Blochwitz et al. 2011), such as Modelica based tools or MATLAB Simulink. The idea behind the FMI standard is to enable comprehensive digital modelling of complex systems. If a real-world product consists of multiple interacting com-

ponents, each governed by intricate physical laws and associated control systems - including electronic, hydraulic, and software-based controls - then it should likewise be possible to digitally assemble a virtual counterpart from individual models representing these subsystems. Each FMU is packaged as a zip archive comprising an XML file with static meta-information, and a C library used for evaluating model equations and their derivatives. This library can be provided in source form or as a dynamically linked compiled library (DLL), and is suitable either for static or dynamic linking. FMI defines two primary forms of interconnection: model exchange, in which interactions occur at the level of a differential-algebraic system of equations (DAE), and co-simulation, which handles discrete input-output interactions at specific communication time points. The FMI standard 3.0 further introduces the scheduled execution format supporting concurrent computation of model partitions on a single computational resource (e.g. specific CPU-core). Although primarily designed for transient simulation scenarios, the FMI standard has been applied in previous research to perform steady-state (design-oriented) simulations, typically involving static single-step computations (Gohl et al. 2024). Similar to our intended use-case, FMUs have also been used as transfer interfaces for three dimensional FEM models (Gödecke et al. 2012).

While the FMI standard and FMUs are well suited for modular modelling and simulation, integrating uncertainty handling and automation features remains an active area of development. The Modelica Credibility Library (Otter et al. 2022), for instance, offers structured mechanisms to represent uncertainty directly within Modelica models and supports traceability, credibility assessment, and transparent documentation of assumptions. However, it has not yet been used in our concept for two main reasons: first, the library lacks interfaces for automated simulation workflows or integration with Python-based environments; second, the current data is derived solely from predefined GPS, so detailed traceability is not yet a priority. Recent contributions such as FMUGym (Wrede et al. 2024) have extended FMI applicability to machine learning scenarios. FMUGym is a Python-based interface that supports reinforcement learning-based control of FMUs and accommodates model uncertainty. It handles co-simulation FMUs compatible with FMI 1.0, 2.0, and 3.0, linking simulation environments with reinforcement learning libraries. In a simplified manner, FMUGym also allows a standardized evaluation of simulation model outputs under specified input distributions and varying system parameters. This makes it suitable for analysing the tolerances of technical systems.

3 Proposed Concept for Geometric Tolerance FMUs

This chapter presents how FMUs can be set up for the simulation of geometric tolerances of mechanical components

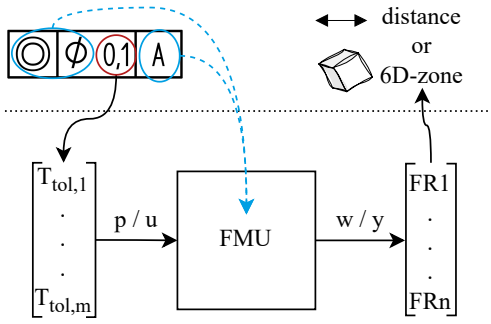

Figure 2. FMU Concept: Tolerance zone size T_{tol} from ISO feature control frame as input and Functional Requirement FR as output depending on the method used for tolerance calculation.

and which interfaces they provide. The actual computation of the tolerance values is not subject of this paper, as this depends heavily on the selected method and the considered application - a brief explanation and assessment of the suitability of various methods can be found in subsection 2.1. The goal is rather to formulate a generic specification of interfaces in line with the FMI standard, in particular with regard to possible inputs and outputs as shown in Figure 2. For the static case considered in this paper, both parameters (p) and input variables (u), as well as local variables (w) and output variables (y), can be treated equivalently to represent mechanical tolerances. It should be noted, that a differentiation between these categories would be necessary in the context of dynamic simulations (e.g. with external forces).

The idea for structuring the interfaces is based on the elements of the tolerance feature control frame according to ISO-GPS. The scalar values of the tolerance field variables are provided as input variables - i.e. the numerical value in the second box of the ISO tolerance field (see Figure 2). Further information, such as the specific tolerance type, geometric datum references or other model-dependent details, are only included in the internal structure of the FMU. This separation makes it possible to keep the external interface stable and generic, while the internal modelling can be flexibly adapted to different analysis methods. The FMU must also be capable of modelling several FRs at the same time, as complex systems can rarely be reduced to a single FR. This results in the need to integrate several analysis models within an FMU. To the outside world, each tolerance defined in the CAD-model or drawing only appears as a single parameter T_{tol} representing the size of the tolerance field. An exemplary realisation of this structure can be found in the case study in section 4.

The output of the FMU are the individual FRs, which can take different forms depending on the model type and analysis objective. In the simplest case, the output is a scalar, e.g. to describe a distance between two points. However, even in these simple approaches, the result is typically given as a range with statistical or worst-case limits for this distance - effectively requiring two output variables per FR to represent minimum and maximum

DOI
10.3384/ecp218765

values. For more complex models such as the Jacobian torsor or the deviation domain, deviation ranges or three-dimensional spaces can be expected as outputs. The actual reduction to interpretable individual values, such as worst-case values, then proceeds outside the FMU. Probability distributions could also theoretically be the output. However, we suggest to carry out the actual statistical evaluation outside of the FMU, as the FMU should only provide the geometric tolerance calculation.

The choice of FMUs as the basis for this approach is suitable in particular because they allow modular, standardised integration into existing simulation environments and promote the reusability of complex analysis logic.

4 Case Study

The following case study shows an example of how a geometric tolerance simulation can be integrated into an FMU and subsequently used as such. The starting point is the analysis of an assembly with the commercial simulation tool CETOL. Based on this analysis, an FMU is created that calculates the same FRs as the reference analysis internally and uses the interfaces described in section 3.

4.1 Application Example

The example shown in Figure 3 shows a simplified model of a stepper motor with translational output. A magnetic field is generated in the stator (S), which causes the magnetic rotor (R) to rotate. The rotor is held between two balls (B) and drives the nut (N) via a spindle (not shown here), which converts the rotary movement into a linear movement. The assembly is completed by the end cap (C), which also serves as a linear bearing for the nut.

The contact graph in Figure 4 illustrates the relationships between the individual components and contains the labels of all relevant connection points, whose interactions are explained in more detail in the following subchapter. The values and types of tolerances are listed in Table 2.

The study focuses on the gap widths $FR1$ and $FR2$ marked in Figure 3. $FR1$ describes the air gap between the stator and the rotor through which the magnetic field flows, while $FR2$ relates to the mechanical fit of the linear bearing on the output. The upstream analysis in CETOL also serves to identify those tolerances within the defined mechanical chain that have a relevant influence on the FR under evaluation. Parameters that are not categorised as relevant in this analysis are not taken into account in the subsequent FMU implementation. This approach is useful as only the relevant parameters should be included, even in the event of a future automated FMU export. For the present case study, this reduces the manual calculation effort when implementing the FMU.

The following additional boundary conditions for the implementation of the FMU result from the example application and the setup of the CETOL analysis. These are particularly relevant in regard to the comparison of the calculations implemented here with the previously presented analysis methods from the literature:

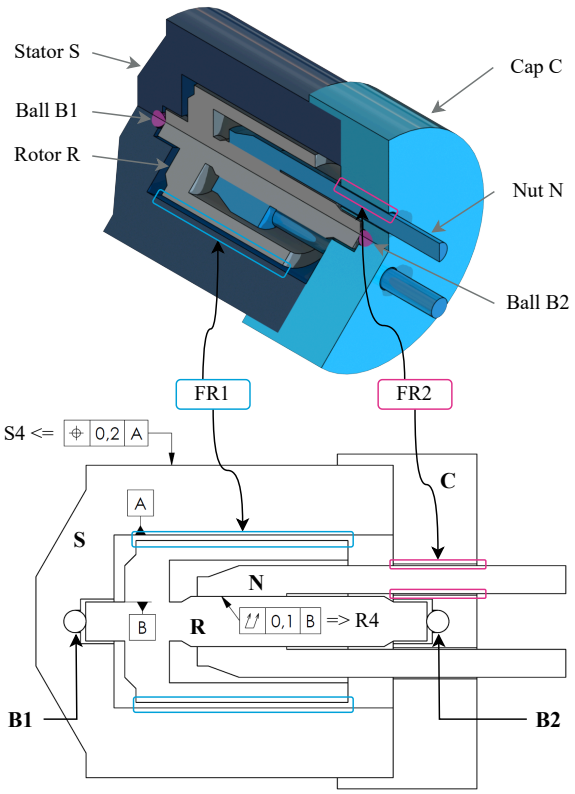

Figure 3. CAD model of a stepper motor with component labels and FR positions used for the case study. The assignment of the labels for the geometric tolerances is shown as an example for S4 and R4.

- Rigid solids without deformation are assumed.
- Contacts between components only occur at defined connection points.
- Shape tolerances are not fully mapped in accordance with ISO standards.
- The assembly sequence specifies manually defined kinematic dependencies between the components.
- Parallel tolerances are simplified by making assumptions about their degrees of freedom.

4.2 Implementation as FMU

In this example, the analysis of the mechanical tolerances is limited to a 2D plane. This simplification is acceptable due to the predominantly rotationally symmetrical components; minor deviations in the non-rotationally symmetrical nut (N) and end cap (C) are accepted for the benefit of clarity. It is not the scope of this paper to demonstrate how complex 3D analysis methods can be automatically translated into executable code, but rather to show the basic process of using an FMU to transfer the tolerance analysis model. Therefore, the internal content of the FMU must still be manually created and verified. A simplified case such as the one presented here is particularly beneficial

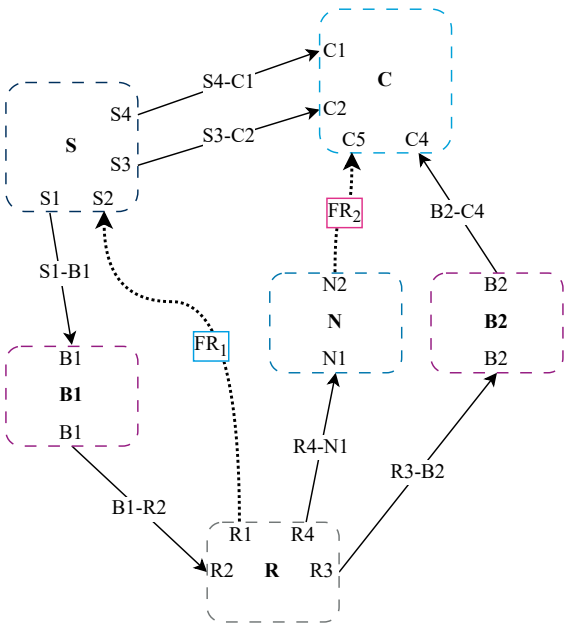

Figure 4. Contact graph of the motor with part labels and links between tolerances

in this context, as it allows for transparent modelling and easier validation of the implemented logic.

As described in subsection 2.1, the existing analysis methods differ fundamentally in their calculation logic. Accordingly, the internal code within an FMU also varies depending on the underlying method. For this case study, the following procedure was chosen to build the FMU:

1. Analysation of the tolerances and joints defined in CETOL
2. Derivation of the kinematic chain and constraints
3. Analytical calculation of the influence of all part tolerances on the investigated FR
4. Implementation of the resulting equations as an Modelica algorithm, including the summation of the final results
5. Export of the Modelica model as FMU

Table 2. Type and size of tolerance zone T_{tol} of all tolerances relevant for calculating the FRs

Tol	*Type*	T_{tol}	*Kinematics*	*FR*
R1	diameter	0.1 mm	linear	$FR1$
S2	diameter	0.1 mm	linear	$FR1$
S4	position	0.2 mm	tilt	$FR1$, $FR2$
C4	profile	0.1 mm	tilt	$FR1$, $FR2$
C5	diameter	0.2 mm	linear	$FR2$
R4	runout	0.1 mm	tilt	$FR2$
N2	diameter	0.1 mm	linear	$FR2$

In combination with the previously defined boundary conditions, the approach is similar to the vector loop method. To simplify the implementation, a solver algorithm for determining the linking states is not used. Instead, all relevant cases are solved analytically and are integrated into the FMU as equations.

For $FR1$ and $FR2$, this results in a compact set of equations for the relevant tolerances listed in Table 2. R1 and S2 describe the simple linear variation of the air gap $FR1$ on both sides. The same applies to C5 and N2 with regard to the fit of $FR2$. The tolerance variations of C4 and S4 result in different tilting movements of the kinematic chain, which influences both FRs. R4 is also a tilting move only affecting $FR2$.

To determine the resulting worst-case tolerance, the effects on the target dimension are calculated separately for each individual tolerance along the kinematic chain - as shown below. Finally, all partial solutions FRn_i are summed up and added to the nominal value of FRn.

Our calculation is based on the radius (y-axis in Figure 5), which is why all diameters are halved. In the linear cases (see Table 2), the tolerances in this example - due to the symmetrical tolerance zones - are each taken into account in the calculation with half the value of their tolerance zone width. The individual contributions thus result directly from the width of their corresponding tolerance zone T_{tol}:

$$FRn_{i,max} = +T_{tol}/4 \tag{1}$$

$$FRn_{i,min} = -T_{tol}/4 \tag{2}$$

The rotational deviations can be derived geometrically from the kinematic joints by combining several vectors from the loop. The tilting cases with relevant geometric parameters for deriving the equations are shown in Figure 5.

Changes in the tolerance of C4, as defined by the joint configuration, result in a tilting of the rotor R around the contact point at B1 (Point O in Figure 5), caused by moving B2 by $t = T_{C4}$ along the y-axis. Under this assumption, the tilt angle can be calculated:

$$\alpha_{C4} = \arcsin\left(\frac{t}{l_R + r_B}\right) \tag{3}$$

Changes in R4 are a simple rotation of part N on part R around the center of the cylinder axis. This results in a direct influence of the tolerance zone rotation on the final result. The total rotation angle is determined by the characteristic length c_{R4}, which corresponds to the length of the cylindrical surface defined by the geometry of part R for the runout tolerance R4 (see Figure 3):

$$\alpha_{R4} = \arctan\left(\frac{T_{R4}}{c_{R4}}\right) \tag{4}$$

DOI
10.3384/ecp218765

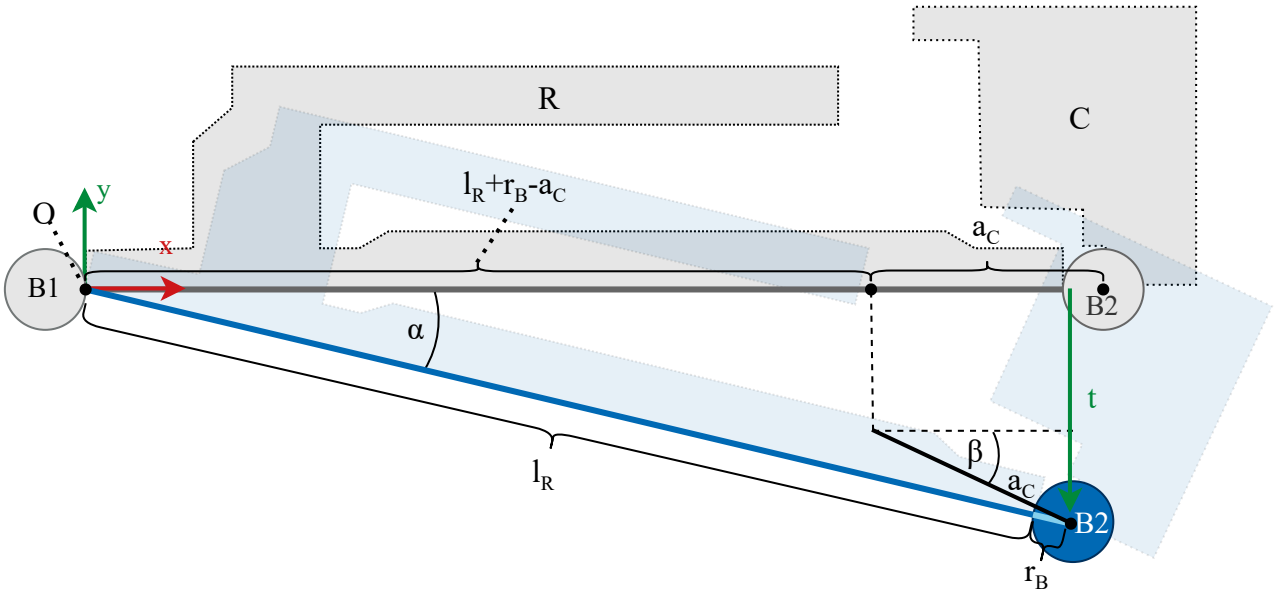

Figure 5. Geometric relationships for calculating the tilt angle α of the rotor between the bearings B1 and B2

Changes in the tolerance of S4 result in a tilting of the rotor R around the contact point at O at Ball B1, as well as a tilting of the cap C around the ball B2. During these movements, contact between the cap C and the stator S in the x-direction is maintained (with the contact defined at a fixed distance a_C). The tolerance variation affects the angle β in this case, which is calculated by using the tolerance zone width T_{S4}: $\beta_{S4} = \arctan(T_{S4}/c_{S4})$. The characteristic feature length c_{S4} can be derived from the geometry of part S. S4 defines the tolerance of the outer cylindrical surfaces shown in Figure 3. Corresponding to Figure 5, α_{S4} can then be determined using this equation:

$$\alpha_{S4} = \arccos\left(\frac{a_C \cdot \cos(\beta_{S4}) + l_R + r_B - a_C}{l_R + r_B}\right) \quad (5)$$

The tilt angles α can be used to determine the change of FRn_i in relation to these measuring points via the position vector of the FRn. For $FR2$, it should be noted that in the case of S4 the reference point for measurement in part C is also rotated by the angle β_{S4}.

Finally, the partial contributions determined in this way are summed up:

$$FRn_{max/min} = FRn_{nominal} + \sum FRn_{i,max/min} \quad (6)$$

The values of FRn_{max} and FRn_{min} calculated in this way form the output of the FMU for this example. The equations are transferred to a Modelica model (Appendix Listing 1) and subsequently exported as an FMU using OpenModelica.

4.3 Results and Verification

A comparison of the results calculated with the FMU and CETOL is shown in Figure 6. The worst-case calculation is performed directly within the FMU based on a predefined set of model inputs, which correspond to those used in the CETOL analysis. The values calculated by the method described above are very close to the result of CETOL with deviations from the worst case values of less than 3%. These minor deviations result from the fact that the assumptions made in this paper regarding the kinematic chain do not exactly reproduce the specific behaviour of the numerical solver used for the joint configuration in CETOL. This FMU can now be integrated into a system simulation to calculate the two FRs and the influence of the mechanical tolerances can be analysed across domains.

To further demonstrate the applicability of the FMU and at the same time present a complementary verification method for the results, additional testing was carried out using FMUGym as a feasible tool for this purpose. The FMU implementation presented above calculates only worst-case values and does not perform any statistical analysis internally. Therefore, a Monte Carlo simulation with 1000 samples was conducted with FMUGym to compare the statistical results with those from CETOL. As in the reference analysis, a process capability index (Cpk) of 1.0 (equivalent to $\pm 3\sigma$ limits) was assumed for all input variables, with random variation around the mean value following a normal distribution.

The results of this Monte Carlo simulation are also plotted in Figure 6. It can be seen that the statistical results from the FMU simulation also match the reference values from CETOL very well. While CETOL computes statistical parameters and sensitivities using the method of moments, based on first-order approximations derived from the partial derivatives with respect to individual variables, our approach leverages Monte Carlo simulation, which may lead to slight differences in the results.

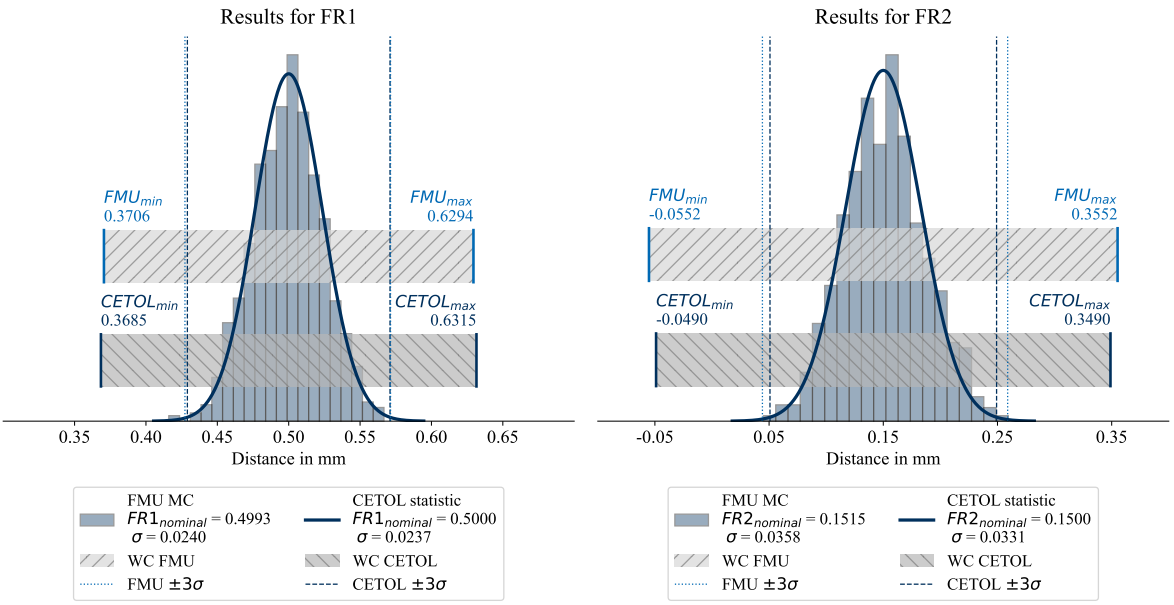

Figure 6. Results of FMU for Worst Case (WC) analysis and Monte Carlo Simulation (MC) as well as the results of the analysis with CETOL. It can be seen that both WC and statistical results of the two methods are close to each other. The deviations result from the assumptions regarding the kinematic chain and the different approaches to determine the statistical results.

5 Discussion

5.1 Evaluation of the Implemented Approach

In the presented case study, the FMU was successfully used to perform a Monte Carlo simulation via the external tool FMUGym. While this demonstrates one specific application scenario, the general concept of using FMUs for tolerance analysis is not limited to this context. All functionalities of FMUs - ranging from simple parameter sweeps to integration in full system simulations - remain applicable.

The FMU developed in this work focuses solely on computing geometric quantities related to the defined FRs. However, in a broader system simulation, these results could be interpreted and used across domains. For example, as described in the case study, the air gap ($FR1$) influences torque generation in the magnetic circuit of the stepper motor, while the guide clearance ($FR2$) can introduce friction forces at the mechanical output. These interactions imply how geometrical tolerances can have a measurable impact on system-level behaviour and performance.

5.2 Usefulness of the FMU Approach

The use of FMUs enables seamless integration of tolerance analysis into complex system models, facilitating cross-domain simulation workflows. This modularization allows tools like FMUGym or Modelica-based environments to interact with geometrically defined tolerances without reproducing detailed internal logic on the system level. The FMU outputs can thus be interpreted either in purely geometrical terms or as system-relevant input variables, depending on the simulation context.

The benefits of standardized, automatable interfaces for solving geometry-related problems in 3D system models has also been supported by recent literature in the field of MBSE (Lehner et al. 2025).

In the future, FMUs offer significant potential for extended applications, such as dynamic simulations with time-dependent input and output variables. This could include non-rigid components or evolving relationships between assembly parts, enabling the modelling of effects like deformation under load, wear, or reconfiguration of mechanical constraints during operation. In the long term, the FMU approach may also allow internal processes and models to be manipulated externally for example, by selecting tolerance types, defining contact graphs, or detecting contact zones. These advanced capabilities, however, are highly dependent on the specific analysis method used and would need to be evaluated individually for each application.

5.3 Limitations

The approach demonstrated in this case study is subject to several limitations that currently restrict its broader applicability. Most notably, the FMU represents a static analysis of rigid-body behaviour and does not account for dynamic effects, deformation, or time-dependent interactions. As such, the FMU output reflects only a snapshot of the geometric relationships under worst-case or statistical assumptions. Without dynamic analyses or automated FMU exports, the approach therefore currently only involves additional implementation effort.

Moreover, the internal structure of the FMU is tightly coupled to the specific tolerance scheme used during its generation. Any modification to the tolerancing concept

DOI
10.3384/ecp218765

- such as changes in the type or arrangement of tolerance elements, beyond the mere numerical values - requires the FMU to be re-generated manually. This limits flexibility, particularly in early design phases where such schemes are subject to frequent change.

Based on the results presented in this paper, a fully automated export of FMUs is not yet feasible. Possible approaches to enable such automation could include systematically translating the methods from subsection 2.1 into DAE systems or representing their behavior using response surfaces as meta-models. A key prerequisite for enabling such automation would be the availability of freely accessible toolchains for geometric tolerance analysis. To our knowledge, the only freely available tool in this domain is *politopix* (Delos and Teissandier 2015). However, since politopix is based on Deviation Models, integrating it into an automated FMU generation workflow would be significantly more complex than with methods such as the Vector Loop approach. Nevertheless, its open accessibility could make it a valuable starting point for future developments in this direction.

6 Conclusion and Outlook

This work introduced a structured concept for integrating geometric tolerance analysis into system simulations using FMUs. A consistent interface based on the FMI standard was proposed, enabling the encapsulation of tolerance logic in a modular and reusable format. Through a case study, the practical feasibility of implementing a manually derived FMU was demonstrated and successfully verified against a commercial analysis tool.

While the current implementation is limited to static, rigid-body models and requires manual derivation of code, it shows that FMUs can represent mechanical tolerances with sufficient precision for system-level applications. With future development, including automation of model generation and support for dynamic or deformable systems, FMUs could serve as a practical bridge between detailed mechanical analyses and multi-domain system simulations.

In the long term, enabling FMU export directly from commercial CAT tools would be a desirable step to facilitate a broader application of geometric tolerance analysis within MBSE processes.

Abstract

Marine operations are often developed with the aid of numerical simulation, in particular lifting operations and transfer of cargo between different units at sea. The effect of the environmental conditions is often the limiting factor and must be included together with models of different components and sub-systems. This paper describes an approach to synchronize spatial and temporal environment information such as universal constants, current, wind, and wave for use in co-simulations of marine operations. Co-simulation models in marine operations will inherently use physical constants, wind and current velocities to calculate forces. Wind and current velocities can have spatial and temporal variations that require the models to synchronize the values. In the event of simulations in waves, the position of the ocean surface, wave particle velocities must be coherent between individual co-simulation models. This paper suggests a structured description of an environment for co-simulation of marine operations. This is illustrated through the implementation of a co-simulation of an offshore lifting operation where a vessel model, a crane, wire and payload model, as well as positioning system models are all integrated with a common environment.

Keywords: FMI, Environment, Maritime, Marine operations, Co-simulation

1 Introduction

Co-simulation of marine operations is increasingly popular both in industry and research. The co-simulation methodology enables increased fidelity through domain specific models. The FMI (Modelica Association 2014) based framework Open Simulation Platform (OSP) (OSP 2025) has introduced additions for easier configuration of marine co-simulations with pre-defined connection types implementing power bonds and control system signals. It is common for simulation models to implement a physical system situated in an environment where common physical quantities are shared and interfaced to individual models. For co-simulation of marine operations it is important that all models have an identical perception of the environment. For operations in waves the harmonic representation of the ocean surface and wave loads is of particular importance as out-of synch models will result in chaotic results where control systems, cranes, payloads and vessels have time-shifted harmonic excitation. It is also important to ensure that all models use the same constants and fluid properties when calculating the forces. Defining a common specification for how a sea environment should be represented in a marine operations co-simulation model is one of the objectives of the SEACo project(SINTEF 2021). An environment model for co-simulation of marine operations must have a mechanism for synchronization of harmonic motions between models. Another issue is the possible variations in current and wind during the simulation. Wind and currents have natural spatial and temporal variations in addition to the influence of the vessel hull and superstructure on these flow fields.

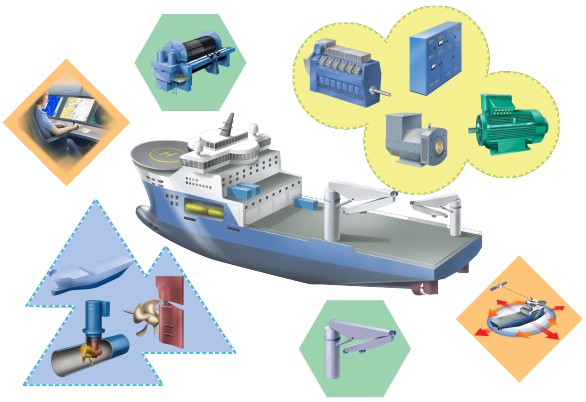

Figure 1. Systems and components important for performing safe and efficient maritime operations. Figure borrowed from the ViProMa project, (SINTEF 2025).

1.1 Marine lifting operations

Marine lifting operations are often complex and demanding, particularly when conducted from floating structures like ships. The precision of these operations is significantly influenced by environmental conditions such as wind and vessel motions. Additionally, when performing lifting operations through the splash zone and below, the lifted payload will encounter substantial environmental forces from currents, waves, and potential slamming forces upon entering the water.

To enhance operational precision, minimize environmental impact on the payload, and boost safety and efficiency, it is crucial that the entire vessel, along with all its essential systems, as depicted in Figure 1, functions seamlessly and in harmony. Therefore, the focus must shift from optimizing individual subsystems in isolation to prioritizing full-system optimization. This holistic approach is vital for improving overall performance, though it introduces significant complexity due to the intricate interdependencies between various subsystems, especially as the trend towards increased autonomy in demanding marine operations continues.

To illustrate, the *Dynamic Positioning* (DP) system must maintain the vessel's position and desired orientation with precision, while the crane operates, largely independent of the DP system, to control the payload's motion. Both the crane and DP systems draw power from the vessel's power system and are significantly affected by stochastic environmental conditions, which also impose requirements on onboard power production. This example merely scratches the surface of the complexity involved in such operations.

Minimizing the risk of operational failure, which can manifest as exceeding safety limitations or damaging the payload, is crucial. This risk can be mitigated through various methods, such as crew training, advanced onboard decision support systems (Skjong, Lars T Kyllingstad, et al. 2019; Lars Tandle Kyllingstad et al. 2023), and virtual prototyping of the operation itself (Skjong and Pedersen 2017a). The latter involves testing different operational strategies in simulators, as demonstrated in this work. Additionally, onboard decision support systems can be either data-based, physics-based, or a combination[1].

1.2 Sea environment

The important environmental conditions for marine operations are wind and current together with waves. Current is commonly represented in simulation models as vector fields with spatial variation. The temporal variation is often neglected since the time scales of changing ocean currents are usually larger than the duration of lifting operations. The temporal variations of wind cannot be neglected. Wind is described by a mean wind speed and direction, but with added gust variations in both speed and direction. Gusting describes flow phenomena that has a statistical description in the form of spectrums. Depending on the direction, the wind may be disturbed by the superstructure, creating a wake.

The surface waves that comprise a sea-state is a complex phenomena that is described by wave spectrums. Wave spectrums define the distribution of energy between different wave frequencies in a specific sea state. The distribution can be derived from oceanographic modelling, measured experimentally or from standardized wave spectra parametrized by simpler statistics such as significant wave height and peak period. For long crested seas all waves share the same direction whereas short crested seas make use of a directional spectrum to distribute wave energy among wave directions. In this paper we assume JONSWAP (K. Hasselmann et al. 1973) distributed wave energy and a simple $\cos^2$ directional distribution around a mean direction. A wave spectrum is a model of how energy is distributed between different wave frequencies in the frequency domain, while most simulation frameworks are developed for the time-domain. Wave spectrums can be converted to the time-domain by sampling the spectrum in the frequency domain and lumping the energy from the continuous spectrum into a finite set of harmonic functions. Figure 2 illustrate the process of converting a wave spectrum into a time-domain wave. To avoid an unreasonably large response at the origin, each component in the realisation must be phase shifted by a random value.

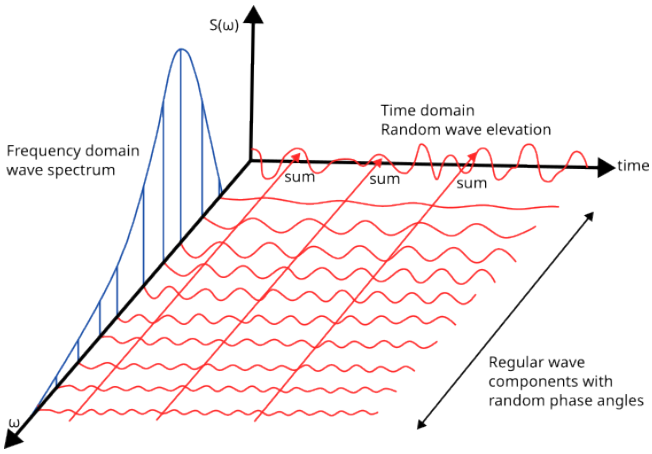

Figure 2. Relationship between frequency domain wave spectrum and time domain realisation by Fourier series. Adapted from (Faltinsen 1993)

Wind and waves are realised in the time domain in a fashion similar to Fourier series where frequencies and amplitudes are selected to replicate the energy distribution of the underlying power spectra. A shared environment model for marine lifting operations must represent:

- Ocean current magnitude and direction with possible spatial variation
- Wind speed and direction with gust variations, spatial variation and possible shielding effects
- Frequency and directional distribution of wave energy

In a co-simulation setting this information must be synchronized across all participating models. Particular attention has to be paid to the Fourier-series.

1.3 Previous work

Common parameters and calculations are easily implemented in monolithic simulation environments. Envi-

[1] A combination of data- and physics-based is preferable over pure data-based methods due to the reduced need for extensive training data required.

DOI
10.3384/ecp218775

ronments based on the Modelica language enables sharing of common resources with the inner/outer instances of generic classes. An example of a purpose built tool for marine operations is FhSim (Reite et al. 2014; Su et al. 2019) that implements numeric integration of ODE models, where the environment information and calculations are centralized in an environment model that is directly accessible by memory location as a global resource. A global singleton object is a common solution when all of the connected models are in a single process. Simulation models that are distributed and communicate across narrowly defined interfaces are nevertheless an attractive proposition in the marine industry where multiple models, and sometimes physical equipment, must be integrated in simulators for training, operation design and integration tests. Training simulators are a particular case where heterogenous software and equipment are combined to place a human operator in an immersive simulation environment operating in real-time. High-Level-Architecture (Dahmann, Fujimoto, and Weatherly 1997) has seen widespread adoption for integrating heterogenous models into a common simulator, particularly for training simulators. (McTaggart et al. 2021) shows the development of an HLA based simulator for ship-to-ship replenishment at sea. The simulator case is similar to offshore crane operations in the sense that it consists of a sea environment, a vessel, an external load, and interaction effects. The interaction effects are dissimilar in that instead of propulsors interacting with themselves, the environment and hull. The simulator in (McTaggart et al. 2021) consists of two ship federates, a replenishment equipment federate, a seaway federate and a hydrodynamic interaction federate to capture interaction effects between the two ship federates. HLA relies on common software libraries that communicate over an Run-Time-Infrastructure (RTI), and even if the HLA standard facilitates re-use by the definition of Federate Object Models, simulators must use a common RTI software to manage execution and exchange data. This is different from the FMI standard that describe co-simulation with a minimal interface between models where the same binary code can be used in different simulation environments.

There has been demonstrations of FMI based co-simulator frameworks for marine operations such as (Z. Liu et al. 2023), where a FMI based co-simulation software was used to simulate vessel motions and an attached crane. The environment in model in (Z. Liu et al. 2023) is described as affecting the vessel motions but not the crane. The crane lifting wire, slings, and payload is absent from the simulation and is therefore not connected to the environment definition. The environment model in (Z. Liu et al. 2023) describe the sea state as a collection of Fourier components.

2 The SEACo environment

A sea environment description for FMI-based co-simulation must represent quantities ranging from simple constants to power spectra. The purpose of placing the environment in a single model is to reduce errors by providing a common source of values. A single data source can provide wind, current, and waves from both conventional constant values, from pre-calculated datasets, and time-domain realisation of power spectrums on standard forms. The models in a co-simulation of marine operations will often calculate environmental forces by either assuming slender structures and applying the Morrison's equation (Eq. 1), and/or apply linear wave theory with superposition of forces generated by individual waves as described by Eq. 3.

Eq. 1 is applied to rigid bodies where the submerged volume V , drag coefficient C_d, added mass coefficient C_a are intrinsic to the shape and the fluid density ρ, the relative velocity v and relative acceleration $\dot{v}$ are properties of the environment.

$$F = \frac{1}{2}\rho A C_d v^2 + C_a \rho V \dot{v} \tag{1}$$

Fluid density, acceleration and velocity will have temporal and spatial variation in marine simulation models, i.e., when currents vary in magnitude and direction through the water column, or varying density from patches of brackish water. A shared environment model needs to provide both physical constants and fluid velocity information as a function of time and place.

Linear wave theory can represent a wave spectrum by a sum of sin-functions. models can calculate the surface elevation by evaluating Eq. 2

$$\zeta(x,y,t) = \sum_{i=0}^{N} \zeta_{a,i} \sin(\omega_i t - k_{x,i} x - k_{y,i} y - \varepsilon_i) \tag{2}$$

where $\zeta_{a,i}$,ω_i,$k_{x,i}$,$k_{y,i}$ and ε_i is the individual wave height, wave frequency, wave numbers in x and y direction and random phase angle respectively from the spectrum realisation. The choice of $\zeta_{a,i}$, $k_{x,i}$ and $k_{y,i}$ and ω_i for individual waves depends on the two spectra for the energy distribution between frequencies and the energy distribution in the wave direction. The method of converting the frequency domain wave spectrum into Fourier components and allocating the individual waves to a direction depend on the choice of number of Fourier components, random number generation and implementation of the spectra distribution functions.

A representation of the wave surface with superposition of pre-calculated amplitudes precludes the use of higher order methods to describe waves. However, the linear superposition of waves allows models to compute the instantaneous surface position. The dynamic pressure, wave particle velocity and accelerations can be derived from the individual wave velocity potentials as seen in Equation 3.

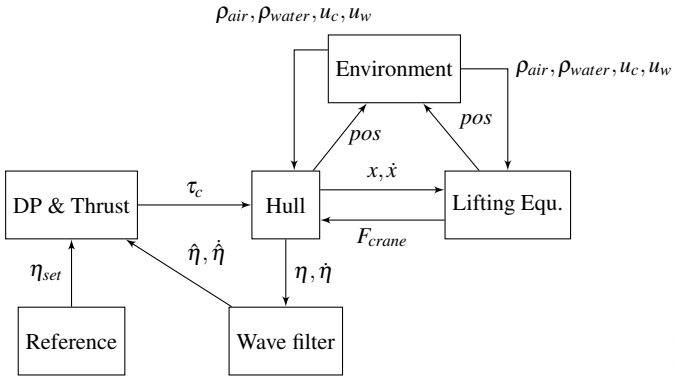

Figure 3. Co-simulation setup of vessel in a dynamic positioning operation with lifting equipment.

This makes it possible to model wave forces on slender structures such as crane wires and payloads in marine lifting operations.

$$\Phi_i(x,y,z,t) = \frac{\zeta_{a,i}g}{\omega_i} e^{-kz} \sin(\omega_i t - k_{x,i}x - k_{y,i}y - \varepsilon_i) \quad (3)$$

Eq. 3 contains the same variables as Eq. 2 and the combination of the equations can be used for calculating forces on slender structures and ventilation of propellers. Linear wave theory is also used in sea-keeping calculations that derive hydrodynamic forces as a function of wave frequency, direction and amplitude. See (Faltinsen 1993) for common applications of linear wave theory in offshore applications.

This paper propose dividing the specification sea-environment for co-simulation of marine operations into levels as seen in Table 1. Not all models need information about the waves, nor spatial and temporal variation of current and wind. The levels of specification makes it possible to classify a simulation model as supporting synchronized environments on different levels. Global current and wind can be discerned from spatial current and wind by checking model connections for a coupling of position information between the model and the environment with the origin as a default value for input port values.

Specification level 0 would make the constants required in Eqs. 1-3 available from a common source. The level of the environment description that is shared is increasingly sophisticated and the last level would include interaction between models through the environment for instance loss effects on propulsors from interaction effects between propeller jets, hull and surface.

3 Methods and Materials

3.1 Models and simulation setup

Figure 3 illustrates the co-simulation setup for the case study presented in this work. The subdivision into FMUs represent different disciplines that cooperate to establish a model of a marine operation. Control systems (DP-controller, wave-filter, thrust-allocation), Hydrodynamics (hull, propulsors), Mission specific equipment interconnected with the common Environment. Other subdivisions are possible, but the separation into FMUs reproduce real-world system boundaries where signals are sampled in control systems. ρ_{water}, represents the water density, and ρ_{air}, the air density. The vector u_c holds the water current speeds, which can be depth-dependent, and u_w holds the wind speed. τ_c is the thrust force vector in the vessel's body reference frame calculated by the DP control system. The yaw angle of the vessel is represented by ψ. The position and velocity vectors for vessel being fed to the lifting equipment model are x and $\dot{x}$, respectively. F_{crane} is the force feedback from the lifting equipment model. The desired position and orientation of the vessel are given by η_{set}, while $\hat{\eta}$ and $\dot{\hat{\eta}}$ represent the filtered position and orientation of the vessel, along with their corresponding rates. Finally, η and $\dot{\eta}$ denote the position and orientation of the vessel, and their corresponding rates. Note that information provided by the environment about the surface elevation (due to waves) are omitted in the figure. It is out of scope here to describe each model shown in the figure in detail, but a brief overview will be provided in the following.

3.1.1 Environment

A simplified environmental description was implemented that supported specification levels 1-3 from Table 1. The sharing of information is implemented with the port system and the environment output include acceleration of gravity (g) and the densities for air and water (ρ_{air} and ρ_{water}, respectively). The output of wind and current magnitude and direction is implemented with a vector input for positions with a corresponding output with velocity magnitude of wind and current. The first three values in the position input correspond to the directional components of the wind and current in the first three output values. Here, the wind is assumed constant while the current profile follows an exponential decay with increasing depth:

$$v(z)_{curr} = v(z=0)_{curr} e^{-az} \quad (4)$$

The wind, current and decay rate values are set as parameters. The waves are generated from a JONSWAP spectrum for a given significant wave height (Hs) and peak period (Tp) pair, and the mean wave direction. Here, the number of Fourier components are set to 24 and the spectrum is realised by random sampling of the wave frequency in the interval $(0, 2\pi]$. The wave direction is randomly selected from a cos^2 distribution centred on the mean wave direction. The wave directions are assigned to the individual waves by descending wave amplitude and distance from the mean wave direction. Wave phase angles was randomly selected. Each wave require four values, as shown in Eq. 2, to be specified resulting in 4 vector ports or 96 individual ports to be connected to the other models. The values on the output ports of the simplified environment model are constants. But usage of the port

DOI 10.3384/ecp218775

Table 1. Specification levels for synchronized environment.

Level of Specification	*Description*	*Example*
0	Basic constants	Identical constants are used from a common source. Can be achieved with constant value signals.
1	Global current and wind	Global wind and current values as input coupled to a common source. Can be achieved with constant value signals.
2	Spatial current and wind	Wind and current based on individual positions. To model spatial and temporal variations in current and wind around the vessel and in the water column. Requires input of position where wind and current is observed, eg. payload position as input results in output of current and wind velocities at payload position. Centralized implementation of wind gust spectrum.
3	Synchronized wave definition	Centralized implementation of wave energy and direction spectrum formulas and realisation of individual waves. Output list of wave components allows connected models to calculate surface elevation, wave particle motions and utilize sea-keeping results from linear wave theory.
4	Propulsor interaction	Propulsor losses can be introduced by phenomena such as the Coanda effect, inflow disturbance and propeller jet interaction. There are no general methods for including such effects in a flexible reconfigurable environment such as co-simulations.

system ensures that changes in environment values will be reflected in the interconnected models.

3.1.2 Hull

The hull geometry is analysed using *HAMS*, an open-source computer programme for the analysis of wave diffraction and radiation of three-dimensional floating or submerged structures (Y. Liu 2019). The hydrodynamic results from the analysis are transformed into a state-space time-domain formulation as presented in (Thor I. Fossen 2005). The equation of motion for the hull is given in Eq. 5.

$$\dot{\eta} = \mathbf{J}(\Theta)\nu \tag{5a}$$

$$\mathbf{M}\dot{\nu} + \mathbf{C}_{RB}\nu + \mathbf{D}\nu + \mu + \mathbf{g}(\eta) = \tau_{env} + \tau \tag{5b}$$

In (5) the vector η represents the generalized position and orientation of the vessel given in the NED-, *North, East, Down*, reference frame. The matrix $\mathbf{J}(\Theta)$ is the transformation matrix dependent on the Euler angles Θ, which describe the vessel's orientation. The vector ν represents the generalized velocity of the vessel, including both linear and angular velocities. The matrix $\mathbf{M}$ is the generalized mass matrix, which includes both the rigid-body mass and the added mass due to hydrodynamic effects. The matrix $\mathbf{C}_{RB}$ represents the Coriolis and centripetal forces due to the rigid-body motion of the vessel. The matrix $\mathbf{D}$ is the linear damping matrix, which accounts for the hydrodynamic damping forces acting on the vessel. The vector μ represents the memory effect of the fluid, which is modelled as an integral term involving the retardation function. Note that μ can be approximated by a linear reduced-order state-space model, as described in (Perez and Thor I. Fossen 2011). The vector $\mathbf{g}(\eta)$ represents the restoring forces and moments due to gravity and buoyancy, which depend on the position and orientation of the vessel. The vector τ_{env} represents the environmental forces acting on the vessel, including wave, wind, and current forces. The vector τ represents the control input forces and moments applied to the vessel.

The hull model outputs position, orientation, and corresponding rates for its centre of gravity, as well as for fixed positions on the hull. It takes forces as input, both described in the NED reference frame and in the body-fixed reference frame. The hull also gets environmental information from the environmental model, such as information about the water density (ρ_{water}), the wave components (direction, amplitude, frequency, phase, etc.), and the wind conditions (speed and direction).

3.1.3 Lifting Equipment

This lifting equipment model consists of a crane-tip, a wire model, four slings and a rectangular payload, and the model is developed based on the framework presented in (Skjong, Reite, and Aarsæther 2021), which focuses on lumped, constrained cable modelling using an explicit state-space formulation. This model simulates the dynamics of a payload being lifted by a crane-wire, accounting for various forces acting on the system, including wind forces, buoyancy, first-order wave forces, and drag forces. The drag force is calculated with Eq. 1 and the first-order wave force is calculated by assuming a fully submerged payload and using Eq. 3 to calculate the wave force from

each wave component as

$$F_j = \sum_{i=0}^{N} \rho_{water} V \frac{\delta^2 \Phi_i}{\delta j \delta t} \quad \text{for j=x,y,z} \tag{6}$$

Where V is the payload volume and Φ is given in Eq. 3.

The model employs a lumped parameter approach, where structural elements are represented by discrete mass nodes connected by constraints. These constraints are solved explicitly using an elastic version of Baumgarte stabilization (Baumgarte 1972), ensuring numerical stability and avoiding singularities in matrix inversions. The Baumgarte stabilization method reformulates constraint forces to handle differential-algebraic equations, allowing efficient numerical integration. The model receives the vessel position, orientation and corresponding rates and offset from the center of gravity as inputs and calculates a force vector that is applied to the vessel in the centre of gravity through a port coupling.

3.1.4 DP, thrust and references

The DP controller is here assumed to be a simple PID-controller that controls the global thrust force vector needed to keep the vessel in position, as presented in (Skjong and Pedersen 2017a). The equations in the DP-controller are given as

$$\tau_c = (\mathbf{R}_z(\psi))^\top \left[\mathbf{K}_P \mathbf{e}_P + \mathbf{K}_D \dot{\mathbf{e}}_P + \mathbf{K}_I \int_0^t \mathbf{e}_P \, dt \right] \tag{7}$$

In the equation the control force vector is denoted by τ_c. The rotation matrix $\mathbf{R}_z(\psi)$ is a function of the yaw angle ψ, which describes the vessel's orientation about the vertical axis. The transpose of this rotation matrix is $(\mathbf{R}_z(\psi))^\top$. The proportional gain matrix is $\mathbf{K}_P$, and the error in the position vector is $\mathbf{e}_P$. The error is defined as the difference between the desired position and orientation of the vessel, and the measured (filtered measurements) position and orientation of the vessel. Note that the desired position and orientation of the vessel could be fixed scalars or slowly varying variables, and are modelled in the *Reference* model shown in Figure 3. The derivative of the error in the position vector is $\dot{\mathbf{e}}_P$, and the derivative gain matrix is $\mathbf{K}_D$. The integral of the error in the position vector over time is $\int_0^t \mathbf{e}_P dt$, and the integral gain matrix is $\mathbf{K}_I$.

In this co-simulation study, propulsors and thrust allocation are omitted. The global thrust command vector from the DP controller is acting directly as the thrust force on the hull. This can be argued for since the main focus is the lifting equipment and the payload being lowered into the sea with a common envionment. For a well designed thrust allocation algorithm and well-tuned control system, the dynamics of the complete propulsion system should be comparable to the output of the DP-controller.

3.1.5 Wave filter

The wave filter is used to filter out first order motion oscillations for the vessel, which in general, is not needed to compensate for, nor possible in realistic operations without spending an enormous amount of energy. Hence, the wave filter provides the dynamic positioning system with the filtered vessel position, orientation, and corresponding rates. The filter is of a passive non-linear observer design, as elaborated in (Thor I Fossen and Strand 1999), and its dynamics are described by the equations listed in (8).

$$\dot{\xi} = \Omega \xi + \mathbf{K}_1 \bar{\mathbf{y}} \tag{8a}$$

$$\dot{\eta} = \mathbf{J}(\mathbf{y}) \hat{\mathbf{v}} + \mathbf{K}_2 \bar{\mathbf{y}} \tag{8b}$$

$$\dot{\mathbf{b}} = -\mathbf{T}^{-1} \mathbf{b} + \frac{1}{\gamma} \Lambda \bar{\mathbf{y}} \tag{8c}$$

$$\mathbf{M} \hat{\mathbf{v}} = -\mathbf{D} \hat{\mathbf{v}} + \mathbf{J}^T(\mathbf{y}) \dot{\mathbf{b}} + \tau + \frac{1}{\gamma} \mathbf{J}^T(\mathbf{y}) \mathbf{K}_3 \bar{\mathbf{y}} \tag{8d}$$

$$\hat{\mathbf{y}} = \hat{\eta} + \Gamma \xi \tag{8e}$$

In the filter, the state vector ξ represents the wave-induced motion. The matrix Ω describes the dynamics of this motion, while $\mathbf{K}_1$ is the observer gain matrix for the wave-induced motion. The estimation error vector is denoted by $\bar{\mathbf{y}}$. The position and orientation vector of the vessel is η, and $\mathbf{J}(\mathbf{y})$ is the transformation matrix dependent on the vessel's position and orientation. The estimated velocity vector of the vessel is $\hat{\mathbf{v}}$, with $\mathbf{K}_2$ being the observer gain matrix for the position and orientation. The bias vector $\mathbf{b}$ accounts for slowly varying environmental disturbances. $\mathbf{T}^{-1}$ is the inverse of the diagonal matrix of bias time constants, and γ is a scalar tuning parameter. The matrix Λ scales the amplitude of the estimation error. The mass matrix of the vessel is $\mathbf{M}$, and $\mathbf{D}$ is the damping matrix. The transpose of the transformation matrix $\mathbf{J}(\mathbf{y})$ is $\mathbf{J}^T(\mathbf{y})$. The control input vector is τ, and $\mathbf{K}_3$ is the observer gain matrix for the velocity estimation. Finally, $\hat{\mathbf{y}}$ is the estimated measurement vector, and Γ is the matrix representing the relationship between the wave-induced motion and the measurements.

This filter gets the vessel position and orientation as inputs, and is tuned with knowledge about the wave conditions and the vessel dynamics. The output of the filter is the filtered vessel position and orientation, along with corresponding rates. Figure 4 shows illustrates the performance of the wave filter, where the vessel's first order motions in the north position has been filtered.

3.2 Co-simulation setup

The Open Simulation Platform programme `cosim` (OSP 2025) was used to run simulations. cosim includes a `VariableGroup` mechanism to ease interconnection of models with a large number of ports, and the wave component parameters were combined into `VariableGroups` for ease of use. Main parameters used in the co-simulation is shown in Table 2

Simulations were run on a Intel I9-12900 with 64GB RAM and the simulation consumed 1006[s] CPU time for 1200 [s] simulation time (790[s] wall-clock time due to parallel execution).

DOI 10.3384/ecp218775

Table 2. Main parameters in co-simulation.

Parameter	*Value*
Ship size	$36.25[m]$ x $9.6[m]$ x $2.7[m]$
Ship mass	574 $[tons]$
Crane height	8 $[m]$
Crane boom length	5 $[m]$
Crane base offset	5.5 $[m]$, -4.5 $[m]$, 1.15 $[m]$
Payload size	$1[m]$ x $1[m]$ x $1[m]$
Payload mass	5 $[tons]$
Wire diameter	0.03 $[m]$
Winch speed	0.05 $[m/s]$

4 Results

The system model shown in Figure 3 was defined in `cosim` with separate FMUs for each box in the figure. The communication stepsize was $0.01[s]$ and results from the individual FMUs were saved in separate csv files. A VTK based visualization was developed that animated the visual components from the different FMUs in 3D based on the contents of the individual csv files. The results of a hull with attached crane & payload in a irregular wave field is shown in Figure 5. The parameters of the individual waves in Figure 5 is transmitted to both vessel an crane & payload model. The resulting position trace for the hull, crane tip and payload from a $120[s]$ simulation with the payload in the wave zone for $Hs = 1[m]$ and $Tp = 7[s]$ is shown in Figure 6. The position trace shown the harmonic oscillations of the vessel in linear and angular degrees-of-freedom and amplified by the lever arm at the crane-tip, the figure also shows the resulting motions of the payload at the end of the crane wire. The payload will experience wave forces in the wave zone together with buoyancy and The tension in the crane wire and the magnitude of the buoyancy and first-order wave force on the payload are shown in Figure 7. The buoyancy and wave forces are only activated when the payload is in contact with the ocean surface as shown in the bottom panel of Figure 7. Note that this model does not include slamming loads that is a limiting phenomenon in offshore lifting operations.

Two $1200[s]$ cases were simulated to allow the payload to transition through the wave zone and through the water column. The simulation time also test the wave filter and DP-controller ability to keep the position in response to the wave, current and wind loads on the hull. Two moderate and severe JONSWAP sea states with $Hs = 1[m]$ & $Tp = 7[s]$ and $Hs = 2.5[m]$ & $Tp = 10[s]$ were simulated with $5[m/s]$ wind and $0.5[m/s]$ current. Crane wire tension, buoyancy force and magnitude of the wave force are shown in Figures 8a and Figure 8b, respectively. From the bottom panel of the figures it is evident that the longer waves of the $Hs = 2.5[m]$ sea state influence the payload for a longer time than in the $Hs = 1.0[m]$ case. The time spent in the wave zone is longer as shown in 'noisy' buoyancy force and resulting hull motions are evident as larger variability in the crane wire tension.

Figure 9a and Figure 9b show the magnitude of the wave and drag forces as a function of payload depth. Wave forces decrease with depth as suggested by Eq. 3. The drag forces in Eq. 1 depend on the relative velocity and will be affected by both crane tip motions propagating down to the payload and the current. It should be noted that the wave forces are exiting forces while drag forces act against the relative motion of the payload.

5 Discussion and Conclusion

This paper has demonstrated a practical example of how a synchronized sea-environment model can be included in a co-simulation. The sea-environment model is accompanied by a hierarchical specification of synchronization levels to clearly identify which parts of the environment description are shared between models. The choice of converting the frequency-domain wave spectrum to time-domain before transmitting individual wave components

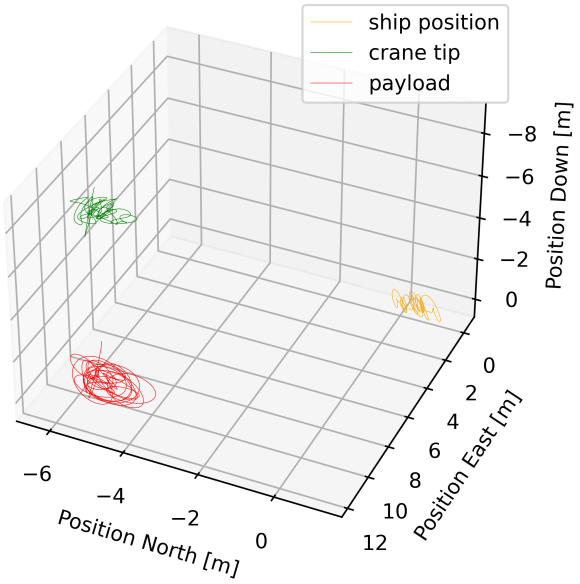

Figure 6. Position of the vessel centre of gravity, crane tip and payload. Cyan dots show the element centres for main wire and slings

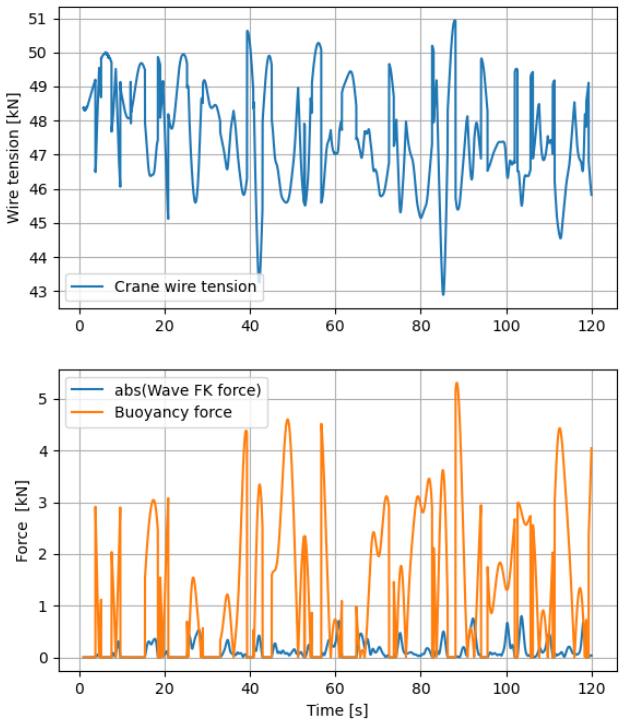

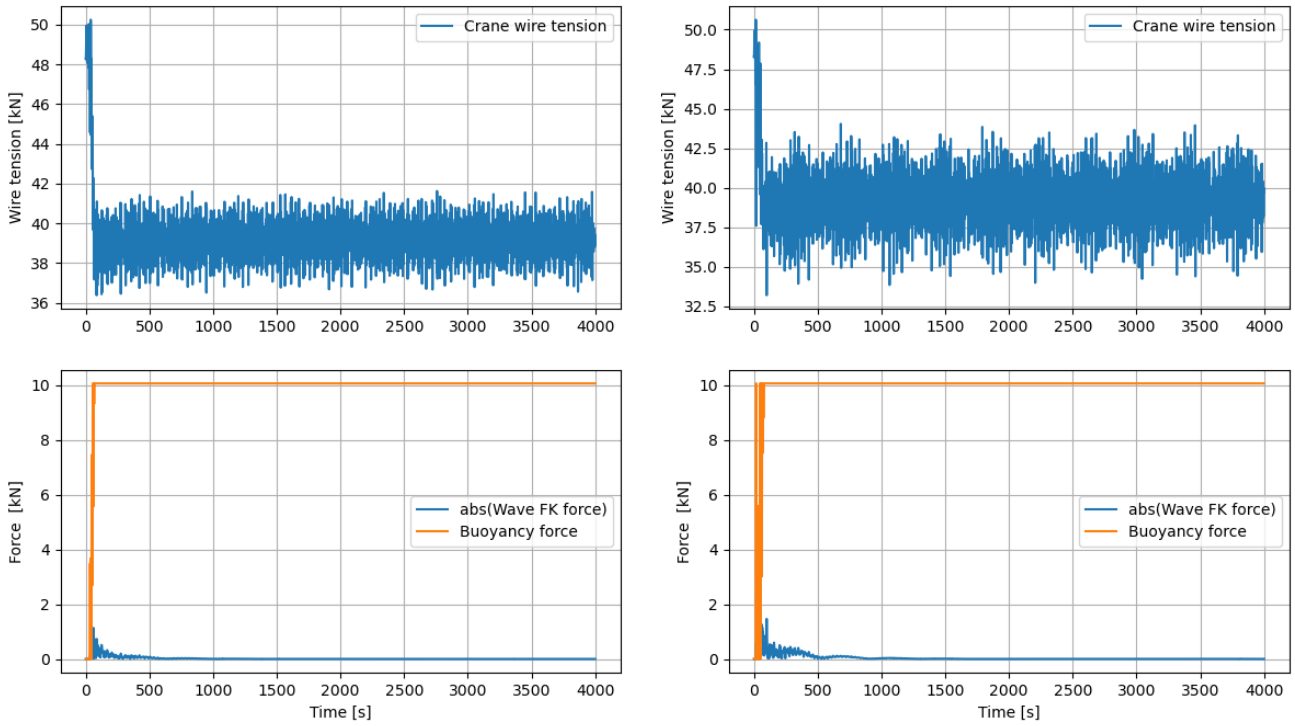

Figure 7. Crane and payload forces over 120 [s] as the payload hangs in the wave zone.

is an engineering approach that limits the model to linear wave theory. Linear wave theory is widely applied in ocean engineering, and this solution is compatible with common methods for evaluating sea-keeping and allows the models to apply Eq. 3 to derive wave properties, but limit the simulation to a description of the wave zone that relies on superposition to describe waves and current. The proposed interface in this paper does not preclude advanced methods for describing current and wind, precomputed velocity fields can be read by the environment model and used to output magnitude and direction at any point. There is neither a necessity that the environment model is a 'pure' model, as a model of a vessel can implement the environment interface and connect to models of propulsors and lifting equipment that interface with an environment a model description that is tightly coupled to the vessel geometry. However, only one model implementing the environment interface would be permissible in a co-simulation. The proposed interface place a large burden on the simulation developer since a great number of ports must be connected. The interface is not well suited for basic FMI v1 and FMI v2 tools due to the large number of interconnections required, it is technically possible but the workload on the simulation developer would be excessive and negate many of the advantages of GUI tools. Software with special features such as VariableGroups in 'cosim' allows easy coupling of models to the environment, and FMI v3 with vector ports would negate the need for extensions in the co-simulation software. Usage of the port system for exchange waves components is not necessarily required as a shared library for computing wave spectrum values, randomly sampling them and computing phase angles can be developed. Control of the random number generator is necessary in such approaches to ensure that random phase angles, frequency and direction random samples are identical between models. It would be difficult to verify that all models actually used the shared library, and that each instance of the library is of the same version as time progresses, and from the authors perspective this would allow for version drift between models and limit the selection of simulation environment where models interfacing with the environment could be developed. An attractive property of transmitting wave components on ports is when components are sorted by amplitude a reduced number of components would mean a reduced fidelity wave field prioritizing the the most energetic waves. Propulsor interaction in co-simulation is a difficult problem as the interaction and loss effects are interdependent on wave conditions (distance from surface), geometries (hull surfaces) and other propulsors (jet and flow effects). One method would be to extend the linear superposition of wave particle velocities to propeller jets superimpose propeller jet velocities on a volume downstream of the propulsor. This would allow propulsor jets to influence other objects and change the inflow conditions of propulsors in the jet, but would not be sufficient to capture the interaction effects between jets influencing the flow patterns and in-

teraction between propulsor jets and hull surfaces. The co-simulation model in this paper is fairly complete, but simplified. In general, the global thrust vector command from the DP controller must be transformed to local thrust forces and distributed to all the available, and operating, propulsors. This is done using a thrust allocation algorithm (which can be a simple thrust allocation matrix in some special cases). Such a setup is shown in (Skjong and Pedersen 2017b) where the thrust allocation is formulated as a non-angular *Model Predictive Control* (MPC) problem to be solved. The payload model include first order wave forces, but not the larger slamming forces experienced during wave impacts in the wave zone. Slamming pressure is larger than the regular dynamic pressure in the wave and must be accounted for in decision support applications. The proposed interface enables software such as

'cosim' to detect and verify the environment specification level for the co simulation. Common physical parameters, wind and current input with or without position feedback would be interpreted as specification level 0, 1 and 2 receptively while input of wave components would place the co-simulation at level 3. This also enables a partition of the models in the co-simulation into models participating in a sea environment, while models representing for instance control systems are identified as not directly influenced. The work on developing a sea-environment specification has highlighted the need for a reference frame specification. Different disciplines and application areas have different traditions for axis systems, and this makes verification of the wind, current and wave forces important as the simulation developer in principle can be without access to the source code of the models in the co-simulation.

Decreasing Risk in the Design of Large Coupled Systems via Co-Simulation-Based Optimization and Adaptive Stress Testing

Severin Sadjina[1] Lars T. Kyllingstad[2] Stian Skjong[1]

[1]SINTEF Nordvest, Ålesund, Norway {severin.sadjina,stian.skjong}@sintef.no
[2]SINTEF Ocean, Trondheim, Norway, lars.kyllingstad@sintef.no

Abstract

Optimization and stress testing are key aspects of the design and verification process for large, high-risk systems. Optimization is about improving the capabilities and performance of a system; stress testing is about uncovering its weaknesses and faults. Both require a quantitative representation of the system's behavior, and for complex, multi-physical systems, co-simulation can be a very powerful method to create such a representation. However, co-simulation frequently involves the use of black-box subsystem models, which poses challenges to traditional optimization and stress testing methods. Here, we review the state of the art in co-simulation-based optimization and stress testing, focusing especially on *adaptive stress testing* in the latter case, and discuss open research questions and promising research directions. In particular, we make the case that a co-simulation is not an entirely black box even when some or all of its subsystems are; it may be possible to exploit the visible system structure, coupling variable values, and partial subsystem information. We use examples from the maritime industry to motivate and illustrate the discussion, centering on the highly contemporary design case of an autonomous ferry.

Keywords: co-simulation, optimization, stress testing

1 Background

Like most other industries, the maritime sector finds itself in the middle of a "twin transition": a green transition to a low-carbon future, intertwined with a digital transition towards data-driven decision making and autonomous systems. And like any other, the maritime industry has its own, particular set of challenges in that regard.

The main obstacle to decarbonization lies in finding alternatives to the fossil fuel oils that power virtually all of today's ships. At this point in time, there are few readily-available zero- or low-carbon options for ships that spend many days or weeks away from shore, such as long-distance transport ships and large fishing vessels. In the meantime, fuel-saving and transitional solutions like hybrid and dual-fuel power systems significantly increase the complexity of a ship in terms of design, construction, operation, and maintenance.

When it comes to maritime digitization, the frontier is moving towards remotely operated, semi-autonomous, and eventually autonomous shipping. While automating the navigation of a ship through well-regulated seaways is arguably an easier problem than autopiloting a car through chaotic city streets, the consequences of any one accident are likely to be orders of magnitude larger – possibly in terms of human life, depending on the ship type, but also in terms of environmental and financial impacts. Reducing risk and increasing safety are therefore prime concerns.

Hence, the maritime industry is, now more than ever, in need of new methods for design, verification, and assurance of highly complex, energy efficient, and *safe* systems. Such methods must be able to account for the fact that the design, construction, and commissioning of a large ship is a significant undertaking which involves a great number of stakeholders, a wide array of engineering disciplines, and tight regulatory and budgetary constraints.

This is the context within which we have launched the research project *OptiStress: System optimization and stress testing in co-simulations*. Our basic premise is that co-simulation,[1] as a modeling and simulation paradigm, fits the bill in terms of its suitability for multilateral virtual prototyping of multi-physical and cyber-physical systems. This is in large part because it enables one to build simulations of complex systems from loosely coupled black-box subsystems. However, this becomes a *disadvantage* when it comes to design optimization and whole-system assurance, because some of the assumptions underlying existing numerical methods no longer hold.

In *OptiStress*, and in this paper, we will look at two key design and verification processes and explore how co-simulation may be embedded within them in a way that leverages its strengths and mitigates its drawbacks. The first is *system optimization*, in particular the use of numerical optimization algorithms to choose the system configuration and parameters that best fulfill the system design goals. The second is *stress testing*, which is concerned with pushing a system to the limits of its safe operating space to see what breaks, how, and why. Here, we'll look specifically at *adaptive stress testing* (AST), where reinforcement learning is applied to find the most likely paths to a failure event (Lee, Mengshoel, et al. 2020).

[1]The term "co-simulation" is sometimes used loosely in the academic literature to mean different things. Here, we refer specifically to *continuous-time* co-simulation, as defined by Kübler and Schiehlen (2000) and Gomes et al. (2019).

The goal of this paper is to provide a concise summary of prior work and outline the main research needs. To this end, separate discussions on optimization and AST are given in the context of co-simulation in sections 2 and 3, respectively. Section 4 concludes by commenting on how both can be combined in the same design workflow or even the same algorithmic loop.

We will use an autonomous battery-electric car ferry as an illustrative example throughout. Challenging situations such as waves and wind from the side or crossing traffic in conjunction with strict safety and energy-efficiency requirements, make its design, verification, and assurance daunting tasks. With the present paper, we hope to be able to convince the reader that co-simulation-based optimization and adaptive stress testing are fitting tools for decreasing the risk in the design of such large coupled systems.

2 Optimization

There are four main challenges when it comes to optimization of large coupled systems: the number of design parameters to consider is large; there are multiple, possibly contradictory, objectives for the system performance; the objective functions are globally non-convex so gradient-based optimization may yield only local optima; and substantial computational cost can severely restrict the exploration of the solution space. Significant progress has been made on these issues in the field of *multidisciplinary design optimization* (MDO) (Martins and Lambe 2013; Wang, Fan, and Qiang 2023), which has so far found most of its applications in the aerospace and automotive industries, and more recently in the maritime domain (Ojo, Collu, and Coraddu 2022; Serani, Scholcz, and Vanzi 2024).

2.1 Background

Co-simulation-based optimization has recently awoken interest across various domains and applications as a natural extension of the utilization of co-simulation's strengths: the decoupling of the component modeling and system simulation processes, the ability to hide sensitive information within black-box models, the use of software tools and solvers most suited for the individual subsystems, and the ability to distribute the simulation burden across several parallel processes. Additional challenges emerge when the objective function is computed on the basis of co-simulation, however:

- *Complex or unpredictable behavior.* Knowledge of how the physics inside a subsimulator is implemented is often spotty, or may lack entirely. More so, models need not be based on physics representations at all. A wide variety of model types may be used in co-simulations, including discrete event models, stochastic models, agent-based models, or even look-up tables. Hence, assumptions about the functional form of objective functions, such as linearity, convexity, or smoothness, can often not be made.
- *Lack of information.* Access to gradients is typically sparse, or lacking completely for most models. The same goes for access to system states, which are usually not accessible at all with co-simulation.
- *Lack of features.* Important features such as the ability to save and restore the simulation state are often not available.
- *Coupling errors.* Errors stemming solely from the co-simulation coupling lead to significant uncertainty with respect to the validity of the system response. In turn, this can cause issues with traditional algorithms due to numerical instability or invalid model outputs.
- *System reticulation.* How the system is reticulated (split into subsystems) for the purpose of co-simulation and how the coupling between these subsystems is realized can have a significant influence on accuracy and stability (Sadjina, Kyllingstad, Skjong, et al. 2017; Sadjina, Kyllingstad, Rindarøy, et al. 2019). This is especially worth keeping in mind if system reticulation and model interfaces are themselves subject to optimization (discrete component optimization).

In light of this, it is natural to turn towards algorithms that fall under the broad heading of *black-box optimization methods*.

Black-box optimization

Perhaps the simplest, and thus highly popular, method is *ranking and selection*, whereby a small number of preselected scenarios are compared manually via an objective function. It is used, for example, by Rüdenauer, Han, and Geimer (2012) to optimize the design of a tractor's front axle in a collaborative co-simulation setting, and by Wirth et al. (2017) to find (Pareto front) optimal geometry designs of an airfoil in a fluid-structure co-simulation coupling.

Among algorithmic methods, *meta-heuristic algorithms*, especially genetic algorithms and swarm intelligence optimization methods, are popular choices for co-simulation optimization (Vega and Chevrier 2024). The *constrained multi-objective evolutionary algorithm with multiple stages* (CMOEA-MS) is used by Tan et al. (2022) to optimize the design and the thermal–hydraulic performance of nuclear plate-type fuel. Another variant, *covariance matrix adaptation evolution strategy* (CMA-ES), is used by Ahmed, Oekermann, and Kirchner (2014) to minimize forces acting on a steering mechanism. An evolutionary algorithm is also used by Arslan, Suveren, and Moghaddam (2023) to optimize the design of a co-simulated cart-pole test system. Another example is the *non-dominated sorting genetic algorithm II* (NSGA-II) which is used by Hou et al. (2023) to optimize a valve of a ship HVAC system, or the *multi-objective genetic algorithm* (MOGA) used by Anguek and Bounab (2022) to

DOI 10.3384/ecp218785

optimize the design of a gun station bracket with respect to minimal mass and frequency response under stress constraints. The *differential evolution algorithm* (DEA) is used by Anderson et al. (2020) to find optimal dimensions and bandgaps of semiconductor layers to maximize the efficiency of a solar cell. *Swarm intelligence optimization* comprises nature-inspired meta-heuristic algorithms. One popular candidate is *particle swarm optimization* (PSO), an *a posteriori* algorithm which generates a set of alternative solutions (Pareto optimal set) and prunes them with multi-criteria methods to present to the decision maker for a final choice. It is used by Zadeh, Sayadi, and Kosari (2019) to introduce a multi-objective collaborative optimization framework based on surrogate models, albeit not in conjunction with co-simulation.

Surrogate models

It is worth noting that the term *surrogate model* can have two meanings in the context of simulation-based optimization. In the above-mentioned paper by Zadeh, Sayadi, and Kosari (2019), it refers to an approximation of the objective function(s) which is being maintained and updated by the optimization algorithm based on selective evaluation of the actual objective function. The purpose is generally to reduce the number of computationally expensive direct evaluations needed. Other methods in this vein include the *radial basis function optimization* (RBFOpt), which is used by Waibel, Evins, and Carmeliet (2019) to sample an unknown black-box cost function for the study of the coupling between building energy demand and supply, and *constrained optimization by linear approximation* (COBYLA), used by Yamanee-Nolin et al. (2020) to optimize an evaporator process with respect to minimal product stream mass flow oscillations.

The other meaning of "surrogate model" refers to models used *within* the simulation(s) that form the basis for the objective function(s). Here, the point is to replace high-fidelity models with approximated models that are faster to calculate, to replace black-box models with white-box approximations that provide more information (e.g. derivatives), or both. Examples for co-simulation optimization include the use of weighted sums of several individual surrogate models based on either radial basis functions, response surface models, or Kriging surrogate models (Hou et al. 2023), or using feed-forward artificial neural networks to approximate objective functions and calculate gradients (Tuli et al. 2022).

Looking inside the box

Despite the challenges that co-simulation brings to the optimization table, things are not necessarily quite as bad as they may first appear: A co-simulation itself is not entirely a black box, even when its individual subsystems are. We do have access to the connection structure and the signals exchanged between the models, and this can be used to estimate errors and speed up the simulations (Kyllingstad, Sadjina, and Skjong 2024). Moreover, at least some of the subsystems may just as well *not* be black-box models. Instead, they may reveal some of their internal workings to us, granting access to gradients and, though rarer, access to system states. For example, if both the decision variables and the objective function are associated with such model types, it may still be possible to use gradient-based methods.

Gradient-based optimization generally requires derivatives and may only yield local optima because of globally non-convex objective functions. Used in conjunction with co-simulation, examples include *back-propagation of gradients with respect to input* (GOBI) which is proposed by Tuli et al. (2022) to find optimal scheduling decisions for fog computing, or *block coordinate descent* (BCD) used by Sadnan et al. (2021) to solve the decentralized optimal power flow problem in a distribution grid.

Combining optimization and co-simulation

Most examples of co-simulation optimization use an optimization routine *on top* of the co-simulation loop. Ranking and selection currently seems to be the most common such strategy, solely making up almost 45% of all methods investigated by Vega and Chevrier (2024). It consists of simply running a batch of pre-selected co-simulation scenarios, collecting and analyzing the results, adjusting the design, and repeating until satisfied. Ranking and selection can also be supplemented with post-processing techniques such as Pareto front (Wirth et al. 2017), *goal-driven optimization* (GDO) (Zhaoju et al. 2019), or by using a weighted sum of multiple objective functions (He et al. 2021). Verification by co-simulation is a slightly different take used by Assadi et al. (2023) to gauge the thermal-management performance of a high-density electric-vehicle fast charger based on the topology of a heatsink that was first optimized in a (monolithic) thermo-fluid simulation.

A different approach is *optimization-in-the-loop* whereby optimization happens inside of a co-simulation. One such example is *control optimization* which aims to move the system along a desired path as it evolves dynamically. The objective function then depends on a set of actions taken at discrete time instances. This could, for example, be relevant for dynamic positioning or routing tasks. Control optimization is used by Bharati, Chakraborty, and Darrah (2021) to find the optimal control of consumers and generators in a hardware-in-the-loop co-simulation of the interaction of a real-World microgrid facility with a real-time model of a power grid. It is also used by Tuli et al. (2022) for scheduling optimization, or by Sadnan et al. (2021) to minimize communications between agents controlling subgrids in a distribution power system for optimal decentralized power flow.

2.2 Research needs

Some black-box optimization methods seem to remain relatively unexplored in the context of co-simulation still. A

prominent example is the class of methods that go under the heading of *Bayesian optimization* (Garnett 2023), which has seen a resurgence in recent years due to its usefulness in machine learning, in particular for tuning neural networks. In Bayesian optimization, the objective function is treated as a random variable to be inferred in light of prior expectations (i.e., assumptions) and data collected (i.e., function evaluations). In our opinion, this seems like a promising approach when co-simulation is involved, one that should be investigated further.

A fact that does not seem to be discussed much in the current literature on co-simulation-based optimization is that co-simulation coupling gives rise to errors that are not present in a monolithic simulation of the same system. As mentioned, this exacerbates issues with simulation accuracy and stability, both of which are difficult to estimate or control for co-simulations (Kyllingstad, Sadjina, and Skjong 2024). A systematic way needs to be found to make sure that the optimization is robust enough to deal with this situation and to avoid over-optimization. In addition, methods for co-simulation error control can help speed up simulations and thus prove useful in optimization contexts.

Lastly, exactly how optimization and co-simulation can or should be used together is a matter that appears to be far from settled. More generally, a systematic analysis identifying which optimization methods work best for system optimization based on co-simulation, under which conditions, and for which cases seems to be lacking. This is also reflected in a large variety of strategies to be found in the literature, see Section 2.1.

2.3 Example: Optimizing the design of an autonomous battery-electric ferry

A fully battery-electric ferry needs to be fitted with a sufficiently large battery capacity and be as energy-efficient as possible to handle the vast range of environmental conditions it will encounter during operation. Maneuvering, acceleration, transit, and deceleration must all use as little energy as possible, while different environmental and loading conditions typically require different operational modes for optimality. The ferry design is also constrained by safety considerations. For example, it may have to handle (temporarily) reduced or completely unavailable charging capacity and stay maneuverable even under extreme weather conditions. Lastly, it has to be designed in a way that minimizes seasickness-inducing motions.

When setting up a co-simulation of such a system, a typical approach is to split it into subsimulators representing

- the hull (including effects of waves and currents),
- the power system,
- individual propulsors (e.g. propellers),
- individual pieces of heavy machinery (e.g. car ramp hydraulics),
- individual sensors (e.g. GPS and radar), and
- individual control systems (e.g. autopilot and power management system).

Depending on the vendor constellation involved in its construction, it may also make sense to split the power system further into subsystems representing battery packs, frequency converters, switchboards, back-up generators, and so on.

This system is characterized by strong interdependencies, foremost of which is that all on-board energy consumers are powered by the same, strictly limited, energy source. Multiple control systems are at play, controlling individual components, groups of components, or the entire ship, forming a hierarchy with both upwards and downwards dependencies. Hence, even though the system is loosely coupled and quite naturally separable for purposes of co-simulation, it is very tightly coupled in a system optimization perspective.

3 Adaptive Stress Testing

Traditionally, safety has been based on strategies such as introducing redundancy for critical components or by implementing safety functions that are triggered by a controller to prevent unsafe system states (Meulen and Myhrvold 2022). Such strategies are insufficient when dealing with complex and autonomous systems, however, where safety – or lack thereof – emerges as a consequence of the interactions of a large number of interconnected and interdependent controllers (Leveson 2012). This makes simulation-based validation of system safety and compliance a great tool for identifying the effects of these interactions at the system level.

Several approaches have been proposed for trying to find failures[2] in systems in complex interactions with their environment. They can broadly be divided into two categories (Lee, Mengshoel, et al. 2020): *Formal verification* attempts to use mathematical proofs and is able to identify failures as well as absence of failures. Of course, it is often ill-suited for complex engineering systems with stochastic environments. *Simulation-based sampling*, on the other hand, relies on the (manual or automatic) creation of environment instances and initial conditions, and performs searches over the parameter space to find failures in the simulated system–environment interactions. The main challenge is to handle the overwhelming set of possible parameters to test, not least figuring out which are the relevant ones. This calls for methods for automatically running, evaluating, and re-running simulations in a sequence which is *intelligently* guided towards the violation of desired system properties. One such method is *adaptive stress testing* (AST) (Lee, Kochenderfer, et al. 2015) which we believe is a promising candidate for use with co-simulation.

[2]Here, we understand a failure as a violation of a safety property (Corso, Moss, et al. 2021).

DOI 10.3384/ecp218785

3.1 Background

The principal idea behind AST is to try to identify the most likely failures of a complex system in an environment through actively guiding failure path sampling. This is especially useful when a formal mathematical falsification or the exhaustive search over the space of initial conditions, parameters, and over a significant length of time are not feasible. This will typically be the case for complex systems in stochastic environments for which the governing equations are not known. AST is a powerful method with applications in airspace safety (Lee, Kochenderfer, et al. 2015; Durling et al. 2021; Guo, Brittain, and Wei 2023), autonomous road vehicle safety and control (Koren, Alsaif, et al. 2018; Corso, Du, et al. 2019; Koren and Kochenderfer 2019; Corso, Lee, and Kochenderfer 2020; Corso and Kochenderfer 2020), software testing (Corradini et al. 2022; Durling et al. 2021; Hellhake et al. 2022), validation of AI systems (Julian, Lee, and Kochenderfer 2020), and collision avoidance of autonomous ships (Torben et al. 2023; Hjelmeland et al. 2022).

The classic formulation of AST (Lee, Kochenderfer, et al. 2015; Koren, Alsaif, et al. 2018) models the problem as a sequential Markov decision process and uses *deep reinforcement learning* with tree search to find action paths with a high failure likelihood. This approach either requires full access to the system states or, when unavailable, full control over the generation of random numbers in the system and the environment (Lee, Mengshoel, et al. 2020). The former case is rendered irrelevant by most industrial co-simulation use cases, while the latter is at least challenging to implement in practice.

3.2 Research needs

Unlike for optimization, we have been able to find little to no prior work on combining stress testing with co-simulation. Again, the black-box nature of co-simulations poses challenges, in this case when it comes to the interpretability of the results and the inference of causal chains, as well as issues regarding numerical accuracy and stability. At the same time, stress testing based on reinforcement learning (AST) presents itself as a good fit for co-simulation because it relies only on subsimulator inputs and outputs and thus goes together well with black-box models.

Depending on the specific restrictions and requirements of the case at hand, other approaches and formulations could prove useful and should be further investigated for use with co-simulation:

- If the failure paths need to be interpretable, *signal temporal logic* can be used together with *genetic programming* (Corso and Kochenderfer 2020) or *Gaussian processes* (Torben et al. 2023) to optimize action paths which lead to system failure. This approach also allows to encode domain-relevant requirements and compliance (such as minimal safety distances).
- The *backwards algorithm* (Koren, Nassar, and Kochenderfer 2021) can significantly speed up failure discovery with AST by first running it on a low-fidelity simulator before improving on the results using a high-fidelity simulator. Fidelity differences can induce spurious errors and disagreement in the discovered failures, though the algorithm is in principle able to learn to overcome these issues.
- The use of domain-specific heuristics for the reward function can improve AST performance, for example, by encoding improper system behavior or the inclusion of a dissimilarity measure between paths to try to avoid finding the same failure types repeatedly (Corso, Du, et al. 2019).
- If heuristic rewards are not available, AST performance can suffer from impeded learning due to a lack of reward information before a failure is found. The *go explore* (GE) algorithm can be used to improve AST performance under such conditions (Koren and Kochenderfer 2020).
- The use of a *recurrent neural network* with *long short-term memory* layers can yield a more robust and efficient detection of failures across the entire space of initial conditions (Koren and Kochenderfer 2019) by being able to learn relationships between different paths.
- AST also allows for differential stress testing (Lee, Mengshoel, et al. 2020) to compare failure paths against a baseline. This is useful, for example, when changes to an existing design need to be validated.

Other interesting approaches include the direct estimation of the distribution of failures (Corso, Lee, and Kochenderfer 2020), trying to find the boundary between compliant and non-compliant behavior based on parametric scenarios (Petrov et al. 2022), or extending AST to complex failures involving several autonomous agents and improper environment conditions together (Guo, Brittain, and Wei 2023).

3.3 Example: Stress testing the design of an autonomous battery-electric ferry

Our prior discussion of a battery-electric autonomous ferry in section 2.3 came short in terms of making sure that the design solutions are not only optimal but also *safe*. The ferry will have to handle all kinds of potentially dangerous situations, such as: vital sensor signals dropping out, becoming unreliable, or even actively being manipulated; collisions with crossing traffic; propulsors becoming unavailable; battery errors and other power electronics errors; or communications issues with a remote operation center. Worse, it will have to handle all sorts of *combinations* of such situations because the most severe system failures in complex systems stem from the interdependencies between subsystems.

A typical AST approach here would be to have a reinforcement learning agent define a policy that determines how a simulated scenario unfolds, for example how a crossing ship behaves or how the weather changes. The agent would then learn from the scenario outcomes, in particular how close the system came to failure, and in what sense. A proper evaluation of the latter could quite naturally depend on information which would normally be hidden in a co-simulation. One example might be the onboard control systems' internal representation of the state of the system and its environment; another might be the internal causal structure of a complex subsystem (e.g. the power system).

4 Outlook

Optimization and stress testing are not completely separable aspects of a complex system design workflow. Safety is an important design objective, and therefore something to be optimized for. Conversely, optimization of other factors could easily affect safety. Keeping to the maritime domain, one example would be a ship power plant which is tightly optimized for energy efficiency in ordinary operating conditions, but which does not have sufficient reserve power and therefore causes a critical black-out in extreme weather conditions. Having found good methods to implement optimization and AST with co-simulation-in-the-loop, the next obvious step is therefore to integrate the two processes in one design loop.

At least two strategies seem to be worthy of further investigation here:

- *nested*: including the results of stress testing when computing the objective function(s) in an optimization loop
- *sequential*: optimize the system, perform stress testing, evaluate, adjust optimization constraints/goals, repeat

We suspect that the first would, at least in principle, be capable of yielding the best results, but be very computationally expensive. The second might be more tractable in terms of computation time, but determining how to constrain or target the optimization procedure to reduce the likelihood of identified failure paths seems a highly nontrivial task, especially when dealing with black-box systems. Lastly, some synergies could potentially be exploited when it comes to surrogate models (optimization) or the use of low-fidelity simulators (AST with the backwards algorithm) to speed up implementations of co-simulation optimization and stress testing. But for now, this all remains conjecture and a highly interesting direction for future research.

This being a contribution to the *International Modelica & FMI Conference*, we would be amiss if we did not comment on FMI's role. Luckily, the standard already provides the complete feature set needed for co-simulation optimization and stress testing. The abilities to read and set derivatives and to store and restore model states, for example, are both already part of the FMI specification (Blochwitz et al. 2011). Therefore, it is up to the model developers to make use of the already implemented features to allow for their models to be used in optimization and stress testing settings.

Abstract

This paper introduces the ShipSIM, a novel free (standard conforming) Modelica library for modeling and simulation of ship maneuverability. This first Modelica library in the field of ship propulsion and maneuverability provides the components and flexibility to model the ship propulsion, hydrostatics and hydrodynamics to develop ship maneuvering simulations fully compatible with the Modelica Standard Library components.

In this paper is presented the library's key features and structure and introduce the underlying physical and mathematical foundations and modeling approaches. In addition, current implementation status, applicability limits and future development is discussed.

The library development is coordinated by the authors and it is used in several MSc thesis. ShipSIM library is available on https://github.com/BasilioPV/ShipSIM

Keywords: Modelica Library, ship maneuverability, marine engineering, ShipSIM

1 Introduction

Navigation safety is essential for all ships and specially for those that carry dangerous goods. On this sense, maneuverability is recognised as an ability to avoid dangerous situations specially near ports, where the coast, traffic and harbour facilities produces significative hazards.

For this reason, the International Maritime Organization (IMO) was increasing the maneuvering requirements to ships by means of A.601(15) (Organization 1987) [1] and later by MSC.137(76) (Organization 2002a) [2] and their associated guidelines (Organization 2002b) [3] where mathematical models can be used to demonstrate manoeuvring compliance on design stages. In addition, the same mathematical models can be used to correct sea trials performed with environmental conditions that deviate to those indicated on the regulations. On this sense, the integration of 1D simulation on Model Based Systems Engineering (MBSE) is clearly an advantage on shipbuilding.

Computational Fluid Dynamics (CFD) has great relevance on marine industry and nowadays is essential to estimate ship resistance in conceptual and basic designs, prior to towing tank tests and, in some cases, replacing them. But CFD has the disadvantage of large computation time, more man hours to produce a model, and low reusability when compared with 1D simulation. On the other hand, CFD can capture small design details that 1D simulation parameter cannot and the results was in general more precise than 1D simulations, especially when flow shedding phenomena occurs.

Previous approaches on ship specific simulation libraries using Modelica was SEECAT[4] from Bureau Veritas (Marty et al. 2012). This library provides a full set of ship specific components to simulate a power plant from the energy and fuel consumption perspective on a determined route. The main difference with ShipSIM is that on SEECAT only 1DoF is modelled, so manoeuvrability simulations are not possible.

DNV R&D in Greece has developed COSSMOS[5] library in gPROMS language (Dimopoulos and Kakalis 2010)(Dimopoulos, Georgopoulou, et al. 2014) focused on process simulation of ship energy systems. This tool is used in several ship types, such as LNG carriers (Dimopoulos, Stefanatos, and Kakalis 2016) to analyse from process point of view the ship systems. COSSMOS does not provide movements or navigation simulation, so manoeuvring or alternative means of propulsion, such as wingsails, are not possible to simulate.

Other applications can be found in MANSIM software (Aksu and Türkay 2017), that uses the same methodology of ShipSIM, but it lacks connectivity with other components or software. This inconvenience is found in other commercial software, such as MARIN SHIPMA 7 or ProteusDS ShipMo3D toolset.

[5]COmplex Ship Systems MOdelling and Simulation

The rise of the digital twin technology on shipbuilding industry creates the needs of develop simulation models that can run at a speed several times less than real time to aid the operators into their decisions (predictive) or check if the system behaviour is the expected (diagnostic). Ship systems are composed by several components from many manufacturers, so the simulation model needs to integrate component from different sources. For this reason, the use of Modelica Association technologies, such as FMI (Modelica Association 2014) Standard[6] enables reusability of components and efficient system simulation model development.

2 ShipSIM library

ShipSIM Modelica library start this development on early 2021 as an technology demonstrator of the use of Modelica(Modelica Association 2021) in maritime industry, where the digital twin technology was started to gain attention. On July 2021, a webpage[7] was created to spread the use of Modelica in this sector. On April 2023, the authors and other significant Modelica users found *Modelica User's Group of Spain*[8] to spread the use of Modelica languaje and associated technologies in Spanish.

This library is licensed under 3-clause BSD license and the latest ShipSIM library version is available on `https://github.com/BasilioPV/ShipSIM`

2.1 Overview

ShipSIM library is built on top of MSL multibody library (Otter, Elmqvist, and Mattsson 2003) to provide an easier and seamless integration with other components of the Modelica Standard Library. The library is extensively documented for each component, in both documentation section and source code, where description of variables and parameters and main equations comments aids to understand the inner working of the library. Additionally, some parameters default value expression was taken from literature to aid in modelling on conceptual stages or training, where only few data is available.

2.2 Modelica library structure

Library structure adheres to usual MSL structure, where the library is presented to the user with a users guide, license, main authors, release notes, references and contact points. Next on the library are the examples, which provide sample systems that uses the main ShipSIM components. Validation and debugging sections are provided to check the proper working of some models when validated against the literature or test data.

Components section provides the main models developed for this library: ship hydrostatics, inertia, hydrodynamics, propellers and rudders. These components are the core of the library that enables simulation of ship manoeuvring.

3 Methods

The authors of this library considers two main features that deviates from the usual mathematical models found on the literature.

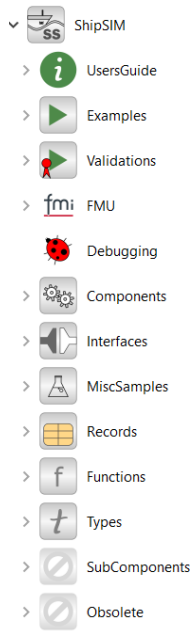

Figure 1. Main ShipSIM library structure.

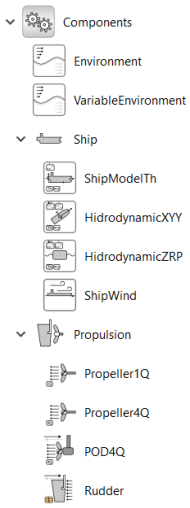

Figure 2. Hydrodynamics and propulsion components.

Usually ship movements are divided in two pair of 3DoF systems, to complete the 6DoF ship movement axis shown in Figure 3. The first one is the surge-sway-yaw, that represents the movement on the floatation plane, which is used for *manoeuvring* calculations. This 3DoF system has no restoring forces (*spring*) and only present *mass* and *damper* forces. The other 3DoF system is the roll-pitch-heave motion, which defines the *seakeeping* ability of the ship. These movements can be modeled as an *spring-mass-damper* system that oscillates around the equilibrium position.

The first feature is to provide a 6DoF enabled model from beginning, where the *manoeuvring* and *seakeeping* forces are modeled separately in order to enable only one 3DoF ability or both. This implementation requires to split the equivalent *mass-spring-damper* system into three main components:

1. Mass, inertia and hydrostatic restoring forces (corresponding to heave, pitch and roll movements)

[6] Functional Mock-up Interface

[7] *www.ShipTwin.com*, now offline and moved to *modelica-spain.org*

[8] *modelica-spain.org*

DOI 10.3384/ecp218793

2. Hydrodynamic damping forces relative to maneuvering (corresponding to surge, sway and yaw movements)

3. Hydrodynamic damping forces relative to seakeeping (corresponding to roll, pitch and heave movements)

This decomposition enables that different methods can be implemented into the library in order to have components with several fidelity levels or adjust the behavioural equations in other situations, such as shallow waters.

Other main feature is the segregation of the rudder from the manoeuvring model. Usually, all papers treat both components together, but for a sake of clarity the best is to be splitted in order to model non-conventional propulsion systems. In addition, the ship connection is placed at the common ship axis origin (rudder stock end at baseline) instead of the middle of the ship or the centre of gravity. With this position is easier to add other ship systems (rudder, propeller, cranes, etc...) because their position onboard is commonly described using these axis reference.

3.1 Ship hydrostatics and inertia

To calculate the new position of the centre of buoyancy, small rotations around equilibrium flotation theory was used. From this approach, the centre of buoyancy rotates around the longitudinal and transverse metacentre of the ship. This is the usual way to calculate hydrostatics forces and moments (Lewis et al. 1988).

Inertia matrix of the ship is usually simplified to only the main three axis inertia, discarding any cross inertia.

Hydrostatic data depends of the middle draft of the ship. Values of displacement, centre of bouyancy and metacentre position was provided using a custom expandable polynomial fit, with real custom numbers for the exponents. Hydrostatic data needs to be fitted previously to this kind of equation to be used.

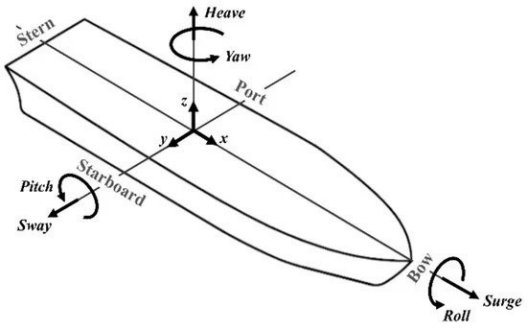

Figure 3. Ship movement axis.

3.2 Ship maneuvering hydrodynamics

Since the 1970's various mathematical models have been developed and validated to reproduce the ship motions during maneuvering (Norrbin 1970). Modern methods are based on the Maneuvering Modeling Group (MMG) standard methodology (Yoshimura 2005; Yasukawa 2015; Taimuri et al. 2020). This method accounts coupled effects from movements in different axis by polynomial functions where the coefficients can be obtained by standard tests.

This method is based on the following assumptions:

1. Hull in-plane forces are represented by quasi-steady flow reactions and described by non-dimensional coefficients referring to motion velocities and accelerations.

2. No shallow water effects are considered

3. Heave, pitch and roll motions are assumed to be small and represented by the linear relations of forces and motion components.

4. Memory effects are not taken under consideration.

Since mass and inertia effects are provided by other component, this component only accounts for the hydrodynamic force due to ship motion. According to MMG method (Yoshimura 2005; Yasukawa 2015), these in plane hull forces was defined by the following empirical equations:

$$X'_{Hull} = X'_{vv}v'^2 + X'_{vr}v'r' + X'_{rr}r'^2 + X'_{vvvv}v'^4 \tag{1}$$

$$Y'_{Hull} = Y'_{v}v' + Y'_{r}r' + Y'_{vvv}v'^3 + Y'_{vvr}v'^2r' + Y'_{vrr}v'r'^2 + Y'_{rrr}r'^3 \tag{2}$$

$$N'_{Hull} = N'_{v}v' + N'_{vvr}v'^2r' + N'_{vvv}v'^3 + N'_{r}r' + N'_{vrr}v'r'^2 + N'_{rrr}r'^3 \tag{3}$$

These equations provide the hydrodynamic forces as a function of several ship specific hydrodynamic parameters for surge ($X'_{vv}, X'_{vr}, X'_{rr}, X'_{vvvv}$), sway ($Y'_{v}, Y'_{r}, Y'_{vvv}, Y'_{vvr}, Y'_{vrr}, Y'_{rrr}$) and yaw ($N'_{v}, N'_{vvr}, N'_{vvv}, N'_{r}, N'_{vrr}, N'_{rrr}$), when multiplied to non-dimensional sway speed (v') and yaw (r'), raised to the power up to three. This methodology accounts for coupled response of the sway, surge and yaw movements. On MMG method, only the above mentioned coefficients were found relevant to define the behaviour of the ship when manoeuvring.

Ship resistance is modelled into the MMG method as a drag factor that multiplies the square of the vessel speed, to be added to the X'_{Hull} of Equation 1. Ship resistance is usually obtained from CFD studies and towing tank test. The results of ship resistance versus speed does not fit exactly with a square function. For this reason, on this library a custom polynomial function is introduced to fit the resistance results and enhance the precision. The end user shall perform a curve regression fit on the resistance curve data obtained by CFD or towing tank test, by using a polynomial function where the number of terms and power factors are not restricted to get a best fit of the data.

Hydrodynamics coefficients can be obtained from PMM (Conference 2017) [9] tests for a given ship. By default, this library provides an estimation based on several literature sources (Taimuri et al. 2020) that can be used for large ships with one rudder-propeller configuration in advance speed.

3.3 Ship propulsion and steering

Over years, Wageningen B-series propellers was used as default propellers on conceptual designs. The availability of propeller data and geometry makes easy to implement into simulation software (Oosterveld and Oossanen 1975). On this library, Wageningen B-series was implemented in both one-quadrant (Oosterveld and Oossanen 1975) and four-quadrant (Roddy, Hess, and Faller 2006) behaviour. One-quadrant represent the usual situation where the propeller has positive advance ratio and the ship is moving ahead. On the other hand, four-quadrant depends on the blade attack angle, and can be used for all the propeller situations, such as reversed thrust in a crash stop.

[9] Planar Motion Mechanism tests, see *ITTC Procedures 7.5-02-06-02 Rev05*

On this component, main propeller characteristics are defined, such as diameter, pitch ratio, number of blades and blade area ratio to select the Wageningen B-series propeller from the catalogue. Propeller inertia and added mass inertia can be also defined. By default, these parameters are calculated using built in correlation formulas for this kind of propellers.

To correct the behaviour of the propeller from open water test to propeller behind hull arrangement, coefficients of wake fraction, thrust deduction and rotative relative are used. Wake fraction represents the percentage of the ship advance speed that reach the propeller disc due to turbulence produced by ship hull. When the propeller is producing thrust, the water is accelerated by suction just ahead of the propeller disc. On this situation, the hull drag on the small part of the hull near the propeller is increased and treated as a propeller thrust deduction. Finally, the ship's hull is surrounding the propeller by above, which usually benefits the propeller working, produces a change in the propeller efficiency accounted with the rotative relative factor.

By default, these three factors are calculated using empirical formulaes (Harvald 1983; Holtrop 1984; Brix 1993) with main ship dimensions, but letting to the final user substitute for real values obtained from self-propulsion tests or CFD.

Finally, the water stream accelerated by the propeller directly impacts on the rudder, modifying the water speed on a determined zone. This rudder zone affected by the propeller is calculated by using flow straightening theory (*vena contracta*) (Taimuri et al. 2020).

Figure 4 shows the representation of rudder forces and flow velocity at the rudder plane. On this figure $V_R, V_{X,R}$ and $V_{Y,R}$ are the flow velocity of the water to the rudder, and their components in X and Y reference axis. The flow drift angle at rudder, β_R, is represented among with the rudder angle δ. Then, the hydrodynamic profile of the rudder will produce a lift force represented by $Y_r ud$.

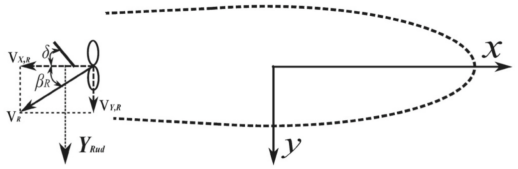

Figure 4. Representation of the rudder forces and flow velocity at the rudder plane. (Taimuri et al. 2020)

Ship steering model is composed by an hydrodynamic profile that rotates about a vertical axis, producing both lift and drag (Liu, Quadvlieg, and Hekkenberg 2016). This library contains several NACA 00xx symmetrical profiles lift and drag data, obtained for a range of Reynolds numbers and for attack angles from zero to 180 degrees (Sheldahl and Klimas 1981). In addition, a quick check of cavitation warning was implemented (Burrill 1955).

The water speed and direction is corrected with the propeller thrust affected zone to account for propeller-rudder interaction effect. In the relevant literature (Taimuri et al. 2020), lift reduction factor in way of the slip-stream radius is included. In a same manner, the influence of the hull ahead of the rudder can be included in the rudder force as a factor that represents the increase of the lateral force due to the presence of the hull above the rudder root. Also, the flow passing through the hull of the ship reduces the angle of attack on the rudder. This effect is usually accounted using flow straightening coefficient. This library tends to implement an interchangeable rudder profile data, that instead use a unique coefficient for lift and drag, uses a results table for full 180 degree angle of attack and several Reynolds number. For this reason, direct implementation of the formulae provided in the literature is not possible and adaptations are needed. At the time of this paper was written, neither lift reduction factor, increase of lateral force and flow straightening coefficient was included into the models.

3.4 Environment forces

Current speed and direction is used to calculate the relative water speed and direction and, therefore, include the current into the simulation. Apparent wind forces, composed by external wind speed and direction and ship's speed, can be estimated by the method presented in (Fujiwara, Ueno, and Nimura 1998). On this method, windage areas of the ship over the floatation and their respective centers of gravity was used. At the time of this paper was written, no sea waves forces was included into the library.

4 Application

4.1 Case study description

Turning circle is a classical maneuvering test that consist of turn the rudder up to maximum angle when the ship is navigating at full speed. The ships starts to navigate in circles where the following conditions shall be met (Organization 2002a):

1. The test speed (V) used in the Standards is a speed of at least 90% of the ship's speed corresponding to 85% of the maximum engine output.

2. Turning circle manoeuvre is the manoeuvre to be performed to both starboard and port with 35° rudder angle or the maximum rudder angle permissible at the test speed, following a steady approach with zero yaw rate.

3. The test shall be performed at deep, unrestricted water; calm environment; full load (summer load line draught), even keel condition and steady approach at the test speed.

Under the above conditions, the following criteria shall be complied:

1. Advance is the distance travelled in the direction of the original course by the midship point of a ship from the position at which the rudder order is given to the position at which the heading has changed 90° from the original course. The advance should not exceed 4.5 ship lengths (L).

2. Tactical diameter is the distance travelled by the midship point of a ship from the position at which the rudder order is given to the position at which the heading has changed 180° from the original course. It is measured in a direction perpendicular to the original heading of the ship. The tactical diameter should not exceed 5 ship lengths in the turning circle manoeuvre.

Figure 5 shows a graphical description of the definitions used above.

The ship selected for this example is a single shaft and rudder propulsion configuration. Main ship dimensions are described in

DOI 10.3384/ecp218793

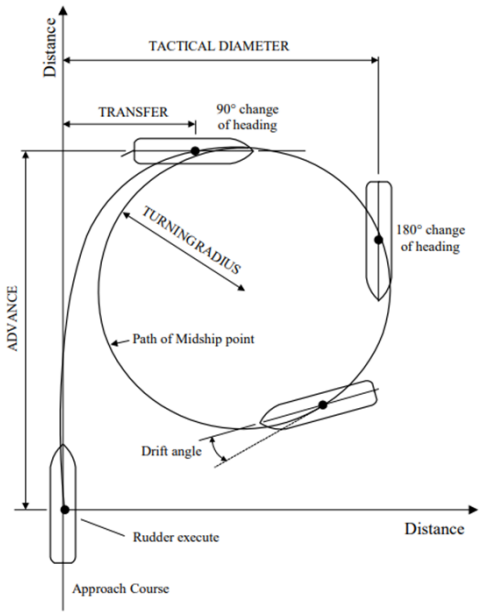

Figure 5. Turning circle manoeuvre. (Organization 2002a)

the Table 1. Hydrostatics was calculated by designing a custom hull lines with the main data shown in the table and fitting the values of displacement, metacentre radious and bouyance centre with polymonial fit. Windage areas was also included in the simulation model.

Propeller characteristics are defined in the Table 2, where a *Wageningen-B* propeller type was selected. Similarly, the rudder selected is a *NACA 0015* profile with a chord of 2 metres and a span of 3.5 meters. The rate of turn of the rudder comply with IMO regulations and was set to 2.5º/s, with a maximum rudder angle of 35º. Table 3 shows rudder main data.

Table 1. Main ship characteristics

Parameter	*Value*
Length	100 m
Beam	20 m
Draft	4 m
Block coefficient	0.693
Displacement	5,681ton
Num. of propellers	1
Num. of rudders	1
Trans. wind area	316 m^2
Lateral wind area	1,337 m^2

Figure 6 shows the simulation model diagram developed with ShipSIM library. The ship is modeled using three components. The first component is the mass, inertia and floatation forces that define the static floatation forces and inertia. The second one is the hydrodynamic forces, that define the forces induced by the movement of the ship in the water. In addition, a wind resistance force is added to the simulation. This wind force is lesser when comparing to the hull hydrodynamics forces.

The propulsion system is modeled using a four-quadrant propeller coupled with a rudder. The propeller speed is controlled by a constant signal and the rudder angle is controlled also by a constant signal that actuates from the beginning of the simulation.

Table 2. Propeller characteristics

Parameter	*Value*
Diameter	4 m
Type	*Wageningen-B*
Num. blades	4
Blade area ratio	1.0
Pitch diameter ratio	1.0

Table 3. Rudder characteristics

Parameter	*Value*
Chord	2 m
Span	3.5 m
Profile	*NACA 0015*
Rate of turn	2.5º/s
Max. rudder angle	35º

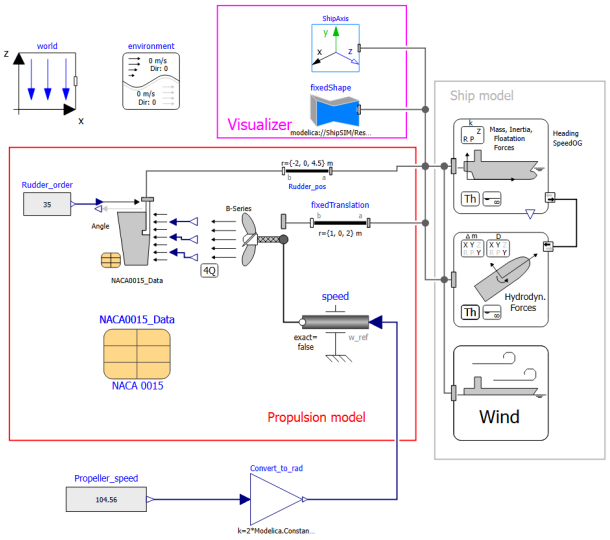

Figure 6. Simulation model diagram.

The ship is navigating at steady state with constant propeller r.p.m. where the rudder order is set to maximum rudder angle. In this condition, the rudder starts to rotate from the initial zero angle to maximum. Then, the ship start to turn and after a transient movement the ship start to navigate in circles, with a constant diameter.

4.2 Results and discussion

The simulation setup is set to a total time of 800 seconds with a time step of 0.2 seconds, using DASSL integration method with variable step size and order on OpenModelica v1.25.0. After compilation, the simulation time lasts less than 2 seconds, thus 400x faster than real time. Figure 7 shows the turning circle

Table 4. Initial conditions

Parameter	*Value*
Ship speed	13 *knot*
Propeller speed	104.56 *r.p.m.*
Rudder angle	0º
Initial rudder angle order	35º

result from this simulation.

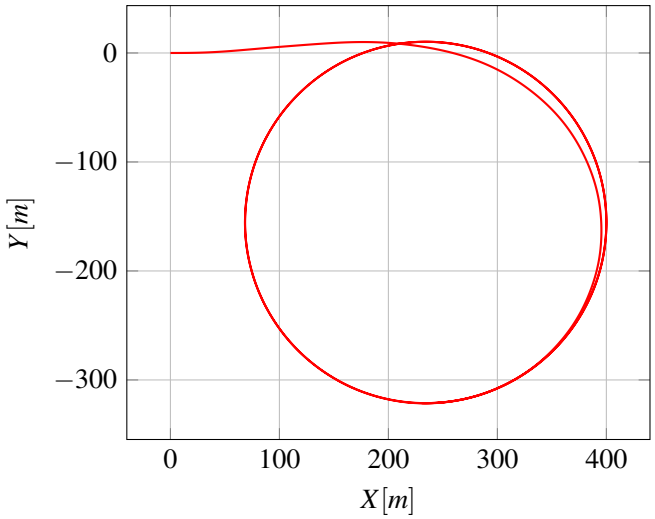

Figure 7. Turning circle test.

To check the compliance with the IMO regulations, Figure 8 shows the heading angle (Yaw) in red, surge position (X) in blue and sway position (Y) in green. As explained before, when the heading angle is equal to 90º, at 65.6 sec, the advance is 361.2 m (less than 4.5 times the ship length). In a similar way, when the heading angle is equal to 180º, at 138.8 sec, the tactical diameter is 291.3 m (less than 5 times the ship length).

This example demonstrate the benefits of perform quick simulation on conceptual design phase of ships to comply with IMO regulations regarding manoeuvrability.

5 Conclusion and outlook

This paper shows a proof of concept for the use of Modelica language into marine industry simulations. After describing the main maneuverability methods an application case is developed and their results presented. Some components need to have further development and validation to achieve the quality required to be used in real scenarios. This paper proves that physics 1D simulation is a reliable and fast method to provide simulation models to digital twin technologies, because the fast computation enables predictive usage.

The development of these physical models in Modelica has the big advantage of the acausal model definition, which enables a higher reusability and is easier to describe the equations that governs the behaviour of each model. On the other hand, collaboration between professionals is a key factor to develop high quality simulation models.

Abstract

This paper describes the use of a MODELICA system model to support the development of a heat management control system for a fossil-free sailing yacht. Due to tight project timelines, the control system was developed and tested virtually, avoiding delays associated with waiting for the physical system to become available. The system model covers key functions such as heat recovery and heat dumping, enabling automated testing of various operational scenarios. This approach not only accelerates development but also reveals early insights into interactions between the control logic and system dynamics. The model is designed to be seamlessly replaced by the real system once it is built. Future comparisons between simulated and real-world performance will guide refinements to improve model accuracy and support model-based tuning of the control system.

Keywords: HVAC, control design, FMU, thermal management, zero emission yacht, ship

1 Introduction

In the year 2022 about 2% of the worldwide greenhouse gas was emitted by the shipping industry (International Energy Agency 2023). In absolute values this means an emission of 858 billion tons of greenhouse gas (Clarke et al. 2023). A transition to cleaner technologies is necessary to reduce those values. FOUNDATION ZERO is a relatively new organization which aims to share technical innovations to promote sustainable technologies in various sectors. It is active in the maritime industry, having previously provided its PowerHub to provide the sail team BCN in the 2024 America's Cup with fossil free energy (Foundation Zero 2024b). The source code of which has since been open sourced (Foundation Zero 2025b). One of the bigger items being covered by FOUNDATION ZERO is PROJECT ZERO, which is attacking the problem of shipping emissions with traditional propulsion with sails and the comfort of today. It is developing a 69-meter sailing yacht that aims to be the first of its kind to operate entirely free of fossil fuels. To achieve this, the project relies on the development of advanced technologies that balance energy generation, storage, and demand on board. The project also aims to share these innovations on an open-source basis, with the goal of accelerating the maritime industry's energy transition (Leslie-Miller and Someren 2022). Key systems enabling the yacht's fossil-free operation include a propulsion system that is capable of hydrogeneration by reversing the propellers, generating up to 750 kW of power that can be stored in a 5 MW h battery bank. Top-of-the-line insulation (Foundation Zero 2024c) and a heating, ventilation and air conditioning system (HVAC) that includes adiabatic cooling and natural ventilation through the mast (Foundation Zero 2025a) reduce the energy needed to control the climate on board, which typically accounts for up to 50 % of a yacht's energy use. Additional energy savings are achieved through the "Thermal Harvesting and Recovery System" (THRS), which is the focus of this paper. A simplified diagram is shown in Figure 1.

The THRS reduces electrical energy consumption by leveraging thermal energy (heat) alongside electrical energy. It harvests heat using custom-developed PVT panels capable of generating both electrical (PV) and thermal (T) energy, optimizing the limited surface area available on board (Foundation Zero 2024a). Additionally, it recovers waste heat from the propulsion system and electrical components, providing an extra source of thermal energy while reducing cooling demand, as this heat would otherwise accumulate inside the yacht. Thermal energy is stored using a phase change material (PCM) that acts as a thermal battery, providing heat to the domestic hot water supply and an adsorption chiller. The adsorption chiller supplies cool water to wall and ceiling panels throughout the yacht, reducing the load on the electrically driven HVAC system.

Recovering heat that would otherwise be discarded via cooling water and reusing it in place of electrical energy, for example for domestic hot water use, can offer significant energy savings. However, it also introduces the challenge of efficiently managing thermal harvesting, storage, and consumption while maintaining safe and stable operation of critical subsystems. This requires an intelligent control system with the ability to respond other systems on board, integrating inputs such as trip itineraries, weather forecasts, and consumption profiles,

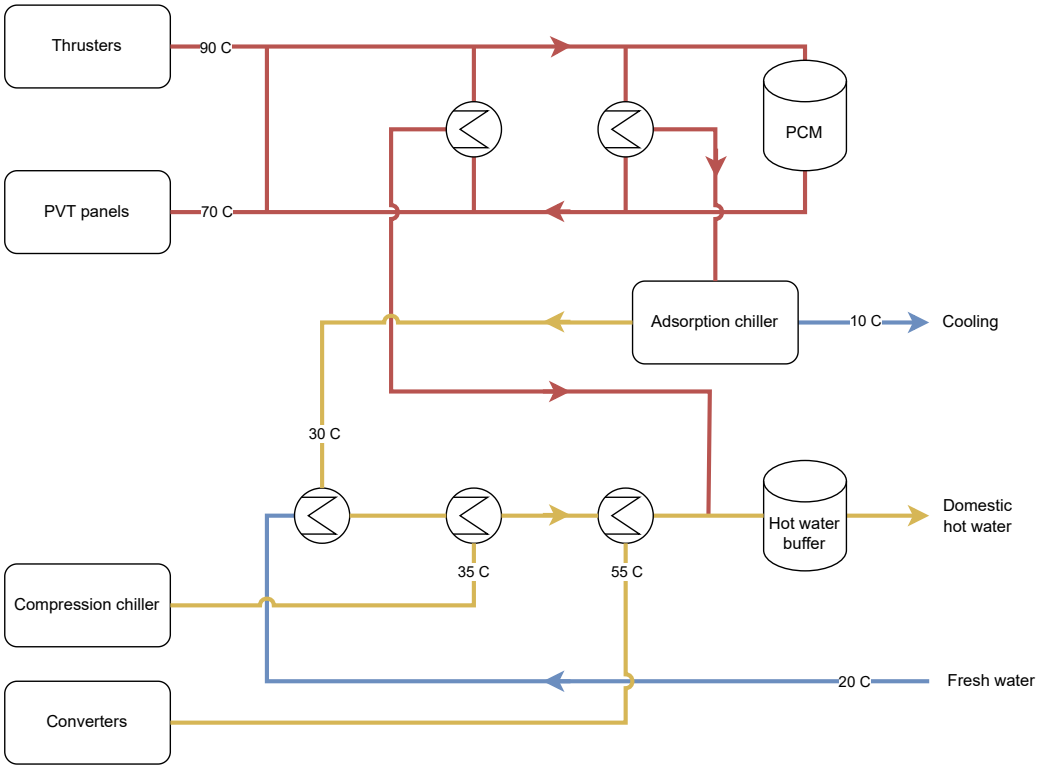

Figure 1. Simplified diagram of the thermal harvesting and recovery system

while also providing feedback to crew—for example, recommending optimal times for energy-intensive activities like laundry.

To manage the complexity of the system, it is divided into functional submodules, each with its own control logic to deliver basic functionality. The THRS system submodules are the high temperature circuit, the hot water circulation circuit, the buffer tank boost circuit, the buffer tank fill circuit, the chiller circuit, the booster circuit and two low-medium temperature circuits. These submodules operate under distinct control modes and setpoints, determining, for example, whether heat from the propulsion system should be harvested or rejected via seawater cooling—and at what temperatures. The high-over control system can then coordinate the modes and setpoints across submodules based on current or forecasted onboard conditions. The control modes of the submodules each have a flow configuration. That is achieved through valve and pump settings and includes basic control loops to maintain temperature and flow targets.

A more practical challenge is the tight timeline of the construction and commissioning of the yacht. In addition to these reasons, there are issues of availability and high costs, meaning that Hardware-in-the-Loop (HiL) or even proper testing of the controller in the real system are out of the question. This has motivated the creation of a dynamic model of the physical system, which facilitates co-development of the control logic alongside the physical system, effective troubleshooting before the system is installed, and isolation of individual subsystems for testing. MODELICA is used for the Software-in-the-Loop (SiL) approach to model the plant model. The controller is implemented in Python, as the goal is to use the implemented Python code in the real system as well. In addition, the entire project focuses on open access, so Python is preferred over conventional tools, which are mostly commercial. Further details of how the implementation of the control logic in Python is pointed out in Section 3. Once validated, the control logic can seamlessly transition from simulation model to real-world operation by replacing the dynamic model with the yacht's actual input/output interfaces during commissioning (see Figure 2). When replacing the plant model with the real system, latency effects are expected to occur, but these can be neglected due to the high capacities and inertia of the THRS. This paper demonstrates this approach for a submodules component of the THRS that recovers heat from the yacht's propulsion system.

The paper is structured as follows: In Section 2 a functional description of the thermal harvesting and recovery system is given. Section 3 describes how MODELICA is integrated in the project architecture and explains the interface between the developed MODELICA model and the rest of the tool chain. To demonstrate the viability of this approach, the focus lies on a single component of a submodule that recovers heat from

DOI 10.3384/ecp218801

the thrusters. A detailed description of the thrusters component and its modelling in MODELICA is given in Section 4. Section 5 presents simulation results of the MODELICA model coupled with the developed Python control. Finally, a summary and outlook are given in Section 6.

2 Description of the Thermal Harvesting and Recovery System

The THRS (see Figure 1) comprises components that produce, consume, or store thermal energy. When sailing—either in propulsion or hydrogeneration mode—the thrusters generate heat and require cooling, providing a potential heat source of up to 13.3 kW at 90 °C that can be recovered by the system. PVT panels contribute additional thermal input that is also available when at anchor, typically harvesting at around 70 °C during peak sunlight hours. Other onboard sources include the waste heat from the compression chiller and electrical converters, which offer a more constant source of energy, but at lower temperatures.

Thermal energy is consumed by domestic hot water demands at 48 °C (e.g. showers, laundry, and dishwashing) and by an adsorption chiller, which requires hot water between 50 °C and 95 °C to produce chilled water for onboard cooling. To balance fluctuating availability and demand throughout the day, heat can be stored in both a phase change material (PCM) storage unit and a hot water buffer tank. To manage thermal energy efficiently across different temperature levels, the system is divided into a high-temperature and a medium-temperature circuit. This split enables harvesting energy at both high and low temperatures - for example allowing use of the waste heat from the adsorption chiller to preheat water entering the medium-temperature loop. The high-temperature circuit primarily supplies the adsorption chiller and can supplement the medium-temperature circuit as needed. Figure 1 presents a simplified schematic of the system. For clarity, elements such as valves, pumps, and seawater coolers are omitted. In practice, each critical component includes a seawater-based backup cooler to ensure safe operation when thermal energy cannot be stored or utilized.

As an illustrative example, the thrusters component is highlighted, which is responsible for cooling the thrusters during operation and, when possible, feeding the recovered heat into the rest of the system. This component is described in detail in Section 4, which also presents its implementation in MODELICA.

3 Using MODELICA to design a control system

The main objective of the project underlying this paper is to develop a dynamic model of the THRS that can be used as a development environment for the control logic. A scheme of the according software architecture is shown in Figure 2: The box at the top shows the Python control module. The Module is implemented with pytransitions which is a library for finite state machines (Alexander Neumann 2025). It takes as input sensor values and computes the desired control outputs based on the control logic as output. Sensor values include temperature and flow sensor readings, but also states of other systems on board, such as the propulsion system. On the receiving

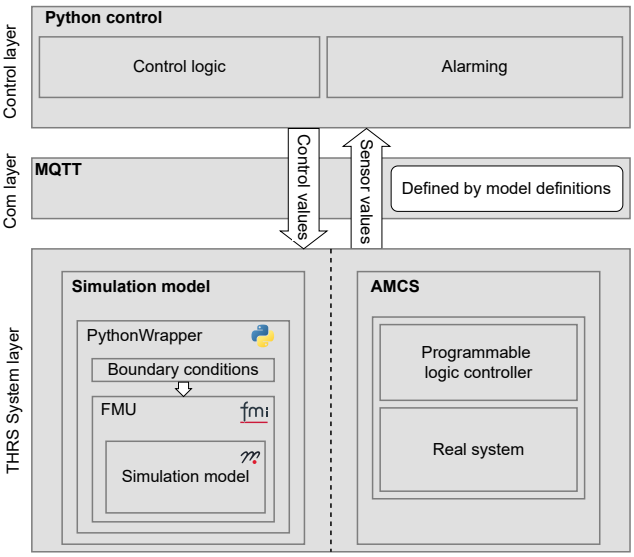

Figure 2. Architecture - Dividing into control layer, communication layer and THRS system layer. Simulation model and AMCS are interchangeable.

end of the control, shown at the bottom box, one finds either the simulation model or the ship's real alarming, monitoring and control system (AMCS). The AMCS provides an interface for critical systems on board, such as power management and propulsion control. It handles most of the ship's sensors data and control signals and is connected to the physical components of the THRS through a programmable logic controller (PLC). The interface between the control logic and the simulation or the AMCS is realized with the message queuing telemetry transport (MQTT) protocol (Banks et al. 2019).

In this setup, the THRS IO and control are completely separated, and simulation and AMCS are interchangeable. This means that the control logic can be developed and tested with the simulation model, and then seamlessly transitioned to the AMCS without changes to the control code. Other than changing the MQTT broker to which the

control code connects there is no meaningful difference between simulation and the actual system. Therefor potential difficulties which might ordinarily occur when going from model to compiled code don't apply. One can expect latency effects between the computer running the control code and the AMCS. It is assumed that those effects are small compared to thermal capacities and inertia of the THRS.

3.1 Setup of the THRS system model

The THRS components are modeled with the MODELICA library HVAC (XRG Simulation GmbH 2025) in combination with the MODELICA STANDARD LIBRARY (Modelica Association 2023). The HVAC library is designed for fast simulations of thermo-hydraulic and air distribution systems. It provides models for cooling towers, heaters, turbo machines, heat exchangers, heat pumps, chillers, humidifiers, water separators, storages, sensors, photovoltaic panels, thermal collectors, fittings, pipes, valves, sinks, sources and other HVAC relevant components (see example icons in Figure 3). To model the THRS a selection of the above-mentioned models are used. In addition to that, a model for PCM based on Brunnemann (2020) is integrated to the system. A detailed description of modeling the entire THRS would be beyond the scope.

The model of the thruster component (see Figure 4) is embedded into an interface model in MODELICA. Real inputs, representing control values or boundary conditions, and outputs, representing sensor values, are defined in a way to match the real system. To prevent sudden changes or unexpected jumps of the input signals, a first order block is placed behind the inputs to smooth them before they are passed on to the thrusters component. To use the MODELICA model as the replacement of the

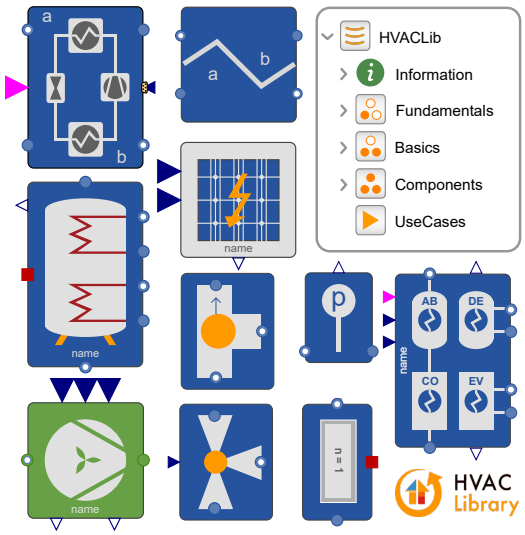

Figure 3. HVAC LIBRARY with example models for heat pump, buffer tank, fan, heat exchanger, photovoltaic panel, fitting, sensors and adsorption chiller

AMCS, it is compiled into a FUNCTIONAL MOCK-UP UNIT (FMU). A Python wrapper enables the FMU to communicate via MQTT with the control module (see Subsection 3.2). The development and compiling of the model is done in DYMOLA 2025X. Co-Simulation with the solver Cvode is selected. The FMI version chosen is 2.0. To enable recompilation of the FMU on another operating system, the source code export is included. It is recommended to deactivate the tools flag "evaluate". Another way to enable the model to communicate with the control module via MQTT is to use the MODELICA DEVICE DRIVERS LIBRARY (Thiele et al. 2017). Since there are more options to integrate a FMU into any workflow the compilation in a FMU is the preferred way. This opens greater flexibility in the event of changes to the process.

3.2 Python integration

The FMU is executed using FMPy (Dassault Systèmes 2025), enabling compilation and execution of the FMU in a Python environment. From here, a Python wrapper is constructed that provides the MQTT interface to the FMU. The wrapper is responsible for reading the control values from the MQTT broker and writing them to the FMU inputs. It also reads the sensor values from the FMU outputs and writes them to the MQTT broker. The data schema for all these values is defined using the Pydantic Python package (Colvin et al. 2025). Pydantic is a data validation and serialization library for Python, which allows for the definition of data models with type annotations. This enables automatic validation of the data being passed to and from the FMU and AMCS.

One of the key aspects of the setup is the ability to exchange the real system with the simulation model. This means that the control code is fully unaware of that difference. Specifically, the interface of the simulation (the sensor values it sends, and the control values it receives) should be identical to those of the real-world system (i.e. the AMCS). This is done as follows:

- Model definitions: Pydantic models are defined that describing sensor values and control values. The models follow the structure of the MQTT messages as defined by the AMCS.
- FMU mapping: The Pydantic models are translated to the FMU's input and output variables. This is done by maintaining a strict naming convention for the FMU's variables.
- FMU boundary condition input: The system model requires some additional inputs that are not part of the control values (e.g. seawater temperature), which are injected in the simulation as boundary conditions. These are also defined by Pydantic models as either constants or time series.

DOI 10.3384/ecp218801

- Unsimulated sensor values: any sensor values that are not simulated in the FMU are added to the simulation output (and must also be defined as simulation inputs). An example is the signals from the ship's propulsion control system indicating which thrusters are active.

With this setup there is a complete stand-in for the real-world system, abstracted behind a Python class which receives control values and output sensor values. This class can read and write MQTT messages and translate them to FMU inputs and outputs. The control loop reads the sensor values, enters those into the control logic and feeds the control values back into the simulation.

4 Thrusters Component in Modelica

This section describes in more detail the simulation model of the thrusters component within MODELICA (see Figure 4). Its main subcomponents can be identified as a circulating pump (1), the two thrusters, a forward thruster (4) and an aft thruster (8) and a seawater cooler (14). It also includes several control valves, fittings and different types of physical sensors ((3), (6), (7), (10), (16), (18), (19), (27), (28)). The medium, a 20 % glycol-water mixture, is assumed with constant fluid properties.

The module has three main operating modes, an idle mode, the heat recovery mode and the direct cooling mode, which are described in Section 5.

4.1 Circulation Pump

The flow in the thrusters component is provided by the circulation pump (1) (highlighted in light purple in Figure 4). For reasons of redundancy there are two parallel pumps which are represented by one circulation pump. The two identical pumps do not operate at the same time, so it is sufficient to use only one pump model with a built-in pump changeover sequence. The pump model is parametrised with one characteristic pump curve for a specific speed. The pump gets a relative speed as control parameter and operating points deviating from nominal values are approximated from characteristic curve with affinity laws.

4.2 Forward and Aft Thruster

As mentioned before, the thrusters of the yacht are generating heat during operation and must be cooled. Therefor the thruster model ((4), (8)) is simplified to transfer a certain heat load to the coolant and to have a linear pressure loss model, which is defined by nominal parameters. The heat load is given through an input and can be varied during the simulation. Forward and aft thruster are shown with a red frame in Figure 4.

4.3 Valves and fittings

There are three types of valves used in the thruster module, the switching valves ((11), (20)), the mixing valves ((13), (21), (22)) and the flow control valves ((5), (9)). The switching and mixing valves are three-port valves and are based on the same model. The flow control valves are two-port valves. Each valve is parametrised with a KV nominal value, provided by their data sheets. The opening for the two-port valves and the flow direction for the three-port valves are set as relative ratios and can be varied during the simulation. There is a leakage of 0.01 % to make the overall model more robust against numerical issues. The opening is implemented with a time delay behaviour.

The fittings can be divided into splits ((2), (25)) and joins ((12), (15), (17), (23), (24), (26) (29)). The joins are designed with a control volume-based approach and flows are ideal mixed. Splits can be used either with predefined split ratio or with a computed ratio provided by outer components which are generating mass flows.

4.4 Seawater cooler

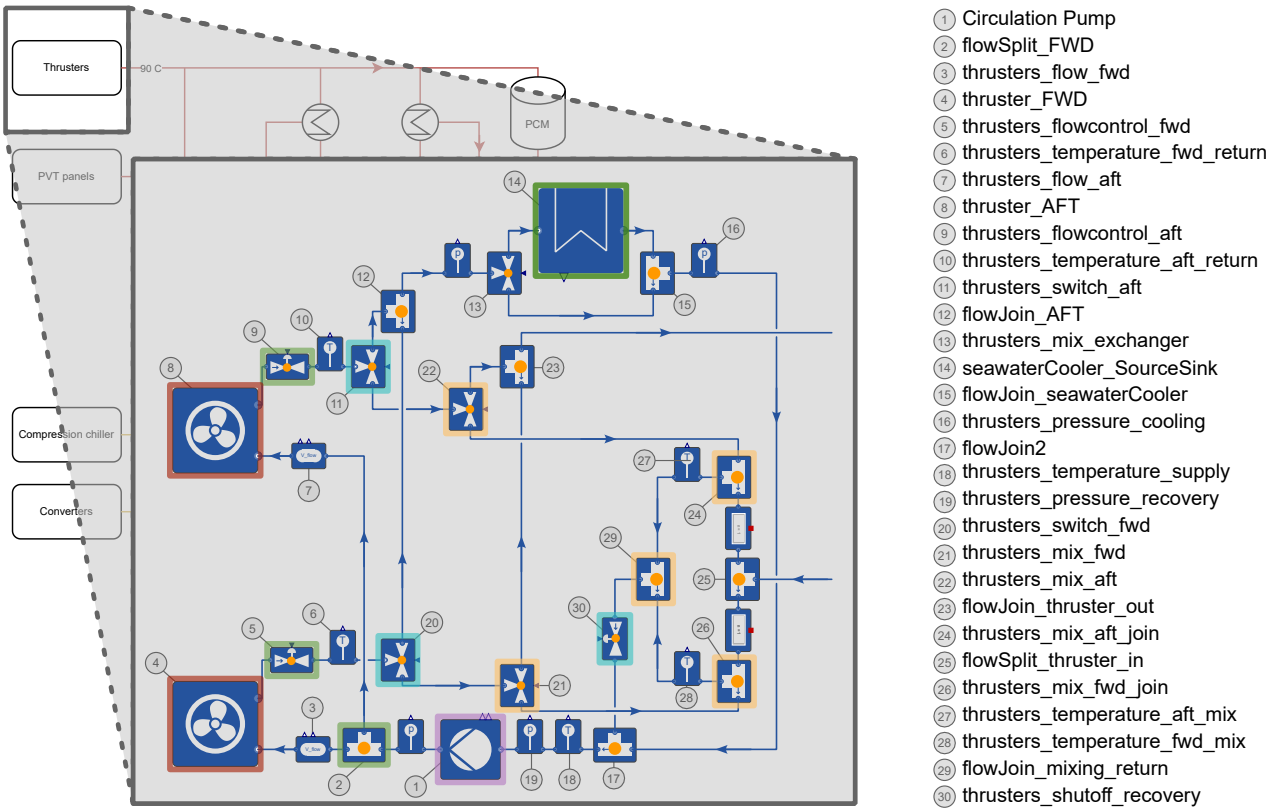
The seawater cooler (14), highlighted in green in Figure 4, is implemented to guarantee the cooling of the two thrusters. The heat transfer is modelled as an eps-NTU approach (Hesselgreaves 2001). Nominal data from datasheets parameterize the model. A seawater medium with constant data at 30 °C is created for seawater side of the heat exchanger. A simple quadratic nominal pressure loss is implemented to model the relation between flow and pressure. The volume flow and temperature of the seawater are variables and can be set as inputs during the simulation.

5 Application Scenario

5.1 Thrusters control

Based on the sensor values coming from the simulation model, the control module determines control values to reach the desired setpoints. The control logic for the thrusters module covers several key functions:

- **Flow control:** The total flow is calculated as the sum of the setpoints for each individual thruster and is regulated by a PID controller that adjusts the pump speed accordingly. The flow is balanced between the thrusters using the flow control valves ((5), (9)). Each valve is controlled by a PID controller, with control values offset to ensure that one valve always remains fully open to avoid unnecessary counterpressure. The system also adapts to thruster activity—closing the flow control valve and reducing pump speed when only one of the two thrusters is active.
- **Mode switching:** As mentioned before, there are three operational modes : idle (no flow), heat recovery, and direct cooling. The control must support all modes. Each mode has distinct flow and temperature setpoints. Mode transitions are triggered by sys-



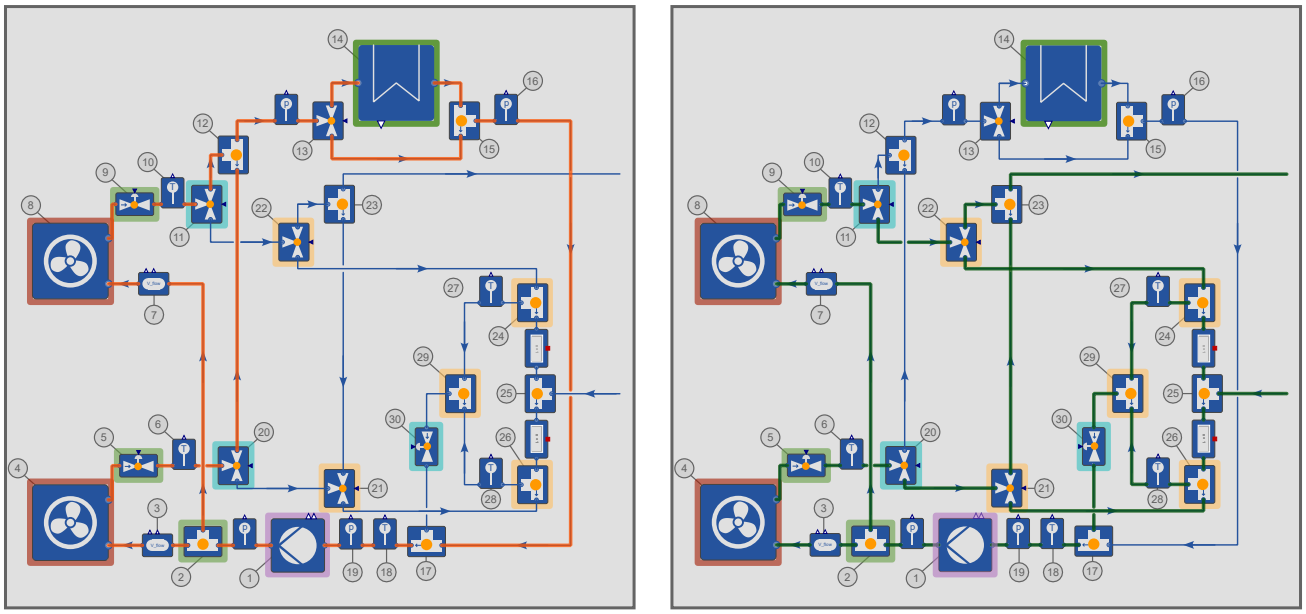


Figure 4. MODELICA model of the thrusters component with legend on the right side.

tem conditions — for example, engaging a thruster switches from idle to recovery, while an overheating alarm may switch from recovery to cooling. Overheating can occur when there is no thermal demand in the rest of the system, causing the inlet temperature to rise too high for safe thruster cooling. In such cases, excess heat must be dumped via the seawater cooler (14).

- **Cooling temperature control:** In direct cooling mode (see Figure 5a), the primary goal is to ensure safe thruster operation by rejecting heat directly, without recovering it for onboard use. It is triggered when the supply temperature of the thrusters passes a set threshold, to prevent overheating. The flow path in this mode is marked in orange. From the circulation pump (1) the flow starts its way through the forward (4) and aft thruster (8). The shutoff recovery control valve (30) is closed and the three-way valves after the forward thruster (22) and the aft thruster (11) are controlled to direct the flow to the flow join (12) where both streams are mixed. After passing the flow join the coolant reaches the three-way valve (13) in front of the seawater cooler (14). This valve is implemented to control the ratio between the flow through the seawater cooler (14) and its bypass flow. This is done by a PID controller to reach the desired setpoint temperature of return flow. From the seawater cooler (14) the coolant flows via a flow join (15) back to the circulation pump (1).

- **Recovery temperature control:** The heat recovery mode (see Figure 5b) is engaged when there is a demand for thermal energy (or available storage) in the rest of the system. The flow path in this mode is shown in green. From circulation pump to the three-port valves ((11), (20)) the flow takes the same pass as in direct cooling mode. Instead of the coolant flowing in the direction of the flow join (12) upstream of the seawater cooler, it heads into the two mixing three-port valves ((22), (21)) which are highlighted with a yellow frame. One part of the medium leaves the thrusters component via the flow join (23) into the high temperature circuit of the yacht. The other part of the medium is directed to two mixing flow joins ((24), (26)). Both are connected via the flow split (25) with supply flow from high temperature circuit into the thrusters component. After mixing both flows with the supply flow the water-glycol mixture is headed back to the circulation pump with the shutoff recovery control valve (30) which is opened in this mode. Regarding the control, the temperature of the return flow is controlled by a PID controller that adjusts the three-port mixing valves ((21), (22)) regulating the amount of coolant that recirculates past the thrusters to reach the desired return

temperature. This way, a minimum return temperature of the module is guaranteed (flow which is leaving the join (23)).

The control logic is demonstrated through a simulated operation of the thrusters module governed by a Python-based controller. Figures 6 and 7 present consecutive segments of a two-hour simulation run. Figure 6 illustrates the first hour, during which the system transitions from idle into heat recovery mode with both thrusters active. The simulation parameters and control setpoints are provided in Tables 1 and 2, respectively.

Each figure includes a top plot showing control signals sent by the module, consisting of valve setpoints and the pump duty point, which regulates flow depending on the current control mode (cooling or recovery). The bottom three plots display system variables—primarily sensor readings—except for the module supply temperature, which is predetermined as a simulation parameter.

While the top plots of both figures appear similar, they represent different data: the uppermost shows valve setpoints (desired positions) given by the control, whereas the second plot reflects actual valve positions that are read as sensor values. These diverge because physical valve actuation takes time (approximately 1 degree per second), resulting in about 90 seconds for valve to open or close.

5.2 Heat recovery

In the first five minutes of the simulation, the thrusters are off, the system is in idle mode, and there is not flow. The seawater return temperature starts at the default 30 °C but stabilizes to 32 °C, as specified in the parameters.

After five minutes, the thrusters are activated and trigger the control to go into recovery mode. The pump starts running and the flow control valves of each thruster are opened. The aft and forward thruster return temperatures rise due to flow past their respective heat sources (9 kW and 4.3 kW). Once the aft return temperature reaches the 60 °C recovery setpoint, the *aft mix* valve opens, allowing heated return flow to exit the module (*module return*) and supply the THRS. Simultaneously, the aft inflow begins drawing from the *module supply*, lowering the *mix aft* temperature and ultimately returning it to the supply temperature of 50 °C as the mix valves fully opens.

The forward thruster, generating roughly half the heat of the aft thruster, warms more slowly. When its return temperature eventually reaches the 60 °C setpoint, the *fwd mix* valve begins opening. Due to insufficient heating power, the PID controller causes the valve position to oscillate before settling near 0.25. This behavior

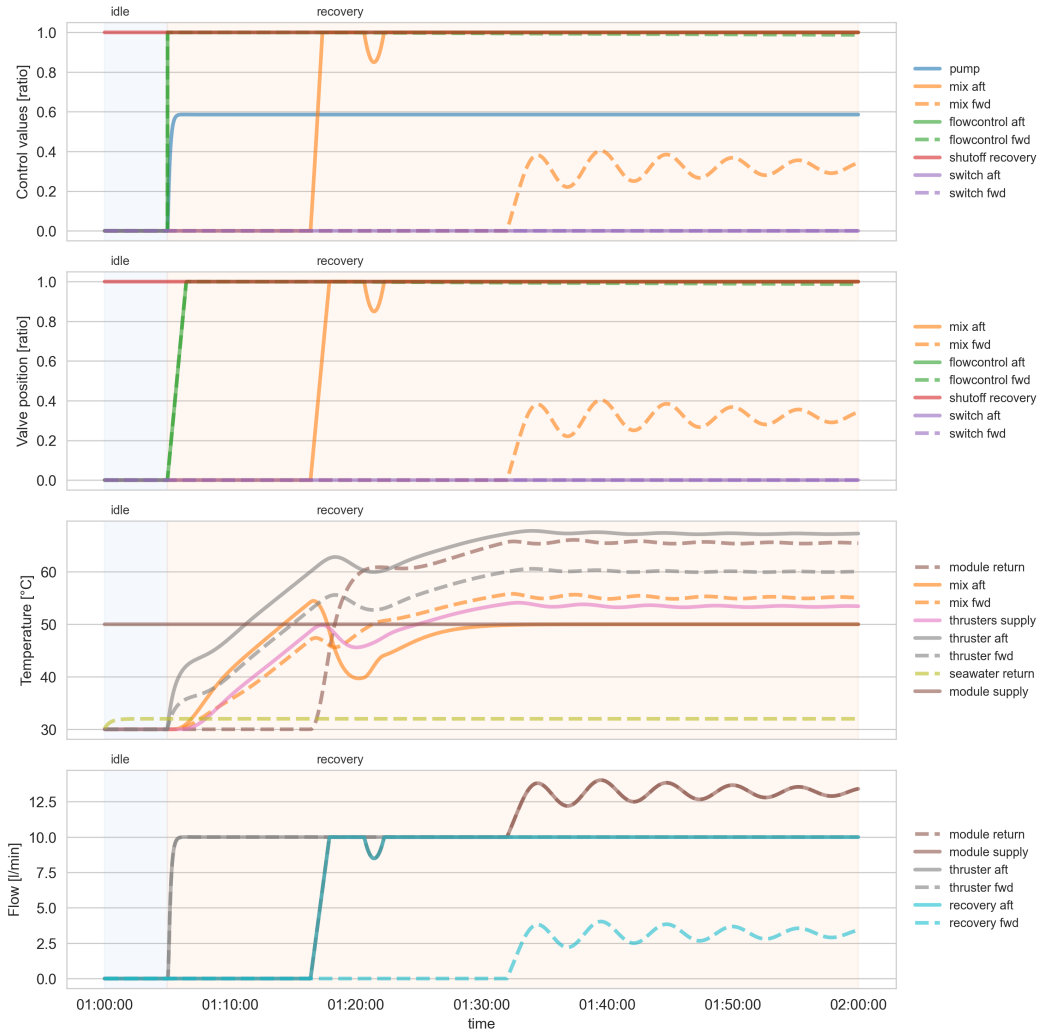

Figure 6. First hour of simulation in recovery mode, showing initialization and mixing control of the aft thruster.

indicates that some recirculation is required to maintain the desired temperature, and results in the *thrusters supply* temperature stabilizing slightly above the *module supply* temperature of 50 °C.

5.3 Mode Switching

Figure 7 depicts the second half of the simulation. At 02:00, the forward thruster is deactivated. In response, the controller shuts off flow to the forward thruster by closing *flow control aft*, and adjusts the *pump* duty to maintain the aft flow setpoint.

At 02:30, the *module supply* temperature is raised from 50 °C to 80 °C. This leads to the *thrusters supply* temperature to pass the 70 °C limit, triggering the cooling mode. This switches the valves *switch aft*, *switch fwd* and *shutoff recovery*. Note the difference between the control signal and the actual movement of the valves. In cooling mode, the *seawater return* temperature increases as heat is expelled through the heat exchanger, while the *thruster aft* temperature decreases as the control will maintain the cooling setpoint.

6 Summary and Outlook

This paper introduces a workflow to use MODELICA in the control system design and development process of a zero emission yacht's thermal system. It is shown that a MODELICA model of the thermal system can be compiled into a FMU, which is then embedded to a python wrapper to enable communication via MQTT to the control layer.

This enables the design of a control system even though the real system has not yet been finalized. It is also possible to assess scenarios that are quite difficult to evaluate in the real world. When the project has a tight schedule, the time taken to implement the control parameters of the real system can be reduced. An assessment of the time and cost savings by using this method may also be of interest.

For this project, the creation of the remaining submodules and their assembly into the whole system is still pending. Once the yacht has been constructed, it will be possible to evaluate the quality of the parameters

[4]Claytex, United Kingdom, alessandro.picarelli@claytex.com

Abstract

Vehicle performance optimisation is the primary target in the development of race cars and road hypercars. Considering the complexity of modern vehicles, a holistic approach to analyse the interaction of vehicle dynamics, powertrain cooling systems, brake cooling, and human drivers in the same simulation can be crucial to maximise the overall performance (*Bouvy et al., 2012*). This paper is a follow up of a previous article written by Dallara and Claytex *("Race Car Cooling System Model for Real Time use in a Driving Simulator", Stellato et al., 2023*), which describes a one-dimensional (1D) cooling system model integrated with a vehicle multibody model, used in the Dallara dynamic driving simulator (Figure 1). This collaboration has led to a further step, where Dallara has developed a model to optimise the brake cooling of its vehicles, with Claytex's VeSyMA suite used for the auxiliary vehicle systems and code compilation. The model was validated through the comparison with real-vehicle data, demonstrating good accuracy in i.) sizing a race car braking system; and ii.) providing a refined assessment of the global vehicle performance on the driving simulator.

Keywords: brakes cooling, cooling systems, real-time, driving simulator

1 Introduction

Optimising vehicle performance is a primary objective in the development of high-performance vehicles. A holistic simulation approach that integrates key component models, such as powertrain and brake cooling systems, with vehicle dynamics and driver behaviour, is essential for maximising overall performance. With this regard, in a previous paper *(Stellato et al., 2023),* a car cooling system model was integrated inside the vehicle multi-body model. This integration allowed the definition of the best cooling system architecture for every project, targeting the trade-off to maximise the vehicle performance, especially in a professional driving simulator with a human driver. As a further step, the previous model was extended with the braking system thermal model, to predict the braking system's main components' temperatures (disc and caliper) and neighbouring components (disc bells and rims). As for the cooling system, this integration allows the evaluation of several layouts for air intakes, brake ducts, disc, and caliper size in different boundary conditions, finding the best configuration for aerodynamic, handling, and cooling targets, based on the vehicle mission and the driving style.

In the first design phase, the simulation model may run offline, using vehicle speed and brake pressure profiles coming from:

- Track data acquisition, if the activity involves an existing vehicle update, and thus, there is already data available.
- Quasi-static lap time simulations, in the case of designing a new vehicle.

Then, in a more advanced phase, it can be integrated directly into the Dallara dynamic driving simulator to obtain more accurate and precise feedback from the driver.

In the remainder, this article is organised as follows: Section II presents the Claytex VeSyMA suite utilised in the project; Section III delves into the proposed models; Section IV discusses the main results; and Section V summarises the main conclusions.

Figure 1: Dallara dynamic driving simulator

2 Claytex VeSyMA suite

The VeSyMA (**Ve**hicle **Sy**stems **M**odelling and **A**nalysis) simulation suite was used to form the backbone of the Dallara vehicle model. Comprising various subject-specific Modelica libraries built on top of a common base, the VeSyMA suite was originally developed by Claytex using Dymola and Modelica. More than 25 years of experience in the motorsport world supporting customers from Formula 1, IndyCar and NASCAR with Dymola and Modelica simulations was drawn upon in the creation of VeSyMA (*Hammond-Scott and Dempsey, 2018*).

Conceived and built in a hierarchical structure, all subject-specific libraries (such as Suspensions for Vehicle Dynamics analysis, Motorsport for motorsport-specific requirements, PTDynamics for the simulation of drive trains and gearboxes, etc.) inherit from the base VeSyMA library. This fully leverages the concepts of model reuse and inheritance present in the object-oriented Modelica language, helping users to efficiently manage their own simulation libraries.

The cornerstone of model reuse in the VeSyMA suite is the utilisation of the open-source Vehicle Interfaces library. All vehicle models found within VeSyMA are built from templates located in the VeSyMA library, which are built up of component templates from Vehicle Interfaces. Integrating third-party libraries built on the same open-source Vehicle Interfaces library into VeSyMA base vehicle models is thus a simplified task. Such a feature is of use in a study such as this, as the implementation of customer-developed libraries into VeSyMA vehicle models is straightforward.

Beyond templates, the VeSyMA suite contains packages of commonly found vehicle components, with simplified versions found in the VeSyMA library, and detailed versions found within the subject-specific libraries. Scalability of the detail in a model is therefore possible by selecting which component is used, which is of benefit as it enables vehicle models to be configured to focus on the detail where required. This can be done both for intellectual clarity and efficient use of computational resources. All component and vehicle models found in the VeSyMA suite have been built from the outset with performance in mind, with optimisations made in key areas such as state selection.

3 The Model

Figure 2 shows the cooling and braking system models connected to the vehicle model and the human driver. The interface with the multi-body vehicle model allows further dynamic analysis to improve vehicle performance.

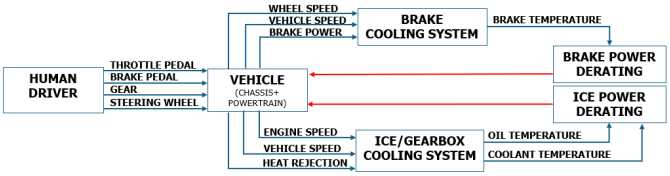

Figure 2: Cooling and braking system interactions with vehicle model and human driver

Regarding the cooling system model, the coolant and oil temperatures are defined as model outputs. Therefore, they affect the internal combustion engine (ICE) power curve according to the derating strategies agreed with the engine supplier. Instead, for the braking system model, the outputs are the disc and caliper temperatures, which will affect the friction coefficient inside the vehicle model. A temperature increase will decrease the coefficient, forcing the driver to increase the braking distance.

3.1 Architecture and Physics

Figure 3 shows the components of the braking system model and describes how the heat is propagated among them.

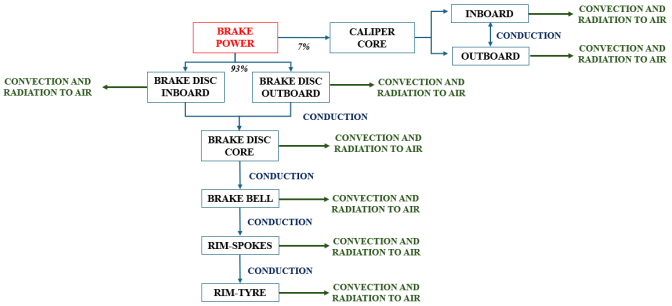

Figure 3: Heat fluxes in the simulation model

The first block is the "Brake Power", where the brake power, and thus the overall system heat rejection, is calculated by the following equations at each time step:

$$P_B = \mu F_n R \omega \quad (1)$$

$$R = \frac{R_e + R_i}{2} \quad (2)$$

$$F_n = p A \quad (3)$$

P_B = brake power [W]
μ = friction coefficient [-]
F_n = disc normal force [N]
R = disc mean radius [m]
ω = wheel angular speed [rad/s]
R_e =disc external radius [m]
R_i =disc internal radius [m]
p = brake pressure [Pa]
A = brake pistons area [m^2]

DOI 10.3384/ecp218811

A 7% fraction of the heat rejection produced is assigned to the caliper core. This fraction is exchanged to the inboard and outboard areas through conduction and finally dissipated by convection into the environment. This percentage was estimated after several validation processes on different types of Dallara vehicles (race cars, hypercars, road cars). To align the track data with the simulation model, the values fell in the range of 6.5% to 7.5%. This matches well with both the standard estimation of 5-10% and the values reported in recent studies (*Vdovin and Sebben, 2018*). As a further step in the model, the implementation of a disc rotational model in contact with the pads could be considered, where this percentage will be given as output of the boundary conditions.

The remaining 93% of heat rejection is assigned to the inboard and outboard brake disc area, equally distributed. The heat is then conducted to the disc core, and thereafter, it passes through the brake bell, rim-spokes and rim-tyre. All these components dissipate the heat by convection and radiation into the environment.

To evaluate the temperature of each component, the first principle of thermodynamics is applied. First, the heat transferred to the component is calculated. This is the instantaneous difference between the heat rejection (HR), produced by the braking system or exchanged from the neighbouring component by conduction, and the heat dissipated by convection to air (HD):

$$HF = HR - HD \tag{4}$$

HF = overall heat flux [W]
HR = heat rejection [W]
HD = heat dissipation [W]

At this point, the component temperature can be calculated at each time step by:

$$T_{t1} = T_{t0} + \frac{HF\ (t_1 - t_0)}{C} \tag{5}$$

T_{t1} = temperature at time t_1 [K]
T_{t0} = temperature at time t_0 [K]
C = thermal capacity [J/K]
t = time [s]

The thermal conduction is evaluated by the following equation:

$$\dot{Q}_{cond} = K\ \frac{A}{d}\ \Delta T \tag{6}$$

$\dot{Q}_{cond}$ = thermal conduction [W]
K = conductivity coefficient [W/mK]
A = component reference area [m^2]
d = component reference length [m]
ΔT = delta temperature [K]

While the thermal convection is given by:

$$\dot{Q}_{conv} = HTC\ (T - T_{air}) \tag{7}$$

$\dot{Q}_{conv}$ = thermal convection [W]
HTC = heat transfer coefficient [W/K]
T = component temperature [K]
T_{air} = air temperature [K]

3.2 Parameters

The model input parameters are obtained from computational fluid dynamics simulations (CFD), experimental tests, and CAD data (computer-aided design). In detail:

- The heat transfer coefficient (HTC) for each component (disc, caliper, brake bell, rim-spokes and rim-tyre) is the output of CFD simulations that consider both convection and radiation. The HTC is a function of vehicle speed and component heat rejection: for each component, 9 different HTCs are evaluated at 3 different speeds (100, 180, and 300 km/h) and 3 heat rejection rates (minimum, average, and maximum). As an example, Table 1 illustrates an HTC map for one component. The instantaneous value in the 1D simulation is then extrapolated or interpolated from these tables. Figure 4 shows the outputs of the CFD simulations, where the variability of HTCs can be appreciated: for the inboard disc surface, close to the air duct, the values are practically doubled with respect to those of the outboard.

HTC [W/K]		Heat Rejection [kW]		
		2.4	7.2	12
Vehicle speed [km/h]	100	7.52	6.96	7.2
	180	11.6	10.56	10.16
	300	16.72	15.52	14.56

Table 1: HTC map for 3 different heat rejections and vehicle speeds

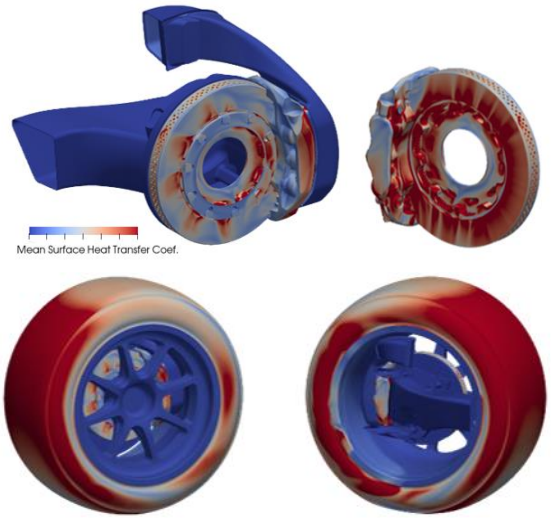

Figure 4: HTCs values from a CFD simulation

- The brake friction coefficient is provided by the manufacturer and is described in a table as a function of surface temperature and brake pressure. Figure 5 reports an example: it has to be reported that the unit of measurement of the x-axis is [bar·rad/s], as the map takes into account also the disc angular speed.

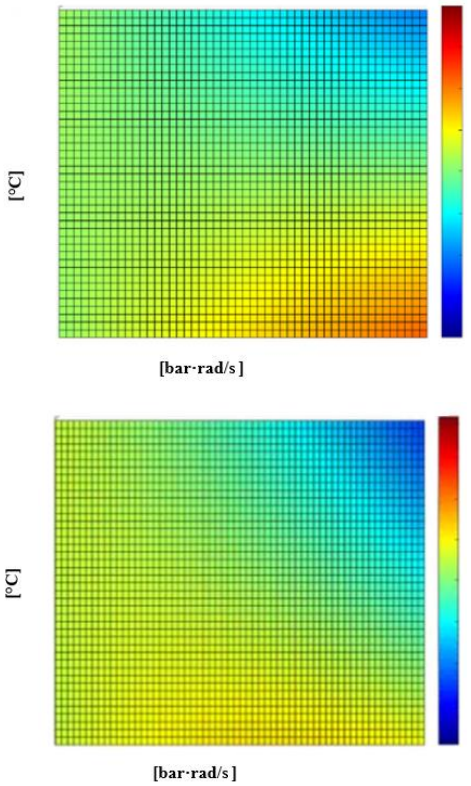

Figure 5: Brake friction coefficient maps for front brakes (top) and rear ones (bottom)

- The component's physical properties, such as density, emissivity, conductivity, and specific heat, are obtained from the supplier's datasheets. The evaluation of the reference area and length for the calculation of the heat exchanged by thermal conduction is done by direct analysis of CAD data. The main parameters for each component are summarised in Table 2. An interesting note concerns the rim. To have a better discretisation, it has been divided into two parts: rim-spokes and rim-tyre. The first part considers the spokes and the area close to the brake bell. The other one is the part close to the tyre (Figure 6). Each part has its own HTCs.

Table 2: Components geometrical and physical properties

Overall, if the model is executed offline, e.g., outside the Dallara simulator, it requires input data for the brake pressure at each caliper, the vehicle speed, and the angular velocity profiles of each wheel during a representative track lap. Otherwise, if deployed online in the Dallara dynamic driving simulator, the human driver and the vehicle model will directly provide these inputs.

3.3 Real-time Features

In terms of real-time setup, the proposed model follows the same methodology as the previous paper on this subject (*Stellato et al., 2023*). Dymola's fixed-step Euler solver was employed, running at a sampling time of 1 ms. Preliminary testing of the model was undertaken on a 2.8 GHz I7 processor SSD-equipped desktop workstation; successful real-time simulation on this machine ensured the model would be suitable when deployed on the more powerful hardware associated with Dallara's DiL simulator.

The VeSyMA – Driver-in-the-Loop library was utilised for the compilation of the vehicle and cooling models into a real-time app capable of running on the Dallara simulator. A 2nd order Runge-Kutta explicit solver method was used for the real-time application, with advanced inline settings (*Dymola manual*) contributing to a robust and high-performance real-time model (*Hammond-Scott and Dempsey, 2018*).

DOI 10.3384/ecp218811

Regarding the brake thermal model in real-time use, some first-order filters (with a 5 ms time constant) were added when solving non-linear equations.

4 Virtual Validation

4.1 Offline Simulation

For any simulation activity, the validation phase represents the crucial moment to assess the correctness of the model. For this work, it consisted of the following steps:

- Implementation of the braking system architecture of an existing vehicle.
- Offline simulation using measured vehicle speed, brake pressure and ambient temperature as input data.
- Comparison between the simulated temperature profiles and the measured ones on the track.

Figure 7 shows the comparison between the simulated disc temperature profile and the real logged data of a hypercar with more than 1000 horsepower at Vallelunga track. The average difference between the measured temperature and the simulated one is ~12°C, with a root mean square error (RMSE) of ~15 °C, and a mean relative error of ~2%. This level of accuracy, given the high temperature range profile (from 400 to 780 °C), is considered acceptable for sizing the braking system and analysing its performance. Similarly, Figure 8 shows the comparison for the caliper temperature profile. In this case, the average temperature difference between the measured and the simulated one is ~3.3°C, the RMSE is ~3.9 °C and the mean relative error is ~2.7%.

Overall, the accuracy of the model is considered acceptable for sizing a race car braking system and doing a refined assessment of the global vehicle performance on the driving simulator.

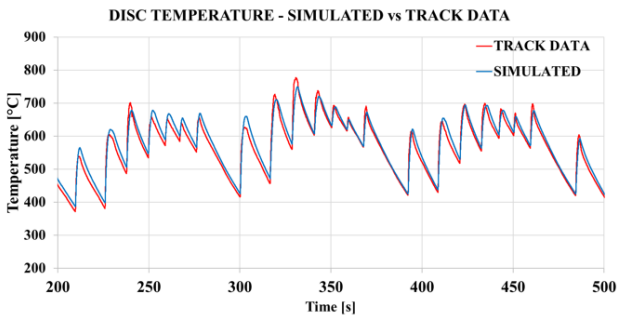

Figure 7: Simulated disc temperature vs real logged data

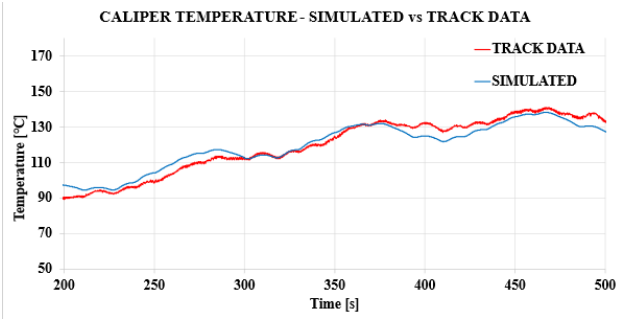

Figure 8: Simulated caliper temperature vs real logged data

4.2 Real-time Simulation in the Dallara Dynamic Driving Simulator

The same model was also deployed directly on the Dallara Driving Simulator, where the human driver performed a series of laps at maximum vehicle performance on the Zandvoort track. From this experimental campaign, the main target is the evaluation of:

- Disc temperature before the braking point. This is a value assessed by the supplier to preserve the disc and avoid excessive wear of the component.
- Friction coefficient reduction (due to the increased disc temperature), and thus the brake power.

The following figures show the results of a simulator session, where the driver performed a run (a total of 8 laps) at maximum performance to test the braking consistency and effectiveness. In Figure 9, the front left (FL) and front right (FR) brake disc outboard temperatures are plotted: after 400 seconds, the peak temperature stabilises between 900 and 1000 °C.

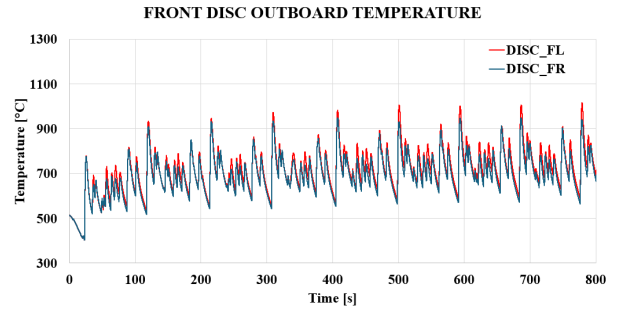

Figure 9: Front discs outboard temperature in a driving simulator session

It can be noted that the left disc is warmer than the right one in the heaviest braking zone. This is attributable to the different brake pressure values for these turns (Figure 10), caused by the ABS (anti-lock braking system). However,

from the driver's point of view, this temperature imbalance did not affect the performance.

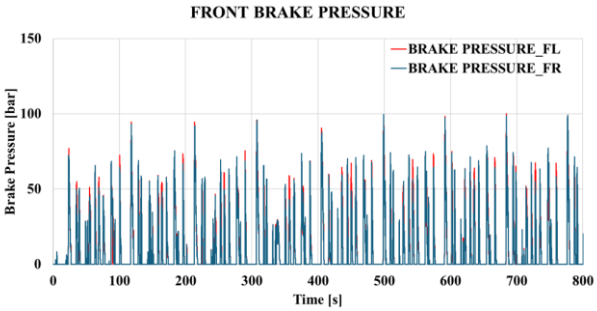

Figure 10: Front brakes pressure in a driving simulator session

The most interesting part turns out to be the friction coefficient trend. As mentioned in the previous paragraph, inside the model, it is discretised as a look-up table, function of brake pressure and disc temperature. Figure 11 shows the actual friction coefficient during the whole run. As expected, increased temperature leads to overall friction degradation, therefore, a reduced braking performance. In the track's hardest braking zone, the disc temperature reaches 1000°C, and the coefficient is reduced by more than 20% from its optimum value.

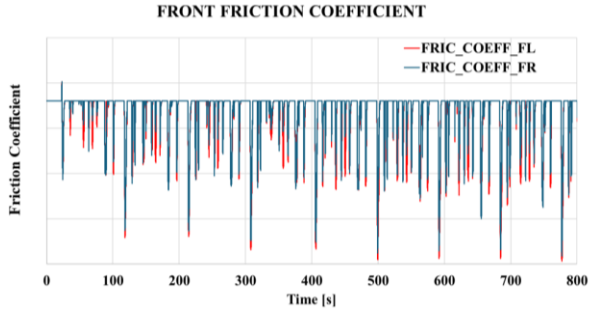

Figure 11: Front brakes friction coefficient in a driving simulator session

The same analysis can also be done for the rear brakes, where the disc outboard peak temperature is approximately 350 °C lower than the front ones (Figure 12). Also, in this case, the left side is slightly warmer than the right one, but with a smaller gap than before.

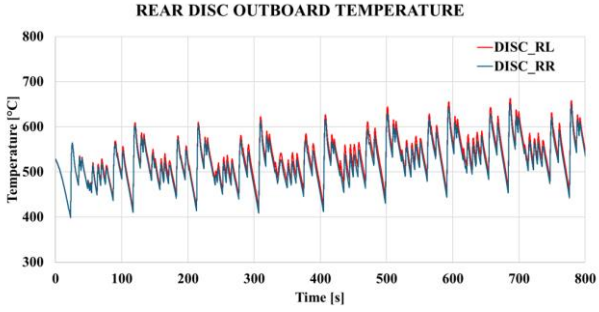

Figure 12: Rear discs outboard temperature in a driving simulator session

However, the mean lower temperature results in a different friction coefficient trend. If for the front brakes, its value varies over the lap course, then for the rear ones it is practically constant, with only two turns leading to a reduction of about 10 % (Figure 13).

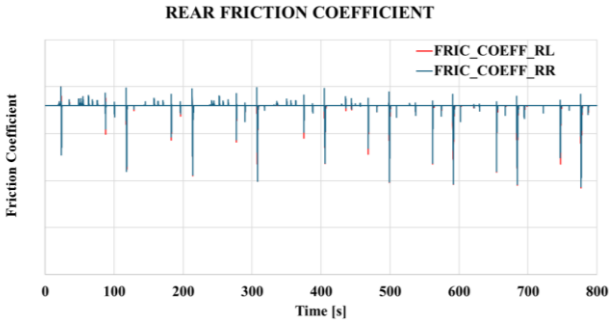

Figure 13: Rear brakes friction coefficient in a driving simulator session

The driving simulator and this simulation model can also be useful in preparing for race weekend by evaluating the ideal air duct size, if necessary. Several blanking percentages for both front and rear brakes can be tested, accounting for different ambient temperatures and race conditions (qualifying, traffic, free air, etc.). So, based on the situations they face, track engineers have a precise assessment of the necessary blanking, which ensures the best trade-off between performance and reliability.

5 Conclusions and Further Developments

The proposed simulation model, as developed and validated, is currently used at Dallara to size the braking system and analyse the vehicle performance on the driving simulator for different tracks, driving styles and boundary conditions (brake size, materials, aero configurations, ambient temperature). As all these parameters affect the overall results, the simulation model is useful to evaluate each effect to develop the best braking system architecture for every project, targeting the maximisation of vehicle performance (*Stellato et al., 2023).* The duty cycle analysed for the case study is a track lap at maximum performance, but additional critical driving cycles can be studied on the simulator, such as the brake warm-up during the out lap. Certainly, a key aspect turns out to be the friction coefficient sensitivity. The temperature calculation allows the thermal effect to be considered, defining the ideal design for the cooling ducts in each track. However, the variable friction coefficient makes it possible to evaluate the impact on lap time and vehicle performance. For example, in some tracks, the air duct size could be decreased to reduce the aerodynamic drag. Consequently, the temperature will increase, and the friction coefficient will decrease, resulting in worse

DOI 10.3384/ecp218811

braking performance. However, thanks to the improved aerodynamics, the lap time will improve. This scenario represents the typical trade-off that is analysed by the simulation model.

Further refinement and improvements are planned for the simulation model. Currently, the thermal discretisation stops at the rim. The next step will be to predict the thermal conduction from the rim to the tyre and integrate the tyre thermal model. This latter feature will further expand the holistic approach and enable a greater optimisation of vehicle performance by considering the temperature effect on the tyre's lateral and longitudinal grip and its correlation to the brake thermal performance.

Abstract

One of the most popular ways of measuring signals for various components in vehicle on durability tracks will be Road Load Data Acquisition (RLDA) which gains load data through accelerated customer usages tests on either proving ground or field, using an instrumented vehicle. However, under the current circumstances, not only does a vehicle development cycle get shorter but also new mobility concepts keep being developed, a methodology is needed to cope with overall durability assessment in advance of a physical prototype being made for testing. In this study, this virtual testing methodology will be called Virtual RLDA.

Keywords: Durability, Multi-Physics, Vehicle Simulation

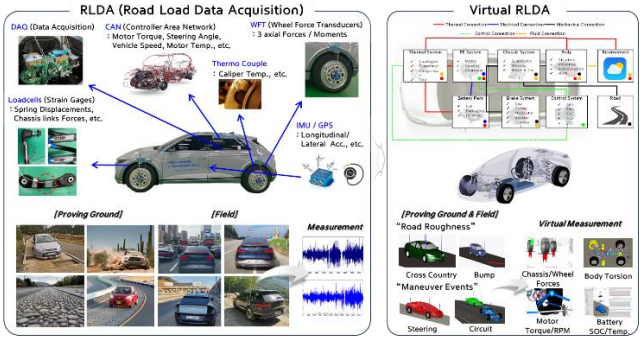

Figure 1. Idea of Virtual RLDA from Conventional Measurement Campaign

In this study, one of the most well-known electric vehicles in market is from Hyundai, with 2 in-wheel motors in rear which was chosen as the target vehicle. First, 6 major sub-systems such as vehicle controller, suspension, hydraulic brake, motor, battery and thermal management are modelled and validated separately, then they are integrated into one large vehicle model as a part of establishing the Virtual RLDA Platform which will be used for overall vehicle level durability development in early stage in Hyundai Kia Motor Company (HKMC).

1 Introduction

1.1 Background of the project

From the overall durability point of view, an electric vehicle still requires a number of studies to figure out unknown failures and degradation mechanisms especially on the motor, inverter and battery which has different failure mechanisms from conventional ICE vehicle. If the durability failures are divided into two large aspects, one aspect will be structural failure and the other will be powertrain related failure. The objective of this study is to develop the vehicle model that can cover both structural and powertrain related failures depending on the choice of the level of fidelity.

First, when it comes to structural durability of an EV, a high voltage battery system weighs about 300kg more than a fuel tank in ICE vehicle. Also, with regards to in-wheel motor systems, the motor system is integrated in each wheel assembly which have much heavier unsprung mass than conventional wheel. This weight increase has a significant influence on the amount of damage to the suspension system and each body mountings due to the increased reaction forces.

Moreover, powertrain coupled components such as subframes, motor mountings and driveshafts are also expected to have more damage due to the reaction torque from a motor as an electric motor can theoretically generate maximum torque at low speed. For this reason, a multi-physics model which can efficiently simulate a motor's movement aligned with powertrain coupled

suspension is essential to replicate the coupled reaction using both table-based electrical motor model and powertrain dynamics-based suspension in a single simulation environment.

As for powertrain durability, the heat generated from motor during driving is the key factor for the degradation of powertrain systems. Also, since the hydraulic brake assembly is integrated within the in-wheel motor system, most of the brake heat during braking is directly radiated to the motor system. For this reason, there should be a realistic method to simulate the thermal interface between hydraulic brake and motor system. In order to simulate the above phenomenon in the model, the first thing we need is thermal management system, modelled with TiL Library, which controls temperatures for both coolant and refrigerant to be maintained in a proper level for most driving scenarios. The second thing we need is the vehicle controller model which simulates pure hydraulic brake pressure that is used as an input signal from thermal brake model by subtracting regenerative motor torque from the total required brake torque in a vehicle. This is one of the reasons why the vehicle controller is required in the vehicle model.

The virtual RLDA platform which is developed in this study to simulate various perspectives of durability influences in vehicle level consists of the following systems below:

- Vehicle Controller.
- Hydraulic Brake (Mechanical / Thermal)
- Vehicle Dynamics (Ideal & Bushed Suspension)
- Motor (Electrical / Thermal for Standard & IWM)
- Battery (ECM / Thermal Cell & Pack)
- Thermal Management (Entire Vehicle Circuit)
- Integrated Vehicle Model (Assembly)
- Durability Scenarios (Tire / Driver / Road Models)

1.2 Motivation of Using Modelica

The vehicle level durability simulation environment based on Modelica libraries has distinctive advantages as follows.

First, each system in a vehicle behaves based on their own physics. It would take numerous efforts to model each different domain systems from scratch as it requires each domain-specific expertise for the modelling. However, the eco-system of, Modelica provides each system domain-specific libraries which gives a lot of potential and flexibility to modelling engineers.

Also, the whole vehicle level simulation which exchanges multi-physical signals between different systems in one single simulation environment is possible in Modelica. In this study, 3 different libraries from Dassault Systèmes (battery, motor), VeSyMA (vehicle template, suspension, brake, driver, road, etc.), TiL (thermal management) are integrated to simulate one large vehicle which is the most efficient way for multi-physical simulation.

Lastly, it provides very efficient way of replacing one model to another from component to large-scale level. From the perspective of managing models in different fidelity and types, this makes the modelling process even more scalable and efficient.

The figure below is the model management strategy of the developed models in this study depending on purpose of durability scenarios.

Fidelity Level: Basic Fidelity / High Fidelity — Simulation Output: Category 1 + 2 / Category 2 Only

No.	System Models		Category 1 Proving Ground (Suspension) Road Roughness	Category 1 Proving Ground (Suspension) Maneuvering	Category 2 Proving Ground (Powertrain)	Category 2 Field	Category 2 Circuit	Simulation Outputs
1	Suspension		Bushed or Bushed Subframe		Table-based or Ideal			[Spring/Links/Bush] Force / Displacement

Figure 2. Overall Vehicle Model Fidelities for Different Durability Scenarios

2 System Modelling

2.1 Vehicle Controller

The main function of the vehicle controller in the model is to decide driving torque, regenerative torque, and Hydraulic brake torque relative to the driving conditions. It also decides the clutch engagement and disengagement timing between front and rear motor of all-wheel drive (AWD) vehicle models. Figure 3 shows the vehicle controller model built with Dymola for HMC's AWD electric vehicle.

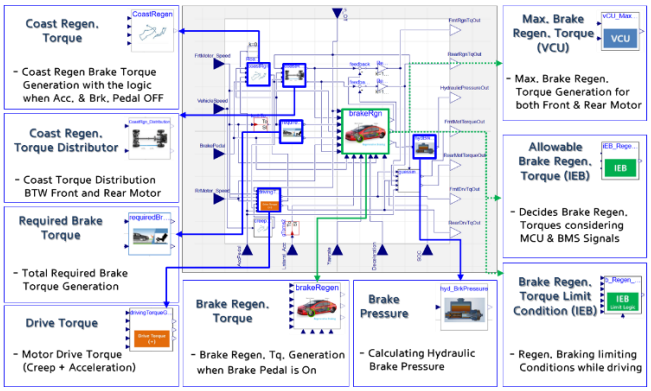

Figure 3. Vehicle Controller Model built for Electric AWD Durability Scenarios

DOI 10.3384/ecp218819

One of the main roles of the vehicle controller is to generate drive torque using both maximum torque map relative to motor speed and tuned torque map in the development stage which has different torque levels in different driving modes and regenerative brake levels dependant on accelerator pedal stroke. For this reason, vehicles can generate different levels of driving torque even with the same vehicle speed and accelerator pedal stroke dependent on different driving modes. The model also generates creep torque while driving using a tuned map when the accelerator pedal is not pressed.

The total brake torque can be divided into regenerative brake torque and hydraulic brake torque. The total brake torque is decided by the table-based tuned map relative to vehicle speed and brake pedal stroke. When regenerative brake torque is calculated considering the status of clutch engagement between front and rear motor based on the logic, the pure hydraulic brake torque can be lastly calculated.

Regenerative brake torque of a motor can be also divided into brake regenerative torque, which occurs when brake pedal is pressed, and coast regenerative torque, which is generated when normally brake pedal is off. Especially for brake regenerative torque, it is mainly decided by the coordinated control between vehicle controller unit (VCU) and integrated electronic brake (IEB). Therefore, the model includes the logics of interaction between different Electronic Control Units (ECUs) to decide the brake regenerative torque in sequence as it happens in real vehicle.

Hydraulic brake torque is obtained from the remaining torque between total brake torque and regenerative brake torque. The hydraulic brake model that will be discussed in the section 2.2 takes hydraulic master cylinder pressure as an input to calculate brake torque which generates disc temperatures. For this reason, additional converter which converts brake torque to pressure is also added to the model.

To validate the developed vehicle controller model, the data measured in one of the highest mountains in Korea, considered as the most severe driving conditions with frequent braking and steep steering, is used for the controller validation in Figure 4.

As it can be seen in the data, the vehicle controller generates driving torques, regenerative torques and hydraulic pressure quite accurately compared to the measurement even with the severe driving condition. There is a bit of inaccuracy in brake pressure around 850s, it is due to in accurate total brake torque from the tuned map as the measurement kept changing its driving and regenerative mode.

Comparing several values with measurement, this vehicle controller model still needs some improvements, primarily the clutch logic between front and rear motor and also for the regenerative brake logic. For this reason, the vehicle controller model will be updated. However, it still shows good prediction if it is not a very special driving case.

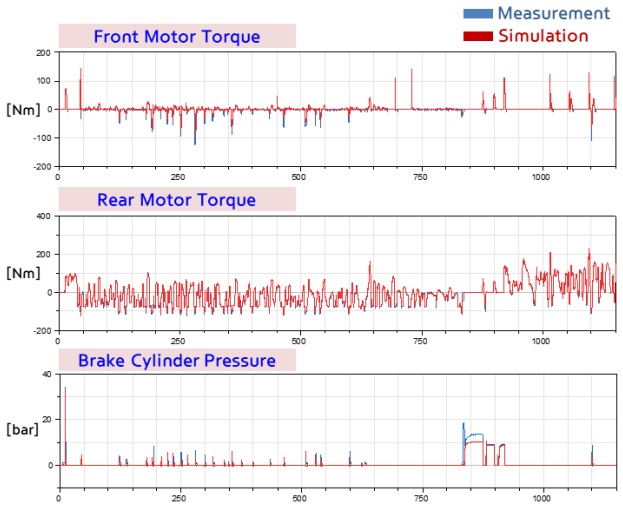

Figure 4. Validation of Motor Torque and Brake Pressure with measurement

2.2 Hydraulic Brake

The Hydraulic brake system has been modelled using Dymola and the VeSyMA library.

During the braking, the vehicle's kinetic energy, which comes from its motion, is converted into brake power through the braking system. This brake power is then transformed into thermal energy (heat) due to friction between the brake pads and the disc. As a result, the brake disc heats up, and the temperature of the disc rises, which is a key factor in brake performance and safety. The brake system modelling is divided into two key sections: hydraulic and mechanical system and the thermal system.

The mechanical brake model generates braking force relative to the driver's pedal stroke to meet the required vehicle deceleration. In high ambient temperatures or during frequent braking, heated brake discs can lead to reduced brake torque, which poses a significant safety issue. Accurate prediction of brake disc temperature is essential for both durability and vehicle safety.

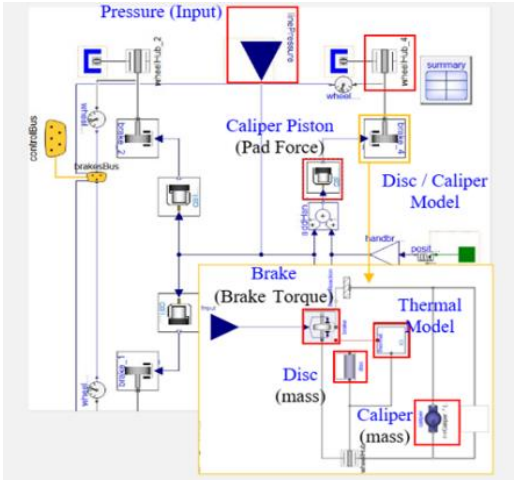

Figure 5. Mechanical brake model

Figure 5 shows the mechanical brake model, with hydraulic pressure coming from controller model, which is equally distributed to the front and rear calliper pistons. Brake Torque in the model is calculated based on pressure, piston area, disc radius, and pad mu.

$$Brake\ Torque = 2 \times \mu_pad \times A_{Piston} + R_{Eff.} \qquad (1)$$

The thermal model, shown in Figure 6, captures key heat transfer mechanisms conduction, convection, and radiation across components like the brake pad, inner/outer disc plates, vane, and disc hub thermal mass, allowing accurate prediction of brake disc temperature during operation.

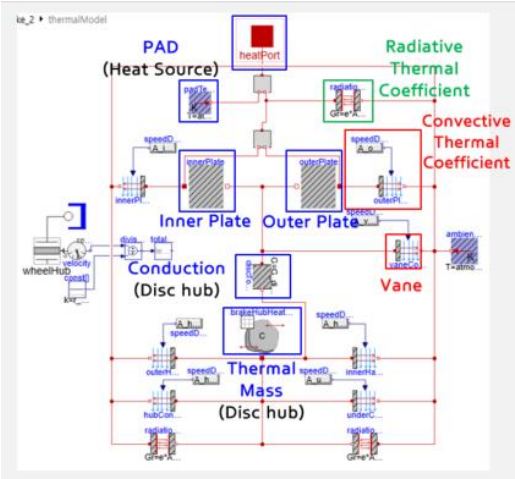

Figure 6. Thermal Brake Model

Figure 7 shows a comparison between the measured and simulated brake disc temperatures for the front left and front right wheels. The close match between the two lines means that the simulation is working well and can predict how the brake disc temperature changes during braking. This confirms that the thermal model is reliable and can be used to study how heat builds up and spreads in the brake system.

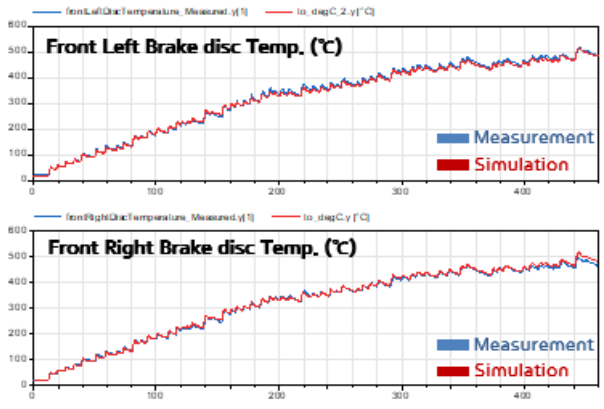

Figure 7. Comparison of the brake thermal model with experimental results

2.3 Suspension and Vehicle Dynamics

The multibody suspension systems are extended and modified from VeSyMA – Suspensions templates and models. The front and rear suspensions are variants of the MacPherson strut and Multilink linkages respectively. With examples of these existing in the VeSyMA - Suspensions library, the principal work was to parameterise them to create variants specific to the Ioniq 5 and validate them against test data.

While the initial aim was to create and validate the Ioniq 5 suspension, the long-term goal was to ensure easy future development, and ability to introduce future linkages and variants for other HKMC models.

There were three levels of fidelity used within the suspension models:

- No Bushed: Joints have no flexibility.
- Bushed: Bushes applied to appropriate linkage joints to match reality.
- Bushed Subframe: Adding bushes to the subframe, in addition to bushed linkage joints.

In all the fidelities, there was no flexibility of any of the components, just the joints, this was to both simplify, optimise but principally because adding component flexibility would add little benefit in terms of accuracy for the additional data and time requirement.

The data required to create each linkage matches the fidelity of the system, but in all cases the following data was required:

- Hardpoint locations (stated in and relative to HMC chosen orientation and origin).
- Component mass and inertia properties.
- Spring stiffness.
- Damper force curve.
- Bump stop force curve and clearance.
- Anti-Roll bar (ARB) stiffness.

In addition to all the above data, when adding bushes to either the linkage or the subframe, each bush needs the following data:

- Force, torque curve and damping constant in each axis.
- Bush orientation relative to the suspension.

When adding bushes to the subframe mass and inertia data is required for the subframe and all attached components as a lumped mass model. One key method to ensure that any future linkage can be easily created, developed and tested, mechanisms were implemented that

DOI
10.3384/ecp218819

reads all required data is read from external files using the open source ExternData Modelica Library[1].

Within ExternData there is a model that reads .xlxs files. Force suspension linkages there is a fixed format file for each linkage, created and used primarily by the HKMC CAE team.

Using this file as a source of all data means that both there was little chance of human error when copying data, but also that any further MacPherson or Multilink suspension from any future model can be created instantly by just changing the file that is being read.

To set this up, there was a parameter that stated the location of each item of data, both in terms of sheet (one parameter used for each group of data) and cell location (specific to each parameter). For the tables of data, such as damper and force curves, sizes of tables also needed stating. Doing this rather than hard coding locations allow any future changes to the .xlsx file format can be easily implemented without requiring version specific variants to be maintained.

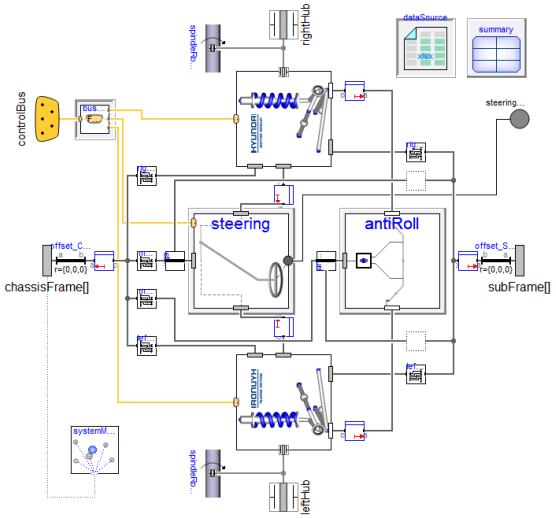

Figure 8. Front Suspension Model built based on HKMC's Standard excel template

One tedious, and repeating task of using any linkage in a vehicle is to ensure that the vehicle and suspension initialises correctly. This is important for 2 key benefits, because the hardpoints stated are for when the vehicle is resting on flat ground at curb weight; therefore, to ensure that when the vehicle settles the bushes and springs have the appropriate preload to ensure that the linkages, and by extension the geometry is in the correct positions. Secondly it ensures that simulations are more efficient because the initialisation of each vehicle is steady-state requiring no settling time at the start of each simulation and improving robustness of simulations by eliminating unstable initial conditions.

Whenever a new linkage, mass distribution, vehicle or bush parameterisation new initial settings need to be evaluated and implemented. But with each vehicle there are several load conditions that each need unique initial settings. Therefore, a series of initial functions were created to automate these tasks, performing the following functions:

- Curb weight Mass: Set the appropriate mass and inertia value in the body to ensure that the mass and inertia of the full vehicle is correct regardless of what components are used.
- Spring preload and initial attitude: find the preload in each spring and vehicle height, roll and pitch appropriate to keep the suspension in the correct position in curb weight condition.
- Bush preloads: Tune and store the preloads in each bush to ensure that the initial offset of each bush is zero when at curb weight.
- Load condition initialisation: Evaluate the body attitude, suspension positions and bush offsets (if included) for each load condition.

For each of the functions above, each value was calculated then the setting applied in the vehicle, half car and/or quarter car models, ensuring that any test at any level is using the linkages with the correct initial settings.

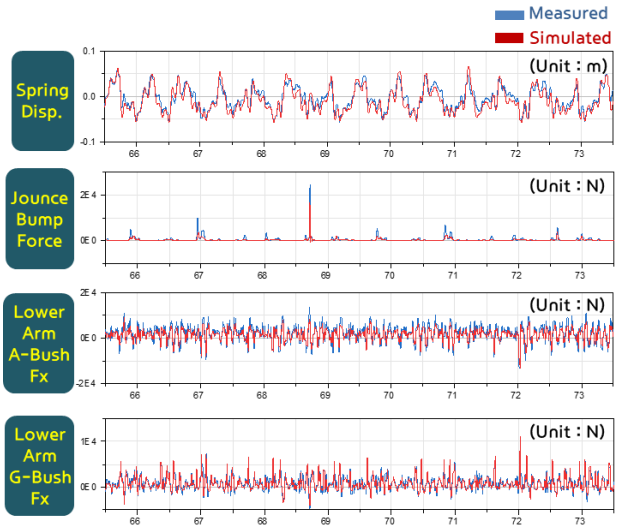

Figure 9. Validation of front left suspension from Half-car rig simulation on Belgian Pave

The first test the suspension models was to validate the dynamic spring length against measured data when a measured set of wheel forces and torques was applied to each wheel hub, comparing to a test that was driving over cobblestones in a 2up load condition. The test consisted of either the half car or full vehicle tests where the body was fixed in place and forces and torques applied to the wheel hubs. The forces and torques time traces were applied with the measured data being read in from the .mat file format they were stored in. The correlation, shown in **Figure 9**.

2.4 Electrical Motor

The investigated electric vehicle architecture combines conventional and in-wheel electric motor designs. At the front axle a conventional synchronous motor with permanent magnet (PSM). In addition, two In-Wheel Motors (IWMs) are installed at the left and right rear wheels. The durability analysis pays particular attention to the temperature development within the individual electric motors.

For building models of front motor and IWMs, the Electrified Powertrains Library developed by Dassault Systèmes is used [2]. Both types of motors are implemented based on table-based machine models from the library. The model computes the required electrical power according to the requested mechanical power with considering machine losses. The different types of machine losses are specified in form of multi-dimensional characteristic maps that typically depend on speed and torque. **Figure 10** shows the top-level structure of the table-based machine model.

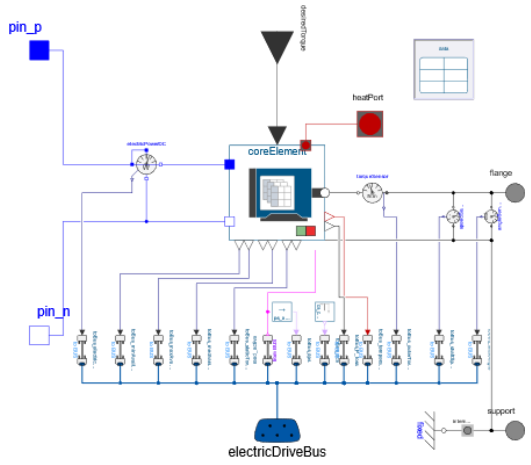

Figure 10. Top-Level structure of electric machine models

The thermal behaviours of the electric machines are modelled by lumped parameter thermal networks (LPTN). Specifically, for the IWMs that are equipped with an inner cooling channel, custom-developed thermal models are created. Heat transfer throughout the different layers of the IWM (housing to shaft and vice versa) is mainly considered in radial direction. The layers of the IWM are represented by thermal capacities in the core. During simulation, the individually computed losses by the electric machine models are injected into the respective thermal capacities. Heat exchange between the different layers is implemented via lumped thermal elements for modelling heat transfer mechanisms of conduction, convection and radiation. The cooling channel is modelled by means of components from the TIL-Library developed by TLK-thermo [3]. Behaviours of the brakes within the IWMs are modelled separately (see section 2.2).

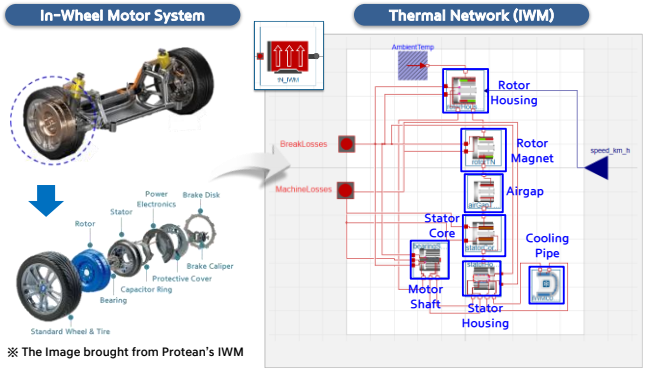

Figure 11. IWM Thermal Network Model

The electrical machine models are parameterised by provided characteristic power loss-maps extracted from test rig measurements. The maps are split into winding, core, magnet and friction losses. The thermal networks are parameterised by motor geometries and material specific properties like thermal conductivities, material densities and specific heat values.

The developed electrical and thermal motor models are validated by means of reference signals extracted from real-world driving scenarios. These reference data include, among other things, winding temperatures, speed and torque profiles at the machine flange, as well as the vehicle's velocity. **Figure 11** shows the validation results of two different compared driving scenarios focusing on the temperature development within the motor windings. The maximum deviation in temperature comparing both results is around 8.4 °C. In the current implementation a simplified setup and control strategy for the cooling channel is used. As a next step the cooling system is adapted to better fit with the real-world implementation.

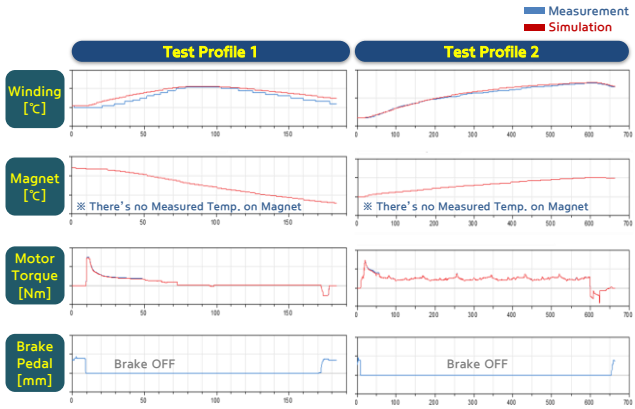

Figure 12. Validation results of the In-Wheel motor models

2.5 Battery Cell / Pack

The battery system implemented in this project is aligned to the battery pack of the Ioniq5 using an 800-Volt technology with a total capacity of up to 84 kWh. The battery pack comprises a variety of interconnected NMC-type lithium-ion pouch cells at the basis. The durability analysis pays particular attention to the temperature development within the individual battery cells of the

DOI 10.3384/ecp218819

pack when applying varying operational and environmental conditions.

Battery cell and pack models are developed based on equivalent circuit models (ECM) from the Dassault Systèmes Battery Library [4]. At the current phase of the project the focus is mainly set on the electro-thermal behaviour of cells (including aging characteristics is planned in a next step). **Figure 12** shows the structure of the used ECM cell model on the left-hand side ("Cell-Level"). The ECM cell is split into three sub-components to model electrical, thermal and aging behaviours separately. All three sub-components are continuously exchanging information via a bus connector during simulation. This approach offers a high degree of flexibility to replace individual sub-components. The selected thermal cell model can be discretised along the height-direction of the cell with additional thermal connectors at the surface sides for modelling heat exchange with the environment.

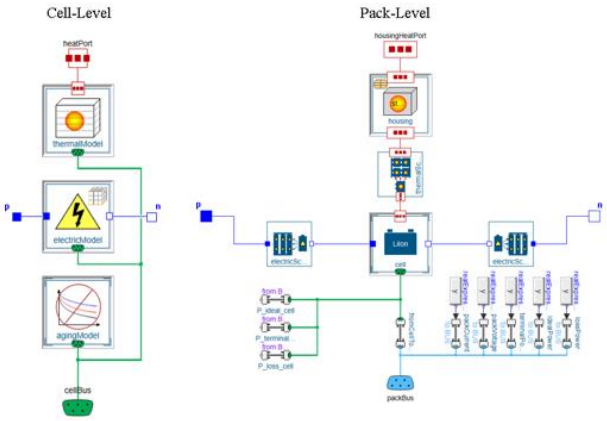

Figure 13. ECM Cell and Pack model concepts

The battery pack is modelled by means of scaled pack templates from the Battery library. Its structure is shown on the right-hand side of **Figure 13** ("Pack-Level"). Using this type of model, the behaviour of one cell instance is computed and scaled up according to the overall selected number of cells in series and parallel. The scaled model implementation is comparable to a pack setup in which all cells behave identically without deviations. This type of pack model is particularly suitable for analyses that focus on the battery pack as a complete system, such as long-term energy or aging studies. In contrast to the scaled packs, the Battery library also supports discretised pack models that calculate the behaviour of each cell individually. Thus, cell-to-cell interactions are also considered during simulation.

The ECM cell model is parameterised based on RC-data tables tested and 3D simulation. RC-data tables are used to compute the inner resistance and open-circuit-voltage of the battery cell depending on its states during simulation with respect to the cell temperature, State-of-Charge (SoC) and applied current loads at the terminal pins. The provided 3D simulation results are reused as reference temperatures within an automated data-correlation workflow for parameterising the thermal cell model.

The developed battery cell and pack models are validated by means of reference signals extracted from real-world test scenarios which consists of 7 laps in the circuit. This reference data includes, among others, captured temperatures, voltage responds and applied load profiles at cell and pack level. In **Figure 14**, the simulation results with focus on the computed temperatures within battery cells for an applied dynamic current load profile are plotted. Input current load profile as well as reference signals for the validation are provided by sensor data that are captured during running vehicle driving scenarios.

In the validation model, a simplified cooling system is implemented for pack cooling at the bottom side. The shown signals *Tmin_Pack* and *Tmax_Pack* in the diagram are the measured min./max. cell temperatures that appear inside the battery pack of the electric vehicle during operation. Signal *Tmean_Cell* in the diagram shows the computed mean core cell temperature of the scaled battery pack model (assuming that all cells behave identically).

The validation results show that computed cell temperatures are kept inside the min./max. reference data boundaries with a slight trend towards *Tmax_Pack*. By means of the scaled model simulations first initial insights into rough pack designs at early development phases are given and worst-case scenarios can be further analysed. As next steps, the use of discretised pack in combination of modified cooling system models are planned.

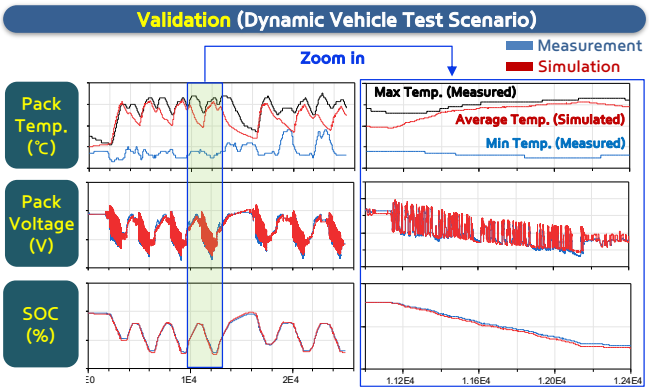

Figure 14. Pack-Level Temperature Validation

2.6 Thermal Management System

Effective thermal management is crucial for maintaining the efficiency, reliability, and longevity of EVs: the main parts (battery, inverts, electrical drive) need to work in specific temperature range for maximum efficiency and the comfort that has to be maintained in the passenger compartment. To be highly efficient and minimise its impact on the vehicle range, thermal management of EVs tries to dispatch and re-use dissipated heat as much as possible, making the circuitry and control logic associated very complex.

To evaluate properly the durability of the vehicle, the thermal management of the car needs to be modelled completely. It consists of:

- Battery Cooling System: Ensures the battery operates within safe temperature ranges to prevent degradation and maintain performance.
- Electric Motor Cooling: Manages the heat generated by the electric motor to enhance efficiency and prevent overheating, though a secondary lubrification loop.
- Power Electronics Cooling: Protects the power inverter and other electronic components from thermal stress.
- Cabin Heating and Cooling: Maintains passenger comfort while optimising energy usage.
- Heat Exchangers and Coolant Loops: Facilitate heat transfer between different components and the external environment.

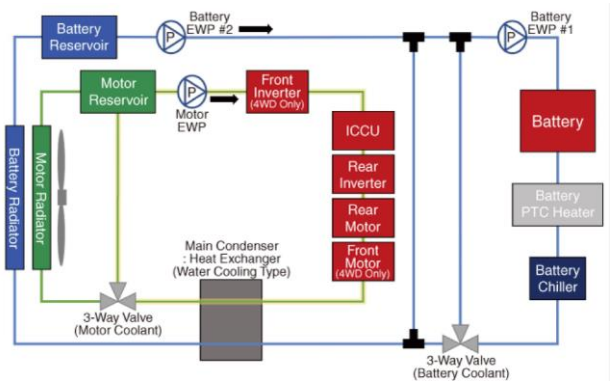

Figure 15. Overview of the thermal management system (Heat Pump is not represented in the figure here)

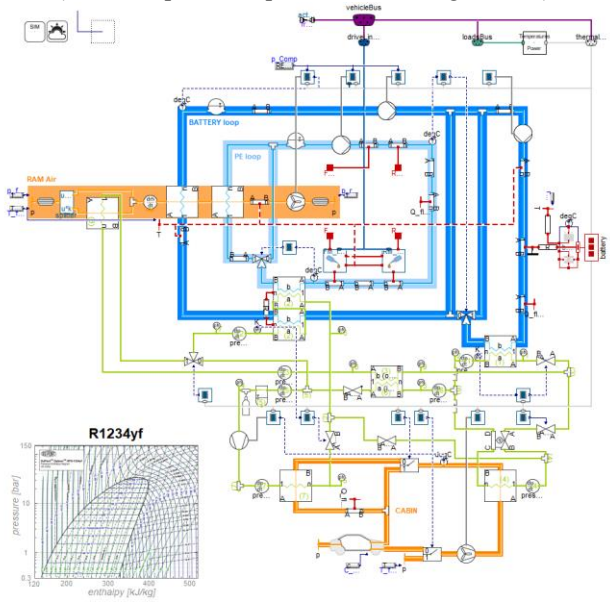

Figure 16. Thermal management system

The complete thermal management of the Ioniq5 has been built within Dymola, using the TIL library and its automotive add-on (pump, fan, compressor, TXV, valve, heat exchangers (plate & MPET), reservoir, cold plate…). It consists of five main paths or loops:

- the ram air for under the hood exchanges,
- the battery loop (glysantin 50%, dark blue),
- the e-drive and inverter loop (glysantin 50%, light blue)
- the cabin cooling path (orange)
- the reversible heat pump (R1234yf, green)

The work has been very meticulous, calibrating each component individually before building the system loop by loop. As much as possible, the model has been validated locally, using three different sets of measurement data: a partial model without the heat pump (replaced with imposed outlet temperature of coolant or air heat exchangers with the refrigerant) has been set-up for calibration.

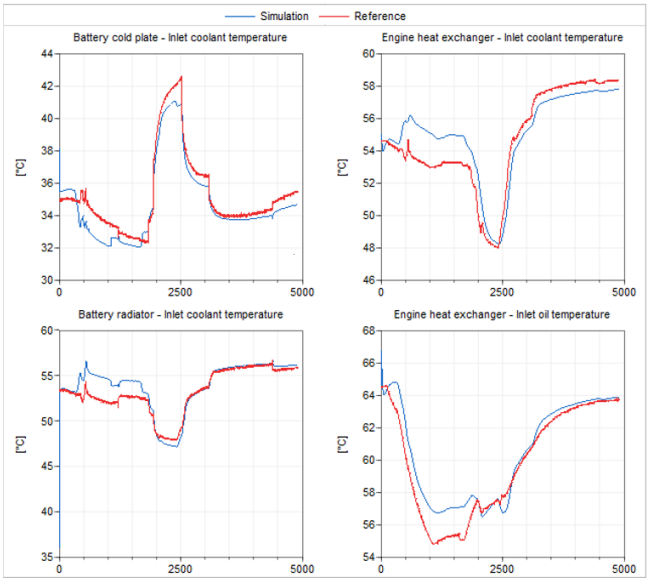

Figure 17. Calibration results for the Coolant loop

Once the loop is calibrated, the complete thermal management model has been assembled, and the control logic has been set-up.

The next step is to validate the complete model at vehicle level. The next step is to validate the complete model at vehicle level using the linkages with the correct initial settings.

3 Vehicle Modelling and Integration

By integrating all system models detailed above, the Ioniq5 electric vehicle model has been built as shown in **Figure 18**.

Since the vehicle model template is based on the VeSyMA library [5], there needs specific interfacing models for motor, battery and thermal management system models to exchange electrical and thermal signals with VeSyMA vehicle. The interfacing models make multi-physical system from different libraries to be simulated in one large vehicle environment.

DOI 10.3384/ecp218819

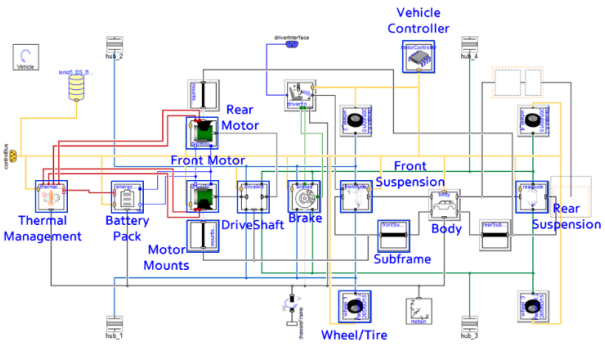

Figure 18. Integrated Electric Vehicle Model

Once the vehicle model is integrated, three representative durability scenarios previously defined in **Figure** 2 are utilised for the validation.

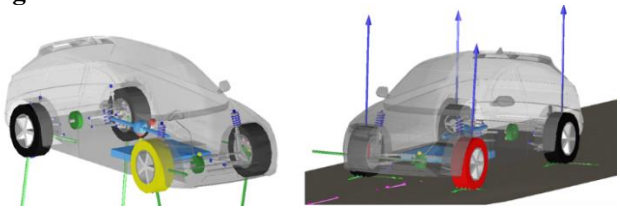

Figure 19. 2 ways of Simulation on Rough Roads

The first scenario for the validation is driving on a rough road which causes mainly longitudinal and vertical damage on suspension linkages and bush mountings. As a representative road roughness scenario, the event of consecutive potholes is chosen. For vehicle simulation, two different approaches are executed to check the availability for both options in the development stage depending on whether the pre-measured wheel forces exist or not. In **Figure 19**, the left case is replaying measured wheel forces directly on each wheel centres of the fixed-body vehicle model just to replicate the physical vehicle-level 24 channel road simulator. The right case is closed-loop simulation which the vehicle model runs on open CRG surface with grid Pacejka tire models simulating multi-contact points using the profile of measured time dependant velocity. **Figure 20** shows the spring displacement both measured and simulated as a representative validation signal for suspension model. Even though simple tire models are used for the simulation on rough road surface, the amplitude and trend are quite good matched to the measurement.

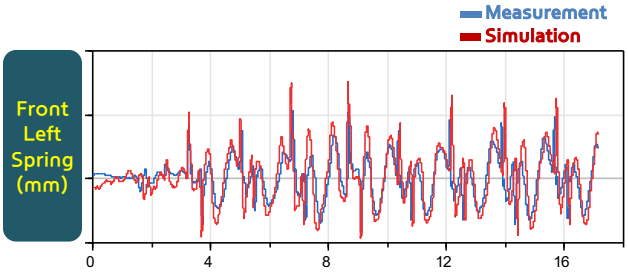

Figure 20. Spring displacement comparison between measurement and closed-loop simulation on CRG surface

The second scenario for validation is harsh acceleration and braking event which causes not only mechanical damage on brake and suspension components in longitudinal direction but also, electrical and thermal damage on the powertrain system.

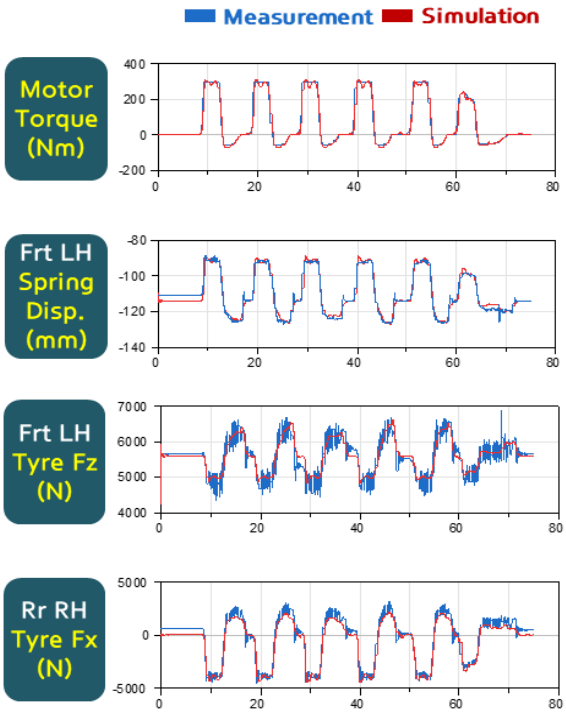

Figure 21. Suspension, Motor and Brake Validation for harsh acceleration and braking Scenario

The simulation is conducted using a closed-loop driver, by imposing measured vehicle speed as a target to drive the simulated vehicle to meet. As a result of the validation, it is due to the non-perfect logic in the vehicle controller, for the harsh braking condition, regenerative torques are not very accurate which also results in inaccuracies on brake pressure. With regards to the vehicle controller, a more accurate way of implementing the controller logic will be required in the future.

The last scenario for the validation is real-world driving scenario which is one of the mountain roads in Korea. First, road model was generated using latitude, longitude, altitude and measured velocity from GPS measurement. The road model defines the velocity target relative to distance which the driver model tries to achieve. In this scenario, powertrain dependant signals such as thermal and electrical behaviours on motor and battery are more taken into account for the durability. As shown in **Figure 23**, both front and rear motor speed are good matched to the measurement. With regards to the temperature on motor and brake, it's because there's no reference signals to be compared with, only simulated signals from the model are shown here but, they show reasonable behaviours relative to measured motor's behaviour which

the vehicle model to be believed that it's quite robust even in the real world scenario.

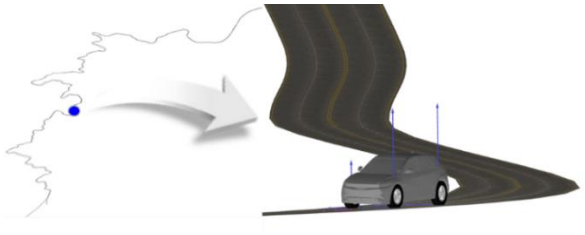

Figure 22. Road Model for field road in Korea

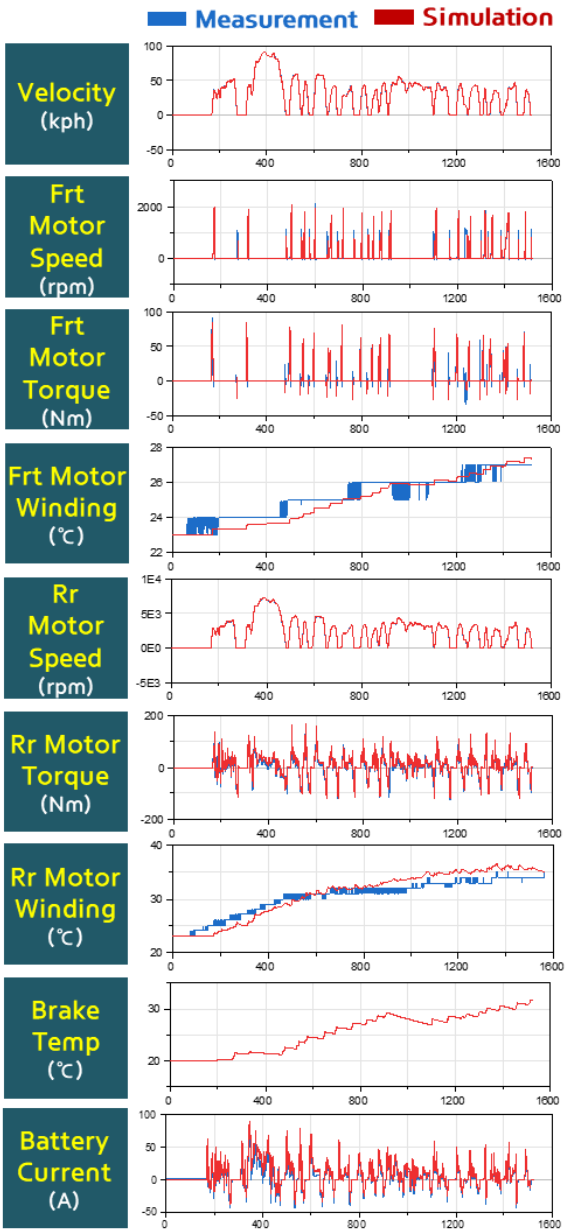

Figure 23. Powertrain / battery / brake related signals validation for the real-world scenario

4 Conclusion

In this study, Virtual RLDA platform has been developed for replacing vehicle measurement campaign for durability in early development stage as a best practice modelled for one of HKMC's electric vehicle.

For doing that first of all, required simulation signals aligned with the level of fidelity for system models are defined from vehicle simulation to quantify electrical, thermal and mechanical damages on each durability related components in systems.

Secondly, systems that are closely related to durability are modelled and validated with measurement. The system and vehicle level modelling templates from the study can be scalable and expendable for next HKMC vehicle development with minimal changes on the templates. In more detail, vehicle controller model is developed with Modelica library to control driving torque and regenerative torque for various driving situations. As for the degradation perspective of motor and battery system, in order to predict accurate working temperatures, electrical and thermal models for both motor and battery are developed along with the hydraulic brake model which generates brake disc heats. With those models, thermal management system modelled with TiL library for the entire vehicle level is coupled together with motor and battery model to cover the thermal behaviour occurred from actual driving conditions. For the perspective of chassis systems, one of the main development is the automated suspension modelling environment which directly imports HKMC's standard multi-body dynamics modelling template from the VeSyMA suspension library based suspension model not only for the initialisation of preloads on kinematic and compliance elements but also for the parameterisation of the suspension. As a result of this, it is expected that engineers can save huge amounts of time for modelling from basic K&C vehicle dynamics model to bushed vehicle dynamics model which can simulate nonlinear reactions on each suspension parts.

Lastly, the developed system models are integrated into one large vehicle model to simulate various different durability scenarios as similar as possible with the vehicle measurement. Different driver and road models are used for vehicle level simulation to validate vehicle model compared to measurement.

The Virtual RLDA platform developed in this study will be used and keep updated as a core model of our durability digital twin strategy to replicate realistic customer usages in virtual environment. By keeping the model upgraded, it is expected that many losses repeatably taken place from the development process could be minimised and it'll consequently result in reducing the number of prototypes for durability testing in the development.

Acknowledgements

This project has been supported by Claytex and Dassault Systèmes for 1 year. Various multi-physical systems and vehicle level modelling and their validities are proceeded. The model shows a lot of potential to be used for various systems in terms of durability development and will

continue to be updated in the future. I'd like to express my sincere gratitude to Claytex and Dassault Systèmes for their unbelievably enthusiastic support during the project.

[2]TLK-Thermo GmbH, Braunschweig, Germany, m.pollak@tlk-thermo.com

Abstract

Solid-state batteries are promising for electric mobility as they potentially offer higher energy densities and therefore increased driving range, longer life and safety. They have different thermal properties and thermal management requirements than liquid battery systems. This paper presents a comparison of a solid-state battery system with a state-of-the-art liquid (Nickel-Manganese-Cobalt) NMC battery system for a simulated electric long-distance bus on a typical real-world long-distance route, requiring fast-charging. The battery characteristics are based on published data. Thermal management is performed by a reversible R744 heat pump. By designing both battery systems for the same energy capacity, the solid-state battery releases more heat during fast charging. For the same battery system size, the solid-state battery significantly outperforms the liquid battery system in driving range and does not require more cooling.

Keywords: Solid-State Battery, Thermal Management, Electric Mobility

1 Introduction

Electric mobility is on the rise worldwide and is recognized as a means to combat global warming and reduces local pollutant emissions (Sanguesa et al. 2021). Long-distance buses, also called coaches, are the most efficient transport option in terms of CO_2 emissions per person and kilometer (Thomas and Serrenho 2024; UK Department for Business Energy & Industrial Strategy 2022). In the current literature, solid-state batteries are discussed as the most promising alternative to state-of-the-art lithium-ion batteries because they have higher energy densities (thereby increasing driving range) and better safety (Schmaltz, Hartmann, et al. 2023). Solid-state batteries come with different electrical and thermal characteristics (Yang et al. 2024) than lithium-ion batteries and offer a larger operating temperature range, extending operation to higher temperatures in particular (Schmaltz, Wicke, et al. 2022). The main difference is the higher internal electrical resistance compared to a liquid battery operating at the same temperature level (Janek and Zeier 2023). First evaluations for the thermal management of solid-state battery vehicles investigated cold start procedures (Hughes and Vagg 2022) and heat pumps for battery pre-heating (Hellmuth, Pollak, T. Heinke, et al. 2023). Kan et al. (2024) reviewed the thermal effects of solid-state batteries and discussed the higher amount of heat generation and the higher operating temperatures of solid-state batteries. Yang et al. (2024) compared the thermal and electrical characteristics of conventional liquid, semi-solid-state and Lithium-Iron-Phosphate (LFP) batteries based on experimental data. Ma et al. (2025) experimentally investigated solid-state batteries and modeled thermal and electrical characteristics. Li et al. (2025) compared semi-solid-state and liquid batteries.

In this study, the effects of solid-state battery implementation in a coach for long-distance operation are evaluated using system simulation in Modelica. The battery data of Yang et al. (2024) are implemented. The following contributions are provided:

- Comparison of state-of-the-art and solid-state batteries in the context of a long-distance bus
- Battery system sizing comparison
- Evaluation of thermal effects in a real-world driving scenario
- Recommendations for the thermal management

2 Description of a coach model with solid-state batteries

To investigate the usage of solid-state batteries in a coach, we use a modular multi-scale vehicle model developed using Modelica (Modelica Association 2025) and integrated models from the TIL suite (TLK-Thermo GmbH 2024b). This approach allows for detailed simulation of electrical, mechanical and thermal interactions across various vehicle components. Similar modeling frameworks have been successfully applied to fuel-cell electric cars (S. Heinke et al. 2019) and to optimize thermal management systems in battery-electric trucks (Hellmuth, Steeb, Pollak, et al. 2023) as well as battery-electric coaches (Hellmuth, Pollak, Schulte, et al. 2024).

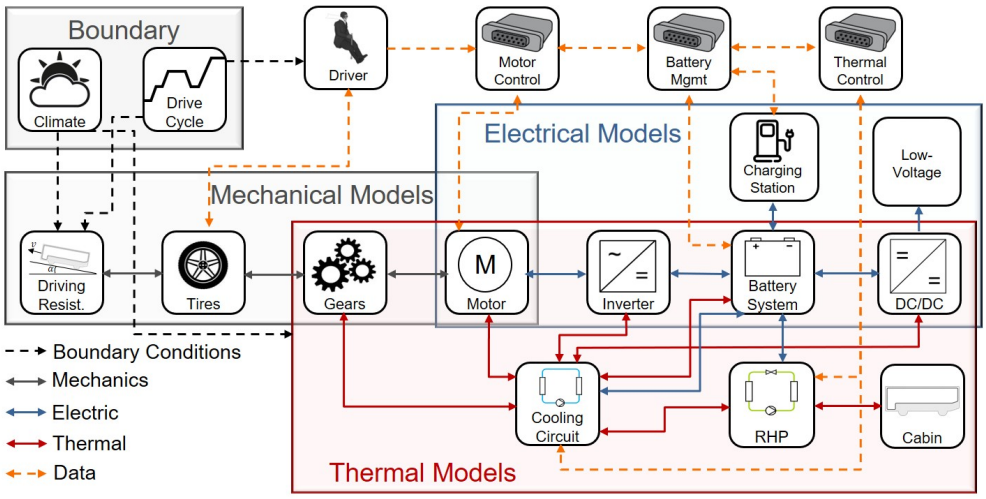

Figure 1. Model of an electric coach including balance rooms for flow variables (heat, electrical and mechanical power), control units, and data connections as well as boundary conditions and a charging station, adapted from Hellmuth, Pollak, Schulte, et al. (2024).

The comprehensive vehicle model is illustrated in Figure 1, highlighting key interactions and dependencies within the system. The balance rooms for the flow variables (heat, electrical, and mechanical power) as well as control units, data connections, and boundary conditions are visualized. The boundary conditions, thoroughly detailed in Section 3, encompass both climate data and a driving cycle. Specifically, we have defined ambient temperature, ambient humidity, and solar radiation as the primary climatic parameters. These factors not only affect driving resistance but also serve as boundary conditions for all thermal models. They have a significant impact on the cabin environment, the cooling circuit, and the reversible heat pump (RHP).

The drive cycle provides time-dependent data on the vehicle's speed and slope of the terrain. For the drive cycle we converted distance-based data into a time-based format. This fits well into the overall solution process of the formulated system of equations. A drive cycle from Karlsruhe to Munich is used in this study. This drive cycle was first described by Hebeler (2024) to investigate the potential of planetary gearboxes for the integration of a Rankine process in a coach. The drive cycle is displayed in Figure 2 showing the velocity and altitude along the route.

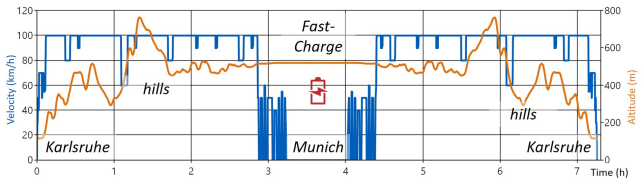

Figure 2. Drive Cycle showing the velocity and altitude profile for a long-distance coach trip from Karlsruhe to Munich and back and a fast-charging break, adapted from Hebeler (2024).

2.1 Mechanical Models for Drive-Train and Force

The mechanical subsystem includes models for driving resistance, tires, gears, and an electric motor to describe the driving dynamics of a configured vehicle. The driving resistance model, in particular, uses interchangeable parameter sets that include the drag coefficient c_w, frontal area A_{front}, vehicle weight $m_{vehicle}$, and rolling friction coefficient μ_{roll}. The parameters (Table 1) are taken from the *vanHool CX45E* (Sustainable Bus 2020). Traction force is calculated by summing the four resistances:

$$F_{Traction} = F_{Roll} + F_{Air} + F_{Grade} + F_{Acceleration} \quad (1)$$

Further description of the mechanical models can be found in (Hellmuth, Steeb, Pollak, et al. 2023; Hellmuth, Pollak, Schulte, et al. 2024).

Table 1. Vehicle parameters used in all scenarios.

Parameter	Value
Vehicle total mass	24 t
Frontal area	7.5 m^2
Drag coefficient	0.4
Rolling friction coefficient	0.006

2.2 Models of Electrical Components

The electrical motor model connects the mechanical and electrical models. Electrical power is calculated based on the required mechanical power. We assume a fixed motor efficiency of 95 % (Gobbi et al. 2024), and the waste heat is rejected to the coolant circuit. The motor is electrically connected to the inverter model, providing a constant voltage level for the motor. A fixed efficiency of 97 % (Sorokina et al. 2021) is assumed, and the waste heat is

DOI 10.3384/ecp218831

rejected to the coolant. The inverter is connected to the battery system that includes a high-voltage network. Furthermore, a low-voltage network provides energy for additional consumers such as ignition and infotainment. The high-voltage network is connected to an external charging station. Activation of the charging station can be requested by the drive cycle or can be time-based. A battery management controller sets the charge power based on charge maps. The charge maps use the actual battery temperature and state of charge to calculate the suitable charging power. While discharging, the battery management ensures de-rating for battery temperatures that are too high or too low as well as for voltages that are too low voltages.

2.3 Battery Model

The battery system is one of the key components of the vehicle model. Therefore, it is modeled in detail. Parts of the model were described before by Hellmuth, Steeb, Tegethoff, et al. (2022), Steeb et al. (2019), and Hellmuth, Steeb, Pollak, et al. (2023). We model a battery cell including copper and aluminum current arresters, a thermal interface material (*gapfiller*) and a simplified cooling plate model. The cooling plate is designed as bottom mounted cooling with round channel coils using a water-glycol coolant. Further discussion on cooling plate design can be found in Epp et al. (2023). One representative battery cell is modeled in details and the voltage, current, and heat flows are scaled up to the system level. The battery system is designed for a voltage supply of 800 V. The battery capacity for the baseline scenario is 473.6 kWh.

A pouch cell is chosen because solid-state batteries require high external pressure and only pouch cells can cope with this requirement (Yin et al. 2024). The battery cell is modeled in a 3D-discretization in Modelica. Figure 3 shows the modeling of the battery cell including the conductors, gapfiller, and cooling plate. In this sketch, the battery cell is discretized in length (x), thickness (y) and height (z). That approach is suited for vehicle simulation as the thermal interactions of the battery with other components are at the top (current arresters) and bottom (cooling plate). Automotive battery cells are usually relatively thin. The battery model comprises a network of 9 battery bundles. Each bundle represents a part of the battery cell including a part of the volume, mass, and thermal capacity along with the number of bundles (Veth et al. 2014). A thermal network is calculated in each bundle. The thermal network is built up from thermal resistors and a thermal capacity. The thermal capacity is implemented as a point mass in the center of each discretization element and is parameterized using the mass and heat capacity of the battery cell. Each resistor uses half of the element's size in a geometrical direction and the thermal conductivity. The thermal properties are assumed for the cell as a homogeneous block with anisotropic thermal conductivity (Wendland 2021).

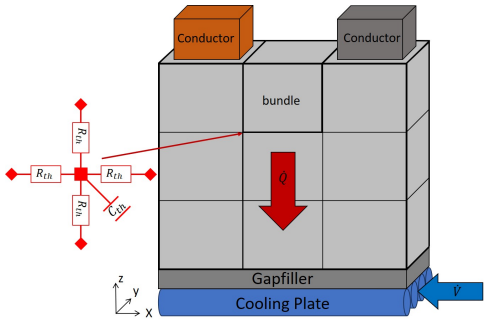

Figure 3. Illustration of a discretized battery cell with one bundle highlighted. Each bundle comprises a thermal network. The system includes conductors, a gapfiller and the cooling plate, adapted from Hellmuth, Steeb, Pollak, et al. (2023).

The battery cell model contains an equivalent circuit model (ECM) as well as a reversible heat model for calculating irreversible heat production ($\dot{Q}_{irrev}$) and reversible ($\dot{Q}_{rev}$) heat (Bernardi, Pawlikowski, and Newman 1985) The ECM calculates $\dot{Q}_{irrev}$ based on the internal resistance R_i of the battery cell:

$$\dot{Q}_{irrev} = R_i \cdot I^2 \tag{2}$$

ECM models contain electrical elements such as *Capacitor*, *Ohmic resistances* or *Warburg diffusion*. The models can be parametrized by resistance data of the cell or data obtained from *Electrochemical Impedance Spectroscopy* (EIS) measurements (Westerhoff 2019). For this study, a simple *R1RC* model (see Figure 4) is chosen as sufficient data are provided for that model complexity and accuracy.

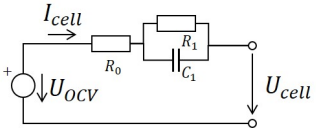

Figure 4. *R1RC* ECM model adapted from Westerhoff (2019).

The reversible heat model uses the entropy coefficient $\frac{\partial U_{OCV}(T,SoC)}{\partial T}$ to calculate the reversible heat $\dot{Q}_{rev}$ at a certain temperature and a given current:

$$\dot{Q}_{rev} = I \cdot T \cdot \frac{\partial U_{OCV}(T, SoC)}{\partial T} \tag{3}$$

From equations 2 and 3, the irreversible and reversible heat dependence on the current I can be analyzed. For calculating the irreversible heat, the current I is squared. The reversible heat depends linearly on the current I. The reversible heat can be released or consumed, depending on the entropy coefficient for different temperatures and different states of charge (SoC). A dependence on the battery state of health (SoH) is not implemented due to a lack of available data yet. A measurement for the load on the battery is the C-Rate, defined as: C-rate $= \frac{I}{Capacity}$

The battery data for this study are obtained from the publication of Yang et al. (2024). They compared the thermal characteristics of a solid-state battery (NMC-S) with one LFP battery and one liquid NMC (NMC-L) battery. Actually, the solid-state battery is a hybrid solid-liquid battery, also called semi-solid (Schmaltz, Hartmann, et al. 2023). In this study, we use the NMC-S and NMC-L battery data for comparison. The NMC-S battery was provided by *ProLogium Technology Ltd* and the NMC-L is a state-of-the-art battery from *CENAT New Energy Ltd*. The NMC-S battery uses NMC for the positive electrode and graphite for the negative electrode. The solid electrolyte is made of $Li_7La_3Zr_2O_{12}$ (*LLZO*). Some $LiPF_6$ liquid is added for filling the interface gap, making it a hybrid (Yang et al. 2024). *LLZO* is a *Garnet-type* oxide solid electrolyte and one of the most promising options (Schmaltz, Wicke, et al. 2022). Data of both batteries are compared in Table 2:

Table 2. Battery data for the NMC-S and NMC-L, adapted from Yang et al. (2024).

Parameter	NMC-S	NMC-L
Length X (mm)	300	311
Thickness Y (mm)	5.5	7.35
Height Z (mm)	100	100
Volume (L)	0.165	0.228
Mass (kg)	0.377	0.520
Nominal Capacity (Ah)	21.3	20
Nominal Voltage (V)	3.6	3.7
Operating Voltage (V)	$4.2-2.5$	$4.2-2.5$
Gravimetric Energy Density ($\frac{Wh}{kg}$)	203.4	142.3
Volumetric Energy Density ($\frac{Wh}{L}$)	464.7	323.7
Max Currents	$3C$	$2C$

The NMC-S battery cell is 27.6 % smaller in volume and 27.5 % lighter in mass and has a slightly higher battery capacity. This results in a much higher gravimetric and volumetric energy density. The operating voltages are similar. The NMC-S battery could be charged or discharged with $3\,C$, while the NMC-L is limited to $2\,C$.

In the first step, both battery systems are designed for the same energy capacity. A $800\,V$ battery system needs approximately 200 battery cells to be connected in series. For the lower nominal voltage, the NMC-S battery is equipped with 205 battery cells in series. To reach the same energy capacity, the NMC-S system is equipped with 30 cells in parallel, the NMC-L with 32. This results in a system capacity of approximately $470\,kWh$. The battery system data are compared in Table 3.

2.4 Thermal Management

The thermal management in the coach is based on a reversible heat pump using the natural refrigerant R744 and additional cooling circuits using a water-glycol coolant. The reversible heat pump provides cooling, heating, and dehumidifying for the cabin, as well as a connection to the cooling circuit. The cooling circuit provides cooling for the battery, motor, and inverter. Waste-heat recovery could also be enabled.

Table 3. Battery system comparison for NMC-S and NMC-L.

Parameter	NMC-S	NMC-L
Battery Cells ($-$)	6150	6400
System Volume (L)	1010	1460
System Mass (kg)	2318	3328
Energy Capacity (kWh)	471	473
Nominal Voltage (V)	738	740

A detailed cabin model (TLK-Thermo GmbH 2024b; Kaiser 2019) was implemented, which models the transient behavior. The interior model is divided into three discretization sections that enable consideration of specific effects, such as the solar radiation on the windshield, and the extraction of recirculated air and supply air from the roof-mounted system in the middle zone. Components, such as the windows and roof, are modeled with their thermal properties. The heat exchangers required for cabin air conditioning are placed in the *Roofbox* and the *Frontbox* (Kaiser 2019).

The reversible R744 heat pump is modeled with the liquid, refrigerant, and gas components provided by the *TIL suite* (TLK-Thermo GmbH 2024b) that enable numerically efficient modeling of thermodynamic systems (Schulze 2013). Components, such as the heat exchangers, are modeled in detail. The main cooling and heating capacity is provided for the cabin. The implemented heat pump uses a four-way-valve for reversing the refrigerant cycle and the secondary loop coolant circuit is used for cooling and heating of the *Frontbox* (Weinreuter and Yildirim 2024). Similar thermal management systems are discussed in previous publications (Hellmuth, Steeb, Pollak, et al. 2023; Hellmuth, Pollak, Schulte, et al. 2024).

The battery cooling circuit operates at temperature levels from $20-40\,^{\circ}\mathrm{C}$ for liquid batteries and up to $40-60\,^{\circ}\mathrm{C}$ for solid-state batteries. For the solid-state battery a de-rating of power is begins above $70\,^{\circ}\mathrm{C}$. A connection to the low temperature cooling circuit allows mixing cold coolant into the circuit, dissipating the battery heat and keeping the temperature level. Different control concepts for various operating strategies and ambient conditions are implemented with a set of *PI-Controllers*. The cabin cooling is prioritized during driving. For fast-charging, the operation strategy shifts to a battery cooling priority. Further optimizations are performed, such as using a dynamic *Gascooler* pressure correlation adapted from Kauf (1999) for controlling the system high pressure.

DOI 10.3384/ecp218831

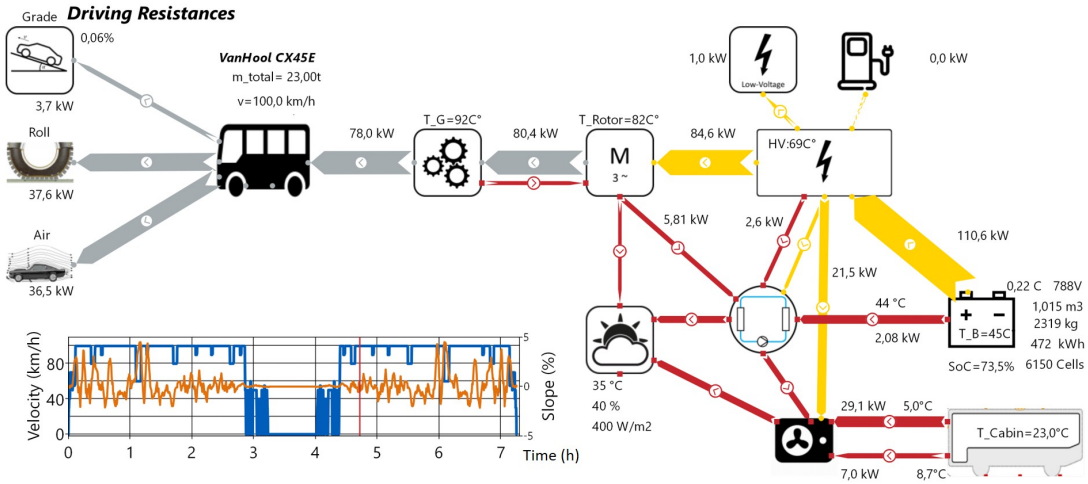

Figure 5. Analysis of energy flows for the NMC-S battery system in the context of the full vehicle, Drive cycle time is indicated by the vertical red line, adapted from Hellmuth, Steeb, Pollak, et al. (2023).

3 Comparison of Battery Systems: Solid-State and Liquid

The solid-state and liquid battery systems are compared in the context of the described long-distance route (see Figure 2). First, the energy flow in the full-vehicle context is evaluated. Next, the battery systems are compared for the same energy capacity. Finally, the systems are compared for the same battery system volume, but different energy capacities.

3.1 Analysis of Energy Flow in the Vehicle

The analysis of energy flows is performed with the software *DaVE* (TLK-Thermo GmbH 2024a). Analyzing energy flows in the full-vehicle context helps to understand cross-couplings in the complex system. The energy flows are depicted in Figure 5. The NMC-S system is taken. At the driving cycle time of the snapshot, the coach drives up a slight incline at a velocity of 100 km/h. This results in a relatively equal distribution of the required power into grade, roll and air resistance. The efficiencies of the mechanical and electrical components can be obtained from the higher electrical energy flow values towards the battery. 110.6 kW electrical power is provided. The battery has a SoC of 73.5 % and the C-rate is 0.22. The battery system voltage is at 788 V.

The snapshot was taken for the driving scenario at an ambient temperature of 35 °C, an ambient humidity of 40 % and a solar intensity of 400 $\frac{W}{m^2}$. Under these conditions, thermal management adds about 25 % to the electrical energy consumption required for the motor. Additionally, 1 kW of electrical power is needed in the low-voltage network for entertainment, lights, and further demands.

The solid-state battery is conditioned to 45 °C and at point in the drive cycle very little cooling is necessary. Therefore, only 2.1 kW of heat is transferred to the thermal management. The cabin is conditioned to 23 °C and therefore, fresh air is provided at a temperature of 5 °C for the main cabin and 8.7 °C for the *Frontbox*. A total of 36.1 kW of cooling power is required for cabin cooling.

3.2 Comparison for same Battery System Energy Capacity

As described above, both battery systems are designed for the same energy capacity. They are compared for the Karlsruhe - Munich - Karlsruhe (Figure 2) long-distance drive cycle. The comparison of both battery systems in terms of battery temperature and SoC is displayed in Figure 6. The NMC-L discharges a little bit faster because it needs slightly more energy for battery cooling while the NMC-S battery is not cooled while driving. The other reason for the higher energy consumption is the higher weight of the NMC-L bus. Also, the NMC-L battery system weighs 1000 kg more, resulting in higher grade and roll resistances while driving.

The battery temperature setpoint for the NMC-S is set to 45 °C. In the first driving section, prior to fast-charging which occurs just after the of hour three of the drive cycle, the battery temperature rises from an initial value of 35 °C up to close 40 °C and stays at that temperature level. Therefore, it is not cooled. The NMC-L is cooled to 30 °C to reduce battery degradation. During fast-charging, NMC-S warms up sharply to 59 °C, due mainly to the high internal resistances of the cell and high currents supplied in the fast-charging process. The NMC-L only warms up to 34 °C. This is attributable to the significantly lower internal resistance.

Figure 7 shows the heat produced by the battery

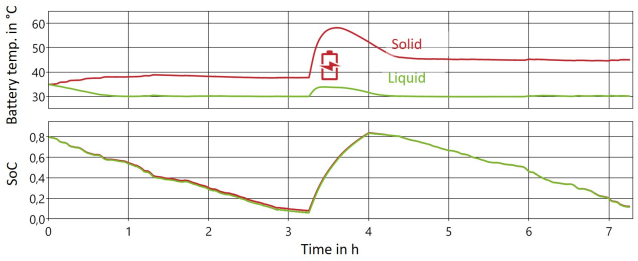

Figure 6. Comparison of the solid-state (NMC-S) and liquid (NMC-L) battery systems along the drive cycle: Battery temperature and SoC.

systems. The heat produced is generally relatively small in normal driving conditions due to the low C-rates. When comparing battery capacity and maximum motor power, the C-rate is limited to a value of 0.76 C while driving; $0.1 - 0.3$ C is typical. This results in relatively low irreversible heat as the currents are squared in calculating it. During fast-charging, the C-rate reaches a maximum close to a value of 2 C (1 MW charging). Therefore, the irreversible heat production peaks at 82 kW for the NMC-S and at 36 kW for the NMC-L. The higher irreversible heat production results from the internal resistances that are higher by the factor 2.3, even at the elevated temperature of the NMC-S.

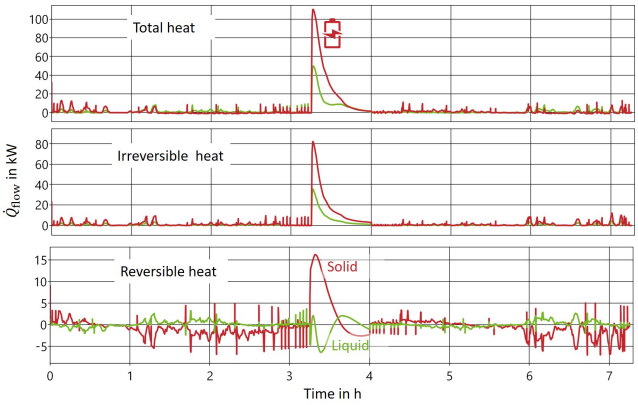

Figure 7. Comparison of battery systems along the drive cycle: Total battery heat, irreversible heat and reversible heat.

The reversible heat can be released or consumed. For the NMC-S, it is negative most of the time while it is discharging (SoC < 0.6), with some positive peaks for recuperation. If the reversible heat is negative, it reduces the total battery heat. The reversible heat dominates for low C-rates; therefore, the battery temperature does not increase for most of the time during normal driving for the NMC-S. Then, at the beginning of charging, it is positive and increases the total heat. For the NMC-L battery, the reversible heat turns to negative values while charging and reduces the produced heat.

3.3 Comparison for same Battery System Volume

In the previous section, it was shown that the solid-state battery heats up to significantly higher temperatures due to higher internal resistances. Because of the higher volumetric and gravimetric energy density, the NMC-S system is smaller and lighter. Assuming a given space for the battery system, sizing the battery systems for the same volume is a logical next step in their comparison. The adjusted parameters for the two battery systems are listed in Table 4:

Table 4. Battery system comparison for NMC- S and NMC- L. Batteries are sized for the same system volume.

Parameter	NMC-S	NMC-L
Battery Cells $(-)$	8815	6400
System Volume (L)	1450	1460
System Mass (kg)	3323	3328
Energy Capacity (kWh)	676	473
Nominal Voltage (V)	738	740

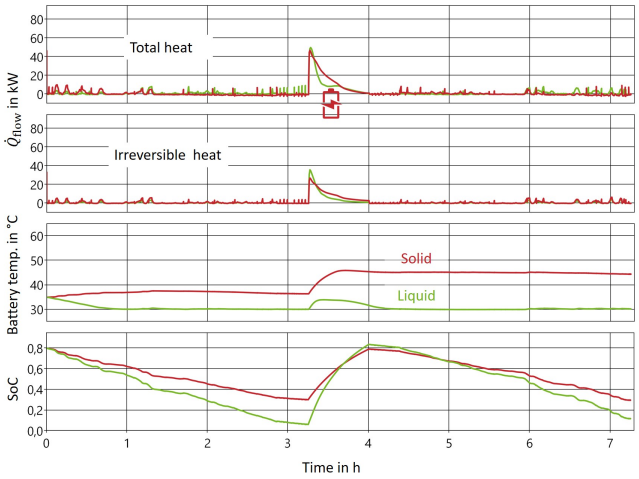

Figure 8. Comparison of batteries at the same system volume along the drive cycle: Total battery heat, irreversible heat, battery temperature and SoC.

In this configuration, both battery systems have approximately the same volume and weight. The NMC-S system has a 43 % higher energy capacity. A comparison of heat flow, battery temperature and SoC for the drive cycle is depicted in Figure 8. The higher energy capacity of the NMC-S leads to much lower C-rates during driving and charging. For this reason, the heat produced by the NMC-S battery is in the same range as that of the NMC-L. The lower C-rates due to the higher capacity compensate for higher internal resistances regarding heat production. Actually, not much cooling is necessary for the large NMC-S. It does not reach the upper setpoint temperature of 45 °C driving to Munich, but slowly heats

DOI 10.3384/ecp218831

up to it during fast-charging.

In the previous comparison, the solid-state battery system's full potential for fast charging is not utilized. In the fast charging it is only charged with a C-rate of 1 C, while up to 3 C would be possible. Also, the battery reaches the charging stop at an SoC of 0.3, so charging is not needed. For a simple scenario adjustment, the bus with the NMC-S battery starts at a SoC of only 0.6 and the charging break is reduced to 30 minutes. Therefore, the charging station is modified to allow up to 2 MW of charging power, which is likely to be possible at large charging stations in the future (Makoschitz 2022).

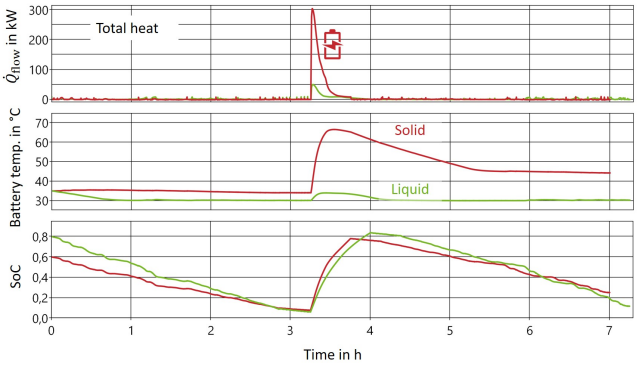

Figure 9. Comparison of batteries at the same system volume along the drive cycle with faster charging for NMC-S battery: Total battery heat, battery temperature and SoC.

An evaluation of the adjusted scenario is depicted in Figure 9. The bus with the NMC-S battery charges in just 30 minutes with a C-rate of up to 2.8 C to an SoC of 80 %. The bus reaches the final destination in Karlsruhe 15 minutes faster with a SoC of 0.25 remaining. During the first driving section from Karlsruhe to Munich, the NMC-S battery does not rise in temperature, due to the low currents and correspondingly low irreversible heat flows. The reversible heat is mostly negative at the low SoCs, so the battery consumes heat. Both effects roughly cancel each other out resulting in a constant battery temperature at the initial 35 °C. The high currents during fast charging result in a heat flow of up to 300 kW for a short time. The battery temperature rises rapidly during charging to 67 °C, this is still below the set de-rating temperature of 70 °C for the solid-state battery. After charging, the battery is slowly cooled down to the operating temperature of 45 °C.

The slow cool-down is caused by the current thermal management battery cooling capacities. More data on degradation of solid-state batteries would be needed for evaluating if such high temperatures for a longer time accelerate battery degradation significantly. The thermal management could be re-designed for enabling higher battery cooling capacities. Different operating strategies optimizing battery degradation and thermal management energy consumption could be tested by system simulation as has been done before for battery-electric heavy-duty trucks (Hellmuth, Steeb, Pollak, et al. 2023).

4 Conclusions

In our study, we demonstrated that a physics-based full-vehicle Modelica model of a battery-electric coach paired with real-world drive scenarios can be used efficiently to compare different types and configurations of battery systems. We implemented battery data from a recent study (Yang et al. 2024) for a liquid NMC battery and a (semi-) solid-state battery into the vehicle model and designed different battery systems. Furthermore, we modeled a state-of-the-art thermal management system using the natural refrigerant R744.

Our results show that in general the higher internal resistances of solid-state batteries lead to higher heat production in the battery system. This is especially the case for fast-charging with high C-rates. The higher operation temperatures of solid-state batteries partially compensate for that. For normal driving of a coach, C-rates are typically very low, resulting in small heat loads. Additionally, the reversible heat plays a role, providing cooling at some operation points. In our first battery system design, both systems are sized for the same energy capacity. The NMS-S produces more heat, but saves weight and only heats up significantly during fast-charging. The maximum temperature during charging of 59 °C is still within the operation limits.

The second battery system design uses the same size or battery volume. Therefore, the solid-state battery has a 43 % higher energy capacity and respectively, lower C-rates during operation. Therefore, the heat production is in a similar range as for the liquid battery.

Future research should evaluate use cases for cold ambient temperatures and discuss battery pre-heating strategies and cold-start performances. Furthermore, battery waste-heat utilization for cabin heating should be explored. Battery degradation, cabin comfort goals as well as thermal management energy consumption should be considered. For this, different thermal management system topologies and operation strategies will need to be evaluated.

Acknowledgments

Our work was funded by the European Regional Development Fund (ERDF) in the EUROPA FÜR NIEDERSACHSEN funding as part of the TOFEBAS research project.
The authors would like to thank the student assistants Jonte Tiedemann and Luca-Leon Lohnert for their help in preparing the data and models.

Abstract

In this paper, we extend our previously presented lithium ion battery model to include electrochemical aging dynamics, considering both calendaric and cyclic aging behavior. Accordingly, the Equivalent Hydraulic Model (EHM) is augmented with side reactions for Solid Electrolyte Interphase (SEI) growth and lithium plating. The model is validated against experimental results, showing a level of agreement that allows us to evaluate the effect of various charging and cooling strategies under real-world duty cycles. A case study concerning a battery electric passenger vehicle that operates under changing seasonal conditions illustrates the advantages of using such a model. Results show that the vehicle thermal management and the recharge strategy play a critical role in ensuring a long and safe operational life. In particular, and in agreement with the existing literature, more frequent charges that maintain a lower average state of charge, together with a lithium plating conscious thermal management, significantly extend battery lifetime.

Keywords: batteries, electrochemical model, aging, vehicle thermal management

1 Introduction

The development and analysis of battery electric vehicles (BEVs) in the context of degradation presents multiple challenges. To begin with, the characterization of aging stress factors of commercial cells is a laborious and expensive task. Moreover, the real life operation of the battery packs, including the thermal management system (TMS) and battery management system (BMS), largely influence the way in which the individual cells of a battery pack will age.

Understanding the mechanisms by which the different functional components of a cell age is crucial. Safety can only be ensured if degradation is mitigated to the extent that batteries do not present hazardous behavior. Some relevant degradation mechanisms include: electrolyte decomposition, solid electrolyte interphase (SEI) growth and breakdown, gas evolution, overcharge, lithium plating, overdischarge, self-discharge, loss of active material, migration of soluble species, particle fracture, mechanical stress and structural changes (Arora, White, and Doyle 1998; Broussely 2002; Vetter et al. 2005; M. Broussely et al. 2005; Christensen and Newman 2006). Recent studies show that both SEI growth and lithium plating constitute the major drivers of aging under typical operating conditions (Ali et al. 2023; Che et al. 2023; Schlasza et al. 2014). Since battery degradation is caused by different stress factors, like high currents, extreme temperatures, or wide voltage windows, recommended limits have been developed to slow down or even avoid unnecessary damage (Fig. 1).

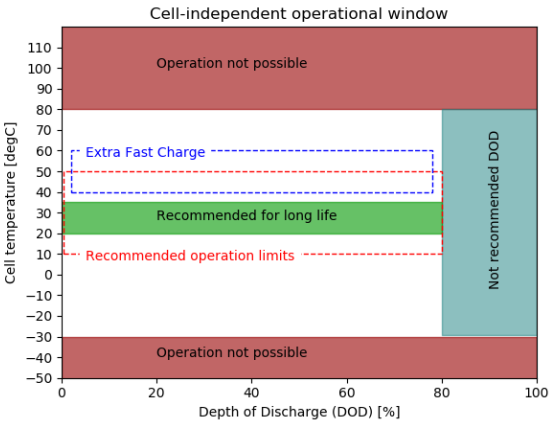

Figure 1. Summary of operational limits and recommendations for commonly used Li-ion cells (several sources)

Characterizing aging using mathematical expressions is needed to predict the likely degradation trajectory followed by the cell. Semi-empirical models have been proposed for this task as a default option because of its lower parametrization effort compared to physics-based models. The reader is referred to (Broussely et al. 2001; Ploehn, Ramadass, and White 2004; J. Wang et al. 2011; Rechkemmer et al. 2019) for different semi-empirical approaches. In general, however, these models can lump aging mechanisms unnecessarily, especially when more insight is needed in order to ensure a higher level of safety throughout the lifetime operation of the battery packs.

A novel physics-based aging model for Li-ion cells was described in (Yang, Leng, et al. 2017), that further enhances the electrochemical model previously developed by the authors (Gu and C. Wang 2000; Srinivasan and C.

Wang 2002). The aging model is based on the assumption that consumption of solvent and lithium plating (considered irreversible) contribute to the growth of the SEI layer, which in turns increases the film resistance and reduces the anode porosity. Since the aging model is applied on the so-called Newman's model (Marc Doyle, Fuller, and Newman 1993), the SEI growth and the appearance of lithium plating is spatially distributed. The model is reported to be effective capturing cyclic aging behavior observed experimentally.The approach is valid for the whole spectrum of C-rate and temperature when an Arrhenius dependency is added to the set of parameters (Yang and C.-Y. Wang 2018).

In a similar fashion (Li et al. 2019) adds an aging model on top of a reduced order electrochemical model, a further derivation of the Single Particle Model (SPM). This reduced order model assumes that the diffusion of lithium in the active material of the entire electrode can be represented by that of a characteristic spherical particle. The spatial gradient along the thickness of the electrodes, in the sense of concentration in solid and electrolyte phases, is therefore neglected. For a detailed description of the SPM and a discussion of the range of validity compared to the Newman's model, the reader is referred to (Chaturvedi et al. 2010).

Building upon these and more recent development in the area of Li-ion cells aging modeling, we have implemented a low complexity aging model that extends our previous reduced-order electrochemical mathematical description (Romero and Angerer 2023). The main feature of our contribution is the coupling of temperature sensitive aging dynamics, suitable for lithium plating side reactions in cyclic conditions (under load), together with calendaric (storage) degradation, all in a minimal implementation of the conservation laws in these kind of cells.

The remainder of the paper is organized as follows. First the electrochemical model with aging dynamics is presented. Next, we briefly describe the validation results for a particular cylindrical cell. A case study is subsequently introduced, and the result of the different operational alternatives analyzed. The last section is devoted to conclusions and future work.

2 Physics-based aging model implementation

2.1 Equivalent Hydraulic Model

The EHM has been used in the literature in order to capture electrochemical dynamics with the lowest mathematical complexity, in particular for control purposes (Romagnoli et al. 2017; Romero, Goldar, Couto, et al. 2019; Goldar et al. 2020). The previous application in the Modelica language was presented in (Romero, Goldar, and Garone 2019; Romero and Angerer 2023).

The EHM considers two electrochemical states, the bulk and surface concentration, in representative solid particles of the positive and negative electrodes. They are normalized with the maximum concentration ($c_{s,max}$) and denoted by SOC (state of charge) and CSC (critical surface concentration) respectively. If we assume that the intercalation dynamics is significantly faster in one of the electrodes (e.g. the positive), the SOC and CSC can be assumed identical and a linear combination of the bulk SOC of the other one (the negative). This assumption is needed for observability reasons(i.e., if the internal states need to be estimated from measured voltage and applied current, as it is normally the case) and can be justified depending on the chemistry and electrode design (Couto, Schorsch, et al. 2016). The model considers current density as input ($I = i/A_{cell}$, where A_{cell} is the electrode area, and i the electrical current, positive if discharge), which allows us to describe the dynamics independent of the cell size.

$$\frac{d\,\mathrm{SOC_n}}{dt} = -\gamma I \tag{1}$$

$$\frac{d\,\mathrm{CSC_n}}{dt} = \frac{g}{\beta(1-\beta)}\left(\mathrm{SOC_n} - \mathrm{CSC_n}\right) - \frac{\gamma}{1-\beta} I \tag{2}$$

$$\mathrm{SOC_p} = \rho\,\mathrm{SOC_n} + \sigma \tag{3}$$

$$\mathrm{CSC_p} = \mathrm{SOC_p} \tag{4}$$

$$V = U_p - U_n + \eta_p - \eta_n - \left(R_{cc} + \frac{R_{film}}{a\,l_n}\right) I \tag{5}$$

$$\eta_{p,n} = \frac{RT}{\alpha F} \sinh^{-1}\left(\frac{\theta_{p,n}\, I}{\sqrt{\mathrm{CSC_{p,n}}\left(1-\mathrm{CSC_{p,n}}\right)}}\right) \tag{6}$$

$$\gamma = \frac{3}{R_s\, a\, F\, l\, c_{s,max}} \qquad g = \frac{147}{20}\tau \qquad \beta = \frac{7}{10}$$

$$\tau = \frac{R_s^2}{D} \qquad a = 3\frac{\varepsilon}{R_s} \qquad \theta = \frac{1}{2\,a\,l\,r_{eff}\, c_{e0}^{1/2}\, c_{s,max}}$$

Equations 1-6, describe the dynamics of bulk and surface concentration, making use of lumped parameters γ, g, τ, and θ. They are used in the second-order Padé approximation (Couto, Schorsch, et al. 2016), and the overpotential η as defined in (Chaturvedi et al. 2010). The purpose of ρ and σ is to determine the static relationship between the state of charge of each electrode, which is a simplification of a more complex lithium dynamic balance. Their values (here -0.94 and 0.92 respectively) depend on the cell electrode design and formation process (Couto and Kinnaert 2018).

Open circuit voltages ($U_{p,n}$, dependent only on $\mathrm{CSC_{p,n}}$), overpotentials, and the internal resistances, are used to calculate the cell voltage. The previously so-called film resistance is now divided into pure ohmic losses (contact resistance, tabs and current collectors mainly, R_{cc}, and the SEI layer resistance R_{film}, time-dependent, which will be derived in the following section.

Exemplary parameters for a cylindrical 21700 Li-ion cell with a nominal capacity of 5 Ah are included in Table 1. Since the focus is on an EHM with fast dynamics

DOI 10.3384/ecp218841

in the cathode, only anode parameters are included. The values provided are temperature or concentration independent, except for r_{eff}, which is considered temperature dependent. The exact expression cannot be disclosed, but typically an Arrhenius relationship is used in the literature. Unlike our previous work, now the active material volume fraction (ε) changes in time as the battery ages. Accordingly, this variation represents the so called Loss of Active Material (LAM), and the details will be explained in the next section. For this reason, we considered ε_0 the initial value of the variable.

Table 1. Cell model parameters

Parameter	Units	Value
Electrode area, A_{cell}	[m^2]	0.1
Mass, m_{cell}	[kg]	0.07
Specific heat capacity, $C_{\text{p,cell}}$	[J/kg K]	800
Radial conductance, G_{rad}	[W/K]	1
Particle radius, R_{s}	[μm]	5
Electrode thickness, l	[μm]	80
Diffusion coefficient, D	[m^2/s]	1e-15
Active material vol. fraction, ε_0	%	75
Specific interfacial area, a	[m^2/m^3]	45e3
Effective reaction rate, r_{eff}	[$\frac{\text{A}}{\text{m}^2}(\frac{\text{m}^3}{\text{mol}})^{1.5}$]	7e-6
Maximum concentration $c_{\text{s,max}}$	[mol/m^3]	30e3
Electrolyte concentration, c_{e0}	[mol/m^3]	1200
Ohmic resistance, R_{cc}	[$\text{m}\Omega\,\text{m}^2$]	0.4

The thermal model assumes lumped properties concentrated on the cell core, typically the warmest region during normal operation. The thermal resistance consists of a serial summation of convection and conduction terms (external and internal heat flow respectively)

$$m_{\text{cell}} C_{\text{p,cell}} \frac{dT}{dt} = i(V - (U_{\text{p}} - U_{\text{n}}) + T\,(\frac{\partial U_{\text{p}}}{\partial T} - \frac{\partial U_{\text{n}}}{\partial T})) - \frac{1}{R_{\text{th}}}(T - T_{\text{amb}}) \quad (7)$$

$$A = \pi D H_{\text{c}} \quad R_{\text{th}} = (\frac{1}{4\pi H_{\text{c}} k} + \frac{\ln(D_{\text{can}}/D))}{2\pi H_{\text{c}} k_{\text{can}}} + \frac{1}{hA})$$

where R_{th} is the thermal resistance of the lumped thermal model of the cell, h is the heat transfer coefficient w.r.t. the cooled/heated section, and $\frac{\partial U_{\text{p(n)}}}{\partial T}$ define the so called entropic heat of the positive (negative) electrode (Dao and Schmitke 2015). We note here that this model approximates the behavior of an infinite cylinder with homogeneous heat generation. In reality, the active cooling/heating area is limited to a portion of the total height of the cell (assuming side cooling), while the rest is cooled passively by natural convection typically with the surrounding air. The cell housing conductivity is high enough, and its thickness sufficiently small, to neglect its contribution in the total resistance. The core to surface conductance in radial direction can be simplified as G_{rad}. The entropic heat, as well as the heat transfer to the air, can also considered to be negligible. Thus, the simplified model can be reduced to

$$m_{\text{cell}} C_{\text{p,cell}} \frac{dT}{dt} = i(V - (U_{\text{p}} - U_{\text{n}})) - UA\,(T - T_{\text{amb}}), \quad (8)$$

where U is the so called overall heat transfer coefficient, which includes internal conductance and external convection terms.

2.2 Aging model

The extension of the electrochemical model is based on the work of (Yang, Leng, et al. 2017). Our adaptation considers the main assumptions:

1. Main aging mechanisms are surface film (SEI) growth, irreversible lithium plating, and loss of active material
2. Negligible aging in cathode material
3. Homogeneous degradation throughout the electrode volume.

The first two assumptions are compatible with the model described in (Yang, Leng, et al. 2017), and the last one is required by the nature of the EHM. In their work, two states are needed to define the accumulated aging, namely the reacted ethylene-carbonate to form new SEI (c_{SEI}) and the lithium plated (c_{Li}). This accumulation in the form of molar concentrations (per unit volume of the electrode) can be represented in the following differential equations

$$\frac{dc_{\text{SEI}}}{dt} = -\frac{j_{\text{SEI}}}{2F} - \frac{j_{\text{lpl}}}{F}\chi \quad (9)$$

$$\frac{dc_{\text{Li}}}{dt} = -\frac{j_{\text{lpl}}}{F}(1 - \chi). \quad (10)$$

where χ is considered null as in the referenced work for simplicity. These two products form the so called SEI layer, a surface film whose thickness is proportional to their accumulation around the surface of the active material particles, or in mathematical form,

$$\delta_{\text{film}} = \frac{1}{a}(\frac{c_{\text{SEI}} M_{\text{SEI}}}{\rho_{\text{SEI}}} + \frac{c_{\text{Li}} M_{\text{Li}}}{\rho_{\text{Li}}}), \quad (11)$$

where $M_{\text{SEI(Li)}}$ and $\rho_{\text{SEI(Li)}}$ are the molar weight and density of each aging products. The thickness of the SEI layer defines in turns its resulting ionic resistance

$$R_{\text{film}} = \omega_{\text{SEI}} \frac{\delta_{\text{film}}}{K_{\text{SEI}}}, \quad (12)$$

with ω_{SEI},K_{SEI} being the volume fraction of SEI in the film and the ionic conductivity respectively .

At this point, we introduce the alternative approach with respect to the work of (Yang, Leng, et al. 2017). Instead of assuming that the drop in porosity dominates the aging behavior, caused by the clogging of the void fraction by the SEI growth, we focus on the loss of active material degradation mechanism. Since the EHM neglects the transport dynamics in the electrolyte, it is not directly affected by changes in porosity. In contrast, one could associate the SEI buildup to the progressive isolation of active material regions, causing an apparent loss of active material (aLAM). This approach is similar to that found in (Li et al. 2019), originally proposed by (Fu et al. 2015). Accordingly, we can define the loss of active material as the decrease in active material volume fraction (ε)

$$\frac{d\varepsilon}{dt} = -a\frac{d\delta_{\text{film}}}{dt}, \tag{13}$$

where it is explicit that the volume loss of accessible active material is proportional to the SEI volume increase. Equation 13 constitutes the derivative of the third aging state variable. This approach is similar to that followed by MapleSim's Battery Component Library (MapleSoft 2025), where the normalized remaining capacity depends on a cubic function of the SEI thickness. Therefore, our solution is a compromise between empirical simplicity and physical fidelity.

SEI growth is dominated by the concentration of ethylene-carbonate in the SEI layer and its thickness. The expressions found in (Yang, Leng, et al. 2017) were found to be suitable for our model in predicting cyclic aging, the original purpose of the model, but not calendaric aging. Therefore, a modified version of their work is presented here.

The volumetric current density associated to the SEI side reaction can be expressed as:

$$j_{\text{SEI}} = -a\,F\,k_{0,\text{SEI}}\,c_{\text{EC}}^{\text{s}} \exp\left(-\frac{\alpha_{\text{c,SEI}}\,F}{RT}\left(\phi_{\text{s}} - \phi_{\text{e}} - \frac{j_{\text{tot}}}{a}R_{\text{film}} - U_{\text{SEI}}\right)\right) \tag{14}$$

where j_{tot} is the current density, $k_{0,\text{SEI}}$ the reaction constant, and c_{EC}^{s} is the concentration of EC (ethylene carbonate) on the surface of the graphite (Yang, Leng, et al. 2017) or, more precisely, in the SEI layer (Zhao, Choe, and Kee 2018). According to the former, the solvent concentration can be computed with the following algebraic equation

$$-D_{\text{EC}}\frac{c_{\text{EC}}^{s} - c_{\text{EC}}^{0}}{\delta_{film}} = -\frac{j_{\text{SEI}}}{F} \tag{15}$$

which neglects the time dependency of the diffusion process.

The diffusion of EC is considered to be enhanced with temperature, as remarked by (Zhao, Choe, and Kee 2018) following the Arrhenius form

$$D_{\text{EC}} = D_{\text{EC,0}}\exp\left(\frac{E_{\text{a}}}{R}\left(\frac{1}{T} - \frac{1}{T_{\text{ref}}}\right)\right). \tag{16}$$

Most studies on physics-based aging models focus on cyclic aging, where these are fitted to match experimental results under cyclic loading. Research shows (Jin and Liu 2019) that it is possible to derive the calendaric aging based on the concentration of products and reactants in the SEI layer, an approach which may lead to a better performance of the model, both for cyclic and calendaric aging. We have opted for a hybrid approach, where the diffusion of EC during storage conditions depends on the state of charge and the temperature

$$D_{\text{EC}} = k_{\text{cal}}D_{\text{EC,0}}\,\text{SOC}\exp\left(\frac{-E_{\text{a}}}{R}\left(\frac{1}{T} - \frac{1}{T_{\text{ref}}}\right)\right), \tag{17}$$

where k_{cal} limits the increase of calendaric aging as the SOC tends to 100% compared with the cyclic aging. The proportionality with SOC allows to also increase the observed impact of high SOC storage, which may not be captured completely in Eq.(14). This expression has been developed to mimic the behavior of the calendaric aging of the cell considered, but adjustments for alternative chemistries are possible.

Lithium plating is a phenomenon that tends to take place in the interface between anode and separator, and the last assumption is only justified because the aim of the aging model is mainly to capture the cycle or point in time when lithium plating starts occurring. As indicated in the literature (Yang, Leng, et al. 2017), as the SEI grows, the likelihood of plating increases. Therefore, a charging cycle that does not trigger lithium plating in a fresh cell, may do so after certain time in operation. It will be shown, nonetheless, that a model with homogeneous lithium plating captures the capacity loss when it takes place reasonably well, causing the rapid deterioration of the electrode. According to (Yang, Leng, et al. 2017), the side reaction current associated to lithium plating can be formulated as

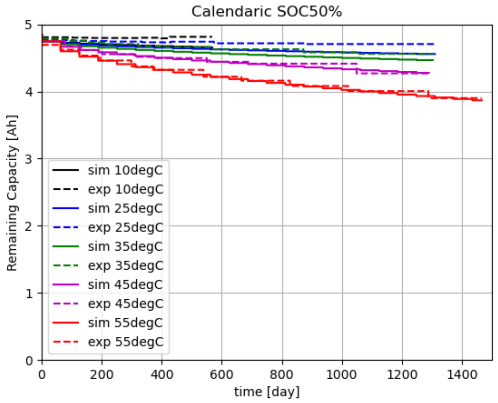
$$j_{\text{lpl}} = -a\,i_{0,\text{lpl}} \exp\left(-\frac{\alpha_{\text{c,lpl}}\,F}{RT}\left(\phi_{\text{s}} - \phi_{\text{e}} - \frac{j_{\text{tot}}}{a}R_{\text{film}} - U_{\text{lpl}}\right)\right) \tag{18}$$

where $i_{0,\text{lpl}}$ is the exchange current density of the lithium plating reaction. It should be noted that this side-reaction is active if the anode potential drops below the Li/Li^{+} equilibrium potential (U_{lpl}), and zero otherwise.

These equations and similar ones have been applied to electrochemical models of Li-ion cells, including SPM (Li et al. 2019). Since the EHM assumes constant electrolyte concentration, and it is therefore not modeled, the overpotential of reactions necessary to calculate the side reaction currents are expressed as follows:

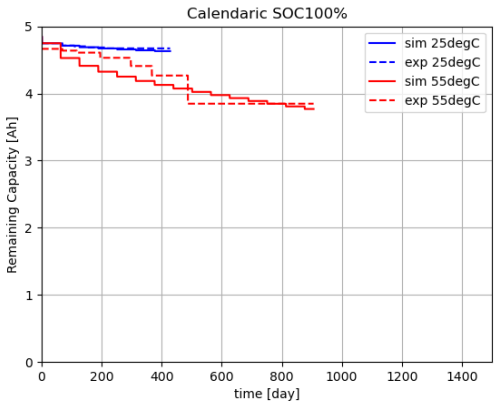
$$\begin{aligned}\eta_{\text{SEI}} =& \phi_{\text{s}}^{-} - \phi_{\text{e}}^{-} + \frac{j_{\text{tot}}}{a^{-}}R_{\text{film}} - U_{\text{SEI}} = \\ & \eta^{-} + U^{-}(\text{C}_{\text{ss}}^{-}) - U_{\text{SEI}}\end{aligned} \tag{19}$$

DOI 10.3384/ecp218841



$$\eta_{\mathrm{lpl}} = \phi_{\mathrm{s}}^{-} - \phi_{\mathrm{e}}^{-} + \frac{j_{\mathrm{tot}}}{a^{-}} R_{\mathrm{film}} - U_{\mathrm{lpl}} = \eta^{-} + U^{-}(\mathrm{C}_{\mathrm{ss}}^{-}) - U_{\mathrm{lpl}} \tag{20}$$

In order to avoid side reactions, the overpotential of the considered side reaction should always be non-negative:



$$\eta_{\mathrm{SR}} = \eta + U(\mathrm{CSC}) - U_{\mathrm{SR}} \geq 0. \tag{21}$$

3 Model calibration

In the first place, the chemistry and the main parameters of the electrochemical model were determined. The cathode composition is high-niquel NMC, and the anode contains mainly graphite as active material, as external laboratory analysis indicate. The total capacity is 5 Ah approximately, and the format is the conventional cylindrical 21700 (21 mm diameter, 70 mm height). Parameters concerning geometry (electrode area and thickness, particle diameter) and weight where measured either in-house or by an external laboratory. The active material fraction was adjusted from a reference value borrowed from the literature (Chen et al. 2020). Thermal behavior ($C_{\mathrm{p,cell}}$, G_{rad}) could be adjusted from a large variety of input-output data from experimental tests under different boundary conditions (free convection at room temperature, controlled temperature chambers with forced air flow, and immersion cooling). The pure ohmic resistance was determined from ACIR (Alternating Current Internal Resistance at high frequency). Diffusion coefficients in the solid phase, as well as the remaining electrochemical properties (including $U_{\mathrm{p,n}}$) were adjusted from different literature sources or external laboratories. Values reported in Table 1 must be taken as exemplary, since the actual values are are kept confidential.

The required cyclic and calendaric aging tests have been conducted in-house to adjust the parameters of the aging model. Exemplary values are given in Table 2 since the actual ones cannot be disclosed. In addition, literature data and sensitivity analyses have been used to best characterize the cyclic and calendaric aging behavior. More specifically, U_{SEI} is taken from (Zhao, Choe, and Kee 2018), while the remaining parameters were taken directly from (Yang, Leng, et al. 2017), or adapted from this source (mainly D_{EC}, Ω_{SEI}). The activation energy was directly fitted from experimental data. Different temperature and SOC storage conditions were used in the storage tests (Fig. 2), while different current and temperature values were used under cycling, with emphasis on the corner cases where lithium plating was observed (Fig. 3). The observation involved a non-linear, accelerated capacity drop, as well as *post mortem* tear-down examinations. In particular, tests with CCCV charges 0.7C and 1C were chosen at temperatures below which, according to the manufacturer, lithium plating may occur (25°C and 35°C respectively).

4 Case study

In order to highlight the benefits of the model presented above, we conducted a set of tests with varying operating conditions that affect the rates of calendaric and cyclic aging. The target cell corresponds to cylindrical cell similar to that described in previous sections. The full description of the pack, which uses immersion cooling in direct contact with the cells can be found in (Romero and Angerer 2023). Its size (60 kWh) is similar to that of a pack for mid-size battery electric vehicles. Only the behavior of a single cell is analyzed here, as though all cells would operate under the same boundary conditions. In reality, the resulting temperature spread within the pack will lead to heterogeneous aging, but this is out of the scope of this work.

All models described in this paper have been implemented in Dymola, but compatibility with other Modelica tools, i.e., OpenModelica, was ensured. Before describing the boundary conditions and the case study, we introduce two key components included in the case study simulation template.

4.1 Thermal control

Electric vehicles use a sophisticated thermal management system, with control algorithms set to ensure an optimal operating temperature window. In our application, we define a hysteresis loop with immersion cooling (ON: 30°C, OFF:25°C) and heating (ON: 10°C, OFF:15°C) that ensures practical operational temperatures. Sufficient thermal power is assumed, with a fixed temperature source of 30°C when heating and 25°C when cooling. In addition to the active cooling boundary, the cell model is thermally connected to the environmental temperature. The active thermal management guarantees around 100 W/m^{2}K of heat transfer. A convective overall heat transfer coefficient to the ambient of 1 W/m^{2}K is assumed. Both values have been experimentally determined for the pack considered where the cells are installed, and approximate values are reported.

4.2 Cycler

Modelica classes have been developed to automate, in a virtual environment, the classical laboratory performance and cyclic aging. This includes lifetime simulations, where a rich set of mixed protocols are linked sequentially. This includes, e.g., CCCV charges and discharges, duty cycles, capacity check cycles, and DCIR tests. The `ModelicaStateGraph2` library (Otter, Årzén, and Dressler 2005) is used to control the cycler states, but the building philosophy could be adapted to other similar libraries. An example of a custom cycler with profile input during the discharge state (without opportunity charge) is shown in Fig. 4. It must be noted that current, voltage or power are assigned in the equation section in the text layer (not shown here). The cycler variant used assumes eight different states or steps:

1. Initial step
2. Pre-charge
3. Constant current charge
4. Constant voltage charge
5. Idle time after charge
6. Pre-discharge
7. Duty-cycle
8. Pre-opportunity charge
9. Opportunity charge
10. Idle time after discharge.

Every day, a number of duty-cycles are repeated before and after a mid-day break, which considers a typical daily commute, including weekend leisure usage. Charging is allowed during nights of certain days (Wednesday, Saturday and Sunday) at a C-rate of 0.1C (w.r.t. nominal energy, 18 Wh), but opportunity charging below certain voltage is also possible (0.7C w.r.t. nominal capacity, 5 Ah). The effect on aging of these two charging possibilities is compared below.

The automotive driving profile was provided by Centro Ricerche FIAT (CRF) at cell level. The final power was re-scaled for an equivalent battery size of 50 kWh. The profile represents a typical WLTC with a duration of approximately 23 km and 1800 s. In the first option (light usage), we consider it is repeated once (1xWLTC) in the morning and once in the afternoon. In a second option (moderate usage), we increase to 2xWLTC, morning and

DOI 10.3384/ecp218841

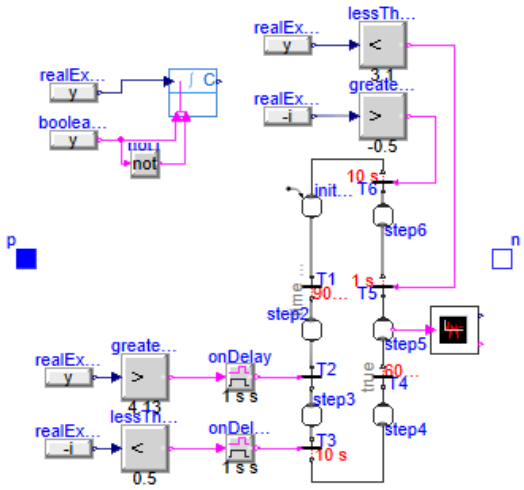

Figure 4. Simple cycler with power profile discharge using `ModelicaStateGraph2`

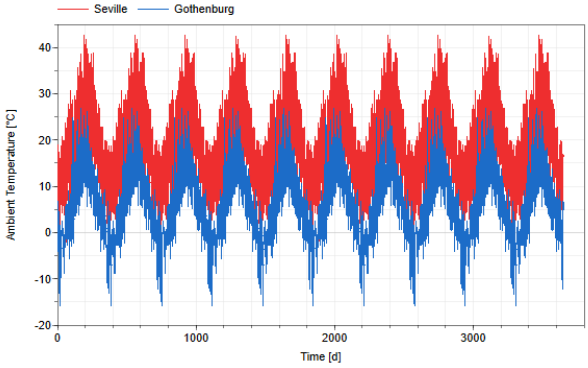
afternoon. Each of these options relate to vehicles driving around 150 and 300 thousand kilometers within ten years respectively.

4.3 Additional boundary conditions

Two locations are considered in our study, namely Seville and Gothenburg. They present two extreme climatic options, represented by their ambient temperature (Fig. 5).



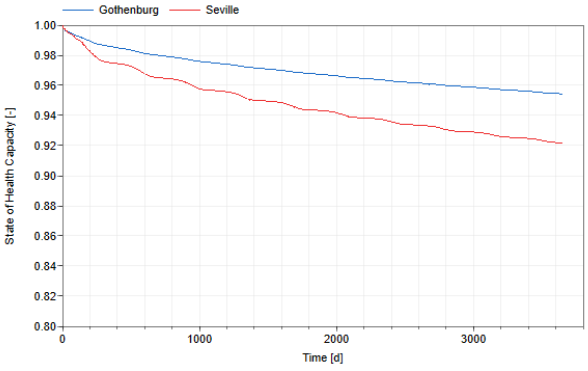


Figure 5. Local ambient temperatures (dry-bulb). Source: https://pvwatts.nrel.gov/

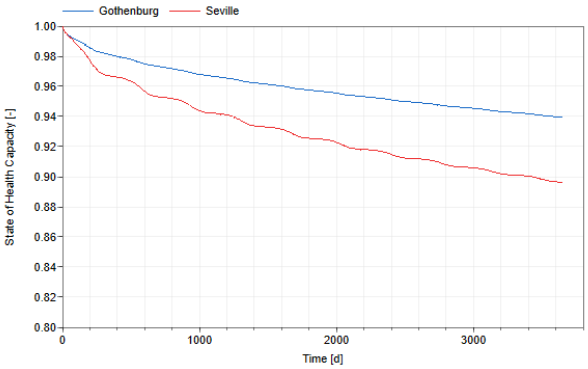
5 Results



5.1 Night charge

We first compare different levels of usage of the battery in Seville and Gothenburg for the night charge condition. Results are shown in Fig. 6 including light and moderate usage and default thermal management, as well as moderate usage and higher temperature cooling.

Figure 7 present results for simulations where thermal control for cooling is limited to an hysteresis loop between 40°C (ON) and 35°C(OFF). This setup affects mainly Seville, since Gothenburg's temperatures seldom reach 35°C.

(a) 2xWLTC per day

(b) 4xWLTC per day

Figure 6. Comparison between the effect of number of cycles per day and ambient temperature

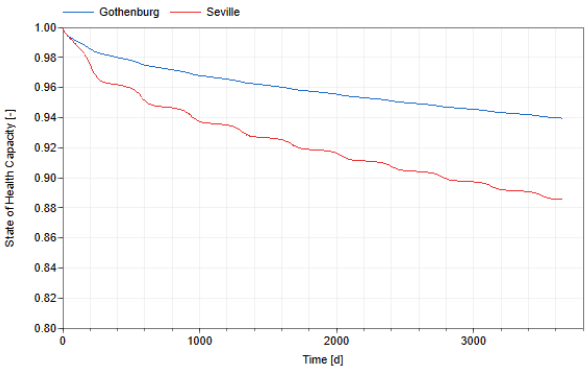


Figure 7. 4xWLTC per day, two locations, higher cooling temperatures

For the case in which the lower temperature is not sufficiently limited by the battery heater (i.e., hysteresis setup 5°C(ON), 10°C(OFF)), the battery may charge or regenerate energy in conditions close to lithium plating. We have also considered the fact that the thermal management is not active during the idling period, which exacerbates the impact of low temperatures (Fig. 8).

For comparison, Fig. 9 illustrates the effect of each charging strategy on the voltage during two consecutive weeks. It can be seen that in both cases the anode potential drops below the lithium plating threshold.

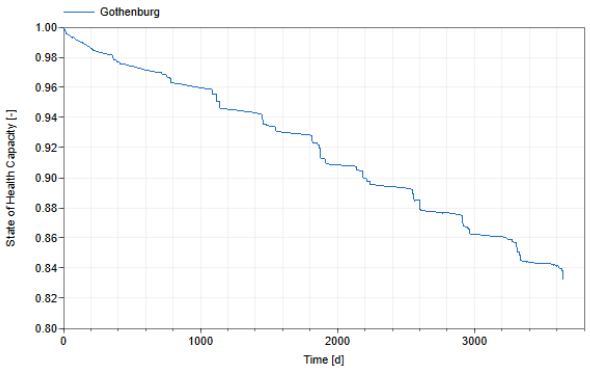

Figure 8. 4xWLTC per day, Gothenburg, lower heating temperature

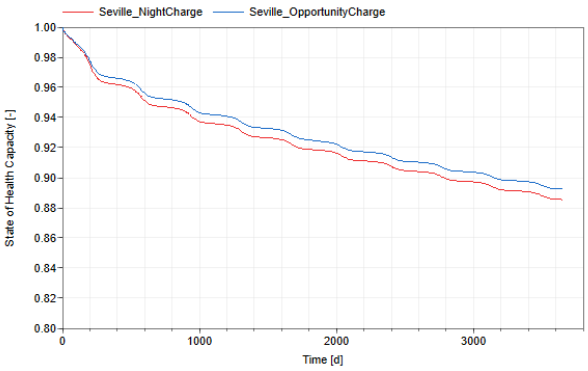

Figure 10. Remaining capacity results considering night and opportunity charge options

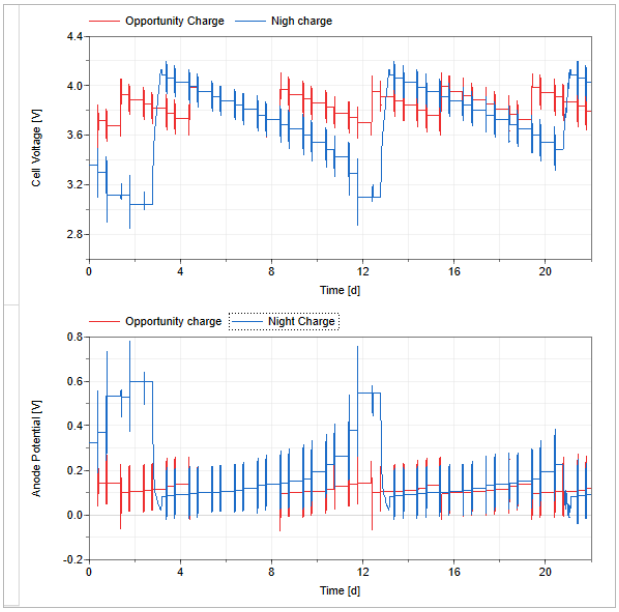

Figure 9. Cell voltage and anode potential considering night and opportunity charge options

5.2 Frequent charges at medium SOC

Finally, we present the results for the case in which the battery is allowed to recharge on-demand if the cell voltage drops below 3.6V, which leads to a lower DOD at lower SOC as in the previous case. As shown in Fig. 10, the opportunity charge can extend the life of the battery by over 400 days compared to night charge for the same SOH. This is so because the cell remains at a higher SOC for longer time than in the opportunity-charge strategy.

To minimize aging, as the literature indicates and we have seen in simulation, charging voltages and DOD should be selected as a function of the available charging locations and times, the daily usage, etc. We have discussed two cities with opposite climatic conditions. It is expected that locations with milder temperatures will require less energy for the thermal management (heater, chiller, etc.) and will result in intermediate SOH trajectories, assuming that the protection against plating is ensured.

6 Conclusions and future work

Aging of lithium ion batteries is a complex and challenging research area, and affects the safety and economics of electrification. This is of special importance in transportation electrification, where the multi-physics approach allows us to explore the effect of driving patterns, charging strategies, weather conditions and, more importantly, the particular aging dynamics of every cell chemistry.

Since full order electrochemical models with aging are computationally expensive and difficult to parameterize, we propose a reduced order model with SEI growth and lithium plating dynamics. The fitting effort is lower for the typical set of calendaric and cyclic tests, and conservative margins can be added to deal with parameter uncertainty and model limitations to better describe operational limits. As an example, we simulated different charging and thermal management strategies. Results show that lower temperatures and more frequent charging that reduce DOD and average SOC are beneficial, provided that anode potentials can be kept above the lithium plating onset.

Ongoing efforts are focused on improving the fidelity of the EHM, which involves an extension to cover electrolyte concentration dynamics (EHMe), as well as a P2D version with minimal discretization complexity to compare the influence of model inaccuracies. Additionally, experimental tests are currently being conducted to verify the simulated results presented.

Abstract

The integration of Functional Mock-up Units (FMUs) enables effective multi-domain co-simulation and model exchange, offering new possibilities for energy systems modelling considering thermo-hydraulic aspects. This paper presents a case study on incorporating an FMU of a seasonal thermal energy storage (sTES), developed in Modelica/Dymola, into a MATLAB/Simscape model of a thermal source network (TSN). While traditional thermo-hydraulic models are typically confined to a single simulation environment, this study demonstrates the feasibility and advantages of FMU-based interoperability between Modelica/Dymola and MATLAB/Simscape.

A key focus is the methodological approach for integrating FMUs into Simscape, addressing interface requirements, solver settings, and model coupling challenges. To illustrate the impact of FMU integration, the authors present simulation results for exemplary operation scenarios: TSN operation with and without an sTES. Additionally, our simulation results offer valuable insights into the influence of sTES on TSN operation and system layout.

Keywords: Functional Mock-up Unit (FMU), Thermal Source Network (TSN), Seasonal Thermal Energy Storage (sTES), MATLAB/Simscape, Modelica/Dymola, Thermo-Hydraulic Modelling

1 Introduction

The ongoing development of heating and cooling networks, such as district heating systems, requires constant integration of emerging technologies and components. Carefully planning these evolving systems demands flexible modelling approaches, which can be challenging when specialized models for new components reside in different software environments. For instance, an advanced sTES model might be developed in Modelica, whereas other system elements or advanced control libraries might only be available in MATLAB/Simscape. In many research and industrial settings, software licensing constraints further limit the ability to adopt multiple environments simultaneously, constraining researchers and engineers to a single "in-house" simulation tool.

To overcome this shortcoming, FMUs have recently gained traction as an enabling technology for sharing tailored simulation models across diverse platforms. By exporting a component from one domain and importing it into another, FMUs allow modelers to exploit specialized models without having to re-produce or re-validate them. This interoperability is particularly valuable in modelling of thermal source networks, where accurate representations of devices such as sTES units are essential for analysing and optimizing network performance.

This paper aims to demonstrate the feasibility of integrating a sTES model, originally developed in Modelica, into a TSN model built in MATLAB/Simscape using the Functional Mock-up Interface (FMI) standard. This approach enables the reuse of a validated sTES model, thereby avoiding the need for reimplementation and validation in Simscape. The study focuses on two core aspects of feasibility: (1) the technical effort required to set up the interface and configure the inputs and outputs, and (2) the stability and computational efficiency of the resulting co-simulation. Two realistic operational scenarios are evaluated as use cases: first, TSN operation without an sTES, and second, TSN operation where the sTES is coupled via a heat exchanger. Overall, this study shows how FMU-based co-simulation can increase the flexibility of thermo-hydraulic modelling across tools and domains, reducing software-related barriers in academic and industrial contexts.

2 Background and Related Work

The planning and design of sTES systems is a highly interconnected and complex process, requiring the evaluation of multiple parameters such as volume, geometry, insulation quality, and system integration (Dahash et al. 2019b). To mitigate risks associated with real-world implementation and to ensure feasibility and

effectiveness, modelling and simulation have become integral to sTES system planning. Moreover, energy system simulations are well-suited for evaluating integration strategies and control approaches that optimize system operation. Commonly used energy system simulation (ESS) tools include TRNSYS, EnergyPlus, Modelica/Dymola, MATLAB/Simulink, and Simscape.

Among these, TRNSYS has been widely adopted for modelling buried water-based TES, owing to its modular structure and availability of specific models like XST and ICEPIT, which facilitate coupling with buildings, heating plants, and other system-level components. For instance, (Li et al. 2019) used the Type 534 model to simulate a 3000 m³ pit sTES in a solar-assisted district heating system, evaluating different control strategies.

On a bright note, other environments have also explored buried sTES modelling. For example, (Dahash et al. 2020) developed and validated a buried tank sTES model in Modelica/Dymola, coupled with a ground model. However, this work was limited to component-level simulations and did not address the broader energy system context. Similarly, (Bott et al. 2022) developed an underground sTES model in MATLAB/Simscape, benefiting from its multi-domain capabilities. Yet, this model also focused exclusively on component-level analysis.

Consequently, validated sTES models integrated into full energy system simulations remain rare. In this context, co-simulation emerges as a promising solution, allowing the integration of component-level sTES models into broader system-level simulations. (Lyden et al. 2022) highlighted this gap, especially for borehole and aquifer TES models, while (Dahash et al. 2019b) noted a similar lack for pit and tank TES technologies.

To address this gap, the present work focuses on two key objectives:

1) Co-simulation of sTES and energy systems through the integration of an sTES Functional Mock-up Unit (FMU) into a top-level model of a real-world energy system, and
2) Optimization of system operation by evaluating the impact of sTES integration compared to a reference case without sTES.

3 Description of the Thermal Source Network

The TSN at the incampus site in Ingolstadt, Germany, serves as the case study in this work.

3.1 Overview of the Case Study

The TSN at the incampus in Ingolstadt (DE), is a pioneering energy system designed to facilitate CO_2-neutral industrial energy supply. The system's core principles include sustainability, modularity, and long-term viability (Müller et al. 2024). Due to the lower system temperature, the TSN offers a significant flexibility in integrating renewable and low-temperature energy sources, unlike conventional district heating systems. Key components in this system approach are decentralized heat pumps, which enable each building to extract or reject heat from/into the system independently from the TSN temperature level.

The incampus TSN undergoes development in multiple construction phases, eventually spanning 9 km of piping and connecting approximately 70 buildings, including:

- Offices, laboratories, and test benches, each with their own decentralized heat pump.
- A data centre acting as a major source of waste heat.
- Energy storage and distribution components, including an sTES and firefighting water tanks repurposed as thermal buffers.

A distinguishing feature of this TSN is that its pipes are uninsulated, allowing for thermal interaction with the surrounding ground. Unlike conventional district heating, where insulation is used to prevent energy loss, this TSN leverages its thermal environment as part of the storage and distribution system, potentially gaining heat or dissipating excess energy depending on the operational strategy. This can be attributed to the temperature levels foreseen in this TSN.

3.2 Energy Flows and System Operation

The TSN operates by balancing local, renewable, and waste heat sources with building-level heating and cooling demands. Unlike conventional heating networks, it functions bidirectionally, meaning buildings can both consume and supply heat leading to the so-called "prosumers." For this, each building is equipped with a decentralized heat pump, which allows it to either extract heat from the TSN for heating or reject excess heat into the network for cooling when operating in reverse operation.

The key energy sources include:

- Waste heat from the data centre (initially 1.83 MW, expandable to 3 MW), a stable and continuous source of low temperature heat in in the range of 18 to 38°C.
- Groundwater wells (1 MW thermal power), originally installed for remediation purposes and later adapted for thermal energy exchange.
- The Danube River (up to 10 MW thermal potential) as an additional cooling and heating source.
- Re-cooling plants (6 MW cooling capacity) for peak load scenarios.
- A seasonal thermal energy storage, designed as a water-gravel pit storage, re-purposing existing basin infrastructure, which reduces investment costs.

The primary objective of the system's control strategy is to balance and manage energy flows dynamically while minimizing operational costs, which for example depend on thermal losses or electricity consumption of heat

DOI 10.3384/ecp218851

pumps. The primary challenge in operating the TSN is finding the optimal strategy for system-wide efficiency. Accordingly, decisions shall be made regarding:

- The optimal TSN supply temperature levels to minimize losses while maximizing heat pump efficiency.
- The selection of thermal sources at different times considering cost, availability of renewable energy or other factors.
- The charging and discharging strategy of the sTES.

3.3 Motivation for FMU-Based Modelling of the TSN

To evaluate and validate different control strategies for the described system, a physical simulation model is a valuable tool. In general, FMUs can be utilized to integrate advanced, pre-existing simulation models of key components, which gives greater flexibility in testing and validation. Herein, this approach also might allow for faster and more accurate simulations, as an existing state-of-the-art sTES model developed in Modelica was directly incorporated rather than recreated in MATLAB/Simscape.

4 MATLAB/Simscape Model Development

4.1 Overall Model Structure

The MATLAB/Simscape implementation is encapsulated in a single .slx file, referencing a custom library to emulate the incampus with four main categories: Energy Hub, Pipes, Substations/Heat Pumps, and Buildings/ Loads.

All basic components which are used in the main subsystems have been taken from the two Simscape libraries *Fluids/Thermal Liquid* and *Foundation Library/Thermal.* The Simscape Toolbox is a MATLAB/Simulink add-on with a physically based, acausal modelling approach. It differs from the causal MATLAB/Simulink approach but is similar to the philosophy of Modelica/Dymola or other tools. This structure automatically derives the governing equations from the topology of the system, making it well suited to multi-domain energy systems. However, this approach has rarely been explored in Simscape (Dahash et al. 2019a).

In the base model, the sTES FMU is not yet included. However, an additional heat exchanger is already integrated into the Energy Hub to facilitate future FMU connections. Specific interface details are provided in Section 5.2 FMU integration.

4.2 Sub-Model Groups and Assumptions

Energy Hub

The Energy Hub comprises separate Simscape blocks for its centrifugal pump, heat exchangers, flow-coefficient valves, and a buffer tank (see Figure 1):

- **Pump:** A variable-speed centrifugal pump, parameterized with reference head/capacity curves, maintains the required volume flow in the TSN.
- **Heat Exchangers:** Two standard Simscape exchanger blocks connect the TSN to data centre waste heat and groundwater wells. A third exchanger is reserved for integrating the sTES FMU. Other heat exchangers to additional thermal sources were omitted.
- **Valves:** Simple flow-coefficient valves direct water through the appropriate heat exchanger or buffer tank, depending on an on/off control signal.

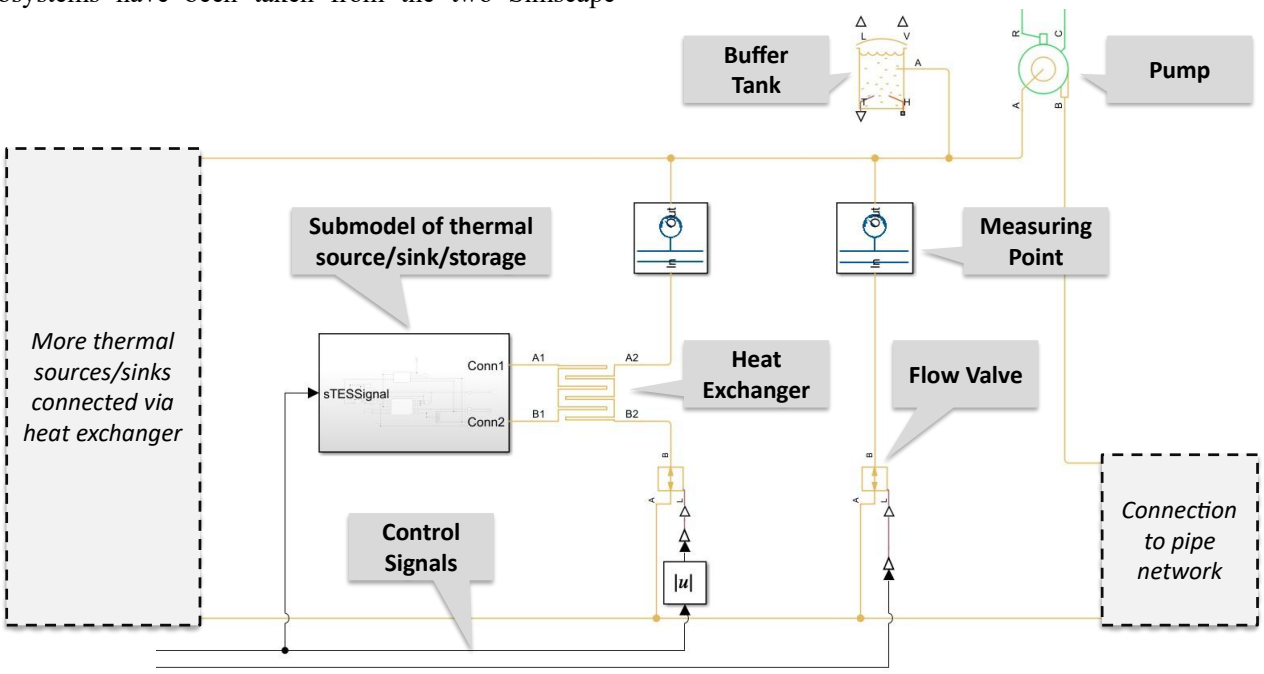

Figure 1. Components and Connections of the Energy Hub Sub-Model.

- **Buffer Tank:** Mainly accommodates thermal expansion (i.e. expansion vessel) in the simulated scenarios.
- **Measurement and Control:** The Hub's interfaces with the TSN piping and the thermal sources are monitored by thermal/hydraulic sensors (flow, pressure, temperature).

Pipes

The supply and return lines of the TSN are each represented by *Pipe (TL)* blocks from the Simscape *Fluids/Thermal Liquid* library, sized according to the incampus layout.

These blocks represent:

- Pressure Drop due to viscous friction.
- Heat Transfer with a seasonally varying ground temperature, using a fixed thermal resistance for the pipe wall.

To capture changes in diameter and branching points for buildings, the network is divided into multiple pipe segments. Thermal capacities of the pipe wall and ground are herein neglected. Flow is governed by the central pump in the Energy Hub, with no additional regulation in the pipes themselves. Pressure and temperature sensors placed at key nodes monitor conditions for system control and analysis.

Substations/Heat pumps

Each building in the TSN is equipped with a single heat pump block, which interfaces between the TSN and the building's heating and cooling circuits. Physically, this design yields six connection ports: supply and return lines for the TSN, and separate supply and return lines for both the heating and cooling circuits on the building side, all in the thermal liquid domain. In practice, the heat pump acts as a mediator, drawing energy from (or rejecting energy to) the TSN as required to satisfy the building's thermal demands.

Within the heat pump model, a Carnot-based approach is used to capture energy flows rather than simulating the full refrigeration cycle. In particular, the model measures the evaporator and condenser temperatures to calculate the theoretical Carnot efficiency, which is then scaled by a Carnot effectiveness factor (typically 0.4 to 0.5 for water-to-water heat pump units). This simplification emerges as a balance between realism and computational efficiency by focusing on overall heat exchange and compressor power, rather than diving into detailed phase-change processes and fluid properties.

From an operational perspective, the heat pump is capable of switching between four distinct modes: 1) heating (with the TSN serving as the heat source), 2) free cooling (where no compressor action is required and the TSN serves as the heat sink), 3) mechanical cooling (with the compressor actively dissipating heat into the TSN via the condenser), and 4) dual operation (with simultaneous building heating and cooling, using the TSN to cover any unbalanced demand).

The operation of these modes is governed by a local control scheme focusing on target supply temperatures in the building's heating and cooling circuits, along with the mass flow present in each loop. At instances where flow exceeds a pre-determined threshold, the heat pump starts automatically, with the objective of maintaining the selected supply temperature. The maximum power output is then limited by a rated thermal capacity. On the TSN side, the reference mass flow is calculated with respect to a prescribed temperature difference between TSN supply and return.

The heat pump model logs thermal energy flows and mass flow rates within the connected circuits, while alongside providing the COP and compressor power consumption as outputs.

Buildings/Loads

Currently, the incampus area is still under development and only two buildings from construction phase one are connected to the TSN (next to the Energy Hub and the Data Centre). Thus, this work simulates a future scenario where two more buildings are connected to the TSN.

The load profiles of the buildings are derived from planning documentation for the incampus energy system. This report provided the total floor area of each planned building, along with its annual heating and cooling energy demands (expressed in kWh/m²a) and peak thermal loads (in kW/m²). By virtue of this data, hourly heating and cooling profiles can be generated for each building and implemented as input signals for the heat flow sources.

Each building model comprises two separate circuits: one for heating and one for cooling. These circuits are each connected to an individual buffer tank, resulting in two tanks per building. Both tanks are connected to the heat pump's supply and return lines in the thermal liquid domain, while a thermal port on each tank interfaces with a controlled heat flow rate source. This source applies the building's time-varying thermal load, based on pre-defined demand profiles.

A key assumption in the building model is the exclusion of a specific thermal node or building capacity. The thermal inertia (i.e. thermal mass) of the buildings is implicitly included in the demand profiles, eliminating the need for detailed physical modelling of the building envelope. The tank serves to bridge the gap between the thermo-hydraulic domain of the heat pump and the demand-driven thermal domain of the load profiles. It is the interface point, facilitating heat exchange between the heat pump and the imposed thermal load. Each buffer tank is sized according to planning specifications (e.g. 1.8 m³ for each tank in the functional building).

To maintain appropriate supply conditions, a thermostat logic governs each tank. In the heating circuit, the tank can be heated up to a maximum of 45°C and allowed to cool to 35°C. In the cooling circuit, the tank is cooled down to 14°C and permitted to warm up to 20°C.

5 Functional Mock-up Units: Creation and Integration

5.1 FMU creation

The sTES FMU is based on a stratified thermal energy storage model integrated with thermo-hydraulic components – valves, pumps, and source/sink elements – from the Modelica Buildings library, enabling dynamic charging and discharging during simulations. The core sTES model is developed using the *PartialStratifiedTank* from the Buildings library. The model dividing the tank into *n* segments with uniform temperatures and allowing for multiple inlet and outlet streams. In the partial tank model, a key enhancement and modification is the adjustment of thermal conductivity to better represent diffusion effects. The model captures buoyancy-driven natural convection, caused by the temperature-dependent density of water, leading to internal recirculation between hot and cold regions. Notably, heat loss at the top of the tank may induce an inverse thermocline, a local stratification anomaly.

This model is coupled to a 2-D, axisymmetric ground model in order to simulate underground sTES configurations. The sTES model was cross-compared against a valid model showing its credibility as reported in (Dahash et al. 2020).

The model allows individual specification of heat transfer coefficients at the top, side walls, and bottom of the tank, reflecting different insulation levels.

Subsequently, the sTES model – comprising both the storage tank and surrounding ground domain – is connected to the aforementioned thermo-hydraulic components to represent a hydraulically decoupled sTES system. In this configuration, the sTES can be integrated into a broader energy system via a heat exchanger interface. The complete model is exported from the Dymola simulation environment as an FMU with the type set to Model Exchange and Co-Simulation using CVode, compliant with FMI version 2.0. This FMU is license-free and allows user-defined inputs for key parameters, including storage volume, height, initial temperature, and insulation quality (top, sidewalls, and bottom). The number of thermal segments within the sTES tank is fixed at 15.

The surrounding ground is discretized into 15 axial segments, with a user-defined outer radius. The inner radius is automatically determined by the sTES tank radius. The radial discretization is fixed at 40 segments. Additionally, the model includes a bottom ground domain extending 15 m beneath the tank, discretized into 15 axial and 65 radial segments, with an inner diameter of zero. The model supports spatially inhomogeneous ground properties, allowing users to define thermophysical parameters independently for the lateral and bottom ground domains.

The FMU requires three primary inputs to operate: the injected mass flow rate (*mDot_in*), its temperature (*T_in*), and a control signal (*yDis*) indicating the charging or discharging phase. Based on the value of *yDis*, the model dynamically determines the appropriate injection port – either at the top or bottom of the sTES – reflecting the current operational mode. Additionally, the user can supply a time-series profile for ambient temperature as input, as well as define the undisturbed ground temperature, enabling realistic boundary conditions for long-term thermal simulations.

The FMU provides several outputs over the simulation period, including the evolution of the top, bottom, and mean temperatures of the sTES. Additionally, it reports the total thermal losses, along with a breakdown of these losses by location (e.g., top, sidewalls, bottom). The FMU also outputs the extraction temperature during both charging and discharging phases.

5.2 FMU integration into Simscape

The sTES model, which was developed in Modelica, was integrated into the TSN simulation environment via the *FMU block* from the Simulink *Extras* library. The FMU was coupled at the Simulink level rather than directly within the Simscape physical domain. This is due to the signal-based nature of FMI, which requires the conversion of acausal physical ports in Simscape to causal signal lines in Simulink, and vice versa, using standard *PS-Simulink* and *Simulink-PS* converter blocks. To prevent algebraic loops resulting from feedback between Simscape and the FMU (e.g. temperature and flow dependencies across the interface), *Unit Delay* blocks were introduced at the FMU outputs. To enable efficient multirate simulation, the FMU was imported in co-simulation mode. This allowed it to operate with its own internal solver and step size, decoupled from the Simulink solver. In contrast, model exchange mode forced Simulink to integrate the FMU dynamics at its global solver rate. This prevented multirate execution and resulted in simulation times that were approximately 300% longer in test runs. Co-simulation was therefore better suited to this application, where the TSN and sTES have dynamics with different timescales. The influence of the communication step size between the FMU and the main model/sample time of the FMU on computational time is shown in Chapter 7.

The sTES FMU was linked to the TSN via a heat exchanger in the Energy Hub. This component remains entirely within the Simscape thermal liquid domain and serves as the hydraulic interface for charging and discharging the storage. On the FMU side of the heat exchanger, a set of interface components was implemented as can be seen in Figure 2:

- A *controlled temperature source* (Simscape) defines the outlet temperature of the sTES.
- A *mass flow rate source*, governed by a custom sTES control block, imposes charging or discharging flow rates.
- A *reservoir* serves as a pressure and temperature reference node in the thermal liquid domain.

- *Mass flow rate sensors* and *temperature sensors* capture input data for the FMU.

The FMU inputs include:

- Mass flow rate measured downstream of the flow source.
- Inlet temperature, measured in the return line from the heat exchanger.
- A charging/discharging signal, generated by the sTES control block.
- Ambient air temperature and undisturbed ground temperature, provided as time series inputs.

The main output of the FMU is the outlet temperature. It is forwarded to the controlled temperature source connected to the supply line of the heat exchanger. Additional outputs—the top and bottom temperatures of the sTES—serve as inputs to the control function that determines which storage operational phase is possible.

Signal conversion and unit consistency between Simscape and the FMU were ensured using *Simulink-PS* and *PS-Simulink* Converter blocks, with units set to Kelvin for temperature and kg/s for mass flow.

The sTES control block was implemented as a MATLAB function block, receiving a high-level charge/discharge request from the Energy Hub controller. It evaluates temperature conditions within the sTES and TSN to determine if the requested action can proceed (as described in detail in Chapter 6).

The sTES FMU employed in this study is a water-based thermal energy storage system whose parameters, including volume, height, initial temperature, and thermal resistances of each boundary surface, can be adjusted. For all simulations, the system was configured with a volume of 10,000 m³ and a height of 5 m, resulting in a nominal thermal capacity of approximately 230 MWh based on a design temperature differential of 20 K. Thermal insulation was modelled by assigning thermal resistances of approximately 0.5 W/m²K for the top surface and 1.3 W/m²K for the sidewalls.

While FMU-based integration enables cross-platform modularity, it also introduces structural limitations. The internal structure of the FMU cannot be modified directly. Changes to core physical assumptions, such as converting from a water-based model to a water-gravel model, would require access to the original Modelica source code and regeneration of the FMU. Nevertheless, the parameterised interface provided sufficient flexibility for the simulation scenarios considered in this study. This integration approach is designed for modularity. If future FMUs follow the same interface logic (inputs for mass flow, inlet temperature, and control signal, and outputs for outlet temperature, top, and bottom temperatures) they can be easily integrated with minimal adjustments, allowing for rapid adaptation to other storage models or components.

6 Control Structures

The overall system is governed by four independent control schemes:

- A central controller in the Energy Hub regulates the TSN supply temperature by activating available thermal sources.
- In each building, a local controller maintains the temperature in the heating and cooling buffer tanks within a hysteresis threshold.
- A dedicated controller for the sTES manages its charging and discharging based on system state and surplus or shortage of energy.
- Additionally, a pump controller regulates the TSN mass flow by adjusting the speed of the main hydraulic pump to ensure stable network operation.

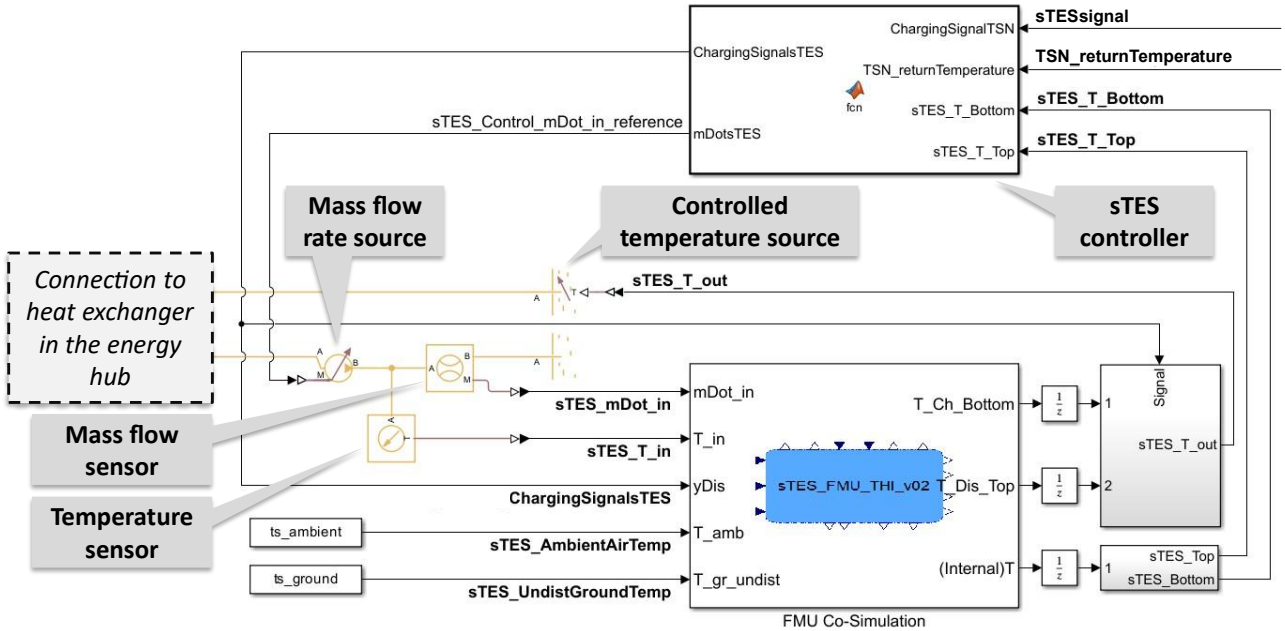

Figure 2. Connections and Interfaces of the sTES FMU.

DOI 10.3384/ecp218851

6.1 Energy Hub Control

The central control scheme ensures that the TSN supply temperature remains within defined limits, adjusting the activation of thermal sources accordingly as depicted in Figure 3. During summer, the supply temperature is maintained between 15°C and 35°C. While in winter, it is regulated within a range of 10°C to 20°C. In summer, a higher temperature reduces cooling losses to the warmer soil, while in winter, a lower temperature helps minimize heat losses to the colder ground. Additionally, the selected temperature bands consider the efficient operation of decentralized heat pumps. To achieve this, the controller can activate three thermal sources: waste heat from the data centre, groundwater wells, and, in future scenarios, the sTES. Herein, the selection follows a simple priority strategy. For both heating and cooling the sTES is prioritized. Only when the sTES cannot meet the demand, the waste heat from the data centre supplies heat as a secondary source, while for cooling, groundwater is used. This overall control logic is implemented using a Stateflow model, which allows for condition-based switching between sources.

6.2 sTES control

The sTES controller, depicted in Figure 4, receives a charging or discharging request from the central Energy Hub controller. Based on this input, it evaluates whether the current temperature levels in the TSN and the sTES allow for the requested operation. Charging is only activated if the bottom temperature of the sTES is at least 2 K below the TSN return temperature, while discharging is allowed if the top temperature of the sTES is at least 2 K above it. If the temperature conditions are met, the

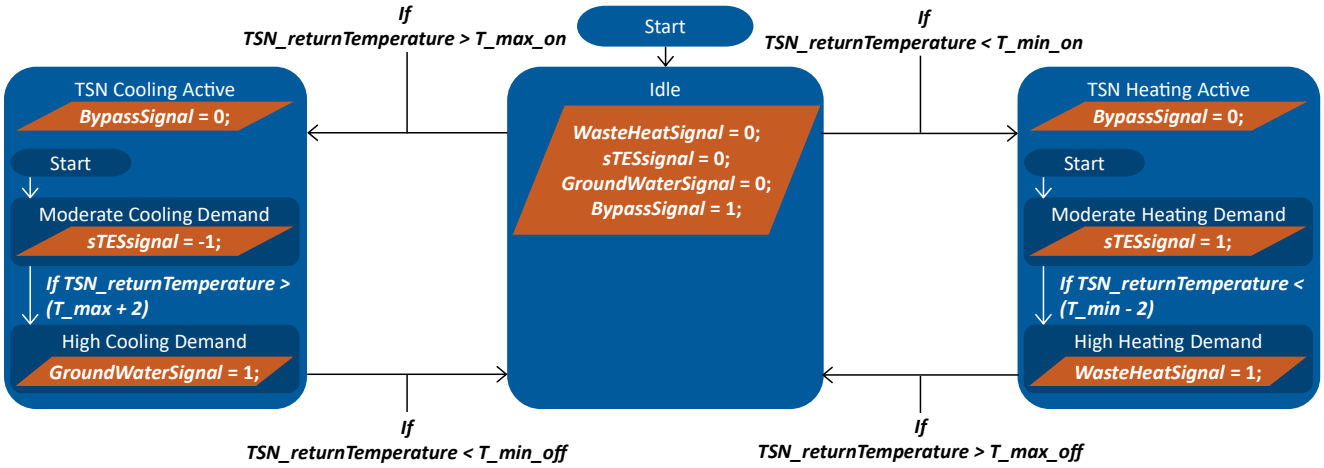

Figure 3. Energy Hub Control Strategy represented as a State Flow Chart.

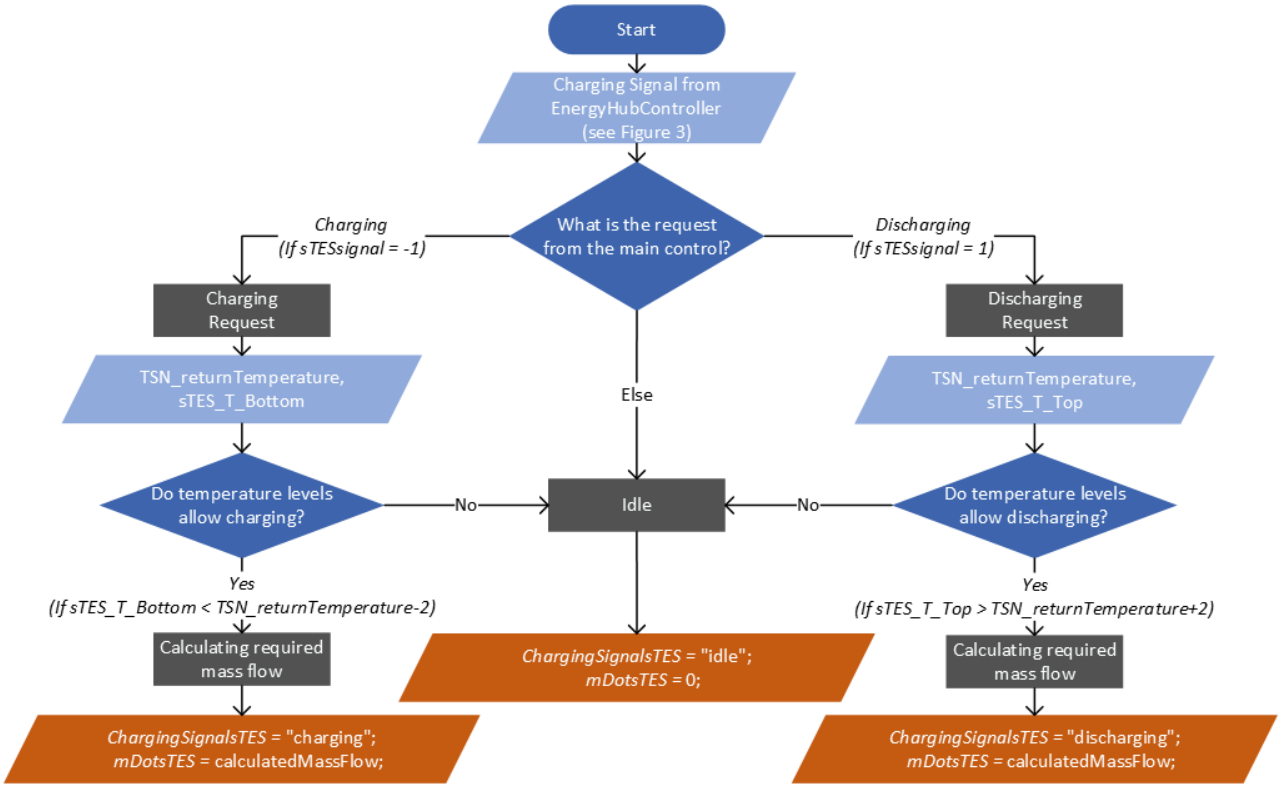

Figure 4. sTES Controller Flow Chart.

controller calculates the required mass flow and sets the operation mode accordingly. If not, the sTES remains idle and no flow is initiated.

6.3 Control Assumptions

To maintain model simplicity, idealized valve behaviour is assumed, and most control actions are treated as instantaneous. However, for pump control, a basic ramp-up function is applied to the control signal to better reflect realistic system dynamics.

7 Results

7.1 FMU Integration Results and Solver Settings

To assess the impact of solver settings on simulation efficiency, the model was evaluated using different combinations of co-simulation step sizes and solver types over a simulation period of 24 hours. Across all configurations, ode23t consistently outperformed all others yielding the shortest simulation times for short-term simulations, while daessc produced the longest, in line with its role in fixed-step real-time applications. Although ode23t was slightly faster than ode15s, it was found to be less stable in long-term simulations, often resulting in errors or early termination. Thus, ode15s was selected for the final year-round simulations, as it provided greater numerical robustness. These outcomes are consistent with MathWorks' recommendations for physical simulations involving stiff systems (The MathWorks, Inc. 2025).

According to MathWorks recommendations, enabling the use of a local solver for Simscape networks can significantly improve simulation performance and numerical stability—particularly in models with complex dynamics or coupled components from different domains. This setup allows the physical network to be updated independently of the global solver, providing greater flexibility in tuning solver configurations for performance and robustness.

In line with this recommendation, a fixed-step local solver was implemented for the Simscape thermo-hydraulic network and evaluated in combination with varying FMU communication step sizes. Both the FMU communication step size and the Simscape solver sample time affected simulation runtime, as illustrated in Figure 5. Larger values for either parameter mostly led to shorter simulation times. However, this came at the risk of reduced numerical stability in long-term simulations.

In the region where the simulation remained stable (specifically including long-term simulations), the Simscape solver sample time was found to be the dominant factor influencing simulation time.

The simulation was stable for Simscape sample times up to 5 seconds and FMU communication step sizes up to 600 seconds, which is attributable to the high thermal inertia of the system. Beyond these values, the model increasingly exhibited temperature divergence and numerical errors, particularly when the Simscape solver was configured with a larger sample time.

For the final configuration, a Simscape solver sample time of 5 seconds and an FMU communication step size of 300 seconds were selected. This combination provided a good compromise between simulation speed and numerical stability and is indicated as the black dot in Figure 5.

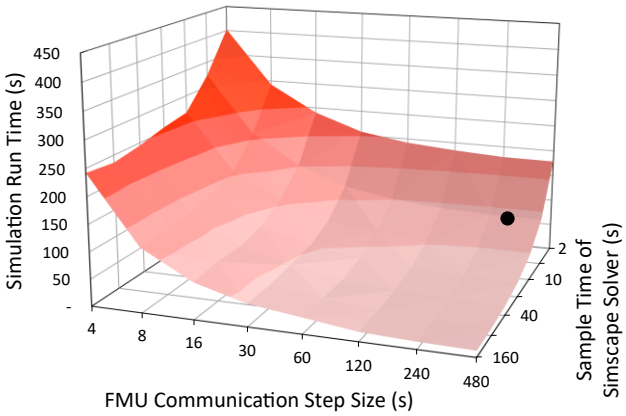

Figure 5. Simulation Run Time of Energy System Model (for 24 Hour Simulated Time) as a Function of FMU Communication Step Size and Simscape Solver Sample Time.

7.2 Energy System Simulation Results

The TSN is analysed in two scenarios:

- Scenario 1 – TSN without sTES: The thermal source network operates using only the available primary sources—waste heat from the data centre and cooling via groundwater wells.
- Scenario 2 – TSN with sTES: The same network configuration is used, but with the addition of a sTES connected to the TSN via a heat exchanger in the Energy Hub. In this setup, the sTES is treated as an integrated extension of the TSN, meaning it is only charged from and discharged to the network. It does not interface directly with any thermal sources or sinks. Charging and discharging occurs according to the control logic presented in Figures 3 and 4.

Figure 6 shows that the TSN return temperatures follow a similar trend in both scenarios. The control logic of the Energy Hub and available thermal sources were sufficient to maintain the requested temperature levels in the network. In the case without sTES, the network temperature fluctuated more drastically, reflecting the direct dependency on real-time availability from primary sources. By contrast, the inclusion of the sTES led to a noticeably smoother return temperature profile. These results showed that the sTES effectively dampened temperature peaks and maintained thermal stability in the network, acting as a buffer between fluctuating demands.

The logged outputs of the sTES FMU provided further insights into the behaviour of the storage unit throughout the simulation year (Figure 7). During the first half of the year, the sTES is gradually charged with surplus heat from the TSN, as seen in the increasing top, bottom, and mean

DOI 10.3384/ecp218851

temperatures (see Figure 7.a). This stratified thermal profile indicates effective layering within the tank. In the second half of the year, the sTES transitions into discharge mode, providing additional thermal energy to the TSN during periods of increased demand. The corresponding thermal power curve (see Figure 7.b) confirms this pattern: negative values represent controlled discharging events, while positive values indicate charging of the sTES. Over the course of the simulation, a total of 289 MWh of heat was charged into the sTES, while 197 MWh was discharged back into the TSN.

8 Discussion

8.1 FMU Integration Results and Solver Settings

From a practical perspective, the integration process using Simulink's built-in FMU block was straightforward, requiring only signal conversion between physical and non-physical domains and careful attention to unit consistency. The most critical aspect was establishing reliable synchronization between the Simscape solver and the FMU co-simulation loop.

Importantly, performance benchmarks showed that the FMU was not a limiting factor in overall simulation time. Instead, simulation speed and stability were more strongly influenced by Simscape solver settings and the choice of global solver.

8.2 Energy System Simulation Results

The simulation results demonstrated that the thermal behaviour of the sTES is strongly influenced by the temperature level of the TSN itself. Since the sTES was connected to the network through a heat exchanger and can only be charged from the TSN, the maximum storage temperature was inherently limited by the network's supply conditions. As a result, the charging potential of the sTES was constrained, particularly during periods when TSN temperatures were suboptimal for storage loading. This limitation could be addressed in future system configurations by enabling charging from alternative sources or introducing a heat pump interface between the TSN and the sTES, thereby decoupling storage charging and discharging from the TSN temperature level leading to addressing sector coupling.

In terms of energy performance, the sTES received a total of 289 MWh of thermal energy during the simulation period and discharged 196 MWh into the TSN, yielding a storage efficiency of approximately 68%. This efficiency reflected the thermal losses to the surrounding ground and environment, as modelled within the FMU, and is within a reasonable range for seasonal storages (Bott et al. 2020).

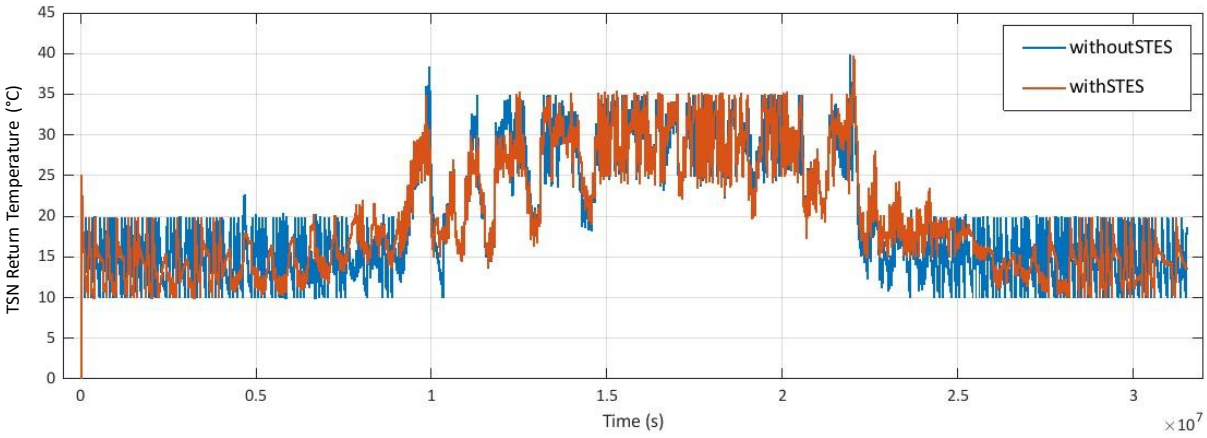

Figure 6. Comparison of TSN return temperature over time for two simulation scenarios.

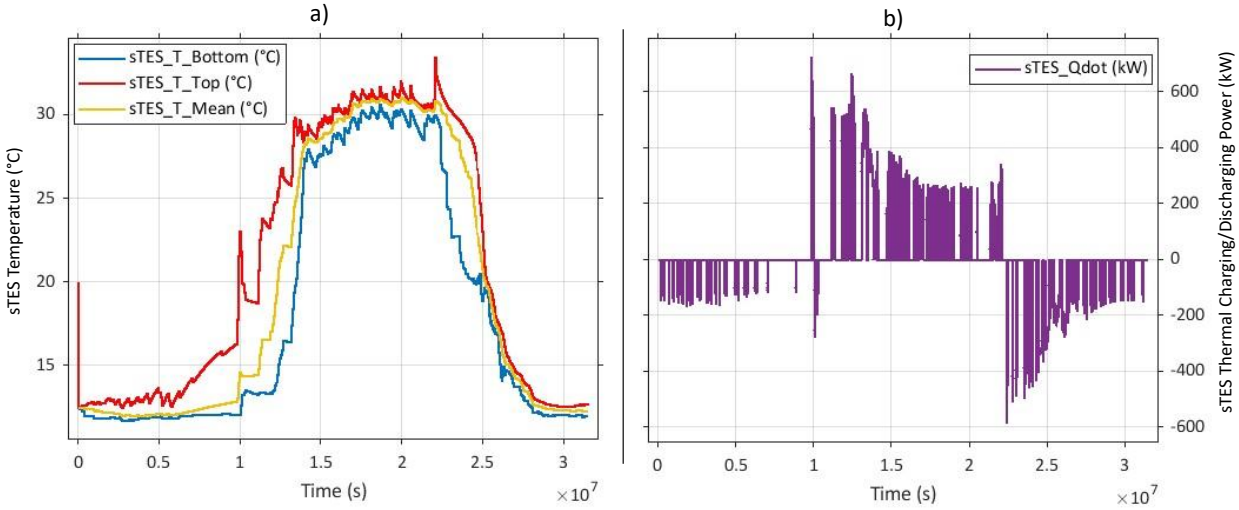

Figure 7. a) sTES temperatures and b) thermal power exchange between sTES and TSN.

8.3 Limitations

While the model successfully demonstrated the integration of an FMU-based sTES and its impact on TSN operation, several assumptions were made to keep the simulation tractable and focused. The pipe-ground interaction was considered using a static undisturbed ground temperature. Furthermore, the heat pump and building models were simplified, relying on Carnot efficiency and load profiles, respectively, rather than detailed thermodynamic or building physics. Additionally, the simulation was conducted over a single year, which limits the ability to fully assess long-term thermal interactions between the sTES and the surrounding ground. The implemented control strategies—both for the Energy Hub and the sTES—were designed for stability and clarity but do not include predictive or optimized logic, and the sTES was treated strictly as a passive TSN extension with no alternative source coupling. Additionally, while the study concentrated on runtime and stability, a more detailed evaluation of numerical precision and energy conservation across the FMI interface is yet to be conducted. Future work will include convergence studies and error analysis to quantify the consistency of energy between the FMU and Simscape subsystems.

9 Conclusion and Future Work

This paper presented a cross-platform simulation approach for modelling TSNs by integrating a Modelica-based FMU of an sTES into a MATLAB/Simscape environment. The co-simulation setup was implemented successfully, highlighting the interoperability potential between modelling domains and enabling the reuse of validated component models without reimplementation.

In the simulated case study, the sTES functioned as an integrated buffer within the TSN, helping to stabilize return temperatures and balance seasonal loads. With 289 MWh of thermal energy charged and 196 MWh discharged, the observed storage efficiency of approximately 68% reflects both thermal losses and current operational limitations, such as temperature coupling through a heat exchanger leading to indirect charging/discharging implying further thermal losses.

Future work will explore more advanced control strategies, such as model predictive control and reinforcement learning, with the aim of improving the operation of the TSN and the sTES. Annual simulations will be used to evaluate the long-term thermal interactions, particularly those with the surrounding ground. Additionally, coupling the sTES via a heat pump or enabling charging from alternative sources could increase flexibility, improve overall system performance, and address sector coupling. Finally, the approach could be extended in reverse by exporting the full TSN model as a MATLAB FMU for integration into Modelica, further demonstrating the bidirectional potential of FMI-based digital twins. It would also be valuable to compare FMU-based sTES integration with a simplified native Simscape implementation to evaluate trade-offs in terms of model fidelity, numerical performance, and cross-domain reusability. Similarly, a quantitative comparison of co-simulation and model-exchange FMUs could help assess the impact of FMU type on accuracy, stability, and energy consistency.

Abstract

This paper demonstrates new methods and implementations of nonlinear solvers with higher-order of convergence, which is achieved by efficiently computing higher-order derivatives. Instead of computing full derivatives, which could be expensive, we compute directional derivatives with Taylor-mode automatic differentiation. We first implement Householder's method with arbitrary order for one variable, and investigate the trade-off between computational cost and convergence order. We find that the second-order variant, i.e., Halley's method, to offer the best trade-off between computational cost and convergence rate, and further generalize Halley's method to systems of nonlinear equations and demonstrate that it can scale efficiently to large-scale problems. We further apply Halley's method on solving large-scale ill-conditioned nonlinear problems, as well as solving nonlinear equations inside stiff ODE solvers, and demonstrate that it could outperform Newton's method.

Keywords: nonlinear solvers, automatic differentiation, Householder's method, Halley's method

1 Introduction

Solving nonlinear equations accurately and efficiently is crucial in many disciplines of science, where nonlinear equations can emerge either directly from the models, or as an intermediate step of solving ordinary differential equations (ODEs)(Byrne and Hindmarsh 1987), partial differential equations (PDEs)(Ames 2014), differential-algebraic equations (DAEs)(Kunkel 2006), and integral equations(Atkinson 1992).

Various methods are available to solve nonlinear equations, and the mostly used ones are Newton's method and its variants(Kelley 2003), which rely on the first-order derivative, i.e. the Jacobian, or its approximations. Newton's method is proved to have quadratic convergence under certain assumptions of the nonlinear function and initial condition(Galántai 2000).

There has been extensive research on improving the convergence order of nonlinear solvers, which can be categorized into two different approaches: (1) multi-step methods that evaluate nonlinear functions and/or derivatives at multiple points in each iteration(Potra 1984; X. Xiao and Yin 2015; Madhu and Jayaraman 2017; X.-Y. Xiao 2022; Singh and Sharma 2023); (2) methods that utilize higher-order derivatives of nonlinear functions(Alefeld 1981; A. Cuyt and Cruyssen 1983; A. A. M. Cuyt and Rall 1985; A. A. Cuyt 1982; K. I. Noor, M. A. Noor, and Momani 2007; Ogbereyivwe, Izevbizua, and Umar 2023; Sariman and Hashim 2020; Germani et al. 2006). Despite their higher convergence order, in order to be more efficient than Newton's method, they must be computationally efficient for each iteration. For example, some multi-step methods(Singh and Sharma 2023) evaluate the function and Jacobian at multiple points, but only invert the Jacobian at one point; in practice, this would mean that for a nonlinear function with n inputs and n outputs, the $O(n^3)$ factorization of the Jacobian, which is the bottleneck of Newton's method, only needs to be done once for each iteration. This ensures that these multi-step methods are not much more expensive than Newton's method for each iteration.

The same considerations also apply to methods of the second category, where higher-order derivatives introduce additional computation burden. It is commonly believed that computing the higher-order full derivative of a function with large input and output dimension n would be much more expensive than the computation of the function itself(Margossian 2019). As a result, they are often approximated rather than exactly computed(Sariman and Hashim 2020; Suleiman 2009; Albeanu 2008; Steihaug 2006), and it is still an open question whether nonlinear solvers can utilize higher-order derivative information for large-scale nonlinear problems in an exact way.

This paper demonstrates new methods and implementations that, instead of computing the full derivative, efficiently and exactly compute the higher-order directional derivative, which is sufficient for nonlinear solvers. This paper is organized as follows. We will first introduce the technique of Taylor-mode automatic differentiation (AD) for efficiently computing higher-order directional derivatives, and its implementation in Julia, in section 2. Then we will demonstrate that Taylor-mode AD can be used to efficiently implement Householder's method with arbitrary convergence order, in section 3. Finally, we demonstrate that a special case of Householder's method, the cubic-convergence Halley's method can scale elegantly to large-scale problems, and could outperform first-order methods by a significant margin, in section 4.

2 Taylor-mode automatic differentiation for higher-order directional derivatives

We first introduce the notation used in this paper. Let U be an open subset of $\mathbb{R}^n$, $f : U \to \mathbb{R}^m$ be a function that is sufficiently smooth. The derivative of f at a point $x \in \mathbb{R}^n$ is a linear operator $Df(x) : \mathbb{R}^n \to \mathbb{R}^m$ such that it maps a vector $v \in \mathbb{R}^n$ to $Df(x)[v]$, which is the directional derivative of f at x in the direction of v, also known as the Jacobian-vector product.

Similarly, for $p \in \mathbb{Z}^+ > 1$, the p-th order derivative of f at a point x is a multilinear operator $D^p f(x) : (\mathbb{R}^n, \cdots, \mathbb{R}^n) \to \mathbb{R}^m$ such that it maps a tuple of vectors $(v_1, \ldots, v_p)$ to $D^p f(x)[v_1, \cdots, v_p]$, the directional derivative of f at x in the direction of $(v_1, \ldots, v_p)$.

First-order forward-mode AD can be viewed as an algorithm to propagate directional derivative information through compositions of functions(Revels, Lubin, and Papamarkou 2016). For example, let $f(x) = g(h(x))$ to be a composite function for $\mathbb{R}^n \to \mathbb{R}^m$, and $x \in \mathbb{R}^n$ to be a specific point in its domain. Suppose that we already have $h_0 = h(x)$ to represent the primal output of h, and $h_1 = Dh(x)[v]$ representing the perturbation of h along some direction $v \in \mathbb{R}^n$. Now for the composite function, we want to know what is the perturbation of f along direction v; in other words, we want to know $f_1 = Df(x)[v]$ in addition to $f_0 = f(x)$. The answer to that is simply the chain rule:

- $f_0 = g(h_0)$
- $f_1 = Dg(h_0)[h_1]$

Similarly, the Taylor-mode AD can be viewed as an algorithm to propagate higher-order directional derivative information through compositions of functions. Suppose that we already have a Taylor coefficients for h at x along v:

$$(h_0, h_1, \ldots, h_p) = (h(x), Dh(x)[v], \ldots, D^p h(x)[v, \ldots, v])$$

and we want to know

$$(f_0, f_1, \ldots, f_p) = (f(x), Df(x)[v], \ldots, D^p f(x)[v, \ldots, v])$$

the answer to that is, in turn, the Faà di Bruno's formula:

- $f_0 = g(h_0)$
- $f_1 = Dg(h_0)[h_1]$
- $f_2 = D^2 g(h_0)[h_1, h_1] + Dg(h_0)[h_2]$
- $\ldots$

In our practical implementation of Taylor-mode AD, a pushforward rule is defined for every "simple" function, so that derivatives of any complicated functions that are composed of these simple functions can be computed automatically, either via operator-overloading or source-code transformation techniques. Our previous work (Tan 2023a) has shown that for any functions composed of elementary functions and arbitrary control flow, the p-th order directional derivative is at most $O(p^2)$ times more expensive than computing the function itself, in contrast to naively nesting first-order forward-mode AD which could be $O(\exp(p))$ times expensive(Bettencourt, Johnson, and Duvenaud 2022). We also provided a reference implementation of this method in the Julia language(Bezanson, Edelman, et al. 2017) using its multiple-dispatch mechanism(Bezanson, Bolewski, and Chen 2018), TaylorDiff.jl(Tan 2023b), featuring an automatic generation(Gowda, Ma, Cheli, et al. 2021) of higher-order pushforward rules from first-order pushforward rules defined in ChainRules.jl(White et al. 2023).

Below, we will demonstrate how to use Taylor-mode AD to implement higher-order nonlinear solvers. For all numerical experiments in this paper, we use the Julia language v1.11.2 on a single core of Intel Xeon Platinum 8260 CPU provided by the MIT SuperCloud system.

3 Efficient implementation of Householder's method

We begin by implementing Householder's method(Householder 1970) for solving nonlinear equations with one variable, i.e. $x \in \mathbb{R}$ in the nonlinear function $f(x)$. This does not immediately generalize to multiple variables, but it is useful to compare the behavior of solvers with different convergence order. The method is defined as follows: given an initial guess x_0, in each iteration we compute,

$$x_{n+1} = x_n + p\frac{(1/f)^{(p-1)}(x_n)}{(1/f)^{(p)}(x_n)}.$$

which requires derivatives up to p-th order and has convergence order $p+1$. Note that when $p = 1$, this method is equivalent to Newton's method; and when $p = 2$, this method is equivalent to Halley's method.

Given f and x_n, we can compute $f(x_n)$ and its derivatives up to p-th order using Taylor mode AD, and then invert this Taylor polynomial to get the value and derivatives of $1/f$ up to p-th order. Our analysis leads to the algorithm 1:

3.1 Cost-effectiveness for Householder's method with different orders.

We implement algorithm 1 as a part of SimpleNonlinearSolve.jl(Pal et al. 2024), which is a package of non-allocating nonlinear solvers that have low-overhead and could solve small nonlinear problems very efficiently. We make several univariate nonlinear functions composed of various elementary functions, and use different orders of Householder's method to solve $f(x) = 0$ given appropriate initial guess. Results are shown in fig. 1.

DOI 10.3384/ecp218861

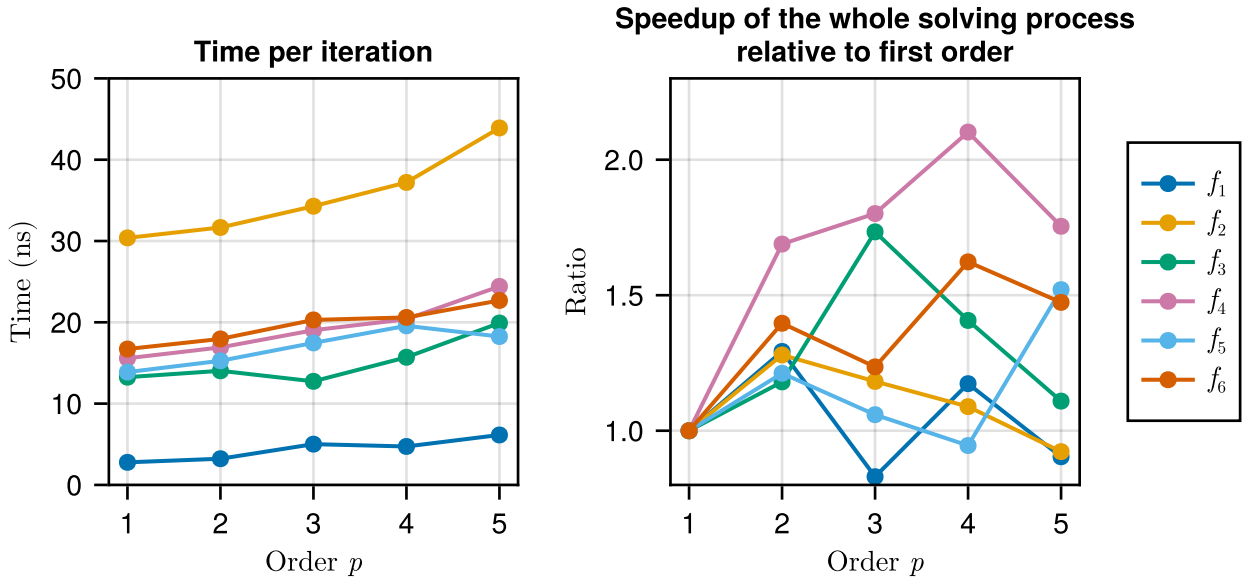

Figure 1. Cost-effectiveness for Householder's method with different orders. Left: the computation time per iteration for each nonlinear function and each Householder's method with different order. Right: the relative speedup for each function of the total computation time to solve the nonlinear equation, normalized by the $p = 1$ solver (Newton's method). The functions and initial conditions are: (1) $f_1(x) = x^2 - 2$, $x_0 = 1.0$; (2) $f_2(x) = \sqrt{x} - \pi$, $x_0 = 10.0$; (3) $f_3(x) = x - \exp(-x)$, $x_0 = 0.0$; (4) $f_4(x) = x^2 - 2^x$, $x_0 = 3.3$; (5) $f_5(x) = x + \sin(x) - 1$, $x_0 = 0.5$; (6) $f_6(x) = \log(x) + x$, $x_0 = 1.0$.

Algorithm 1 Householder's method implementation based on higher-order AD

Define f and initial value x; tolerance t; order p
while $|f(x)| > t$ **do**
  Initialize Taylor coefficients $(x, 1, 0, \cdots, 0)$
  Apply the pushforward rule of f to get $(f(x), f'(x), \cdots, f^{(p)}(x))$
  Apply the pushforward rule of $(\cdot)^{-1}$ to get $((1/f)(x), (1/f)'(x), \cdots, (1/f)^{(p)}(x))$
  Update $x := x + p\frac{(1/f)^{(p-1)}(x)}{(1/f)^{(p)}(x)}$.
end while
return x

For each of the nonlinear functions, the computation cost per iteration only slightly increases as the order p goes from 1 (Newton's method) to 5, but the number of iterations needed to converge could be cut down significantly by the higher-order methods. As the result, the total time needed to converge could be shorter for higher-order methods. We also notice that the most significant improvement is from the first order to the second order, and the improvement from the second order to an even higher order is less significant.

3.2 Generalization to multivariate functions

The theory of abstract rational approximation(A. Cuyt and Cruyssen 1983) gives a method to generalize Householder's method to multivariate functions. In the sections below, we will focus on implementing $p = 2$ case, i.e. Halley's method, with abstract rational approximation formulas, for multivariate functions. Based on the observations from simple univariate problems, we hypothesize that higher-order methods with $p \geq 3$ yield diminishing returns in practice.

4 Scalable and Efficient implementation of Halley's method

Halley's method ($p = 2$) for a multivariate real function $f(x) : \mathbb{R}^n \to \mathbb{R}^n$, derived from abstract rational approximation(A. Cuyt and Cruyssen 1983; A. A. M. Cuyt and Rall 1985), could be expressed as follows: given an initial guess x_0, in each iteration we compute

$$x_{n+1} = x_n + (a_n \odot a_n) \oslash (a_n + [Df(x_n)]^{-1} D^2 f(x_n)[a_n, a_n]/2) \quad (1)$$

where $\odot$ and $\oslash$ are element-wise multiplication and division, Df and $D^2 f$ are the Jacobian and Hessian of f, and a_n is the solution to $Df(x_n)a_n = -f(x_n)$. In the equation above, $D^2 f(x_n)a_n a_n$ can be computed easily using Taylor-mode AD, with just two times more expensive than the computation of $f(x_n)$. After the first linear solve for a_n, we need another linear solve to get $[Df(x_n)]^{-1} D^2 f(x_n)a_n a_n$. Among the two linear solves, the factorization of Jacobian could be reused, similar to the case of multi-step methods(Singh and Sharma 2023). Our analysis leads to algorithm 2:

Looking into the details of algorithm 2, we note that for

Algorithm 2 (Multivariate) Halley's method implementation based on higher-order AD

Define f and initial value x; tolerance t
while $\|f(x)\|_{\text{inf}} > t$ **do**
  Obtain via first-order AD the Jacobian $Df(x)$
  Solve a from $Df(x)[a] = -f(x)$
  Initialize Taylor coefficients $(x, a, 0)$
  Apply the pushforward rule of f to get $(f(x), Df(x)[a], D^2f(x)[a,a])$
  Solve b from $Df(x)[b] = D^2(x)[a,a]$
  Update $x := x + a \odot a \oslash (a + b/2)$
end while
return x

either dense or sparse Jacobian, the construction and factorization of $Df(x)$ (via LU or QR factorization) should be the bottleneck of solving, and these only need to be done once for the two linear solves. In other words, given the factorization, the additional linear solve for b can be computed in $O(n^2)$ time. Therefore, each step of Halley's method can be asymptotically as cheap as Newton's method, which makes it potentially faster than Newton's method.

4.1 Solving nonlinear problems with dense Jacobian

We first test algorithm 2 on nonlinear problems where the Jacobian of the nonlinear function $f(x) : \mathbb{R}^n \to \mathbb{R}^n$ is dense and unstructured. In this case, the factorization of the Jacobian is the bottleneck of the linear solve, and the cost of each factorization is $O(n^3)$. For defining such a problem, we consider the Chandrasekhar's H-function(Chandrasekhar 2013) which is the solution to an integral equation that arises in the study of radiative transfer in astrophysics. The equation is defined as follows:

$$H(\mu) = 1 + \mu H(\mu) \int_0^1 \frac{\Psi(\mu')H(\mu')}{\mu + \mu'} \mathrm{d}\mu' \tag{2}$$

where $H(\mu)$ is defined on $[0,1]$ and $\Psi(\mu)$ is an even polynomial. We consider the most simplified case, where Ψ is a constant. Upon discretization onto n grids for integration, the equation becomes a system of nonlinear equations of n variables, and since each equation depends on the value of H on all positions, the Jacobian of this nonlinear problem is inherently dense. The detailed form of the discretized nonlinear function is available as the 23rd problem in NonlinearProblemLibrary.jl(Pal et al. 2024) which the reader can refer to.

We solve this problem with different problem sizes $n = 4, 8, 16, 32, 64, 128$, and we compare the performance of (1) Newton's method, (2) Halley's method as implemented in algorithm 2, and (3) naive Halley's method implemented in a conventional way(A. A. M. Cuyt and Rall 1985) that computes the full Hessian and then contracts it with vectors. Each of them is solved to the default tolerance. The results are shown in fig. 2.

While the performances are similar for small problems, the naive Halley's method quickly becomes infeasible for large problems(Pal et al. 2024), while our implementation of Halley's method scales similarly as Newton's method. In addition, as the problem size gets larger, the advantage of Halley's method over Newton's method becomes more significant, as a result of fewer iterations needed to converge. For example, for $n = 128$, Halley's method is approximately 40% faster than Newton's method. Finally, more detailed work-precision diagrams comparing Halley's method and Newton's method, within a broader range of problem sizes ($n = 4, 16, 64, 256, 1024$), is shown in fig. 3.

4.2 Solving large-scale ill-conditioned nonlinear problems with sparse Jacobian

Nonlinear problems that appear in solving PDEs are often large, sparse and ill-conditioned(Ames 2014), imposing additional challenges for nonlinear solvers. Below, we will use a two-dimensional Brusselator reaction-diffusion PDE problem as an example to demonstrate the capability of Halley's method to handle these nonlinear problems in practical applications. The Brusselator is a model for auto-catalytic chemical systems that exhibit oscillations in time domain and pattern formation in space domain(Prigogine and Lefever 1968). Let functions $u(x,y,t)$ and $v(x,y,t)$ be concentrations of substances that are defined on $(x,y) \in [0,1] \times [0,1]$ and $t \in (0, +\infty)$, satisfying the following differential equations,

$$\begin{aligned} u_t &= B + u^2 v - (A+1)u + \alpha \Delta u + f(x,y,t) \\ v_t &= Au - u^2 v + \alpha \Delta v \end{aligned} \tag{3}$$

where the source f is defined as

$$f(x,y,t) = \begin{cases} 5 & \text{if } (x-0.3)^2 + (y-0.6)^2 \le 0.1^2 \text{and } t \ge 1.1 \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

and initial conditions,

$$\begin{aligned} u(x,y,0) &= 22(y(1-y))^{3/2} \\ v(x,y,0) &= 27(x(1-x))^{3/2} \end{aligned} \tag{5}$$

and periodic boundary conditions.

$$\begin{aligned} u(0,y,t) &= u(1,y,t) \\ u(x,0,t) &= u(x,1,t) \\ v(0,y,t) &= v(1,y,t) \\ v(x,0,t) &= v(x,1,t) \end{aligned} \tag{6}$$

In the following numerical experiments, the parameters are set to $A = 3.4$, $B = 1$, $\alpha = 10$.

We first consider the time-independent PDE problem, where for $t \gg 1.1$ we solve the steady-state equations $u_t = v_t = 0$ to get the long-time behavior of the spatial distribution of concentrations u and v. In order to apply nonlinear solvers, the spatial discretization of u and v is

DOI 10.3384/ecp218861

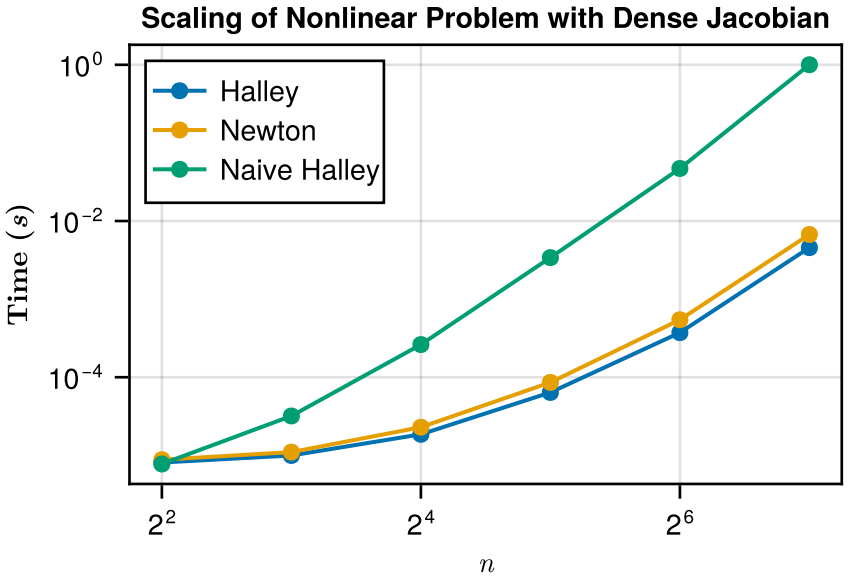

Figure 2. Scaling for solving a nonlinear problem that has a dense Jacobian, at different problem sizes. Solvers: Newton, Halley (Taylor-mode AD), and Naive Halley (full Hessian).

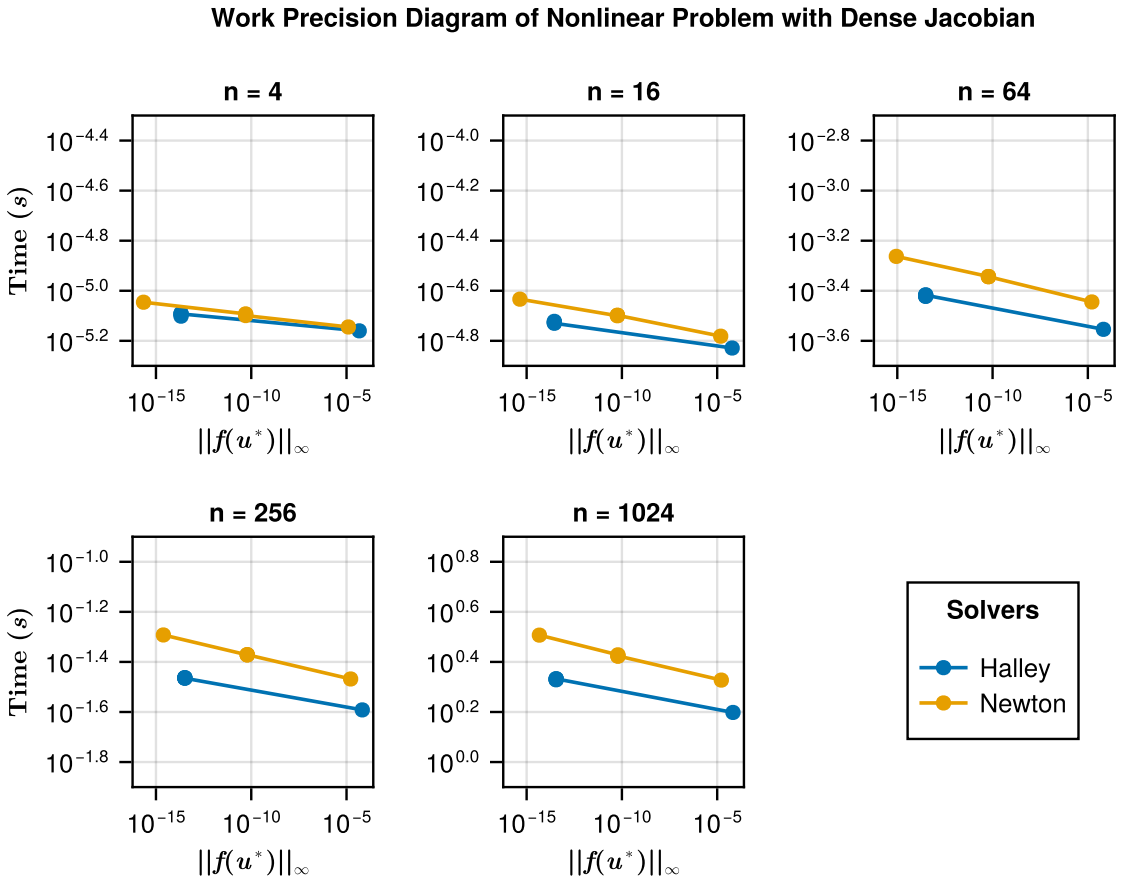

Figure 3. Work-precision diagram for solving a nonlinear problem that has a dense Jacobian, with different sizes. Solvers: Newton and Halley (Taylor-mode AD).

carried out for $K = 4, 8, 16, 32, 64, 128$ grids on x and y directions, and the Laplacian operator Δ is implemented with finite differences. Therefore, each of u and v discretizes to K^2 variables, and the total problem size of the nonlinear system is $n = 2K^2$. Since the variables only interact with nearby grids, the resulting Jacobian is sparse; in addition, when K increases, the coefficients of the finite difference operator become larger and make the Jacobian ill-conditioned.

In order to handle these characteristics, we first try to generate a sparse matrix for Jacobian in order to make factorization easier(Averick et al. 1994). This could be achieved with sparse detection techniques, either in a numerical way(Giering, Kaminski, and Slawig 2005; Walther and Griewank 2009) or in a symbolic way(Gowda, Ma, Churavy, et al. 2019). After sparsity detection, we further use the graph coloring algorithm(Gebremedhin, Manne, and Pothen 2005) to compute the matrix. These tools are available in SparseDiffTools.jl(*JuliaDiff/SparseDiffTools.jl* 2024) and SparseConnectivityTracer.jl(Hill and Dalle 2024) as a part of the Julia community. Finally, factorization of the sparse Jacobian is appropriately handled with LinearSolve.jl(*SciML/LinearSolve.jl* 2024) which has reasonable polyalgorithms for handling ill-conditioned sparse matrices. In addition, we also include the naive method of computing dense Jacobian and then doing dense factorization. The results are shown in fig. 4.

Clearly, the naive method of computing dense Jacobian and then doing dense factorization is inefficient for large problems, while the sparse method scales better. In addition, Halley's method is more efficient than Newton's method for all problem sizes and for both sparse and dense handling of the Jacobian matrix, and the advantage becomes more significant as the problem size increases. For example, for $K = 32$ and corresponding problem size $n = 2048$, Halley's method is approximately 25% faster than Newton's method.

4.3 Solving stiff ODEs

We then consider the time-dependent PDE, where we compute the time evolution of the Brusselator system given initial conditions and periodic boundary conditions above. In order to implement, the PDE is again spatially discretized with K grids on x and y directions, turning it into an ODE. Due to the Laplacian operator, the linear part of this equation has a high frequency, while the nonlinear part has a low frequency. Therefore, the resulting ODE is stiff. In solving stiff ODEs, implicit solvers are often used to ensure accuracy and efficiency(Kim et al. 2021), and these solvers requires nonlinear solve steps. Since the nonlinear solve steps are often the bottleneck of implicit solvers, impoving the nonlinear solver could accelerate the whole ODE solving process.

We choose problem size $K = 8$, $n = 2K^2 = 128$ to construct the ODE and solve with several common stiff solvers from $t_0 = 0$ to $t_e = 11.5$, and in each of the stiff solvers we test both Newton's method and Halley's method for the underlying nonlinear solver. When solving the ODE, we provide different tolerances which will determine the time step by applying adaptive time-step strategies available in DifferentialEquations.jl(Rackauckas and Nie 2017). We then use a very small tolerance to obtain very accurate solutions to the ODE, namely u_{ref} and v_{ref}, and we define the error to be the relative L^2 error of the final solution at t_e on domain $D = [0,1] \times [0,1]$, i.e.

$$\frac{\int_D \left(|\delta u(x,y,t_e)|^2 + |\delta v(x,y,t_e)|^2\right) \mathrm{d}x\mathrm{d}y}{\int_D \left(|u_{\text{ref}}(x,y,t_e)|^2 + |v_{\text{ref}}(x,y,t_e)|^2\right) \mathrm{d}x\mathrm{d}y} \tag{7}$$

where $\delta u = u - u_{\text{ref}}$ and $\delta v = v - v_{\text{ref}}$ respectively. The results are shown in fig. 5.

In the work-precision diagram, we observe that Halley's method is more efficient than Newton's method for many kinds of implicit solvers, and on average it gives a 5-10% speedup for the whole ODE solving process.

5 Conclusions

In this paper, we have demonstrated that higher-order nonlinear solvers can be implemented efficiently and scalable with higher-order automatic differentiation. We have implemented Householder's method with arbitrary convergence order and investigated the trade-off between computational cost and accelerated convergence. We have implemented $p = 2$ variant, Halley's method, for multivariate functions and have shown that Halley's method can be more efficient than Newton's method for several cases, including problems with dense Jacobian, problems with sparse Jacobian, as well as being integrated as a part of stiff ODE solvers. Backed by the Julia language and NonlinearSolve.jl framework, this method can be applied to a wide range of problems in science and engineering, and we believe that it could be a valuable tool for the scientific community.

The most noticeable limitation of this work is that we have not yet considered the case where the linear equations in each iteration must be solved iteratively, such as the case that the Jacobian is a matrix-free operator, which is common in even larger systems(Knoll and Keyes 2004). In this case, no factorization could be reused between two linear solves required by Halley's method, and the cost of each iteration could be twice as expensive as Newton's method, cancelling out the advantage of higher convergence order. In future work, we might consider constructing alternative versions of Halley's method that could reuse Krylov iterations of large linear solves.

Abstract

This paper presents the *MultiEnergySystem* Library (MESL), an open-source Modelica library designed for the dynamic simulation of integrated district heating and gas/hydrogen networks. MESL introduces a fully equation-based formulation of fluid properties, ensuring model interpretability and enabling compatibility with control and optimization applications. The library includes dedicated models for hydrogen blending studies and supports gas quality indicators such as Wobbe Index (WI), Higher Heating Value (HHV), and Specific Gravity (SG). District heating models have been experimentally validated using data from a real-world test facility, and these datasets are provided to support reproducibility. While MESL currently focuses on thermal and gas domains, planned expansions include a more comprehensive electrical package and experimental validation of hydrogen components. The paper describes the library's design and validation strategy, concluding with illustrative case studies and ongoing development plans.

Keywords: Modelica library, District Heating, Natural Gas, Hydrogen Blending.

1 Introduction

In recent years, the increasing complexity and integration of various energy systems—such as district heating and gas/hydrogen networks—driven by decarbonization objectives, have motivated the development of sophisticated modeling and simulation tools. Aligned with this context, one of the primary activities of our research department at RSE S.p.A. is the development of precise models to study phenomena within and across different energy systems, facilitating both operational and control analyses.

We are currently involved in two research projects that, while not directly correlated, share similar objectives. The first project focuses on applying novel operational and control approaches to integrate thermal and gas energy vectors with the electrical network, using detailed models that can be experimentally validated at the RSE Distributed Energy Resources Test Facility (DER-TF) (Gandolfi et al. 2022). The second project is dedicated to studying the integration of biogas and/or hydrogen into gas distribution networks, with particular attention to understanding the main dynamics of this phenomenon and its impact on gas quality. Both projects highlight the critical need for precise models and share the gas/hydrogen vector as a common energy domain, demonstrating the value of a unified modeling approach.

The Modelica programming language has emerged as a key modeling tool due to its a-causal, multi-domain, object-oriented nature, enabling dynamic and modular modeling of interconnected systems. Indeed, the use of Modelica for studying multi-energy networks has grown significantly. This growth has led to the creation of modeling libraries tailored for these applications, each offering different levels of complexity and focus.

Focusing on open-source Modelica libraries, the *DistrictHeating* library (Giraud et al. 2015) stands out for its emphasis on accurate and reliable District Heating and Cooling (DHC) simulations. More recently, the open-source *AixLib* library (Maier et al. 2024) has proven valuable for simulating large-scale district heating systems and their interaction with building energy systems. However, both libraries focus solely on DHNs and do not include gas or hydrogen modeling, limiting their applicability to multi-energy system studies.

The *ThermoPower* library (Casella and Leva 2006) instead, is one of the most established Modelica libraries for dynamic modeling of conventional thermal power plants. It contains models from multiple energy domains, including thermal and gas, and has been widely used over the past two decades (Casella and Leva 2024). The *TransiEnt* library (Senkel et al. 2021) is a more recent development designed for transient simulations of coupled energy networks, integrating district heating, gas, and hydrogen networks into a unified framework.

Despite their strengths, these libraries rely on external fluid property backends, either via the Modelica Standard Library or through compiled libraries such as *TILMedia* (GmbH et al. 2025). While these tools are effective for simulation, they limit symbolic manipulation, making them less suitable for applications involving control design, optimization, or sensitivity analysis, where full access to model equations is essential. Furthermore, these libraries lack dedicated tools for modeling hydrogen blending and gas quality indicators, such as Wobbe Index (WI), Higher Heating Value (HHV), and Specific Gravity (SG)—parameters that are central to assessing hydrogen integration feasibility and regulatory compliance. Fi-

nally, although many libraries have undergone theoretical validation, they often lack publicly available experimental datasets that allow direct comparison with real-world measurements. To address these needs, and inspired by previous libraries, we developed the *MultiEnergySystem* library (MESL).

MESL provides a comprehensive framework for simulating the dynamic behavior of integrated energy systems, focusing primarily on thermal and gas domains. A key feature of the library is its fully equation-based formulation of fluid properties, implemented entirely in Modelica. Unlike existing libraries such as *ThermoPower* or *TILMedia*, which rely on external function calls (e.g., C-based backends) for fluid property calculations, MESL uses symbolic equations to compute thermodynamic properties. This approach improves customizability, interpretability, and compatibility with symbolic-based applications such as optimal control.

The library also offers dedicated models for hydrogen blending studies, including the ability to compute gas quality indicators—such as WI, HHV, and SG—which are essential for evaluating the technical feasibility and regulatory compliance of hydrogen integration into gas networks. While the initial focus is on gas distribution systems where ideal-gas behavior is often assumed, MESL also incorporates real-gas models (e.g., Papay equation (Papay 1968)) to support advanced studies on transmission networks and gas mixing phenomena.

Another distinctive feature is the library's emphasis on experimental validation. MESL includes a set of district heating models that have been validated against real-world measurements obtained from a scaled-down District Heating Test Facility (DHTF) (Anderis, Muro Alvarado, and Lazzari 2024). These validation datasets are publicly available and integrated with the library, enabling reproducibility and fostering trust in simulation-based studies. Finally, MESL is released as an open-source Modelica library, ensuring accessibility for the research community and encouraging collaborative development.

Despite these features, some limitations remain. MESL currently includes includes only basic electrical modeling, allowing basic electric power calculations of components such as electric pumps, boilers, and combined heat-and-power (CHP) units. A more comprehensive electrical package is still under consideration, with future integration planned alongside existing Modelica libraries. Meanwhile, planned expansions of our DER-TF, which consist of a Gas Test Facility (GTF) implementation, will enable direct experimental validation of gas/hydrogen components; current validation is limited to measuring natural gas mass flow for thermal devices (e.g., boilers, CHP). Once realized, these additions will enhance the library's validated hydrogen models.

The primary goal of this study is to present MESL, describing its design, implementation, and validation, highlighting potential operational and control applications. The remainder of the paper is organized as follows: Section 2 introduces the library's structure, Section 3 explains the validation methodology, Section 4 presents selected study cases, and Section 5 concludes with an outlook on future work.

2 Library Overview

The *MultiEnergySystem* Library contains three main packages.

1. **`DistrictHeatingNetwork`**: All core components needed to model a district heating system.
2. **`H2GasFacility`**: Models for studying gas networks, including biomethane and hydrogen injection.
3. **`TestFacility`**: Various systems and plant configurations representative of RSE's test facilities, plus related validation models and data.

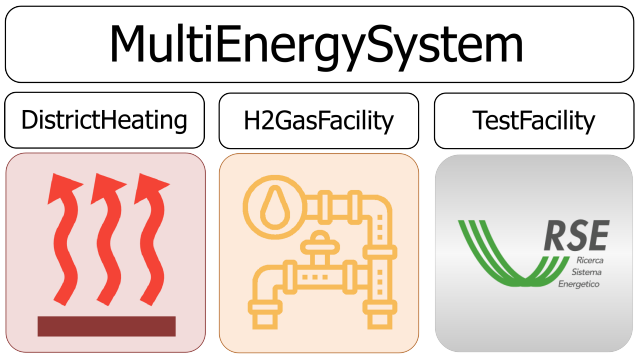

Figure 1. Main packages from MESL.

Within `DistrictHeatingNetwork` and `H2GasFacility`, sub-packages are arranged by functionality. For instance,

- `Interfaces` provides the interfaces to use for the specific energy vector.
- `Fluids` defines water for district heating and the various gas mixtures for gas networks,
- `Sources` contains ideal source and sink pressure and mass flow rate models.
- `Components` contains models like pipes, valves, and other thermo-hydraulic elements,
- `Tests` provides models for verifying the functionality of individual components.

These sub-packages appear in both `DistrictHeatingNetwork` and `H2GasFacility` packages, facilitating a consistent approach to component development. The `TestFacility` package, in contrast, follows its own structure, reflecting the setup of RSE's DHTF and related configurations; it also stores validation data and scenarios. Further details about `TestFacility` will be presented later in this section.

In the following subsections, we introduce each main package or MESL in more detail.

DOI
10.3384/ecp218871

2.1 DistrictHeatingNetwork

As mentioned previously, this package contains different components that can be used to model a district heating network. Because our focus is primarily on building these models for operational and control purposes, we have chosen certain simplifications. For example, the fluid is treated strictly as liquid water, without phase-change effects. In fact, it is possible to consider a constant specific heat capacity and constant density by the assumption that the system works at low pressures; in any case, it is also possible to find variations of the liquid water model with temperature-dependent specific heat capacity and constant density if the user requires this detail; however, this remains liquid water. Likewise, heat-generation devices such as boilers, CHP or chiller are assumed to be ideal outlet-temperature controlled. These assumptions reduce model complexity while still preserving the key dynamics required for control-oriented studies.

Typical components in `DistrictHeatingNetwork` include:

- **`Pipes/RoundPipe1DFV`**: Pipe model described by the traditional 1D finite-volume approach that implements mass, momentum, and energy balances, used for modeling the RSE's DHTF.
- **`Pipes/BrazedPlateHeatExchanger`**: Allow for heat transfer between heat generation and cooling systems.
- **`ThermalMachines/[ControlledGasBoiler,ControlledCHP]`**: Idealized outlet temperature-controlled units, including mass and energy balances as well.
- **`TurboMachines/ControlledPump`**: Support simple control modes if needed for optimization tasks (ideal mass-flow or pressure control pumps).

For further details, readers can refer to (Muro Alvarado et al. 2024).

2.2 H2GasFacility

The `H2GasFacility` package was developed to enable both the integration of gas networks with thermal energy systems and the study of decentralized alternative gas injection in gas networks.

2.2.1 H2GasFacility/Media

A key feature of this package is the custom gas model design. Although our primary focus is on gas distribution networks—where ideal-gas behavior is often assumed, we developed our own gas modeling approach to handle both low-pressure distribution networks and high-pressure transmission lines within a single framework. Rather than limiting ourselves to an ideal-gas assumption, we implemented a fully equation-based formulation that effortlessly switches between ideal and real-gas models. This approach enhances portability, interpretability, and compatibility with optimization and control applications, ensuring that the library can support a wide range of research needs, from conventional gas distribution to high-pressure pipelines and hydrogen blending studies.

At the core of this flexibility is the `PartialMixture` base model, located in the `Media/BaseClasses` sub-package. This foundational model defines essential variables such as pressure, temperature, and mass composition. By extending `PartialMixture`, users can implement custom gas mixture models by specifying the desired thermodynamic equations. The class diagram in Figure Figure 2 illustrates this structure. Each gas mixture model (e.g., `IdealMixture`, `PapayMixture`) defines its own equation of state, enabling tailored simulation of different gas behaviors within the same framework. From these models, users can then define specific gases by setting their composition and other relevant properties, enabling detailed and customizable gas modeling for a wide range of applications.

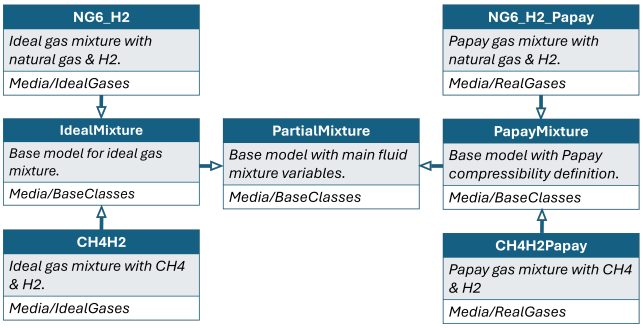

Figure 2. Class diagram for fluid models in `H2GasFacility` package.

2.2.2 H2GasFacility/Components

The `Components` package contains the fundamental building blocks for modeling gas networks. Among these, two key models stand out:

- **`Round1DFV`**: A detailed 1D finite-volume pipe model that implements mass, momentum, and energy balances, as well as the composition mass balance for gas mixtures. This level of detail is especially useful for research that requires transient or multi-species gas flow analysis.
- **`IdealUser`**: An idealized mass-flow consumer that can be placed within a gas network to represent generic demands or loads.

Additionally, `Components` includes the `Manifold` sub-package, which provides manifold and connector models that can facilitate initialization and improve overall network organization.

2.2.3 `H2GasFacility/Tests`

The `Tests` package contains validation models designed to assess gas quality parameters and the accuracy of component models. In particular, the `Subsystem` sub-package includes test models based on literature examples, ensuring consistency with existing studies on hydrogen blending and gas network behavior. Other sub-packages within `Tests` focus on verifying the functionality of individual components.

2.2.4 Considerations

In addition to predefined test cases, users can construct their own gas network models by combining fundamental components from the `Components` package. A basic gas network can be constructed by connecting an ideal pressure source to one or more `Round1DFV` pipes, then attaching one or more `IdealUser` blocks. All pipe connections must have defined inlet and outlet boundaries—either additional pipes, a gas source, or a user. Figure 3 shows the diagram view of one such medium-pressure gas network from (Cheli et al. 2021). Additional details about this test case will be covered in Section 4.

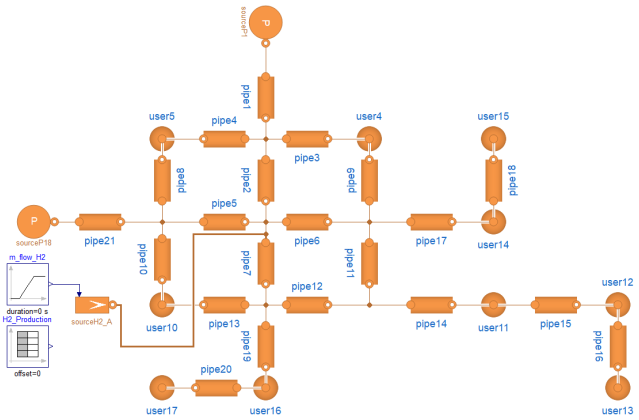

Figure 3. Modelica diagram view of medium-pressure gas network based on (Cheli et al. 2021).

In the modeling of extensive gas networks, it is crucial to carefully consider the initial values, especially for pressure. Although exact initialization is unnecessary, the starting pressure values should align with anticipations of network conditions. Poorly selected initial values may lead to initialization issues, potentially impacting the convergence of the model.

To determine feasible initial values, several approaches can be employed:

- Using real measured data from steady-state operation: When available, historical or real-time measurements from the gas network under steady-state conditions provide a reliable basis for initializing pressures and flows.
- Applying a trial-and-error method with iterative refinement: In the absence of reliable data, a manual approach may be adopted, starting with reasonable estimates followed by successive adjustments based on model feedback.
- Performing steady-state simulations using simplified frameworks: Employing less complex simulation tools (e.g., Pandapipes (Lohmeier et al. 2020)) to solve the network under steady-state assumptions can offer a practical way to generate plausible initial values.

2.2.5 Coupling with thermal energy vector

The `H2GasFacility` package can interface with the `DistrictHeatingNetwork` models by incorporating a gas connector into components such as gas boiler and CHP unit. This additional connector represents the fuel inlet (e.g., natural gas or hydrogen blends), enabling direct coupling between gas and thermal domains. This feature is important for conducting multi-vector energy simulations, allowing researchers to analyze the operational implications of hydrogen blending on both gas networks and thermal generation systems.

2.3 `TestFacility`

The `TestFacility` package contains models, systems, and full plant configurations that replicate the RSE's DHTF. It also includes the corresponding validation test cases. Because the DHTF is currently implemented while the GTF is still under development, most existing models focus on the district heating side of the library. Nonetheless, for demonstration purposes, a few gas-related study cases are already included. As soon as the GTF is operational, we plan to add experimental data and corresponding models to extend the library's scope on the gas/hydrogen side.

This package features more complex systems built from the basic models in the other two packages, forming subsystems and complete configurations of the DHTF. Users can find not only the validation tests within the DHTF environment, but also the experimental data employed in these validations. The sub-package `Resources` stores these datasets according to specific plant configurations. At present, most validations concentrate on centralized setups, but future work will incorporate diverse plant configurations to exploit the full capabilities of the DHTF.

Another important sub-package is `FMUExport`, which includes example models at both subsystem and full-plant scales. These classes enable the generation of FMUs for use in external environments like Simulink or Python, supporting advanced control strategies.

2.4 Availability & Software Compatibility

The MESL is developed as an open-source project and is publicly available at `https://github.com/RSE-TGM/multienergysystem`. The library has been primarily developed and tested in Dymola 2023, ensuring full compatibility with this Modelica environment. However, the

DOI
10.3384/ecp218871

`DistrictHeatingNetwork` package—and models using only its components—have been successfully tested in OpenModelica v1.24.3, demonstrating full functionality in this open-source platform.

On the other hand, the `H2GasFacility` package currently faces some limitations in OpenModelica. While basic gas models run correctly, advanced test cases involving multi-component gas flow present initialization issues. Future work will focus on improving OpenModelica compatibility to enhance accessibility and usability across multiple platforms.

3 Validation

Prior to this work, we had already validated the core district heating components in the `DistrictHeatingNetwork` package—such as boilers, heat exchangers and water pumps—using the RSE's DHTF. Over a series of experiments, we verified each model's accuracy under diverse operating conditions, measuring temperature, pressure, and flow rates. In the most comprehensive configuration (centralized layout), the models achieved a CVRMSE below 18% and an NMBE below 8%, in accordance with ASHRAE Guideline 14 (Muro Alvarado et al. 2024). These results confirm that the library reliably captures the dynamics in a district heating environment and can thus be extended to other energy vectors.

To enable the interconnection with gas networks, we updated specific models from the `DistrictHeatingNetwork` main package, by adding an additional gas inlet connector, drawn from `H2GasNetwork.Interfaces.Connectors` subpackage. In particular, two heat-generation models—the gas boiler and the CHP unit—were extended to calculate gas mass flow rates using Equation 1:

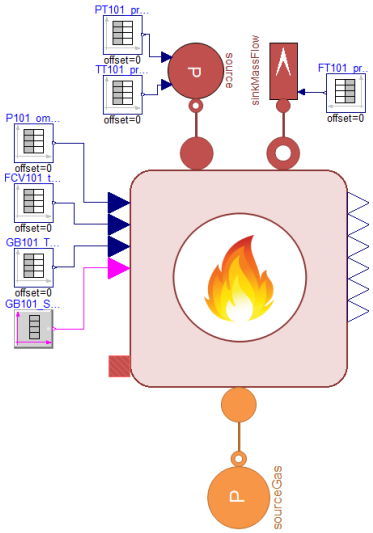
$$w_g = \frac{P_c}{HHV_g \eta_c} \tag{1}$$

where w_g is the gas mass flow (kg/s), P_c is the combustion power (W), HHV_g is the higher heating value of the gas (J/kg), and η_c is the combustion efficiency.

For the computation of the gas mass flow rate, the value of P_c depends on the specific component. In the gas boiler, the combustion power is entirely converted into thermal output, so P_c directly depends on the required thermal power. In the CHP model, P_c can be computed based on either the required thermal power or the required electrical power, depending on the selected control mode configuration.

This connector-based approach allows each gas-consuming component to be directly linked to a gas network model, thereby facilitating a coupling between thermal and gas domains.

To validate these hybrid models, we compared simulated results with experimental measurements from the DHTF. Figure 4 illustrates the test model diagram for a gas boiler configuration. The main boundary conditions—inlet temperature and water mass flow rate—were imposed using measured data (Figure 5.a). For evaluation purposes, we focused on two key variables: the outlet temperature of the boiler system, representing the thermal energy vector, and the fuel mass flow rate, representing the gas energy vector. Although Figure 5.b shows the outlet temperature trend, the performance metrics (CVRMSE & NMBE) were computed based on the temperature difference across the boiler (i.e., outlet minus inlet).



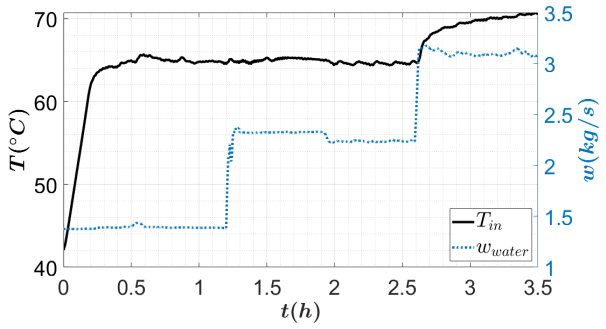


Figure 4. Validation test model for gas boiler subsystem.

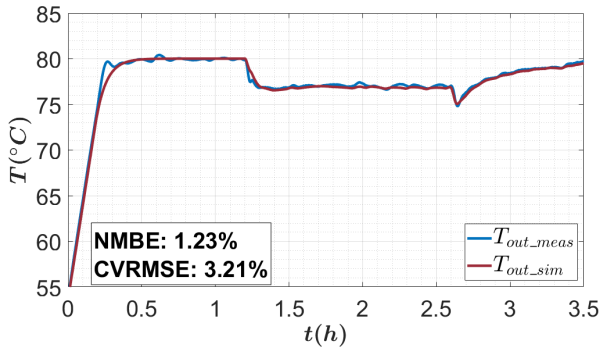
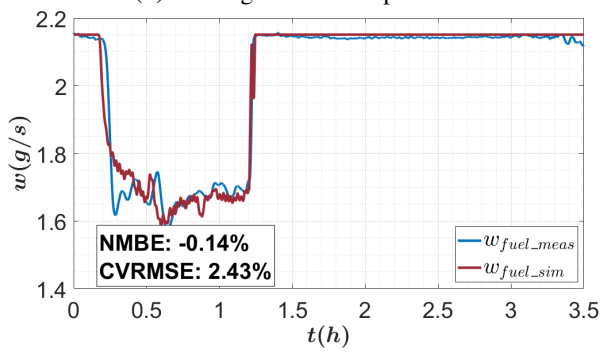


The validation results show good alignment between measured and simulated values: the temperature difference achieved an NMBE of 1.23% and a CVRMSE of 3.21%, while the fuel mass flow rate (Figure 5.c) resulted in an NMBE of -0.14% and a CVRMSE of 2.43%. These results demonstrate both strong accuracy and practical suitability of the model for integrated gas-thermal simulations.

Regarding gas network modeling, one of our primary goals is accurately capturing gas quality parameters (e.g., Wobbe Index) when hydrogen is blended into natural gas networks. We reference (Cheli et al. 2021) for such scenarios, which, although focused on quasi-steady operating conditions, provide a sufficient number of hourly data points to validate our model's compositional calculations. Figure 6 illustrates a representative comparison, showing minimal deviations from the reference data. While (Cheli et al. 2021) does not explore fast transients, our simulation framework allows for the generation of continuous hydrogen injection profiles. This feature becomes particularly useful for investigating faster ramping conditions and transient behaviors beyond the temporal resolution of the reference data.



For more rapid transients (seconds to minutes), we have compared the library's performance with other validated tools—such as the Modelica Standard Library (Fritzson 2011)—yielding negligible discrepancies. Once the

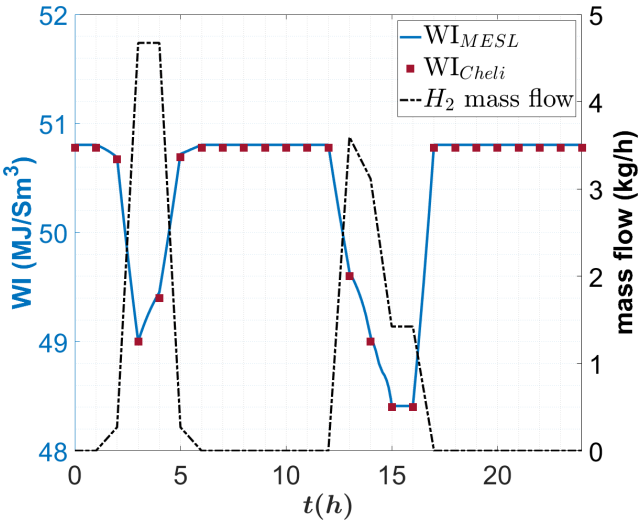

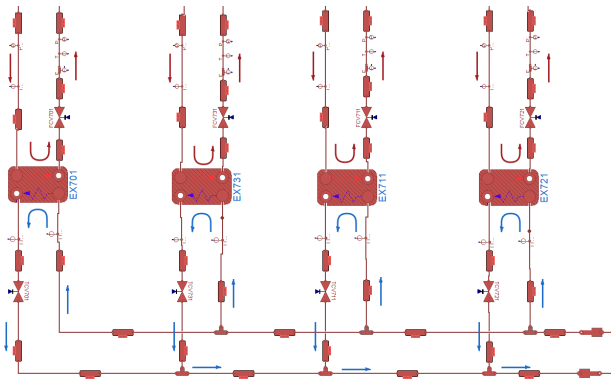

Figure 6. Comparison with (Cheli et al. 2021).

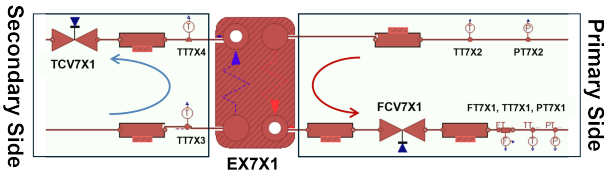
RSE's GTF is fully implemented, additional experimental validation will be performed to improve confidence in these models under dynamic hydrogen blending scenarios.



4 Case Studies

4.1 DHN application

One of the first applications of our library was the development of a decentralized control system for the load section of the DHTF. The load system consists of four heat exchangers (each representing a user in a DHN), connected on one side to a centralized heat distribution system (primary side) and on the other to a cooling system (secondary side) (Figure 7.a). Each user is equipped with pressure, temperature and flow sensors on both the primary and secondary sides, as well as two controllable valves: a flow control valve on the primary side and a temperature control valve on the secondary side (Figure 7.b). By adjusting these valves, the system emulates different heat demand profiles, closely replicating real DHN user behavior.

(a) Full Load system model.

(b) Single Load model.

Figure 7. DHTF Load System using MESL.

Traditionally, centralized DHN controllers regulate the secondary-side outlet temperature to ensure user comfort (Buffa et al. 2021). However, in this study, we adopt a different approach, prioritizing thermal power control at each heat exchanger. This strategy enables more precise energy demand regulation, allowing predefined load profiles. Moreover, it aligns with advanced control methodologies such as Model Predictive Control (MPC), where load thermal power profiles serve as key inputs for optimizing supply temperatures and mass flow rates from the heat generation side. A secondary objective is return temperature regulation on the primary side, ensuring compliance with the operational constraints of heat generators. Consequently, the primary variables of interest are

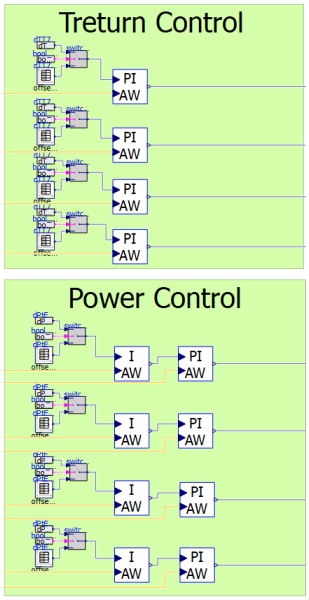
DOI
10.3384/ecp218871

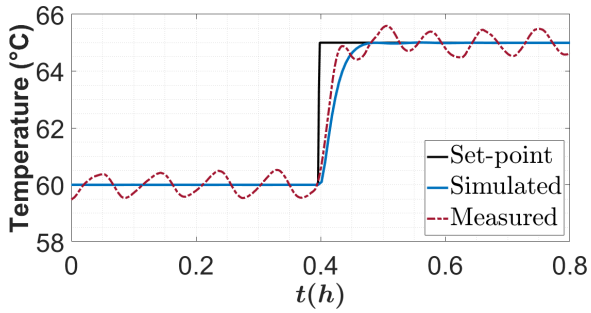
the *thermal power exchanged* at each heat exchanger and the *return water temperature* on the primary side.

To achieve these objectives, we designed a decentralized control system. We used our library to develop an open-loop analysis of the load system in a centralized configuration and verified that (i) Primary-side valve control is best suited for thermal power regulation since mass flow directly governs power exchange, (ii) Secondary-side valve control is better for regulating primary-side return temperature and (iii) the system can be decomposed into independent Single-Input Single-Output (SISO) loops, allowing a decentralized control strategy. For simplicity, the detailed analytical steps of this analysis have been omitted from this paper.

The decentralized control system for the load system, developed using MESL, was validated both in simulations and experimentally in the DHTF. As shown in Figure 8, the final design consists of:

- Four independent PI controllers for return temperature control (secondary-side valves).
- Four cascade controllers for thermal power control (primary-side valves), with a PI controller in the primary loop and an integrator in the secondary loop.





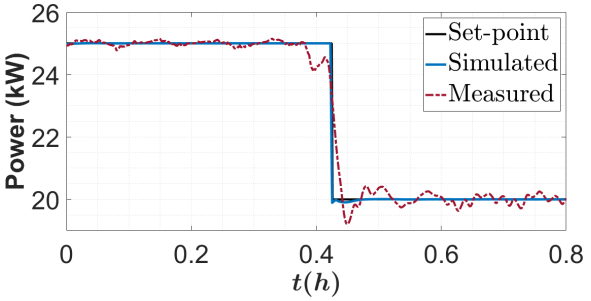


Figure 8. Controller diagram in Modelica.

A comparison between simulated and experimental results for a single load is shown in Figure 9. Trends for both return temperature (Figure 9.a) and thermal power (Figure 9.b) demonstrate the control system's ability to regulate desired variables effectively. While the overall response is well captured, some discrepancies appear, particularly in the return temperature dynamics. These deviations are primarily due to the cooling system's chiller: in real operation, the chiller follows an on/off control

(a) Return temperature.

(b) Thermal exchanged power.

Figure 9. Example of the controlled variables of one load.

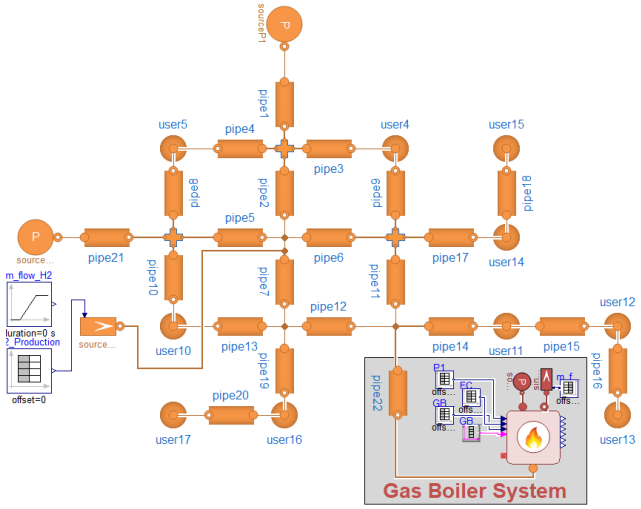
approach, whereas in the simulation, an ideal temperature control assumption was used for simplicity. Despite these differences, the experimental results confirm that the control system successfully regulates the load dynamics, demonstrating the effectiveness of MESL in developing and validating customized control strategies for district heating applications.

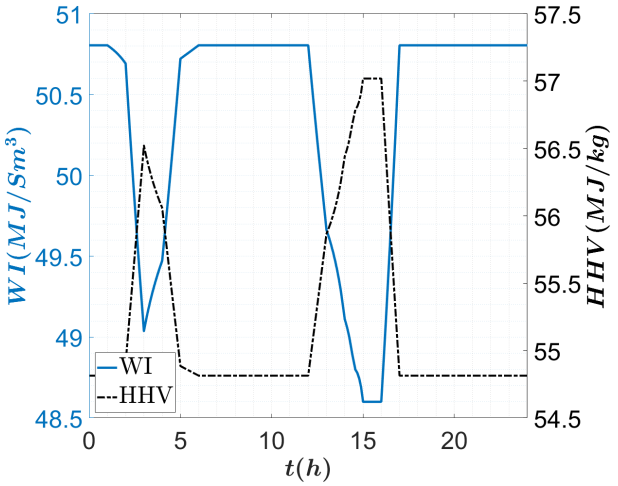
Beyond the decentralized control implementation described above, the package *DistrictHeatingNetwork* has also been used in the design and experimental validation of a MPC strategy for district heating networks. In that study, MESL was employed to simulate the DER-TF environment and support controller tuning. For further details, see (Nigro et al. 2025). This application reinforces the suitability of the library not only for dynamic simulation but also to support advanced control design.

4.2 Integration of Thermal and Gas Domains

As mentioned previously, the gas models within our library have not yet been experimentally validated in the DER-TF. However, given the satisfactory simulation results obtained so far with academic results, we aim to showcase the potential of integrating district heating and gas networks using the developed tools. Specifically, we demonstrate how thermal and gas systems interact and how simulation-based approaches can help predict key network parameters in scenarios involving hydrogen injection.

To illustrate this, we constructed a study case that couples an existing system from the DHTF—the gas boiler system (previously introduced in Figure 4)—with the gas distribution network model described earlier (Figure 3).





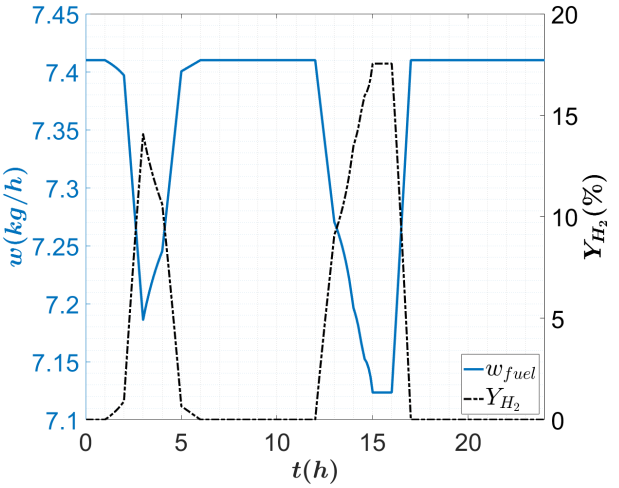


Figure 10. Diagram View of gas boiler system model from the DHTF, integrated in the case study based on (Cheli et al. 2021).

(a) Gas quality indexes.

(b) Fuel flow and hydrogen content.

Figure 11. Time evolution of key gas quality and fuel flow variables.

In this scenario, the gas boiler system is treated as an additional user in the gas network, alongside the existing users. The diagram of this configuration is described in Figure 10. The goal is to assess how the gas composition and flow characteristics evolve when the same hydrogen injection profile used in Figure 6 is applied.

The initial fuel composition consists of 97.20% CH_4, 1.80% C_2H_6, 0.30% C_3H_8, 0.10% C_4H_{10}, 0.10% CO_2, and 0.50% N_2 (vol%). The nominal fuel mass flow rate required by the gas boiler system, once connected to the network, is 7.41 kg/h. As hydrogen injection occurs throughout the day, this mass flow rate dynamically adjusts in response to the changing gas mixture composition, according to Equation 1.

Figure 11 illustrates the impact of hydrogen injection on fuel consumption. As hydrogen enters the system, the fuel mass flow rate decreases (Figure 11.b, blue line), which is expected since the HHV of the gas mixture increases (Figure 11.a, black line). At hour 15, the hydrogen volume fraction in the gas mixture reaches approximately 17.5% vol(Figure 11.b, black line), remaining within the manufacturer's specified limit of 20% vol. In this hypothetical scenario, the gas boiler operates safely within its design constraints despite the hydrogen injection.

This simulation not only provides insights into how hydrogen blending affects gas demand, but also highlights potential operational constraints—not only for the pipeline network but also for end-user equipment, which must be evaluated for hydrogen tolerance and performance limitations.

Complementary to this case, the *MultiEnergySystem* library has also been used in a separate study focused specifically on decentralized hydrogen injection in natural gas distribution networks (Sassaroli, Muro, and Casamassima 2025). That work leveraged MESL to develop a detailed dynamic model that captures transient effects in pressure, temperature, and gas mixing, including hydrogen and biomethane injection scenarios. The case study used a real-world Italian gas distribution network, further demonstrating the flexibility and applicability of the library to current and future hydrogen integration challenges.

5 Conclusion and Future Work

This paper presented the *MultiEnergySystem* Library, a Modelica-based library for modeling, simulating, and analyzing district heating and gas network. The library includes experimentally validated district heating models and a gas modeling approach capable of handling ideal (and potentially real) gas formulations for the study of hydrogen blending.

A key aspect of MESL is its ability to bridge district heating and gas domains, facilitating studies on hydrogen injection impacts and coupled energy networks. The library was successfully used in two case studies: (i) the design and validation of a decentralized load control sys-

DOI
10.3384/ecp218871

tem for the DHTF, and (ii) the integration of a gas boiler system into a hydrogen-injected gas network. These applications demonstrate MESL's versatility for both operational and control-oriented studies.

Despite these advancements, some limitations remain. While district heating models have been experimentally validated, the gas/hydrogen components are still pending validation in RSE's upcoming Gas Test Facility. Additionally, MESL currently lacks a dedicated electrical network modeling package, though electric power parameters can already be estimated for key components such as water pumps, CHP unit, and electric boiler.

Future work will focus on enhancing the library's capabilities. Once the Gas Test Facility is operational, we plan to experimentally validate the gas models, particularly for hydrogen blending effects. Moreover, we aim to expand MESL's electrical modeling, potentially by integrating it with existing Modelica libraries. Finally, the library will be further developed so the models can be used for advanced control applications, exploring co-simulation approaches with tools such as Python or Simulink.

By continuously improving MESL, we hope to provide a comprehensive and open-source simulation tool for multi-energy systems, fostering research and innovation in district heating, gas networks, and hydrogen integration.

Calibration of a Chiller Modelica model with experimental data

Christophe Montsarrat[1] Pascal Borel[1] Ana Paez[1]

[1]EDF R&D, France, firstname.lastname@edf.fr

Abstract

The modelling and calibration of industrial chillers can be challenging, especially when few measurements with a large uncertainty are available. The use of an approximate calibration model is investigated to explore its potential in calibrating a chiller model, constructed in *Modelica*. Based on the results of a well-instrumented experimental rig of a chiller at the EDF laboratory recorded over five days, with a varying outdoor air temperature, an approximated steady analysis is carried out by calibrating the *Modelica* model with the experimental results (mass flow rate, temperatures, pressures). The results indicate a good match between the calibrated model and the experiments and a physical sensitivity in the parameters of the model, consistent with the operation of the machine (isentropic efficiency, compressor flow rate, evaporator overheat regulation). Further work can be done on the unsteady measurements recorded on the chiller to improve the model and its stochastic calibration.

Keywords: Chiller modelling, Approximate Bayesian Calibration, Modelica, R507A

1 Introduction

Chillers play a key role in various industries and notably within nuclear power: they enable to condition air that cools down electrical rooms, which are essentials for plant operation and safety. It is thus required to have numerical models that can predict, with required accuracy, the key quantities of these systems, such as the maximum available cooling power under sizing conditions or temperature of the chilled water produced.

Several approaches exist to model these complex systems. A first approach relies on analytical models, often based on a steady-state assumption for the system. It is used to get a quick evaluation of the system behavior, but accuracy is often poor and a large data-set is generally needed to calibrate the model as exhibited by (Cecchinato, Chiarello, and Corradi 2010).

Another model category is the zonal model which consists in establishing a set of equations for each main components of the chiller such as the evaporator, the condenser, the expansion valves and the compressor. Solving the obtained equations systems, either assuming steady state or studying dynamic response, enable to predict the detailed behavior of the system as proposed by (Mouneer, Aly, and Mina 2021), (Afzali and Mahalec 2017) or (Lissandrin et al. 2017).

Computational Fluid Dynamics (CFD) can be used to study the details of the flows within some parts of the chiller. However, this approach is generally not affordable at the integral scale.

Calibration of chiller models is a key aspect of the zonal or analytical as the model relies on parameters that generally cannot be directly deduced from geometry and associated input data of the system. On a design phase, correlations are generally used to compute the required coefficients for the model to run (e.g. heat exchange coefficients). Once the system is in operation, data assimilation techniques can be used to calibrate model parameters. Various techniques can be used to calibrate models: amongst most used methods are least square methods (linear or non-linear), to minimize the differences between observed data and model prediction. In a more general way, Bayesian calibration techniques can be set up to estimate the posterior distribution of the parameters to be calibrated on a given dataset as described by (Marin, Robert, et al. 2007). (Zhen, Niu, and Tian 2023) propose to calibrate a chiller analytical model from the Modelica Buildings library (Wetter et al. 2014) by optimizing the improved indicator of the mean normalized bias error of model predictions.

The primary objective of this study is to calibrate a zonal Modelica chiller model using experimental data obtained from experiments conducted at the EDF laboratory.

First, a description of the Modelica-based chiller models is provided, along with a justification for the approaches used to model the different components of the chiller. Next, the rationale behind the statistical calibration techniques employed is presented, followed by an overview of the experimental facility used for the experiments.

The results from the experiment, considered to be steady, are discussed and then compared with the model predictions resulting from the calibration process. Discussions on the significance of the measurement uncertainties are also addressed.

2 Theory

2.1 Nodal modelling of a chiller

The modelling of a chiller is based on three components developed through an in-house library in `Modelica`. The motivation is to use components as generic as possible that can be adapted to different configurations of chillers without relying too much on geometric characteristics. As

the motivation is to develop a methodology for calibrating chillers, reducing the number of coefficients for these three main components is essential. The main principles of the components used are quickly presented here:

- **Compressor** - it is modelled by four values: one volumetric flow rate Q_v and three efficiencies quantifying its performance. The three efficiencies quantify the different losses encountered on a compressor: the mechanical efficiency η_{mech} for the friction losses, the volumetric efficiency η_{vol} measuring how efficiently used is the volume sucked in (dead volume, impermeability, pressure loss) and the isentropic efficiency η_{is} quantifying the entropy increase due to the compression of the fluid. These four parameters are important to model the enthalpy increase resulting from the compression rate $\Pi = p_{hp}/p_{lp}$ applied:

$$\Delta h = f(\Pi, Q_v, \eta_{mech}, \eta_{vol}, \eta_{is}) \tag{1}$$

- **Heat exchanger** - the model consists of N discrete cells in which heat exchanges occur between a fluid 1, not changing state, and a fluid 2 that absorbs or releases heat both through sensible exchange and change of state. The exchangers modelled can be parallel or counter flow exchangers, with fluids moving in the same or opposite directions. The cell $i-1$ supplies the inlet conditions for the following cell i (phases, pressure, enthalpy, mass flow rate) and three heat transfer coefficients are used: K_{lat} for the latent heat exchange, $K_{sens,vap}$ and $K_{sens,cond}$, respectively for the sensible exchanges between the vaporized fluid 2 and fluid 1 and the condensed fluid 2 and fluid 1. In the modelling here considered, **these three coefficients are kept constant** and used as parameters for the calibration. For each cell i, the heat exchange q_i per area units is modelled with the following expression:

$$q_i = K\,(T_{1,i} - T_{2,i}) \tag{2}$$

  The heat flux applied to the cell updates the temperatures at the outlet of the cell i for each fluid (1 and 2) which are then used as the inlet temperatures of the following cell. Depending on the state of the flow (two-phase, vapor or liquid), the coefficients K_{lat}, $K_{sens,vap}$ or $K_{sens,cond}$ respectively apply in (2).

- **Expansion valve** - it is simply modelled by a relationship between the mass flow rate and the pressure difference across the valve. The relationship is the following, with p_{hp} the high-pressure at the inlet and p_{lp} the low pressure at the outlet:

$$\dot{m} = K_{valve}\sqrt{p_{hp} - p_{lp}} \tag{3}$$

  A dependency on the coefficient K_{valve} can be added to adjust the opening of the valve, for example using the overheat, i.e. the temperature difference between the outlet of the evaporator and the saturation temperature within it.

Figure 1 shows a generic chiller model as used in `OpenModelica` with four main components, representing a classical thermodynamic cycle for a chiller: compression, condensation, expansion and evaporation. The overheat regulation is indicated by the arrow starting at the outlet of the evaporator to regulate the opening of the expansion valve.

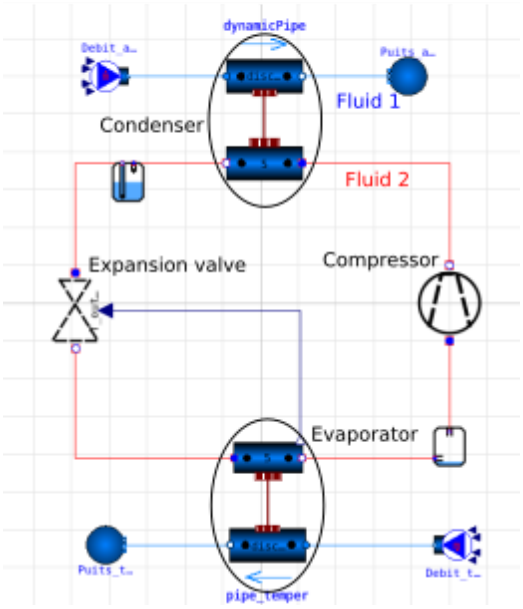

Figure 1. Illustration of a generic chiller model used in the `OpenModelica` GUI.

2.2 Approximate Bayesian Calibration

The purpose of calibration is to estimate the posterior mutltivariate law of the parameters θ to be calibrated of a model function denoted g. This model, $g(\theta, X)$, predicts observed quantities Y based the parameters to be calibrated and observed input parameters X.

$$Y = g(\theta, X) \tag{4}$$

As implied by the Bayes theorem recalled in Equation 5, the estimation of the posterior distribution of the parameters $\pi(\theta|Y)$ usually requires to be able to express the likelihood $\mathscr{L}$ of the observed variable Y, given the prediction of the model $\hat{Y} = g(\theta, X)$.

$$\pi(\theta|Y) = \frac{\mathscr{L}(Y|\theta)\pi(\theta)}{\pi(Y)} \tag{5}$$

A usual approach is to assume that the discrepancies between model prediction $\hat{Y}$ and the measured variable Y,

DOI 10.3384/ecp218881

denoted ε, follow a multivariate gaussian law with a null mean. If the errors are homoscedastic, non correlated and the model $g(\theta,X)$ is linear or locally linear using Taylor expansion, one can apply the Gauss-Markov theorem to obtain the ordinary least square (OLS) estimator $\hat{\theta}$ and its associated variance covariance matrix Σ. Assuming the likelihood function $\mathscr{L}(Y|\theta)$ is Gaussian, the posterior distribution can be expressed as:

$$\pi(\theta|Y) = \mathscr{N}(\hat{\theta},\Sigma) \tag{6}$$

In both linear and nonlinear Gaussian calibration approaches, it is further assumed that the prior distribution $\pi(\theta)$ is multivariate Gaussian. These methods rely on the Gaussian nature of the likelihood and require that the residuals—i.e., the differences between model predictions and observations—have zero mean. This implies that discrepancies are attributed solely to measurement uncertainties, rather than model bias or structural errors.

When the likelihood $\mathscr{L}(Y|\theta)$ has no analytical form, a solution is to use likelihood-free techniques such as the approximate bayesian calibration (ABC method), as suggested by (Turner and Zandt 2012) or (Cant and Evins 2023). This method mainly rely on the definition of a metrics to compare the simulated quantities $\hat{Y}$ to the same observed quantities Y. A threshold ε_0 is then associated to this metrics to consider a candidate point θ producing calibrated quantities. This is equivalent to considering that if the candidate point $\hat{\theta}$ produces predictions close enough to the observed values, then this point has a non-zero probability of being in the posterior parameter distribution $\pi(\theta|Y)$ as illustrated in Equation 7.

$$\pi(\theta|Y) \approx \pi(\theta|\rho(\hat{Y},Y) \leq \varepsilon_0) \tag{7}$$

This approach can also accommodate the presence of model error by specifying a probability density function f_ε to represent it. Using a fixed acceptance threshold, as described above, is equivalent to assuming that the model error follows a uniform distribution. In this case, all discrepancies within the threshold are considered equally likely, regardless of their magnitude. A common metrics used is the sum of the squared errors between the predictions and the observations.

$$RMSE_{Y_i} = \sqrt{\frac{1}{n_{obs}} \sum_{observation} (Y_i^{pred} - Y_i^{obs})^2} \tag{8}$$

$$MBE_{Y_i} = \frac{1}{n_{obs}} \sum_{observation} (Y_i^{pred} - Y_i^{obs}) \tag{9}$$

$$CvRMSE_{Y_i} = \frac{RMSE_{Y_i}}{\overline{Y_{obs}} - Y_{ref}} \tag{10}$$

$$NMBE_{Y_i} = \frac{MBE_{Y_i}}{\overline{Y_{obs}} - Y_{ref}} \tag{11}$$

Common threshold to retain a candidate point is to have $CvRMSE \leq 0.2$ and $NMBE \leq 0.05$ for each observed variable.

Using OpenTURNS (Baudin et al. 2017), a candidate set sample is generated from the multivariate distribution $\pi(\theta)$. Then, for each candidate point, the model g is evaluated allowing the defined metrics to be computed. The multivariate law of the posterior sample is then inferred using parametric or non parametric methods to define notable the most probable posterior values of $\pi(\theta|Y)$. If the posterior sample does not contain enough points regarding a targeted size previously defined, additional samples from the prior distributions can be considered. The above presented algorithm is usually called the basic ABC-rejection algorithm which can be improved using sequential MonteCarlo approach.

3 The R507 Chiller Experiment

3.1 Global Description

The test facility (Figure 2) used in this study operates with R507A, a hydrofluorocarbon (HFC) refrigerant (CoolProp n.d.). The test facility is well-equipped with pressure and temperature sensors installed at the inlet and outlet of each component, complemented by several Coriolis flow meters integrated into the test facility system.

The test facility consists of three main circuits. The first circuit, using Temper 55 as the secondary fluid in the evaporator, is designed to measure the cooling demand. This circuit includes electrical resistances and a pump that allow for the control of flow rate, temperature, and thermal power dissipation. A second air circuit interacts with the condenser to dissipate heat from the refrigerant. The third circuit utilizes R507A as the working fluid and forms the core of the experimental setup.

The refrigeration system consists primarily of a plate evaporator with a surface area of 44.4 m², a condenser of 1157.5 m² equipped with five variable-speed fans, an electronic expansion valve, and a Grasso rotary screw compressor. The compressor allows for variations in the internal swept volume. Depending on the applied compression ratio, the refrigerant flow rate can range from 23.1 m^3/h to 231 m^3/h.

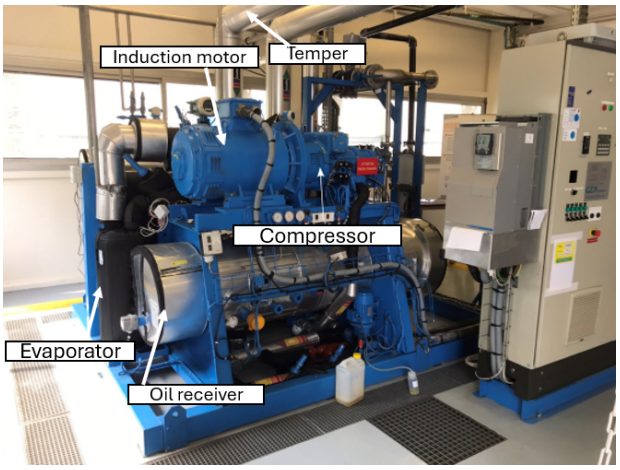

Figure 2. Photo of the test facility

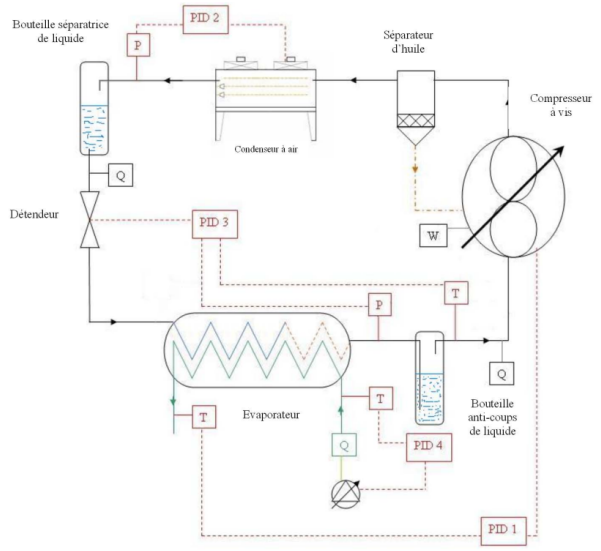

Figure 3. Experimental setup with control loop

Figure 3 shows the four controllers (PID1, PID2, PID3, and PID4) used to regulate the precision of the evaporator, high pressure, overheating, and the secondary pump flow rate of the evaporator circuit, respectively. These regulations will not be considered in the current model.

3.2 Uncertainty of measurements

The expanded uncertainty of each sensor considers the whole measuring chain, from the sensor to the automate errors. The uncertainty given corresponds to a confidence interval of 95%.

The mass flow rate, pressure, and temperature sensors have an accuracy at $\pm 0.1\%$, $\pm 3\%$, and $\pm 0.174°C$, respectively. It must however be noted that the uncertainties on the measurements on the air-side of the condenser are higher and more difficult to estimate.

When a calculation includes several variables, for example the calculation of the cooling capacity, a combined standard uncertainty U_c^2 should be calculated using the equation 12. The method is based on first-order Taylor series, and it is referred to as the law of propagation of uncertainty (Taylor, Barry N and Kuyatt 1994).

$$U_c^2(y) = \sum_{i=1}^{n} \left(\frac{\partial f}{\partial x_i} \right)^2 u^2(x_i) + \sum_i \sum_j \partial_i f \partial_j f r_{ij} u_i u_j \quad (12)$$

where $u(x_i)$ represents the uncertainty of each variable. In this article, the variables are assumed to be independent and with a linear behavior, which allows to neglect the last term of the previous equation that refers to the correlation between the variables.

3.3 Experimental conditions

The experimental results presented in this study were obtained under the following conditions:

- The flow rate of the Temper-55 fluid was maintained at 6 kg/s using the circuit pump. The evaporator pressure was kept constant at 7.5 bar through compressor regulation. To simulate a cooling demand, electrical resistances installed in the Temper-55 circuit provided a constant thermal load of 100 kW.
- The refrigerant overheat was regulated by the expansion valve, ensuring a stable overheat of 6°C. The five fans of the air-condenser operated continuously at maximum speed, allowing the refrigerant's high pressure to vary according to the ambient air temperature.
- Data were recorded every 10 seconds over a period of five days.

4 Results and discussions

4.1 Experimental results

The analysis of the results revealed significant oscillations primarily due to the ambient air temperature and the simultaneous regulation of four controllers, see section 3.1. While these oscillations could provide valuable insights in a future phase, particularly when incorporating regulation into our models for dynamic comparisons with experimental data, our current study focuses on a steady-state analysis.

In order to validate and calibrate the models in steady-state conditions, the experimental results were divided into multiple intervals where the ambient temperature variation remained below 1°C.

Figure 4 illustrates the fluctuations of air temperature during the recording test. To ensure a clear and reliable validation of the model, four representative points are selected on the following criterion: the temperature remains in a $\pm 1°C$ range for at least one hour. The different variables measured and their mean values over these intervals are presented in Table 1.

To validate the data collected from the test facility, an energy balance was performed for both the evaporator, (13) and the global system (14). The energy balance in the condenser was not calculated due to the imprecision of the air measurements.

$$\dot{m}_{\text{Temper}}\, c_{p\text{Temper}}\, \Delta T_{\text{Temper_evap}} = \dot{m}_{\text{R507A}}\, \Delta h_{\text{R507A_evap}} \quad (13)$$

$$\dot{Q}_{\text{evap}} + \dot{Q}_{\text{cp}} = \dot{Q}_{\text{cond}} \quad (14)$$

Figure 5 shows the statistical variations in thermal capacity and the energy balance results for point 0. The data is presented using box plots, as this format allows for the display of key information in a single figure, such as the mean and distribution data. The black boxes represent the data distribution, with the blue horizontal lines inside indicating the mean and the red lines representing the median.

Table 1. Experimental results under different steady-state conditions

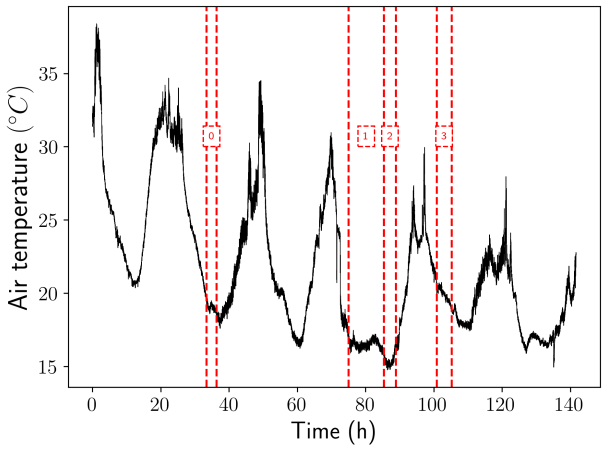

Figure 4. Evolution of the air temperature, measured at the air condenser. The four experimental periods corresponding to the four approximate steady conditions are indicated by the red dashed lines.

The ends of the boxes denote the first and third quartiles, while the black "whiskers" extend to the minimum and maximum values.

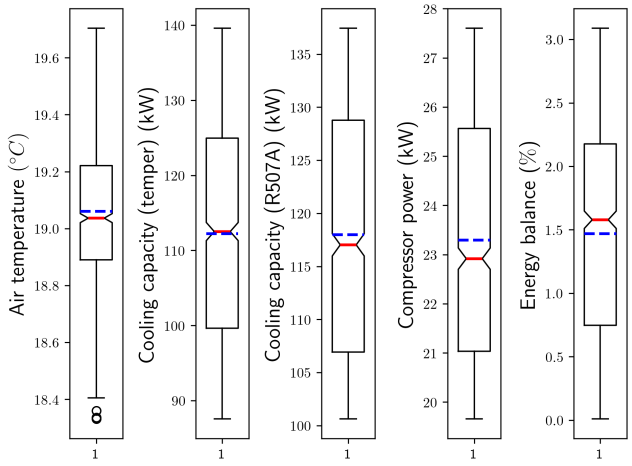

Figure 5. Box plot at point 0 comparing the thermal power exchanged at the evaporator and condenser. Energy balance of the system. Median: red bar, Mean: blue line.

The energy balance revealed a small discrepancy, less than 2.5 %, which validates the measurements taken in the test facility.

4.2 R507 model and calibration

4.2.1 Presentation of the R507 model

A `Modelica` model has been used to capture the behaviour of the chiller tested experimentally. As explained in 3.3, the aim is to model steady-like behaviors of the system. The assumption here made considers that the air temperature fluctuations are small enough to approximate the operations of points 0 to 3 to steady conditions. The chiller is modelled with four main components as shown in Figure 1 and presented in 2.1. Here, the different parameters to be calibrated are presented along with the setup used in `OpenModelica`.

Most of the modelling is based on an adapted version of the `Modelica Standard Libry (MSL)` except for the types of fluid used in the model. Indeed, the MSL does not integrate the possibility of utilising fluids like R507A and Temper-55. The two fluids can be introduced by using the open source library `CoolProp` (Bell et al. 2014), whose integration into the software `OpenModelica` has been done with the library `ExternalMedia` (Casella and Richter 2008).

Overall, twelve uncertainties and parameters can be calibrated in the model as shown in Table 3. They correspond to the uncertainties associated to the values measured experimentally and to the parameters of the components of the model (heat exchange coefficients, efficiency, overheating). The way they are calibrated is explained in the next section based on the methodology described in 2.2. Large uncertainties for the air temperature and mass flow rates were initially taken in the a priori distributions ($2°C$ and 1 kg/s resp.): the resulting calibrated point is consistent with this choice.

The prior distributions are chosen based on the knowledge of the uncertainties ($U_.$) and the parameters. For the uncertainties, the value is sampled into a normal distribution centred into 0 and with a standard deviation corresponding to the uncertainty of the probe (temperature or mass flow rate). This is added to the observed value experimentally as an input of the model. Regarding the rest of the parameters, their distribution is chosen uniform with bounds determined as much as possible from the experience of the user: the larger is the range, the more unphysical operating points for the model will be computed, leading to important errors between the model and the experiment or simply difficulties for the model to converge.

4.2.2 Calibration

Given a random sampling of all the uncertainties of measurements and the parameters to be calibrated in the model done N times according to prior distributions of probability, the principle of the ABC method is to compare the values obtained with the model to the experiment and then select the most relevant.

Min C_vRMSE	Min C_vRMSE	Min $NMBE$	Max $NMBE$
0	0.2	-0.2	0.2

Table 2. Range of acceptable errors for the selection of the parameters of the model.

The relevance is based on criteria defined by the user depending on the values observed and the tolerance accepted for the calibration in terms, for example, of the mean bias error (MBE) and the root mean square error (RMSE) with the experimental measurements. These two criteria are the ones retained for the selection of the points in the sample and can be written as follows for each value observed, as explained in 2.2.

The ranges for the selection of the parameters are indicated in Table 2. It means that, for one set of parameters from the sample, when comparing the values obtained with the model, the set is conserved if the RMSE and MBE are in the range indicated. The choice of 20% enables to keep sets of parameters with a reasonable error compared to the experiment.

The size of the design of experiments concerns 5000 simulations of approximately 30 seconds CPU, that have been carried out. With the RMSE and MBE criteria below 20%, only 6 of them have been selected. By making the criteria looser, for example with accepting results with a 30% error on the RMSE and MBE, 127 could have been retained. Here, the motivation was to show the principle of the method and the good possibilities for a calibration but this could be improved to get a larger sample for the posterior distributions. Also , out of the 5000 samples, some lead to unphysical behaviors and never converge in the model. These can be kept and analyzed to actually understand the potential problems of robustness of the model to the parameters. Only fifty out of the 5000 samples failed in this case, indicating quite a robust model, numerically.

The optimal point for the different parameters and uncertainties calibrated is shown in Table 3. These are determined with the resulting distributions built on the selected points of each parameter. The most probable value in each distribution obtained corresponds to the optimal value.

Figures 6 and 7 show the distributions of the isentropic effiency η_{is} and Q_v, prior and posterior to the approximate bayesian calibration. The distribution in green represents the distribution on which the parameters are drawn to simulate the behaviour of the chiller with the model and the orange one represents the points for which the selection criteria are fulfilled. The blue curve gives an approximation of the orange distribution based on a kernel smoothing

$U_{T_{air}}$	$U_{Q_{air}}$	$U_{T_{temper}}$	$U_{Q_{temper}}$	K_{lat}^{cond}	K_{sg}^{cond}
-1.61 °C	-0.78 kg/s	-0.14 °C	-0.32 kg/s	160.9	136
K_{sl}^{cond}	K_{lat}^{evap}	K_s^{evap}	$Q_v^{compressor}$	$\Delta T_{valve,nom}$	η_{is}
140.8	134.5	117.9	0.022 m^3/s	5.26 °C	0.398

Table 3. Table of the optimal values based on the calibration done with the R507 model.

Mass flow rate of R507	Pressure in the condenser	Pressure in the evaporator
$T_{out,evap}$	$T_{in,cond}$	$T_{out,cond}$
Temperature at the outlet of the evaporator	Temperature at the inlet of the condenser	Temperature at the outlet of the condenser
$P_{th,evap}$		
Thermal power exchanged at the evaporator		

Table 4. Description of the observed measurements used for the comparison with the model.

method (Baudin et al. 2017). A peak in the distribution can be noticed in both cases, meaning that the model is very sensitive to these two parameters for the calibration. Given a compression ratio, the temperature at the inlet of the condenser is strongly affected by the isentropic efficiency. Being too far from $\eta_{is} = 0.398$ therefore seems to lead to probable large errors on the calibration. The same can be inferred on Q_v, which controls the mass flow of the refrigerant. For three other parameters, the posterior distribution is quite different from the prior choice, which indicates a sensitivity of the model to these parameters to be consistent with the experimental observations (ΔT_{valve}, $U_{T_{air}}$ and K_s^{evap}).

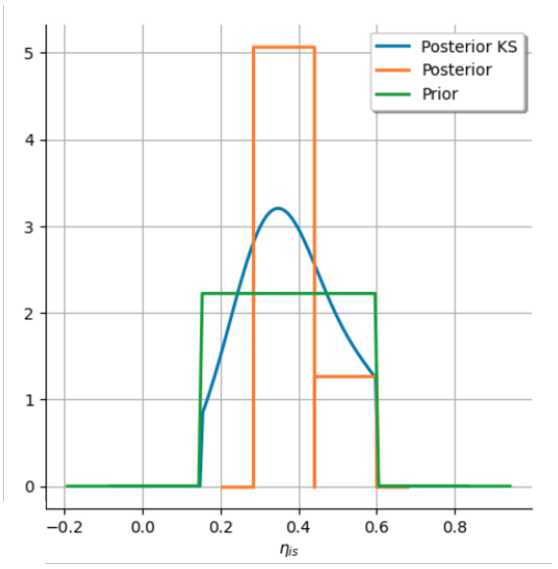

Figure 6. Distribution of the isentropic efficiency, prior and posterior to the application of the ABC method and the selection. The blue distribution approximates the distribution of orange values selected with a kernel smoothing.

It is now interesting to compare the predictions of the model with the optimal set of parameters determined with the ABC method to the actual observations measured experimentally as described in Table 4.

DOI 10.3384/ecp218881

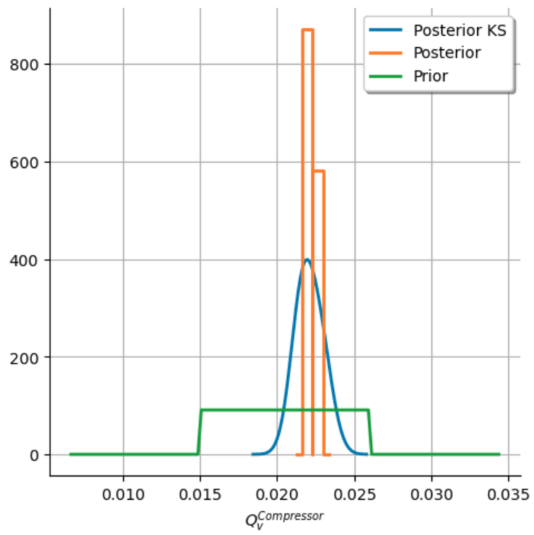

Figure 7. Distribution of the compressor volumetric flow, prior and posterior to the application of the ABC method and the selection. The blue distribution approximates the distribution of orange values selected with a kernel smoothing.

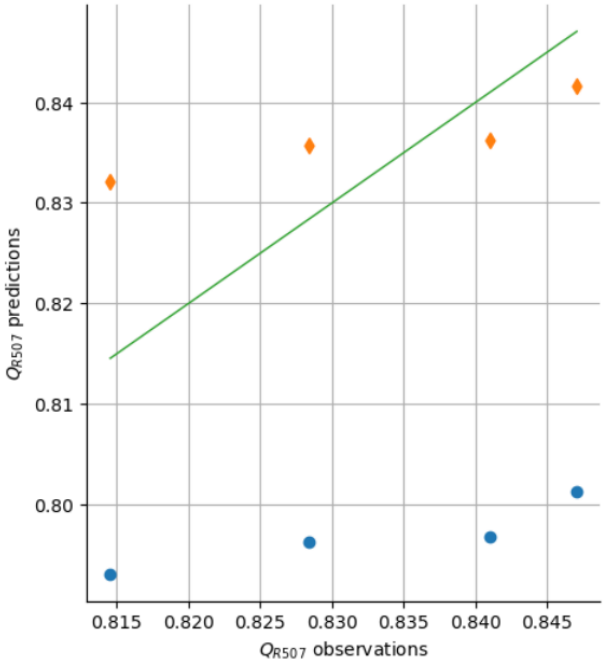

Figure 8. Distribution of the compressor volumetric flow, prior and posterior to the application of the ABC method and the selection. The blue distribution approximates the distribution of orange values selected with a kernel smoothing.

Figure 8 compares the predictions from the model with the experimental values measured on the mass flow rate of refrigerant. The blue dots show the initial predictions based on the most probable set of parameters with the prior distributions whilst the orange dots indicate the predictions from the posterior, built distributions from the selection. The green line is the first bisector corresponding to a perfect equality between predictions from the model and experiments for the different observations. Overall, the ABC method leads to a good calibration of the model, improving clearly the match between experiment and modelled results.

Another view on the comparison between the experiment and the model is shown in Figure 9. It compares the cycles for point 0 (cf. Table 1). What can be observed is the overestimate of the pressure at the condenser for four sets of parameters. The fifth set corresponds to the optimal point and matches quite well with the experimental cycle. Other differences concern the enthalpy at the outlet of the condenser (slight difference) and the specific enthalpy at the compressor outlet.

The advantages of the ABC calibration method over more traditional approaches are clearly demonstrated in this case. Due to the complexity of the model, certain parameter evaluations may lead to simulation failures—situations that ABC is uniquely equipped to handle, as it does not require explicit likelihood evaluations. As illustrated in Figure 6 and Figure 7, the resulting posterior distributions are approximately Gaussian. ABC enables the generation of a discrete sample from this posterior, providing a flexible and robust inference framework. Given the typically nonlinear nature of the models, conventional methods such as nonlinear least squares or nonlinear Gaussian calibration often suffer from poor exploration of the parameter space and high sensitivity to initial conditions. In contrast, ABC facilitates a more comprehensive exploration, especially when the likelihood is intractable or the model is prone to numerical instabilities. Moreover, due to limited prior knowledge about the model parameters, a uniform prior distribution is often the most

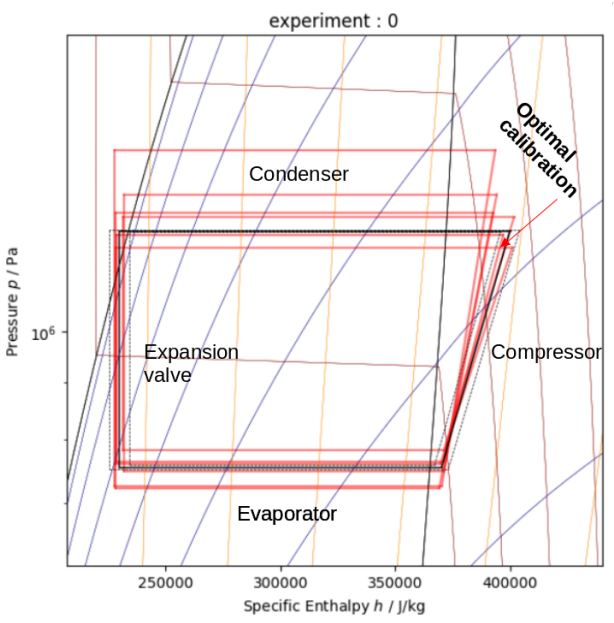

Figure 9. Representation of the experimental cycle for point 0 (black lines) and the ones obtained with the model after calibration with the ABC method. The point resulting from the optimum values in the calibration is shown by the arrow.

appropriate choice. Gaussian priors, by contrast, may introduce unwarranted assumptions and overly constrain the calibration process.

Generally, the calibration enables a quite satisfying fit of the model with the experiment for the four observations on the different values. Although a larger shift can be observed for the inlet temperature at the condenser (or outlet temperature of the compressor), the overall prediction is improved with the calibration. That shift could be explained by the choice made for modelling the compressor with constant efficiencies: a variation of the volumetric and isentropic efficiencies with the pressure ratio may improve these results (Gicquel 2001).

5 Conclusions and further work

This study was motivated by the use of an approximate calibration method for the modelling of a chiller. To the knowledge of the authors, this kind of methods for this type of applications has rarely been done before. Experimental results on a chiller test facility at EDF have been obtained and used to make a calibration of a model representing the chiller in *Modelica*.

With four experimental points approximated as being in a steady state, a calibration has been performed based on the approximate bayesian calibration method. Considering seven variables observed experimentally for these four points, a set of parameters is varied in the model following a design of experiments constructed on probabilistic distributions a priori. The calibration done has consisted in selecting the sets of parameters ensuring an acceptable error between the experiments and the variables modelled.

The results obtained with the calibration are satisfying as they enable to maintain the error below 20% for the sets of parameters kept. Given the initial number of parameters in the model, the ABC method also offers a very interesting way of priorizing the parameters regarding the sensitivity of the variables of interest in the model. In our case, consistently with what is physically modelled, the isentropic efficiency, the volumetric flow rate and the nominal overheating for the expansion valve are the most sensitive parameters.

It is interesting to comment on the use of such methods to analyze further experimental results. In this study, the choice was to start with approximating steady regimes for the chiller with the experimental results based on an assumption of low variations of the outdoor air temperature. The analysis here presented shows that it is possible to calibrate the model to these experimental conditions but it also shows that only a few points are kept in the end, out of the 5000 samples. Different improvements to the current application of the method can be listed here for further work:

- Treating the problem as an unsteady one by considering the variations of the variables over time. In practice, it means that for each time step in the sample considered, the variables observed correspond to an experimental point and the same method can be used with more experimental points. This would imply an improvement of the model to account for the regulation loops in the experiment but also an increase in the CPU cost, with more observations in the method.

- Improving the components of the model: the compressor efficiencies depend on the pressure ratio, which is not the case in the current model. Also, the air-cooled condenser is modelled with a counterflow heat exchanger whilst in reality, it is a cross-flow exchanger.

- With more points selected for the probabilistic distributions, it would then be interesting to transpose the posterior distributions to more extreme air temperature conditions, beyond $40°C$, to make an evaluation of the uncertainties, in particular on the cooling power of the chiller.

- The choice of the prior distributions is essential to avoid non-physical and unstable numerical points in the model. A careful investigation of that choice can significantly help the process of calibration.

A Dynamic Simulation Model of Outdoor Swimming Pool with Thermal Energy Storage, Boiler and Solar Thermal Collectors

Pierre Clément Blaud[1] Imad Mourtaji[1]

[1]Akkodis Research, Akkodis, France, {firstname.surname}@akkodis.com

Abstract

Outdoor swimming pool facilities are significant energy consumers, primarily due to the need to maintain thermal comfort for swimmers, as the pool is exposed to wind and outdoor air. To address the challenge of reducing energy consumption, effective simulation of the dynamical system is essential to identify energy-saving solutions. This paper presents a comprehensive implementation of an outdoor swimming pool simulation model using the Modelica programming language. The simulation model also incorporates a thermal storage system, a boiler, and a solar thermal collector, allowing a detailed analysis of the system. In addition, an in-depth explanation of the physical equations governing the swimming pool is provided, along with the methodology used to construct the Modelica model. The results show that the model allows the simulation of the thermal behavior of an outdoor swimming pool, including various heat losses, solar heat gains, and heat production from the boiler and solar collectors.

Keywords: Swimming pool model, energy system, thermal storage, boiler, solar thermal collectors

1 Introduction

In late 2017, France had 4,135 public swimming pool facilities comprising 6,412 pools and covering a total area of 1.6 million square meters (Cour des comptes 2018). These facilities represent a significant financial burden for local communities, both due to the need to offer affordable access to the public and the high levels of energy consumption required for operation (Delgado Marín, Vera García, and García Cascales 2019). A large proportion of these facilities are aging, with more than 70% built before 1995 (Cour des comptes 2018). The recent energy crisis has further exacerbated the situation, leading to increased operational costs and in some cases, full or partial closures during the winter months (Cour des comptes 2018; Delgado Marín, Vera García, and García Cascales 2019). The high energy consumption associated with these facilities arises from the need to heat large volumes of water to maintaining temperatures between 25°C and 28°C as recommended by the World Aquatics Federation, as well as to power auxiliary systems such as showers, ventilation, lighting, and administrative areas. Modeling the dynamic behavior of public swimming pools and their associated energy systems is essential for analyzing energy use and developing advanced control strategies for heating systems (Li et al. 2021).

Numerous studies have focused on the modeling of indoor swimming pools (Yuan et al. 2021; Kühn et al. 2022), outdoor swimming pools (Buscemi et al. 2024; Bernhard et al. 2019), and the integration of swimming pools with heat production systems (Li et al. 2021). Several of these works use multi-domain modeling languages such as TRNSYS (Delgado Marín, Vera García, and García Cascales 2019; Starke et al. 2017; Liu, Kim, and Shin 2021) or Modelica (Kühn et al. 2022). In the study (Delgado Marín, Vera García, and García Cascales 2019), TRNSYS was used as a simulation platform for implementing predictive control strategies. Their results demonstrated that predictive control significantly reduces energy consumption compared to traditional proportional-integral-derivative (PID) controllers. In the study (Starke et al. 2017) conducted a technical and economic analysis of a pool equipped with solar thermal heating and a heat pump, concluding that this configuration improves energy efficiency. Similarly in (Liu, Kim, and Shin 2021), the authors used TRNSYS to model a swimming pool and adjacent buildings, examining the feasibility of using a fuel cell cogeneration unit for heat and power generation. Although the system was found to be economically viable, the payback period exceeded 10 years. It can be observed that detailed modeling of swimming pool systems with TRNSYS simulation tool is well established in the literature. However, concerning the Modelica modeling language, few studies have addressed swimming pool systems coupled with heat sources, to our knowledge, only one of these studies focused on an indoor swimming pool (Kühn et al. 2022), without considering an outdoor pool and several heat sources.

In the present work, we model a public outdoor swimming pool using the Modelica language including an external pool, consequences of weather conditions on the pool, a thermal energy storage unit and two heat sources: a boiler and a solar thermal collector. The main contributions of this work are:

- The implementation and simulation of a public outdoor swimming pool with consideration of external environment and thermal cover modeling using the Modelica language;
- The development of a complete energy system sim-

ulation that includes thermal energy storage (TES), and two heat sources, with a boiler, and a solar thermal collector (STC);

- And finally to propose a realistic comparative analysis of heat losses, and energy savings with and without the use of solar thermal collectors.

This paper is organized as follows: Section 2 introduces the simulation models; Section 3 depicts experimental setup; Section 4 presents the results of the work; and Section 5 concludes the work.

2 Simulation Model

2.1 Swimming Pool Model

The complete model of the swimming pool is shown in Figure 1. In the following sections, each submodel will be presented in detail.

2.1.1 Energy balance

Figure 2 depicts the energy balance without thermal cover. Assuming that the pool water is fully mixed, the temperature dynamics are governed by the following energy balance equation (Gauthier-Clerc et al. 2023; Buscemi et al. 2024) :

$$V_p \rho_w c_{p,w} \frac{dT_p}{dt} = \dot{Q}_{tot} \tag{1}$$

$$\dot{Q}_{tot} = \dot{Q}_{sun} + \dot{Q}_{heat} - \dot{Q}_{conv} - \dot{Q}_{evap} - \dot{Q}_{rad} - \dot{Q}_{cond} - \dot{Q}_{re} \tag{2}$$

with V_p the volume of the pool, ρ_w the density of water, $c_{p,w}$ the specific heat of water, $\dot{Q}_{sun}$ the heat gain from solar irradiance, $\dot{Q}_{heat}$ the heat power from the heating, $\dot{Q}_{conv}$ the heat loss from convection, $\dot{Q}_{evap}$ the heat loss from the evaporation, $\dot{Q}_{rad}$ the heat loss from the radiation, $\dot{Q}_{cond}$ the heat loss from conduction and $\dot{Q}_{re}$ the heat loss from water refilling and recycling. For the rest of the work, conduction losses are neglected as it contributes to less than 1% of total energy losses (Buscemi et al. 2024).

During the night, it is preferable to cover the pool to reduce heat loss, in this case the energy balance is depicted in Figure 3. The temperature dynamic is equal to (Buscemi et al. 2024):

$$V_p \rho_w c_{p,w} \frac{dT_p}{dt} = \dot{Q}_{heat} + \dot{Q}_{cover} - (\dot{Q}_{cond} + \dot{Q}_{re}) \tag{3}$$

$$\dot{Q}_c \simeq \dot{Q}_{sun} - (\dot{Q}_{conv} + \dot{Q}_{rad}) \tag{4}$$

with V_p the volume of the pool, ρ_w the density of water, $c_{p,w}$ the specific heat of water, T_p the pool water temperature, $\dot{Q}_{sun}$ the heat power from the solar irradiance, $\dot{Q}_{heat}$ the heat power from the heating, $\dot{Q}_{conv}$ the heat loss from convection, $\dot{Q}_{evap}$ the heat loss from the evaporation, $\dot{Q}_{rad}$ the heat loss from the radiation, $\dot{Q}_{cond}$ the heat loss from conduction, $\dot{Q}_{re}$ the heat loss from water refilling and recycling, and with $\dot{Q}_c$ the heat exchange from the pool to the cover.

2.1.2 Solar gain

Since solar irradiance can heat the pool water, the governing equation is equal to (Buscemi et al. 2024):

$$\dot{Q}_{sun} = G_h \alpha_p A_p \tag{5}$$

with G_h the global horizontal solar irradiance, α_p the solar absorptance of the pool and A_p the pool area. The solar absorptance of the pool depends on whether the pool is covered or not by the thermal cover. When the pool is not covered, the absorptance of the pool is equivalent to the absorptance of water (Buscemi et al. 2024). The Modelica graphical implementation is provided in Figure 4. An ideal prescribed heating power is implemented, and a switch controls the flow of covered or uncovered water. Both pool area and solar absorptance gains are incorporated.

2.1.3 Evaporation losses

Evaporation produces a transfer of mass and heat and occurs on the surface of a saturated liquid. This process is enhanced by both natural and forced convection, the latter being induced by wind in the case of outdoor pools (Buscemi et al. 2024). The heat losses due to evaporation are described as (Buscemi et al. 2024):

$$\dot{Q}_{evap} = \dot{E}_p \Delta H_w A_p \tag{6}$$

with $\dot{Q}_{evap}$ the heat loss from the evaporation, $\dot{E}_p$ the rate of evaporation of water, ΔH_w the latent heat of vaporization of water, A_p the pool area. When the thermal cover is unfolded, the evaporation does not occur, $\dot{Q}_{evap} = 0$. The rate of evaporation of water with forced convection and natural convection is equal to (Buscemi et al. 2024):

$$\dot{E}_{p,fc} = (0.28 + 0.784 v_{wi}) \frac{(p_{v,i} - p_{v,e})^{0.695}}{\Delta H_w} \tag{7}$$

$$\dot{E}_{p,nc} = h_m (\rho_{v,i} - \rho_{v,e}) \tag{8}$$

with $\dot{E}_{p,fc}$ the forced convection rate of evaporation, v_{wi} the wind velocity, $p_{v,i}$ the vapor pressure at the water surface depends to the saturated vapor pressure at pool temperature, $p_{v,i} = p_{vs}(T_p)$, $p_{v,e}$ the vapor pressure of the free stream depends to the saturated vapor pressure at air temperature $p_{v,e} = p_{vs}(T_a)(\frac{RH_e}{100})$, ΔH_w the latent heat of vaporization of water, $\dot{E}_{p,nc}$ the natural convection rate of evaporation, h_m the transfer coefficient for natural convection, $\rho_{v,i}$ the vapor density at the water surface and $\rho_{v,e}$ the free stream vapor density. The total rate of evaporation of the pool with the natural and forced convection is (Buscemi et al. 2024):

$$\dot{E}_p = F_A \left(\dot{E}_{p,nc}^{7/2} + \dot{E}_{p,fc}^{7/2} \right)^{2/7} \tag{9}$$

with $\dot{E}_p$ the pool rate of evaporation, $\dot{E}_{p,nc}$ the natural convection rate of evaporation, $\dot{E}_{p,fc}$ the forced convection rate of evaporation and F_A the evaporation surface

DOI 10.3384/ecp218891

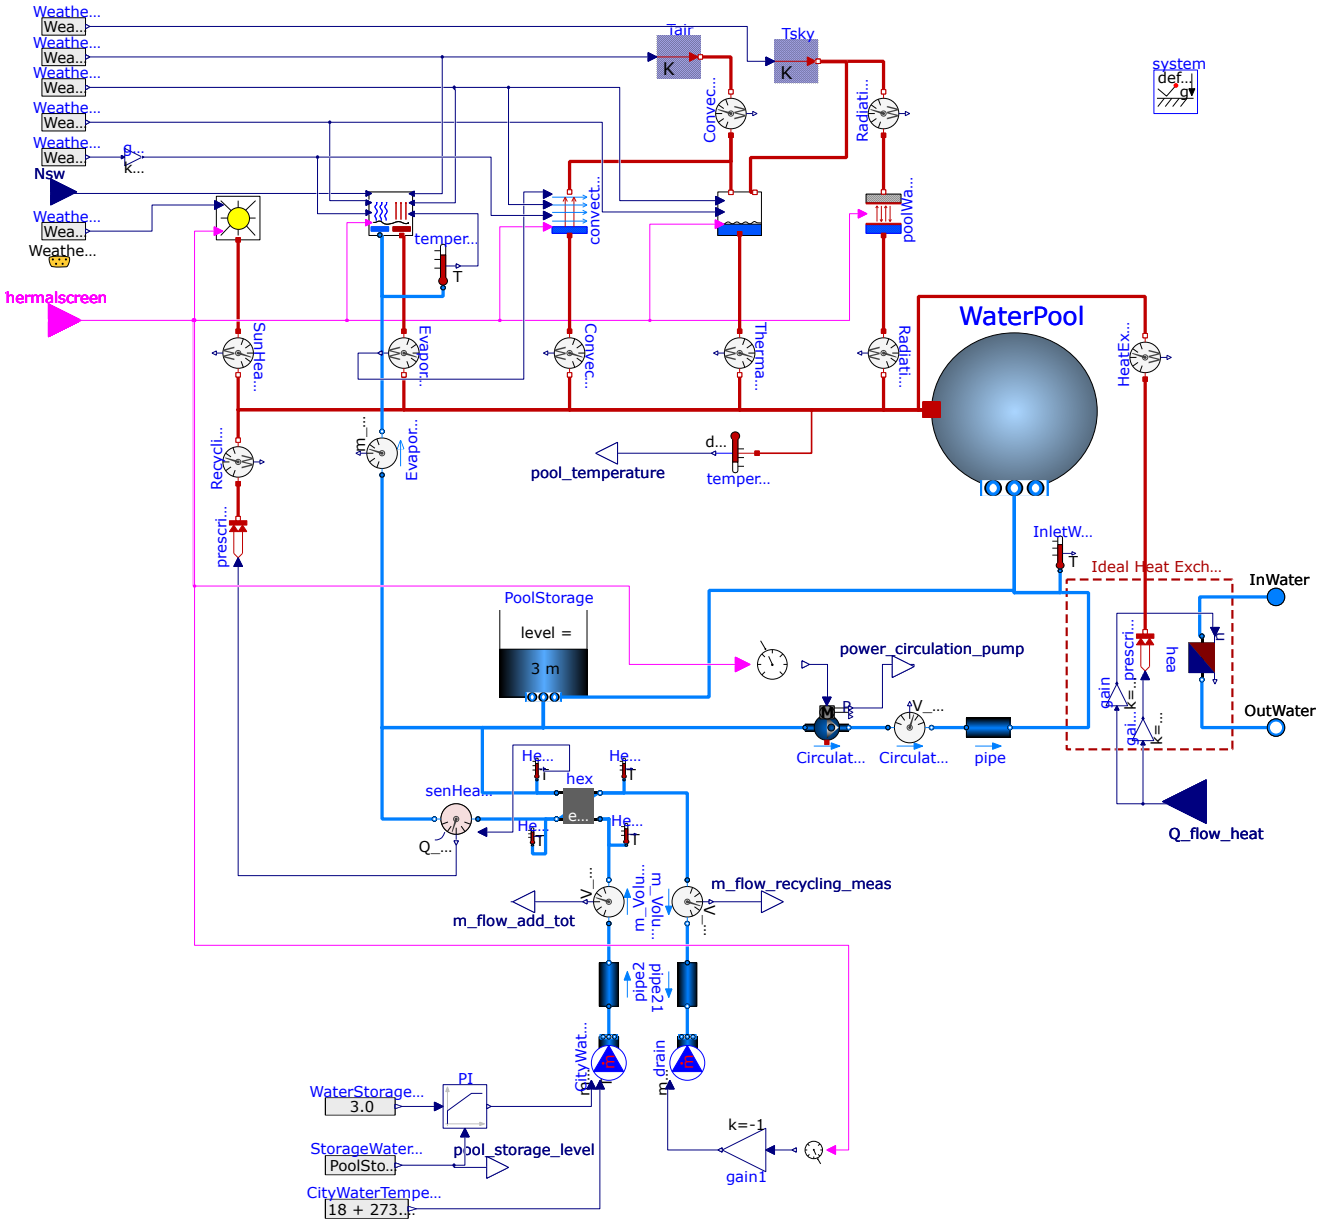

Figure 1. Model of the outdoor swimming pool.

enhancement which depends on the number of swimmer. The evaporation surface enhancement factor F_A is equal to (Buscemi et al. 2024):

$$F_A(F_u) = 1 + 2.3F_u \text{ if } F_u < 0.1 \quad (10)$$

$$F_A(F_u) = 1.2 + 0.3F_u \text{ if } 0.1 \leq F_u \leq 1 \quad (11)$$

$$F_A(F_u) = 1.5 \text{ if } F_u > 1 \quad (12)$$

with F_u the utilization factor of the outdoor swimming pool. The utilization factor is equal to (Buscemi et al. 2024):

$$F_u = \frac{A_{max}}{A_p} N_{sw} \quad (13)$$

with A_{max} the pool area per swimming pool when maximum occupancy, A_p the pool area and N_{sw} the number of swimmers inside the pool.

To calculate the transfer of mass and heat from the evaporation losses within the program, two controlled sources are implemented, one for the transfer of water and the second for heat transfer Figure 5. In addition, a program is written to control the controllable sources Listing 1. A numerical difficulty arises from the calculation of density and pressure differences, Equation 7 is no longer valid. A conditional evaluation was added and set to $\dot{E}_{p,nc}$ or $\dot{E}_{p,fc}$ when both differences become negative.

2.1.4 Convective losses

Convective losses are computed based on the Bowen approach (Buscemi et al. 2024):

$$\dot{Q}_{conv} = R_{Bo}\dot{Q}_{eva} \tag{14}$$

with $\dot{Q}_{conv}$ the heat loss from convection, R_{Bo} the Bowen ratio, and $\dot{Q}_{eva}$ the heat loss from evaporation. The Bowen ratio is equal to (Buscemi et al. 2024):

$$R_{Bo} = \left(\frac{c_{pa,e}p_{a,tot}}{0.622\Delta H_w}\right)\left(\frac{T_p - T_a}{p_{v,i} - p_{v,e}}\right) \tag{15}$$

with R_{Bo} the Bowen ratio, $c_{pa,e}$ the specific heat of air, p_a the air pressure, ΔH_w the latent heat of vaporization of water, T_p the pool water temperature, T_a the air temperature, $p_{v,i}$ the vapor pressure at the water surface and $p_{v,e}$ the vapor pressure of the free stream.

The implementation of convective losses is visible in the list 2. It includes an if-else condition regarding the thermal cover unfolded according to Equation 14 and Equation 15. In addition, there is a numerical issue regarding the Bowen ratio implementation, if vapor pressure at the water surface is equivalent to vapor pressure of the free stream, Equation 15 is no longer valid (division by zero). Especially since, according to (Woolley, Harrington, and Modera 2011), the Bowen ratio could have negative values and convection contributes to heat water. When the Bowen ratio approaches zero, the convective loss is zero (Woolley, Harrington, and Modera 2011), as such, the numerical implements a conditional evaluation with hysteresis with 500 Pascal and 600 Pascal for low and high threshold respectively, and is set to zero.

Listing 2. Sub-model program view of the modeling of the convective losses.

```
...
equation
  Tair = fluid.T;
  Twater = solid.T;
  pvi = psat_TPool;
  pve = psat_TAir*(RH/100);

  if thermalScreen == false then
    Q_flow = Rbo*Qevap;
    delta_p = (pvi - pve);
    if hysteresis.y == true then
      Rbo = (cp_TAir*pAtm/(0.622*hVap))*((
          solid.T - fluid.T)/(pvi - pve));
    else
      Rbo = 0.0;
    end if;
  else
    Q_flow = 0;
    Rbo = 0;
    delta_p = 0;
  end if;
  solid.Q_flow = Q_flow;
  fluid.Q_flow = -Q_flow;
...
```

2.1.5 Radiative losses

The Stefan-Boltzmann equation is used in this work to calculate the radiative heat flow losses between the water surface and the environment (Buscemi et al. 2024):

$$\dot{Q}_{rad} = \sigma\varepsilon_p A_p(T_p^4 - T_{sky}^4) \tag{16}$$

with σ the Stefan-Boltzmann constant, ε_p the long wave emissivity of the pool, A_p the pool surface area, T_p the pool water temperature and T_{sky} the sky temperature. The sky view factor is not considered as it is considered equal to one (Buscemi et al. 2024).

The implementation of the radiative heat flow is visible in Listing 3. It includes an if-else rule regarding the thermal cover unfols.

Listing 3. Sub-model program view of the modeling of the radiative losses.

```
...
equation
  if thermalScreen == false then
    Q_flow = epsilon_p*APool*Modelica.
        Constants.sigma*(port_a.T^4 -
        port_b.T^4);
  else
    Q_flow = 0.0;
  end if;
...
```

2.1.6 Thermal cover losses

When the thermal cover is unfolded, it is in direct contact with the pool water, the heat from the pool is released by conduction on the cover material then by convection and by radiation from the cover to the outside environment. The conduction heat flow of the thermal cover is equal to (Buscemi et al. 2024):

$$\dot{Q}_c = \frac{\lambda_c}{s_c}(T_c - T_p)A_p \tag{17}$$

with $\dot{Q}_c$ the heat flow of the thermal cover, λ_c the thermal conductivity of the cover, s_c the thickness of the cover, T_c the cover temperature and A_p the pool surface area. The convective heat loss of the thermal cover is defined as (Buscemi et al. 2024):

$$\dot{Q}_{conv} = h_{conv}A_p(T_c - T_a) \tag{18}$$

with $\dot{Q}_{conv}$ the convective heat flow of the thermal cover, h_{conv} the variable convective coefficient, T_c the cover temperature and T_a the air temperature. The radiative heat flow losses between the cover surface and the environment is equal to (Buscemi et al. 2024):

$$\dot{Q}_{rad} = \sigma\varepsilon_c A_p(T_c^4 - T_{sky}^4) \tag{19}$$

with σ the Stefan-Boltzmann equation, ε_c the long wave emissivity of the cover, A_p the pool surface area, T_c the cover temperature and T_{sky} the sky temperature.

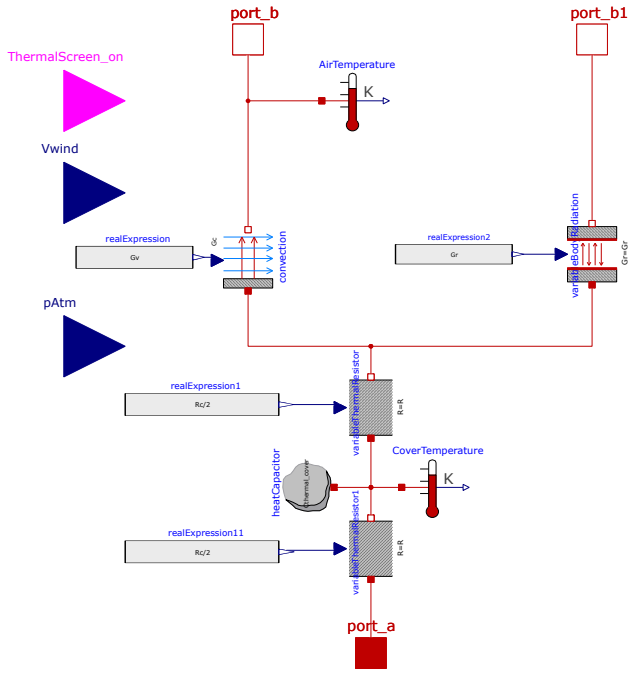

Figure 6. Modeling of the heat flow of the thermal cover.

Thermal cover model model consists of a graphical component, as shown in Figure 6, along with a text-based program designed to calculate the varying thermal coefficients, as detailed in Listing 4.

Listing 4. Sub-model program view of the modeling of the thermal cover heat flow.

```

    Gv = (hnc^(7/2) + hfc^(7/2))^(2/7) *
        APool;
  else
    Ral = 0.0;
    Nul = 0.0;
    hnc = 0.0;
    hfc = 0.0;
    Gr = 0.0;
    Rc = Rts;
    Gv = 0.0;
  end if;
...
```

2.1.7 Heating power

The heat source Q_{heat} for outdoor swimming pools incorporates a water-to-water heat exchanger (Buscemi et al. 2024). An ideal heat exchanger is utilized within the Modelica model, featuring an external circuit connected to the swimming pool to draw energy from the network. This system is coupled with an ideal heat source to supply heat to the water pool model, as illustrated in Figure 1.

2.1.8 Water buffer and recycling

The pool includes a water buffer volume designed to store excess water when swimmers are present, as well as to facilitate the addition of fresh water (Gauthier-Clerc et al. 2023). This fresh water is introduced through a heat exchanger that exchanges heat with gray water. Within Modelica implementation, a controlled water source removes gray water, while a second water source, controlled by a PI controller, maintains a constant water level in the buffer volume. When water volume decreases due to evaporation or removal, the controlled water source adds fresh water Figure 1.

2.2 Energy Systems Model

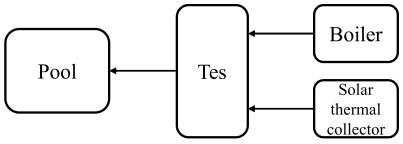

Figure 7. Block diagram of the considered energy system, constituted of pool, TES, boiler and STC.

The block diagram in Figure 7 illustrates the energy system used in the simulation. The swimming pool is modeled as a heat-consuming unit, while TES unit can either store or release heat to the pool. Two heat sources are integrated into the system: a boiler and an STC. The heat generated by the boiler can be directly controlled, whereas the heat produced by the STC depends on solar radiation and cannot be controlled actively. All three components originate from the AixLib Modelica library (Maier et al. 2024), and they are interconnected via pumps and fluid interfaces, as shown in Figure 8. The pool temperature is regulated using a proportional integral controller, while the boiler is managed by a hysteresis control system: the boiler operates at full capacity when the TES temperature falls below a defined minimum, and it turns off when the temperature reaches a specified upper limit. The STC is not actively controlled; instead, its heat output is directly delivered to the TES.

3 Experimental Setup

The swimming pool and associated energy systems were modeled using OpenModelica (Fritzson 2011) version

DOI 10.3384/ecp218891

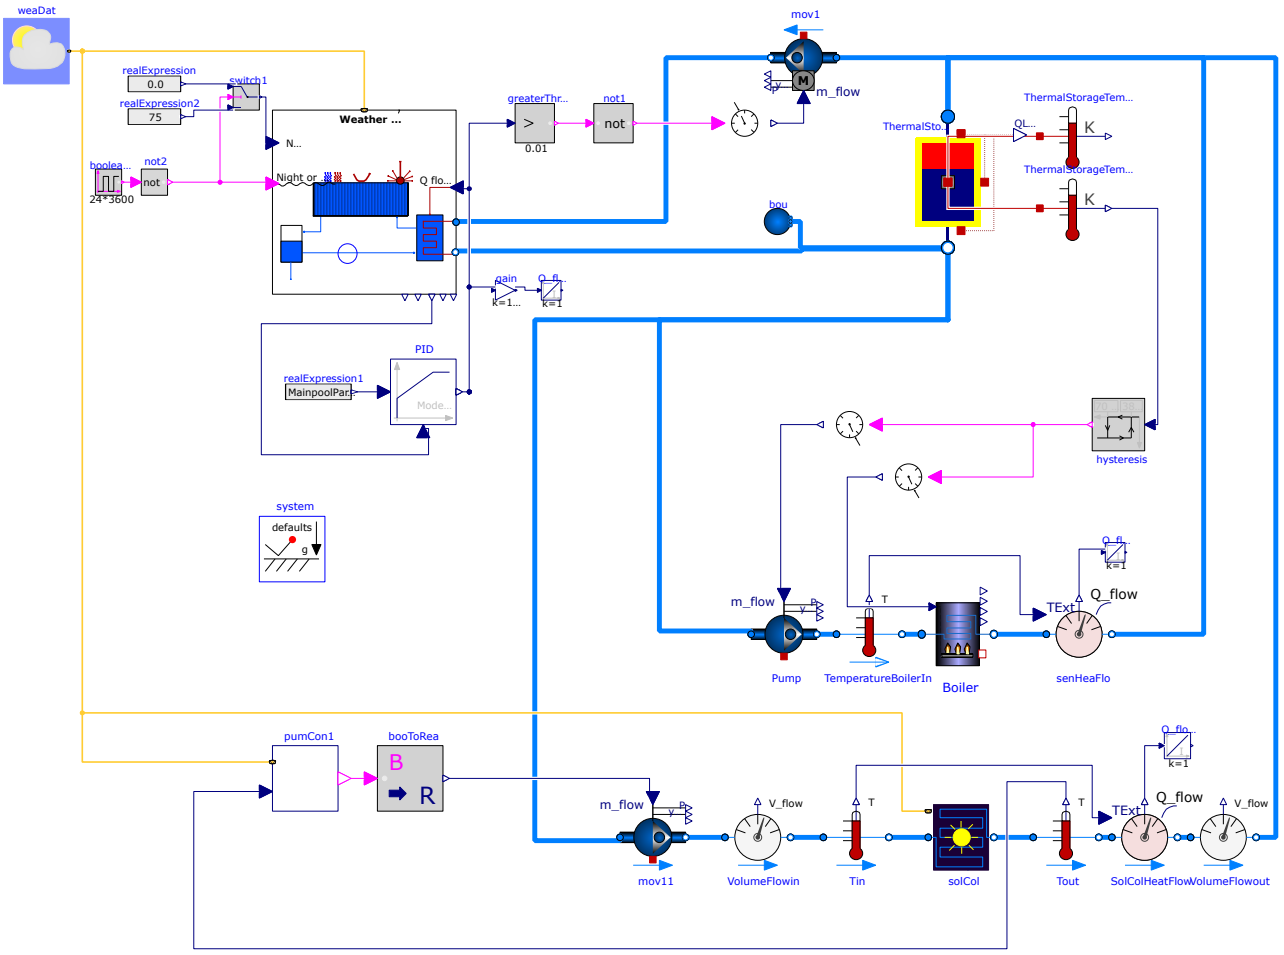

Figure 8. Model of the modeling of the energy system considering the swimming pool, the TES, the boiler and the STC.

1.23.1. Simulations were executed using the Dassl solver (Petzold 1982) on a laptop running Windows, equipped with an AMD Ryzen 7 PRO 7730U CPU and 32 GB of RAM. The system parameters are summarized as follows: Swimming pool: Table 1; Boiler, TES and STC: Table 2. Weather data were synthesized using Typical Meteorological Year (TMY) files for the city of Montpellier, France (*Repository of Building Simulation Climate Data* 2025). These data enabled integration of the AixLib meteorological model (Maier et al. 2024). To adapt the wind speed from the weather station to the pool surface and Equation 7, a 0.35 coefficient wind adjustment was used. One simulation scenario was performed, in which the pool water temperature was regulated at $28°C$. The boiler operation was managed by a hysteresis controller applied to the TES: the boiler was activated when the TES temperature dropped below the lower threshold and deactivated when the temperature exceeded the upper threshold.

4 Results

Figure 9 presents the simulation results, including the thermal power delivered by the heat exchanger, as well as the air, sky, and pool water temperatures. The pool water temperature is successfully maintained at $28°C$ throughout the simulation period. Air temperature ranges from a minimum of $5°C$ to a maximum of $39°C$, while sky temperature varies from $-12.5°C$ to $37.5°C$. The PI controller regulates the heating power between 0 and $5{,}000kW$ to maintain the target water temperature. Notably, between $4{,}000h$ and $6{,}000h$, the heating demand exceeds $2{,}000kW$, despite elevated air and sky temperatures approaching $28°C$. A reduction in heating demand was expected during this summer period, yet evaporation losses contribute significantly to increased thermal requirements.

Figure 10 shows the evolution of the different thermal losses: radiative (Figure 10.a), thermal cover (Figure 10.b), convective (Figure 10.c), evaporative (Figure 10.d) and fresh water heating (Figure 10.c). Radiative losses range from $0kW$ to $250kW$ and are more pronounced during winter ($0h$-$2{,}000h$ and $6{,}000h$-end), exceeding $150kW$. During summer ($4{,}000h$ –$6{,}000h$), they remain below $100kW$, Figure 10.a. Thermal cover losses (Figure 10.b) range from $0kW$ to $400kW$, with noticeable reductions during summer due to more favorable ambient conditions. Convective losses can be either positive

STC	Tilt angle	-180	$°$
STC	Ground reflectance	20	$\%$
STC	Total area	900	m^2
STC	Collector system	Tube	-

or negative, depending on the Bowen ratio. Notable, at $4,500h$, $5,000h$ and $5,100h$, the pool gains heat from the surrounding air through convection, with power values reaching up to $750kW$. In other periods, convective heat losses reach peaks of up to $875kW$. Evaporative losses (Figure 10.d) are null when the thermal cover is in place but can reach up to $2,500kW$ during uncovered periods, especially in the summer. These losses largely explain the increase in heating demand observed from $4,000h$ to $6,000h$. Fresh water heat losses (Figure 10.e) range from 20 to $60kW$, with lower values observed at night when the pool is covered. These losses correspond to the energy required to heat the replacement water that compensates for evaporation.

Figure 11 illustrates the overall distribution of thermal losses and heat sources. Evaporation accounts for the largest share of thermal losses (63.3%), followed by thermal cover (12.97%), convection (11.33%), radiation (8.88%) and fresh water heating (3.5%). Regarding heat inputs (Figure 11.b), solar heat contributes 25.14% of the total, while the remaining 74.85% is provided by the heat exchanger connected to the boiler and thermal storage system.

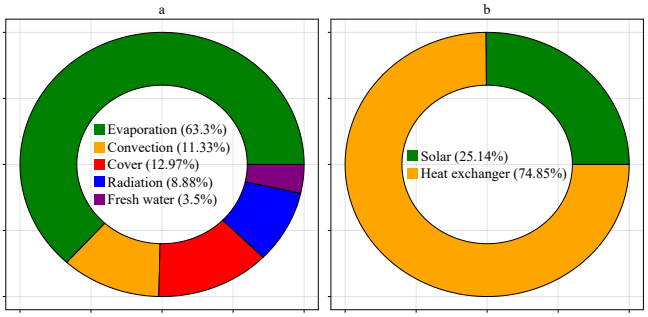

Figure 11. Distribution of the thermal power losses and heating. (a) Depicts the losses distribution with evaporation, convection, thermal cover, radiation and the fresh water added to the swimming pool. (b) Depicts the heating distribution with solar gain and heat added by the heat exchanger.

Table 3 summarizes the annual energy balance. The total heating demand of the pool reaches 1.8×10^{13} J, of which 1.67×10^{13} J is supplied by the boiler, and 0.13×10^{13} J (7.2%) by the solar thermal collectors.

5 Conclusion

This paper has presented a comprehensive dynamic

Table 3. Annual heat demand and production of the energy system.

Pool demand	*Boiler production*	*STC production*
$1.8 \times 10^{13}\ J$	$1.67 \times 10^{13}\ J$	$0.13 \times 10^{13}\ J$

simulation model of a public outdoor swimming pool, integrated with a multi-source energy system comprising a boiler, thermal energy storage (TES), and solar thermal collectors (STC). The model, implemented in Modelica, is based on fine-scale physical representations of the pool's thermal behavior, and has been used to simulate one full year of operation. It accounts for all major heat transfer phenomena, including evaporation, convection, radiation, and interactions with thermal covers. The simulation results demonstrate the model's ability to capture the nonlinear dynamics of the system and provide detailed insights into energy consumption and heat loss distributions. In particular, evaporation is identified as the dominant source of thermal losses, while the solar contribution remains modest in the current configuration.

Future work will focus on coupling this physical model with an Economic Model Predictive Control (EMPC) strategy (Blaud et al. 2023). This advanced control approach will enable the optimization of energy usage and cost by dynamically coordinating the different heat sources. The ultimate objective is to reduce operational expenditures while ensuring thermal comfort and efficient energy use.

Acknowledgements

This work was supported by Akkodis Research, France. The authors' contributions are as follows: Pierre Clément Blaud: conceptualization, methodology, software, simulation, visualization, and writing of the original draft. Imad Mourtaji: supervision and funding acquisition. The authors wish to thank Ludivine Armstrong and Daniel Longworth for their support in defining the pool parameters, and Mounina Tounkara for her valuable help in revising the language and structure of this article.

Abstract

Like any other industry the railway sector undergoes great transformations. To make transportation by rail more sustainable and affordable infrastructure, maintenance is key. However, this needs a managed and collective effort of many players in order to make this efficient and easily accessible to experts of many different fields: Measurement experts, Simulation experts and Engineers who perform the maintenance. In this work, we present a market place which leverages modern technologies and standards like GAIA-X, Functional Mock-up Interface (FMI), Distributed Co-Simulation Protocol (DCP) or System Structure and Parameterization (SSP) to provide accessible and easy to use services and retrieve crucial data from other providers, while protecting sensitive data and know-how. This market place is developed under the Umbrella of the The European Rail Joint Undertaking (ERJU) of the European Union. This work is an update of our publication in Eisenbahn Ingenieur Kompendiumm 2024 (**EIK2024**) and contains several additions regarding the implementation and the usage of Modelica standards. A working prototype will be available in 2026.

Keywords: Data Spaces, Railway, FMI, SSP

1 Introduction

The railway industry is currently experiencing a unprecedented boom, which causes countless challenges. While almost all parties involved are working on innovative solutions, promoting, driving and accelerating innovation to face these challenges, it has become clear that a new form of cooperation and exchange is necessary. The time between an idea, prototype and the approval of new products is still extremely long and hence lacks the necessary speed to solve the tasks at hand. One of the most important issues, as it turns out, is the regulated exchange of knowledge, information, data, mathematical models, simulations, etc. in a controlled manner with defined rules and conditions. It is not enough to simply provide data and but also sharing it anonymously between parties. It should be possible for a third party to obtain an existing model, in return for monetary compensation (for example), enrich it with new data in order to possibly develop a better model, while protecting the know-how. On the one hand, this saves a huge amount of resources of all kinds. On the other hand, and this is the much more important aspect, it makes it possible to build on existing knowledge, refine it and thus develop new models, acquire new findings, etc. much faster and bring them timely to market. It also would open up the possibility of collaborative co-simulations. There are many different scenarios like track-vehicle interaction, interaction between vehicles and infrastructure with the environment of many standardized building blocks which could benefit of leveraging co-simulations for cooperation of different parties from manufacturers to maintainers for vehicles and infrastructure.

However, the reality is very different. Not only is it challenging from a technical point of view. There is also no consensus on how such tasks should be handled, how knowledge can be exchanged or obtained and under what framework conditions this is even possible. The legal, financial and security aspects play a decisive role here.

There are also technical challenges. While nowadays data space solutions exist (see Section 2 below) they are hard to configure and setup. This is why they are not as widely used as they could. It is therefore crucial to provide easy to use solutions which need serious development effort.

1.1 The European Rail Joint Undertaking

The European Rail Joint Undertaking (ERJU) is the direct successor to Shift2Rail, the European initiative to promote innovation, technology and cooperation in the rail sector. ERJU is unique in terms of its scale, both financially and in terms of the number of partners involved. The project volume amounts to around €1 billion, the European Union is funding the initiatives with a further €500 million and several hundred companies, scientific partners and rail operators are involved in the program. (*ERJU* 2023). The latter include Deutsche Bahn, the Austrian Federal Railways (ÖBB), ADIF, SNCF and many more. voestalpine Railway Systems (vaRS) is not only the only system solution provider represented in the consortium, it is also one of the 26 founding members of the ERJU. This is partly due to the excellent results from Shift2Rail.

The focus of ERJU is less on basic research or inno-

vations (which are of course welcome). Rather, the program strives to bring solutions, innovations and technologies developed in recent years to the next level (TRL 5 and higher) by demonstrating and ultimately approving the use of these new products under real conditions. The objectives are:

1) Test, approve and launch products more quickly or make them marketable, 2) tighten the cooperation between rail, industry and science and improve on joint solutions and approaches, 3) strengthen the resilience of rail to current and future challenges and thus ultimately achieve the goals of Shift2Rail and ERJU, 4) become the number one most sustainable form of transportation for people and goods.

ERJU runs until 2029 and will be advertised and processed in two calls, although only the first call has currently been published, which will now run until the end of 2026. The next one will follow in the near future.

2 Data Spaces

In this section, a proper definition of data spaces is provided and it is discussed why they are crucial to the future of the railway industry. Also, a short review of existing projects from automotive industries is given to show some examples of how a rail data space might potentially look like.

2.1 Data Space Market Places

In order to simplify cooperation between individual partners in the rail industry, it is important to make the exchange of data and services as easy as possible. Similar efforts and projects already exist in the automotive sector. Examples include Catena-X (catena-x.net) for the supplier sector and the ENVITED Marketplace (www.envited.market) which is used to exchange geodata and maps to aid the development of driver assistance systems. A marketplace for the exchange of geodata of infrastructure and other data for the various players in the European rail sector is currently developed to make essential data accessible to developers and service providers. This often poses a challenge, as IPs and know-how have to be protected accordingly. This problem should now be solved. One particular aspect that needs to be considered within this framework is the provision of simulations as a service, as implemented in the ÖBB Rail4Future project (`rail4future.com`), among others. It should be possible to purchase the necessary data sources to be able to carry out complex simulations by oneself or through partners. These services can then be purchased or offered on the planned marketplace. Further possible use cases of the marketplace will be discussed in detail in the course of the article. One of the most important considerations is that centralized approaches should be avoided: So, instead of a central location where all data and services are collected, a federated system should be established where all players can offer their data and services and potential customers can use the services locally. The advantage of this is that large amounts of data are not duplicated many times and data waste is avoided. In addition, data protection is guaranteed and the integrity and trustworthiness of the data offered is ensured. In order to meet and take account of these requirements, it is necessary to set up a "Federated Data Space". This term is discussed in more detail in the next section, which also looks at other important technical requirements.

2.2 Federated Data Spaces

A federated data space can essentially be characterized by four features:

1. Unlike databases, data spaces do not store data, but only provide links to the actual data.
2. They do not force the data provided into a standardized schema, but can be made available as they are.
3. Redundancy of data is permitted.
4. They can overlap and a participant can be part of several data spaces (see (Otto 2022), (Franklin, Halevy, and Maier 2005)).

GAIA-X (gaia-x.eu) serves as the basis for this project. It is a European initiative to create a secure and trustworthy digital ecosystem for data and services. This initiative aims to strengthen Europe's sovereignty in data processing and digital infrastructure, particularly in the areas of cloud computing and data management. Federated data spaces (in the sense of GAIA-X) also offer so-called "federation services" that function across the boundaries of several data spaces (see (Franklin, Halevy, and Maier 2005)). The architecture of GAIA-X is based on the IDS ("international data space") architecture (see (Siska, Karagiannis, Drobics, et al. 2023), (Otto et al. 2018)), which provides for the connection of the individual participants via so-called IDS connectors (see (Siska, Karagiannis, Drobics, et al. 2023) and Figure 1 for a graphical representation). These "connectors" help to convert the data correctly and enable any payment transactions between the individual parties.

GAIA-X also stipulates that data transfers should be secured by corresponding policies and certificates. The safeguarding and certification of simulation data and results poses an additional challenge, as the corresponding services that are supposed to perform this safeguarding automatically must be co-developed by the providers due to the fact that this assessment is anything but trivial. Such aspects were considered in the UPSIM project (`upsim-project.eu`), among others, and corresponding processes, standards and automated toolkits were proposed to determine the credibility of data and results in the context of simulations (see (Ahmann et al. 2022)). In order to be able to offer simulations as a distributed service, the aspect that these services can possibly be connected in series must also be taken into account. This aspect is already being considered in Rail4Future. For this purpose,

DOI 10.3384/ecp218901

so-called co-simulation process graphs are used (see (Reiterer, Schiffer, and Benedikt 2022)), which represent a description of the process and dependencies on data sources and can be managed within graph databases. As the name suggests, these special graphs represent processes and co-simulations. By definition, a co-simulation is a collection of individual simulations that exchange their results with each other (see (Gomes et al. 2018)). With the help of these "co-simulation process graphs", instructions for automation software (e.g. Jenkins) can be generated and executed using a service. The special graph structure also makes it possible to represent the occurring co-simulations between different simulation participants and to generate a configuration of the co-simulation that can be received by different co-simulation protocols in order to enable the orchestration of the co-simulation and the data exchange between the individual participants (see (Reiterer, Schiffer, and Benedikt 2022) for a simple example). This can also be used to optimize process flows and ultimately use valuable resources, such as computing capacity and licenses, more efficiently (see (Reiterer and Kalab 2021)). This fairly general representation not only facilitates automation, it also enables the standardization and exchange of processes, as these can be stored and passed on like recipes and individual process steps and data sources can be exchanged or expanded. This simplifies collaboration between individual participants enormously when it comes to offering and exchanging services. For example, it is now possible to offer not only individual simple simulations as a service, but also complex co-simulations that consist of many partial simulations and are fed from a wide variety of data sources, and not necessarily just in one central location, but distributed. As co-simulation process graphs only store links and instructions instead of entire data sets or simulations, they form a good basis for fully implementing the federated data space principle in the area of simulation.

It may be noted that data space technologies are in a constant development and changes to the core technology can happen any time. However, even with the advent of new versions, technologies and standards as well as the fundamental concepts stay the same as in GAIA-X.

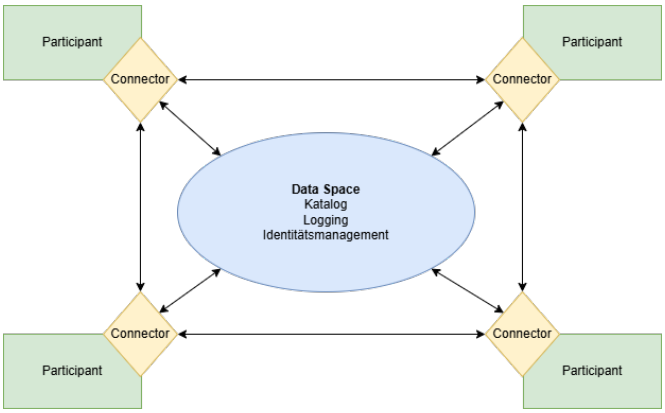

Figure 1. Structure of the Federated Data Space

3 The Railway Market Place

In the course of the ERJU cooperation, as described in Section 1.1, a demonstrator was defined along which the concept of a marketplace for railroad and railroad maintenance data is to be tested. The aim of this ERJU marketplace demonstrator is to provide the basic functionality for customer interaction and interaction with external platforms and federated data spaces. The ERJU Marketplace Demonstrator is used to gather customer experience during a user-friendly test phase. The concept is also the basis to present our innovation to a broad field of potential customers and partners - to get them on board by using our marketplace in the first version as their point of sale for the rail market on the one hand and as consumers on the other. Both customers and partners are spread across the entire rail industry. Railroad companies, manufacturers but also operators of machines, infrastructure and measurement technology. Every single company that wants to use data and services relating to rail transport and infrastructure should be able to benefit from the railroad marketplace.

The targeted customers do not have a broad overview of existing data and services in this area. Concepts for segmenting and structuring the data are therefore of high value, as most customers are specifically interested in finding the information that is valuable for the region or rail network for which they are responsible. Since there is currently no well-organized overview and data exchange facility across the rail industry, the marketplace helps to reduce the effort of creating the same data multiple times by different companies. With faster and wider availability of data, decisions can be made based on data and objectively, ultimately reducing the negative impact on infrastructure availability. In addition, any energy that can be saved is also of great value to our environment as it helps to reduce CO2 pollution and other negative side effects.

Potential partners are also spread across the industry and offer data and/or services relevant to the rail and infrastructure management business. They can use the marketplace as an additional sales channel to become more visible in this market area. This often results in new opportunities from previously unknown interested parties for the data for their own special use cases. The exchange of data should also be made easier for the partners through clearly defined format and quality criteria that should apply to both parties of possible transactions. A mockup of the marketplace view is shown in Figure 2.

It is also important to highlight that usage of data space technologies is complicated, hence, it is important to provide ways like simple web interfaces and services to hide the burden of configuration from the end users. This is one of the key aspects for the design of the market place we propose here and the main reason such data space solutions are not broadly adopted as there is a lot of configuration effort necessary to allow safe data transfers and provide services in a consistent manner.

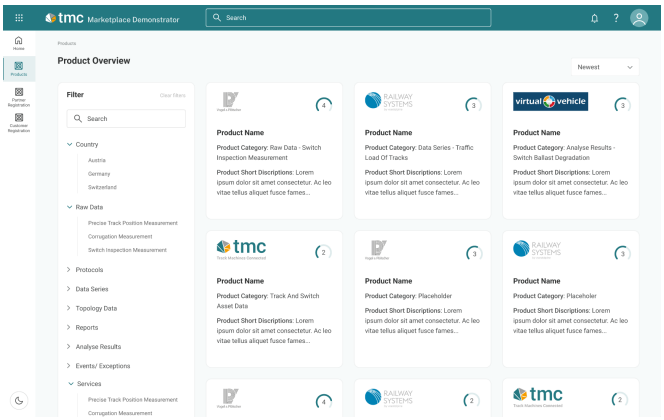

Figure 2. Marketplace View

3.1 Architecture & Services

An important milestone in the ERJU project and the implementation of the marketplace demonstrator is the definition of the architecture. The focus here is on state-of-the-art software technologies and microservice concepts, as these have proven to be extremely powerful in meeting the requirements for flexibility, scalability and maintainability in the fast-moving world of digitization. The basic idea behind microservice architecture is to divide a large and complex software application into smaller, independent services called microservices. Each microservice is responsible for a specific function or task and can be developed, deployed and scaled autonomously.

A detailed overview of the architecture can be seen in Figures 3 and 4. Figure 3 shows the architecture of the marketplace at its core, while Figure 4 shows how external services can be integrated.

The marketplace consists of the core components described in the following sections.

3.1.1 Data Catalog

For the marketplace, the data catalog plays a crucial role in the provision of information and services. This catalog, which is part of the service repositories and the data catalog repository, is at the heart of this state-of-the-art rail data marketplace. The service repository is a carefully managed collection of service self-descriptions. These self-descriptions contain a wealth of information that enables potential customers to understand exactly what type of service is being offered. The details of the data types are described in the data catalog repository. This tells customers what content is available and in what form it can be provided. This clear overview enables customers to search specifically for the data they need. Both data and services are presented as products on the marketplace interface. This creates a user-friendly environment in which customers can easily search for the information they need. Not only provides the data catalog overview pages, but also the product detail pages use these repositories to present the products and product information in an appealing way on the marketplace GUIs.

3.1.2 TrackDB: Railway Infrastructure Topology

To filter data and services as accurately and efficiently as possible, it is essential to not only locate the data country-specifically and geographically, but also to map it within the topology of a railroad infrastructure operator. Since this network model is not static but constantly changing, TrackDB proves to be a crucial tool for mastering the dynamics of the railroad topology network. TrackDB is an innovative service and part of the marketplace that makes it possible to create and manage the rail topology network based on various sources. This service goes far beyond traditional static network modeling and continuously adapts to the requirements and changes in the rail infrastructure by opening up freely accessible sources but also accessing partly (partially) closed data based on partnership with infrastructure operators.

The key to TrackDB's effectiveness lies in its ability to dynamically capture and update information about track sections, switches, signals and other elements of the rail network. This is done in real time, allowing users to access up-to-date data at all times. This means that the content provided by service partners and data providers can also be clearly assigned to the network, allowing this information to be filtered down to sections of specific tracks or even individual components such as switches.

3.1.3 Services

Another way to expand the product range is to host third-party services and ensure the smooth operation of these services. This aspect significantly expands the functionality of the marketplace and offers service providers the opportunity to integrate their specialized solutions directly into the platform. The "Service and Data Center" marketplace acts as a central hub for hosted services from third-party providers. Providers have the opportunity to host their services in this environment in order to make them accessible to a broader target group. This opens up new business opportunities and promotes innovation in the rail industry.

3.2 Simulation Services and Co-Simulation Standards

A special key feature of the market place is to provide simulation services for predictive maintenance.

To enable the seamless integration of these services, service providers must offer "black box" services that can communicate via standardized interfaces. These interfaces serve as templates and enable interaction between the hosted services and the data available on the platform. This ensures that the hosted services can work effectively with the required data inputs.

If a service is filled with data and executed, the next step is to output results and feed them back into the marketplace. Hosted services should be able to provide the results in a standardized file format. This facilitates integration and data exchange between the various services and users on the platform. The ability to integrate hosted

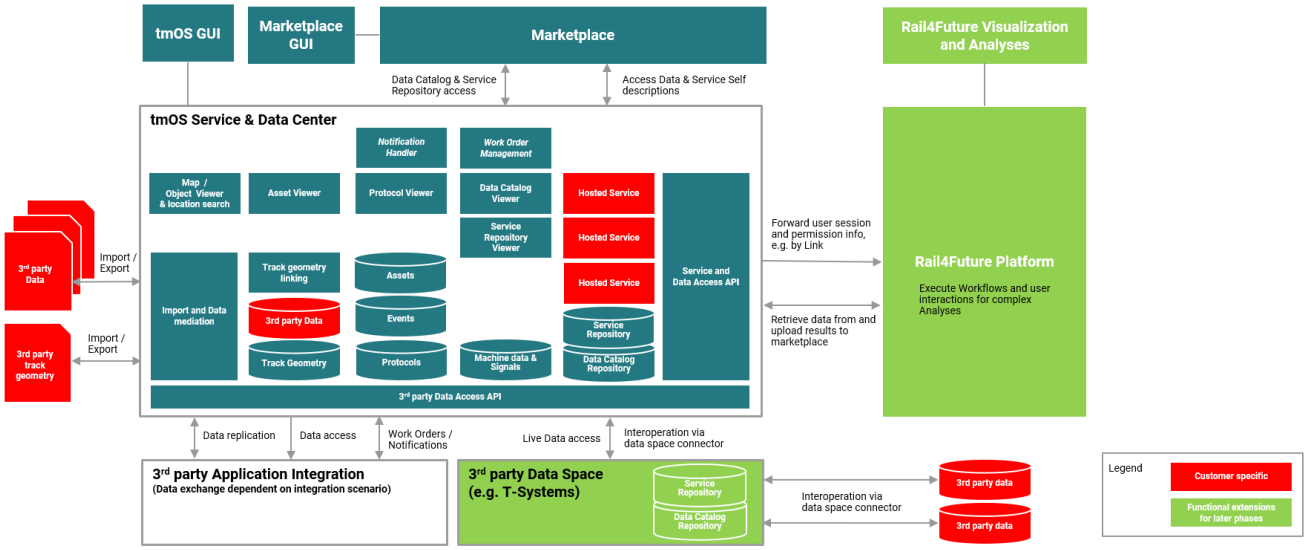

Figure 3. High level System Architecture

services into the platform opens up a world of potential. It allows customers to access a wide range of specialized services, from data analytics to predictive maintenance, without having to leave the platform and without having to worry about running their own platform.

3.2.1 The Role of Co-Simulation Standards in the Context of the Market Place

Co-Simulation standards like the Functional Mockup Interface (FMI) (FMI-Working-Group 2020) and the Distributed Co-Simulation Protocol (DCP) (Modelica Association Project DCP 2019) play a crucial role as they are leveraged to enable easy integration of new simulation services. First, mappings between input data and simulations can be created with ease and tools for reading out inputs and writing outputs can be provided. Second, they provide a standardized interface developers and engineers can rely on to provide a unified way to read and write data from and to simulations. This standardization is crucial as simulations are very diverse and rely on very different forms of input. The metadata file an FMU or DCP participant provides ways to auto generate forms for data provision as other participants know what they have to provide in order to make the simulation run and what to expect as output. We show an example in Section 3.2.2. Since the FMU defines the proper in and outputs this can be used to tell a potential user which data they need to provide (for example as CSV file) and which names the fields have. Another important benefit of co-simulation standards like FMI is that FMUs can be stored as standalone files that can be shared between different parties. This allows of easy exchange of models.

The only real drawback FMUs have is that it is not always easy to guarantee proper runtimes of the underlying models. So proper set-up sandbox environments are needed as well. A data space can help with that as the models can run with an enclosed environment (e.g. on site with the owning party) and just input and output data is exchanged, which only works for non real-time computations of course. However, solutions to this problem also could be provided in the future.

Furthermore, the System Structure and Parameterization (SSP) standard (see e.g. (Hällqvist et al. 2021)) can be used to link different simulation services together. This enables cooperation between different simulation domains and helps with automatic service execution as many tools support these open Modelica standards. As already mentioned, this can be also supported by graph based process descriptions (Stefan H. Reiterer and Clemens Schiffer 2021)(M. Stefan H. Reiterer and Clemens Schiffer 2023) which allow to make reproducible computation processes by auto generating and orchestrating execution pipelines. The viability of this approach in the context of the rail industry was already demonstrated (Ozan Kugu 2023).

Additionally, the data space architecture enables us to use data space connectors to safely upload sensitive data which is necessary for a multitude of simulations. This helps to protect know how of third parties and adds an additional layer of security.

3.2.2 An Example Use Case: Ballast Degradation

As an example to illustrate the diverse interaction possibilities on the marketplace, a use case was chosen called "Monitoring of Track Settlement and Identification of Single-Faults at Switches". One of the goals there involves the monitoring and prediction of ballast degradation in the switch-area, especially below the frog. In order to successfully execute this use case, both the service and all required relevant information sources must be defined in the service repository and the data catalog repository. It should be noted that we want to outline the process to give a better understanding of how this works, rather than explaining the model in detail, because if a simulation is offered as a service the inner workings of a simulation

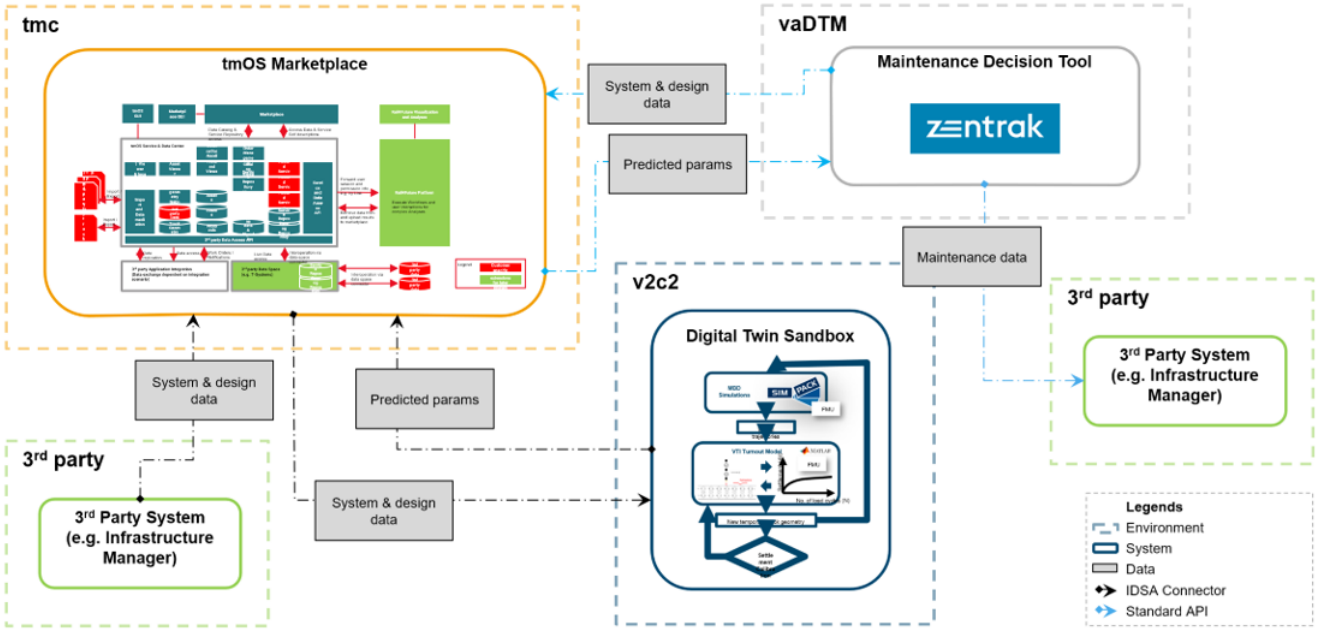

Figure 4. High level System Architecture with Integrated Services

have to be abstracted away within an FMU beforehand to make it usable. However, this heavily depends on the tools in use and would go far beyond of the scope of this work. The execution of this service offering requires several steps on the product offering side and is intended to demonstrate the possibilities for querying multiple, different data from different providers for a specific track section. Several interactions with menu selections and the interactive map function are highlighted. A key aspect is also to show how quickly the customer can filter the area of interest.

Here, the consumer not only buys the needed "raw data" for the simulation from data providers on the market place but also the (automated) execution of a complex simulation for calculating ballast degradation, which requires this "raw data" as input data. The algorithm itself does not run directly in the marketplace but in a separate Rail4Future simulation environment developed by Virtual Vehicle (`www.rail4future.com`).

The simulation itself runs within a Functional Mockup Unit. A generated pipeline is triggered which starts the FMI master. The master reads the data and executes the simulation and then writes out the simulation results.

After the customer has completed the purchase, the marketplace will exchange the relevant data with this environment, initiate the simulation there and finally make the processed data available to the customer again on the marketplace. See Figure 5 for a mock up view on the service.

Nevertheless, there are many more examples of simulations ranging from mechanical simulations (for example vehicle-track interaction), thermal simulations (behavior of infrastructure under changing temperature) and many more. Many tools which are used (for example Matlab or Simpack) provide export capabilities for Modelica standards like FMI or SSP which makes it an obvious choice regarding exchange and co-simulations of models.

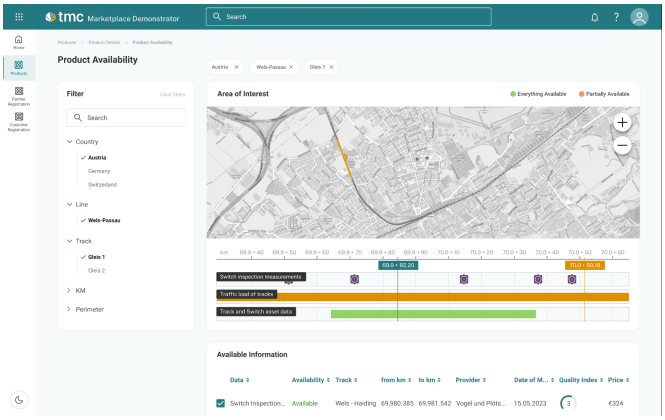

Figure 5. GUI View of the Ballast degradation Use Case

4 Conclusion

Managing Railway infrastructure needs a lot of know-how data and coordinated joint effort. Modern standards and initiatives like GAIA-X, FMI, DCP and SSP provide the foundation to enable the railway industry for a modern, comfortable and standardized workflow, and provides non-experts with a place where they can easily buy services which can be used without much effort.

In this work we demonstrated how such a market place can look like and a practical example how this can work. A demonstration shall be ready in 2026 and is open for collaboration. The ERJU offers the ideal platform for the joint development of further features and the promotion and on-boarding of additional partners. Infrastructure op-

erators and rail transport companies in particular are invited to participate and get involved. Ultimately, they are the ones who benefit from accelerated developments, reduced costs and higher availability and can ultimately pass this on to their end customers.

Abstract

This study proposes a novel discrete-solving algorithm implemented on the MWORKS.Sysplorer platform for power electronics simulation, addressing dynamic stability challenges in multi-energy integrated systems with high renewable energy penetration. For an offshore energy island, detailed component models including direct-drive wind turbines, photovoltaics, battery energy storage, and alkaline electrolyzers are developed and integrated into a standalone DC system. The energy storage system controls bus voltage to enable constant-power operation of electrolyzers. The implemented discrete algorithm provides critical multi-timescale simulation capabilities, advancing the planning and construction of offshore energy island projects.

Keywords: modelica, discrete algorithm, offshore energy island, integrated energy systems, electrolyzer

1 Introduction

The global energy structure has been undergoing rapid decarbonization and sustainable transformation recently. As an emerging paradigm for large-scale renewable energy integration, offshore energy islands have garnered significant attention due to their ability to synergistically couple diverse energy forms, including offshore wind, solar photovoltaics (PV), energy storage, and hydrogen production (wind-solar-storage-hydrogen) into a unified system. Offshore wind power demonstrates superior energy generation efficiency and economic viability compared to its onshore counterparts (Bilgili, Yasar, and Simsek 2011), attributed to its higher wind energy density and more stable operating conditions. Unlike conventional offshore wind platforms, offshore energy islands not only improve renewable energy utilization and reduce long-distance transmission losses but also enable dynamic multi-energy coordination through integrated "electricity-hydrogen" solutions, thus delivering stable and clean energy supplies to coastal and island regions (Igbinenikaro, Adekoya, and Etukudoh 2024).

However, the high proportion of renewable energy sources poses significant challenges to the transient stability and operational security of energy island systems. Under islanded or weak grid conditions, power electronic converter-dominated energy conversion substantially reduce system equivalent inertia, leading to frequent fluctuations in voltage and power, diminished stability margins, and potential risks of equipment overload or operational failure—critical threats to system reliability. (Kundur 2007)(Salmador Gonzalez 2016). To mitigate the stochastic fluctuations of renewable generation, water electrolysis for hydrogen production has emerged as a key flexibility resource for offshore energy islands, using its high energy density and large-scale regulation capacity. By converting surplus wind/PV power into storable hydrogen, this technology enables rapid energy release during peak demand or power deficits, providing essential power buffering and dynamic support to enhance system stability (Arsad et al. 2022)(Xing et al. 2018)(Sterner 2009).

Current research predominantly focuses on optimizing integrated energy dispatch strategies to address renewable intermittency, particularly through adaptive operational mode adjustments for hydrogen production systems. Coordinated multi-electrolyzer switching strategies (Fang and Liang 2019) have been proposed to balance fluctuating wind/PV power. Subsequent studies have refined these approaches to minimize electrolyzer cycling, such as rotational coordination (Xiaojun, Congying, and Hong 2021), duty-cycling optimization (Shen et al. 2018), and start-stop frequency reduction (Tiejiang et al. 2022). Nevertheless, these dispatch-oriented optimizations often overlook critical equipment operational characteristics, limiting their applicability to real-world implementations. Consequently, high-fidelity modeling and simulation of actual energy island components are imperative to bridge this gap between theoretical strategies and engineering practices.

Modelica exhibits unique advantages in multi-physics unified modeling, facilitating detailed equipment-level simulations. Previous studies (Webster and Bode 2019) have developed proton exchange membrane (PEM) electrolyzer models using Modelica, achieving close alignment with experimental results. To further investigate electrochemical dynamics, dedicated libraries like the Electrochemical Reactors Library (Pyschik et al. 2025) have been established. However, existing research pre-

dominantly focuses on standalone electrolyzer modeling, lacking co-simulation frameworks integrating renewable generation sources. Moreover, when interfacing electrolyzers with power grids, most Modelica-based tools face inherent limitations in handling complex dynamic processes. First, in nanosecond-to-microsecond timescale simulations, frequent power electronic switching induces high-frequency dynamics that may trigger numerical oscillations and poor real-time performance. Second, the absence of specialized high-frequency model libraries for power electronic systems within the Modelica ecosystem necessitates manual development of fundamental components, increasing modeling complexity and compromising simulation efficiency.

This study leverages the MWORKS. Sysplorer platform—a Modelica-based system modeling and simulation tool developed by Suzhou Tongyuan Soft Control Technology Co., Ltd.—to construct a high-fidelity offshore energy island model. The platform's advanced electromagnetic transient solver and domain-specific libraries enable precise modeling of key components, including wind turbines, PV arrays, lithium-ion battery storage, and alkaline electrolyzers. The proposed system supports multi-timescale simulations of power system dynamics, providing robust technical validation for parameter optimization and control strategy development in offshore energy island projects.

2 Model Components

2.1 Direct-Drive Wind Turbine

As shown in Figure 1, the topology of a conventional direct-drive wind turbine system typically consists of three key components: wind turbine blades, a permanent magnet synchronous generator (PMSG), and a power converter along with its controller.

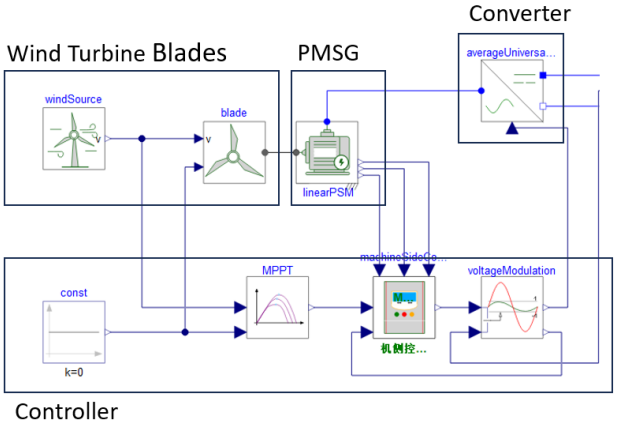

Figure 1. Topology of a conventional direct-drive wind turbine system

Based on aerodynamic theory, the mechanical power output of the wind turbine P_m can be calculated as:

$$P_m = \frac{1}{2} C_p(\lambda, \beta) \rho \pi R^2 v^3 \tag{1}$$

where, C_p is power coefficient, representing wind energy conversion efficiency; λ is the tip-speed ratio; β is blade pitch angle; ρ is the air density; R is rotor radius; v is the wind speed.

The power coefficient C_p, a critical parameter characterizing turbine efficiency, is expressed as a function of β and λ:

$$C_p = c_1 \left(\frac{c_2}{\lambda_i} - c_3 \beta - c_4 \beta^{c_5} - c_6 \right) e^{-\frac{c_7}{\lambda_i}} \tag{2}$$

$$\frac{1}{\lambda_i} = \frac{1}{\lambda + c_8 \beta} - \frac{c_9}{\beta^3 + 1} \tag{3}$$

where $c_1 - c_9$ are curve-fitting parameters that vary slightly across different turbine designs.

The drive train is modeled using a single-mass formulation:

$$H \frac{\mathrm{d}\omega_r}{\mathrm{d}t} = T_m - T_e \tag{4}$$

where, H is the total rotational inertia of the direct-drive system; T_m is the mechanical torque; T_e is the electromagnetic torque.

In the synchronous rotating dq-reference frame, the voltage equations are:

$$\begin{cases} L_s \dfrac{\mathrm{d}i_d}{\mathrm{d}t} = u_d - R_s i_d + \omega_s L_s i_q \\ L_s \dfrac{\mathrm{d}i_q}{\mathrm{d}t} = u_q - R_s i_q - \omega_s L_s i_d + \omega_s \psi_f \end{cases} \tag{5}$$

where, L_s is the stator inductance; R_s is the stator resistance; u_d, u_q are d- and q-axis stator voltages; i_d, i_q are d- and q-axis stator currents; ψ_f is the permanent magnet flux linkage; ω_s is the synchronous rotational speed.

The electromagnetic torque T_e is governed by:

$$T_e = \frac{3}{2} n_p \left[\psi_f i_q + (L_d - L_q) i_d i_q \right] \tag{6}$$

where n_p is the Number of pole pairs.

The operating range of a wind turbine generator can generally be divided into four regions: Pre-cut-in standby phase, maximum power point tracking (MPPT) phase, constant speed transition phase, and rated power regulation phase. In the maximum power point tracking phase, the rotational speed of the wind turbine is less than the maximum allowable speed. An optimal torque control mechanism, known as the Maximum Power Point Tracking (MPPT) system, is implemented to ensure that the wind turbine operates at the maximum wind energy utilization coefficient.

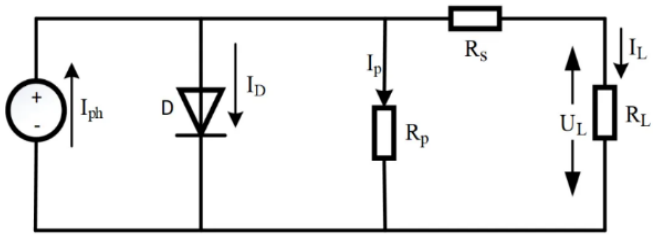

Figure 2. Photovoltaic equivalent circuit schematic

2.2 Photovoltaic

Photovoltaic power can be equated to a photovoltaic current source, a parallel diode, a series resistor R_s, and a parallel resistor R_p, as shown in Figure 2.

The output current I and photogenerated current I_{ph} relationships in photovoltaic systems are given by:

$$I = I_{ph} - I_s\left(e^{\frac{(V+IR_s)}{NV_t}} - 1\right) - \frac{V+IR_s}{R_p} \tag{7}$$

$$I_{ph} = I_{ph0}\frac{I_r}{I_{r0}} \tag{8}$$

where, I_r is the photogenerated current under actual irradiation; I_{ph0} is the reference photogenerated current at standard test conditions; I_s is the diode reverse saturation current; N is the diode ideality factor; V is the output voltage.

In practical PV systems, photovoltaic arrays are constructed through series-parallel configurations of multiple PV modules to meet diverse load power requirements. The system employs a Perturbation and Observation method (P&O) MPPT control strategy (Figure 3). The P&O method periodically perturbs the operating voltage slightly, then compares power before and after perturbation: continuing the direction if power increases, reversing it if power decreases. This iteration adapts to irradiance and temperature changes that shift the maximum power point, enabling stable tracking through the "perturb-and-observe" cycle. It keeps PV modules operating optimally, maintaining maximum power extraction and enhancing system efficiency under fluctuating conditions.

2.3 Energy Storage Battery

The equivalent circuit of the storage battery consists of a signal voltage source, a parallel self-discharge resistor R_{SD}, a charging dynamic model, and a series resistor R_0. The model's base voltage-charge state equation is described by the following equation:

$$V = V_0\left(\frac{SOC}{1-\beta(1-SOC)}\right) \tag{9}$$

where SOC is the ratio of the current charge to the rated capacity; V_0 is the voltage of a fully charged battery with no load; β is a constant that ensures the voltage equals V_1 when the charge is Ah_1. V_1 and Ah_1 can be given

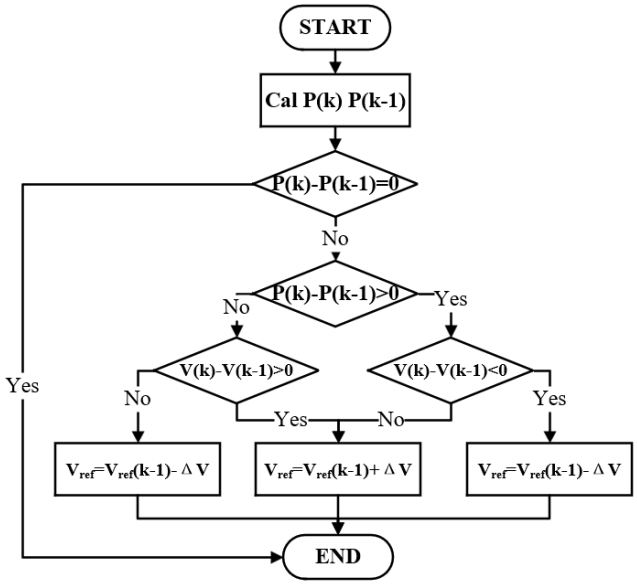

Figure 3. Perturbation and Observation method

through parameter setting, Ah_1 is the charging capacity/charge quantity corresponding to the voltage V_1 under no load, and V_1 is less than the rated voltage.

In energy storage control, the energy storage battery adopts voltage and current dual-loop control, and switches the charging and discharging states of the energy storage battery by outputting control signals. The voltage loop serves as the outer loop, taking the system's DC bus voltage as the control target. It compares the actual voltage with a preset reference voltage, and after processing the deviation through a PI regulator, outputs a current reference value. The current loop functions as the inner loop, which takes the current reference value output by the voltage loop as its target and eliminates the deviation between the actual current and the reference current via PI regulation, thereby generating precise control signals to regulate the charging and discharging processes.

2.4 Alkaline Electrolyzer

During electrolysis, DC power is applied across two electrodes in the electrolyte:

- Anode (Oxidation):

$$4OH^- \rightarrow O_2\uparrow + 2H_2O + 4e^-$$

- Cathode (Reduction):

$$2H_2O + 2e^- \rightarrow H_2\uparrow + 2OH^-$$

The rate of an electrolytic cell reaction is closely related to the current in the cell. According to Faraday's law (Ulleberg 2003), the rate of production of oxygen and hydrogen is directly proportional to the current I passing

through the electrolyzer, according to the following equation:

$$\begin{cases} \dot{N}_{\mathrm{O_2}} = \dfrac{I}{4F} & \text{(Oxygen production rate)} \\ \dot{N}_{\mathrm{H_2}} = \dfrac{I}{2F} & \text{(Hydrogen production rate)} \end{cases} \tag{10}$$

where, $\dot{N}_{\mathrm{O_2}}$ is the molar production rate of oxygen; $\dot{N}_{\mathrm{H_2}}$ is the molar production rate of hydrogen; I is the applied current; F is Faraday's constant (96,485 C/mol).

During the electrolysis of water, the anode and cathode follow the principle of mass conservation, respectively, which is used to describe the dynamic equilibrium between reactants and products:

$$\frac{dN_{H_2O}}{dt} = N_{H_2O}^{in} - N_{H_2O}^{out} + N_{H_2O}^{gn} \tag{11}$$

$$\frac{dN_{O_2}}{dt} = N_{O_2}^{in} - N_{O_2}^{out} + N_{O_2}^{gn} \tag{12}$$

$$\frac{dN_{H_2}}{dt} = N_{H_2}^{in} - N_{H_2}^{out} + N_{H_2}^{gn} \tag{13}$$

where, superscript *in* represents the inflow of substances; superscript *out* represents the outflow of substances; superscript *gn* represents the net generation of substances due to electrochemical reactions (a negative value indicates consumption in the reaction); suffix H_2O, O_2, H_2, respectively, represent water, oxygen, and hydrogen.

The total cell voltage consists of three components:

$$V_{\mathrm{cell}} = V_{\mathrm{rev}} + V_{\mathrm{act}} + V_{\mathrm{ohm}} \tag{14}$$

where, V_{rev} is the reversible voltage (thermodynamic equilibrium); V_{act} is the activation overpotential; V_{ohm}: Ohmic overpotential.

The reversible voltage is determined by thermodynamic equilibrium and is calculated by the Nernst equation (Bard, Faulkner, and White 2022), where the standard reversible voltage is empirically correlated (Roy, Watson, and Infield 2006), reflecting the theoretical minimum decomposition voltage:

$$V_{\mathrm{rev}} = V^0 + \frac{RT}{2F} \ln\left(\frac{p_{\mathrm{H_2}}^{1/2} p_{\mathrm{O_2}}^{1/4}}{a_{\mathrm{H_2O}}}\right) \tag{15}$$

where, V_{rev} is the reversible voltage, affected by temperature; $p_{\mathrm{H_2}}$ and $p_{\mathrm{O_2}}$ are the partial pressures of hydrogen and oxygen, respectively; $a_{\mathrm{H_2O}}$ is the activity of water.

The standard reversible voltage V_{rev}^0 is temperature-dependent:

$$\begin{aligned} V_{\mathrm{rev}}^0 = {} & 1.5148 - 1.5421 \times 10^{-3} T \\ & + 9.23 \times 10^{-5} T \ln T + 9.84 \times 10^{-8} T^2 \end{aligned} \tag{16}$$

The activation overpotential V_{act}, which overcomes the activation energy barrier for the electrochemical reaction at the electrode surface, is caused by electrochemical kinetics and is described by the Butler-Volmer equation (Falcão and Pinto 2020). Typically, the overpotential at the anode is higher than at the cathode:

$$V_{\mathrm{act}} = \frac{RT}{\alpha F} \ln\left(\frac{i}{i_0(1-\Theta)}\right) \tag{17}$$

where, i_0 is the exchange current density; i is the current density; Θ is the electrode surface gas coverage; α is the charge transfer coefficient.

The ohmic overpotential V_{ohm} arises from the internal resistance of the electrolyzer and follows Ohm's law:

$$V_{\mathrm{ohm}} = I \cdot R_{\mathrm{cell}} \tag{18}$$

where R_{cell} is the total resistance of the electrolyzer, including the electrolyte, electrodes, separator, and connecting components.

3 Modelica-Based Power Electronics Simulation

With the widespread integration of high-frequency switching power semiconductor devices in emerging power systems, the system exhibits multi-timescale dynamic behaviors, spanning from nanoseconds (switching transients) to seconds (system-level energy flow and control responses). Traditional Modelica-based power system modeling(Chieh, Panciatici, and Picard 2011) and simulation frameworks are increasingly challenged by the dual bottlenecks of modeling fidelity and computational efficiency(Masoom et al. 2021).

At the modeling level, idealized switch models fail to capture the nonlinear dynamic characteristics of switching transients, as they neglect critical device-level physical phenomena, such as junction capacitance, charge storage, and parasitic inductance. In contrast, physics-based detailed models (e.g., incorporating charge dynamics, temperature dependence, and parasitic networks) offer higher accuracy but are computationally prohibitive for large-scale system simulations.

At the simulation level, conventional variable-step integration algorithms rely on local error estimates to adjust step sizes. However, their gradual step-size reduction mechanisms struggle to effectively resolve both the abrupt transitions at switching events and the slow-varying dynamics of energy storage and thermal inertia components. Moreover, the presence of inherent parasitic parameters—such as stray inductances, device capacitances, and snubber networks—introduces significant numerical stiffness. This stiffness, characteristic of power electronic systems, exacerbates numerical oscillations, increases solver iteration counts, and severely impacts overall simulation speed and stability (Sterner 2009)(Li et al. 2017).

To address these challenges, Suzhou Tongyuan has focused on advancing solution algorithms for power electronic systems, leveraging fixed-step implicit methods as a

DOI 10.3384/ecp218909

foundation. Building on fixed-step implicit Euler and implicit trapezoidal algorithms, discrete forms of these methods have been developed to enhance simulation efficiency and resolve issues specific to discrete simulation, as illustrated in Figure 4.

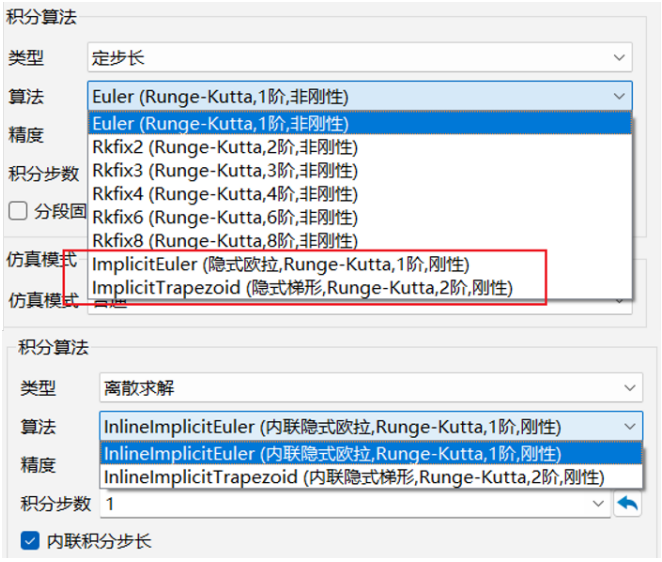

Figure 4. continuous and discrete solving algorithms

Specifically, the implicit Euler method and implicit trapezoidal rule, as core fixed-step implicit algorithms, possess unique properties that underpin their application in power electronic simulations:

The implicit Euler method is based on backward difference approximation, deriving the next-time-step state from the current-time-step state through the formula:

$$\frac{x_{k+1}-x_k}{h} = f(t_{k+1}, x_{k+1}) \tag{19}$$

It features first-order accuracy with strong numerical damping, which can effectively suppress high-frequency oscillations—an advantage when dealing with stiff systems induced by parasitic parameters. While its computational load is relatively low, its accuracy is limited.

The implicit trapezoidal rule combines derivative information from both the current and next time steps, employing trapezoidal integration approximation described by:

$$x_{k+1} = x_k + \frac{h}{2}\left[f(t_k, x_k) + f(t_{k+1}, x_{k+1})\right] \tag{20}$$

It offers second-order accuracy with weak numerical damping, enabling more accurate preservation of the system's inherent dynamic characteristics (e.g., transient oscillations in energy storage components). Though it provides higher accuracy, its computational load per iteration is slightly greater.

Sysplorer constructs a general mathematical model for power electronic system simulation based on the branching method and branching constitutive equations, supporting both continuous and discrete fixed-step algorithms. For discrete fixed-step schemes, the following key design strategies address numerical challenges:

1. Leveraging Piecewise Linear Time-Invariance
   During switching transients, the segmented analytical linearization technique decomposes the nonlinear switching process into multiple linear intervals. Within each interval, system dynamics are described by a linear state equation:

$$\dot{X} = A(t)X + B(t)U \tag{21}$$

   For such linear systems, the implicit Euler method is employed for discretization. Using the backward difference approximation for the time derivative, the discrete update rule is derived as:

$$\frac{X_{k+1}-X_k}{\Delta t} = A_{k+1}X_{k+1} + B_{k+1}U_{k+1} \tag{22}$$

   The core methodology for model discretization incorporates proprietary techniques protected by intellectual property rights and thus will not be elaborated in detail.

   Rearranging terms to solve for X_{k+1}, we obtain:

$$X_{k+1} = (I - \Delta t \cdot A_{k+1})^{-1} \cdot (X_k + \Delta t \cdot B_{k+1}U_{k+1}) \tag{23}$$

   Here, I denotes the identity matrix. This approach transforms state updates into a matrix inversion operation, exploiting the linear structure of the model to avoid nonlinear iterations. When solving the original model directly using the implicit Euler method or other implicit numerical integration algorithms, implicit methods require solving a nonlinear system of equations (the size of which is determined by the number of state variables). Efficiency issues may arise when the scale of this nonlinear system becomes excessively large. In contrast, this discretization method can leverage the inherent linear relationships of the model to further reduce the system equations, thereby improving simulation efficiency. For power electronic systems with inherent numerical stiffness (e.g., induced by parasitic capacitances or inductances), this strategy effectively mitigates numerical oscillations and convergence issues, enhancing the efficiency of fixed-step simulations.

2. **Accurate Switching Event Positioning**
   The discrete algorithms support precise detection of switching events (e.g., device turn-on/turn-off timing). By synchronizing state updates with event triggers, the simulation accuracy of fixed-step algorithms is further improved.

In Figure 5, the average model is based on the state averaging method to establish continuous time-domain

equations, and focuses on the low-frequency dynamic characteristics of the converter by filtering out the switching frequency ripples, which significantly reduces the order of the model to meet the demand for real-time simulation. For the high-frequency characterization of nanosecond switching transients, the detailed switching transient model adopts the segmented analytical linearization technique, which decomposes the switching process into multiple linearization intervals, and accurately characterizes the nonlinear behaviour of the device during the on/off process through the dynamic switching between analytical solving and event triggering. The three types of models are decoupled by time scale and interface variables to form a multi-level simulation framework from microsecond transient to second system response. Switching models are suitable for short-term high-precision analysis, while the averaging model is suitable for long-term or multi-component system simulations (Reindl et al. 2023).

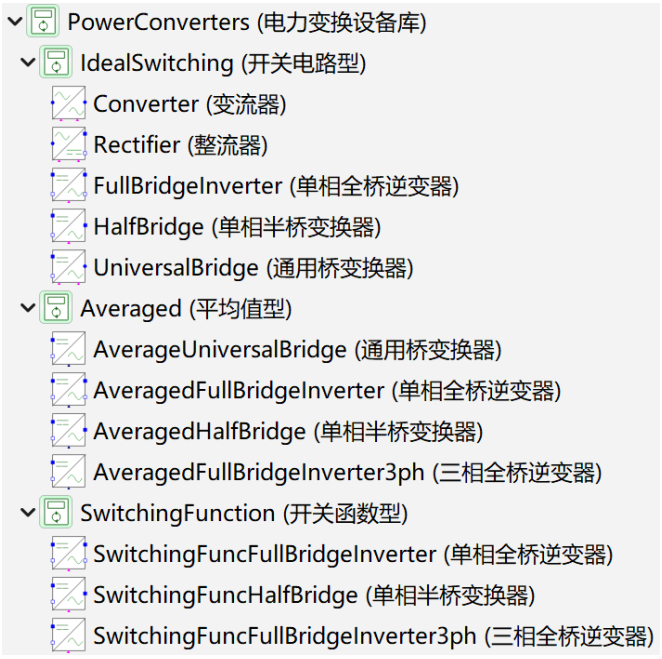

Figure 5. Power Electronic Converter Model

Based on the MWORKS.Sysplorer electromagnetic transient solving algorithm, the DC grid-connected model of the PV system in Figure 6 is calculated, and the simulation time is set to 0.5 s, the step size of the detailed switching model is 1×10^{-5} seconds, and the step size of the average value model is 5×10^{-5} seconds. The simulation results are consistent in terms of key performance variables, and a comparison of simulation times is presented in Table 1. The discrete algorithm incurs longer simulation time than the continuous counterpart. This stems from the model's frequent nonlinear switching events: although segmented linearization decomposes switching transients into linear intervals, repeated matrix inversions across these intervals accumulate computational overhead.

Considering the application scenario of off-grid energy islands, which integrate multiple distributed energy

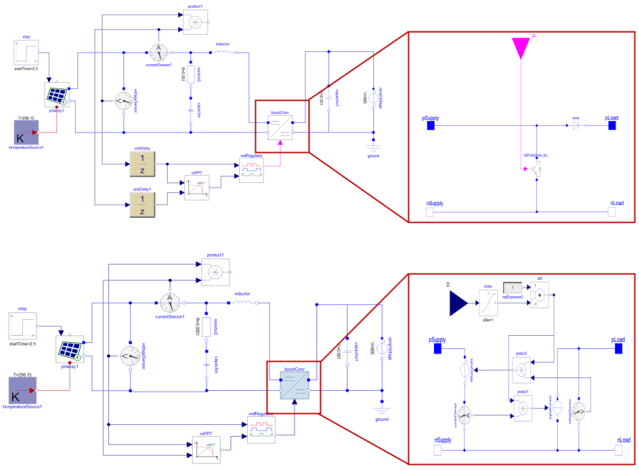

Figure 6. Test PV system for algorithm validation

sources, energy storage systems, and diverse loads with strong system coupling, long-term simulation is often required to analyze energy scheduling strategies, operational stability, and dynamic responses under fluctuating renewable energy inputs. In addition, considering issues such as system coupling and simulation rate, the average value model can meet the requirements of simulation accuracy. Therefore, the converter models in this paper all adopt the average value model.

4 System Modeling and Simulation

4.1 System Configuration

This chapter models an islanded DC microgrid integrating a photovoltaic (PV) system, wind power generation, electrochemical energy storage and an alkaline electrolyzer for hydrogen production. The system employs maximum power point tracking (MPPT) control to maximize renewable energy harvesting from PV and wind power, while a dual-loop adaptive control is implemented in the energy storage system to keep the DC bus voltage stable and smoothen the hydrogen production process. The alkaline electrolyzer is operated under constant power control to ensure optimal hydrogen production efficiency.

Figure 7 illustrates the operating flow of this renewable energy-hydrogen hybrid system. When the renewable energy generation exceeds the power demand of the electrolyzer, the excess energy is absorbed by the energy storage device. Conversely, when the load demand exceeds the renewable energy generation, the energy storage device discharges to compensate for the power deficit, thus maintaining the system in dynamic balance.

Component-level modeling takes a systematic approach: after initial independent validation of the wind, photovoltaic, and hydrogen generation subsystems, a full system simulation is performed with or without integrated energy storage. All simulations were performed using the discrete InlineImplicitEuler algorithm with a fixed time step of 5×10^{-5} seconds.

Table 1. Comparison of Simulation Time for Different Converter Types and Algorithms

Converter Type	Simulation Time	
	Continuous Algorithm	Discrete Algorithm
Detailed Switching (step size: 1×10^{-5})	0.477	3.223
Average Model (step size: 5×10^{-5})	0.058	0.362

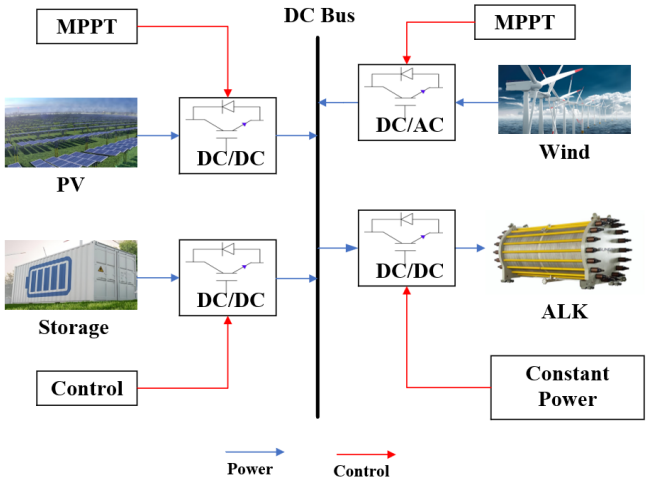

Figure 7. Schematic diagram of the structure of a Wind-PV-Storage Integrated Hydrogen Production system

4.2 Subsystem Validation

4.2.1 Wind Power System

According to Equation 1 – Equation 6 and the control method to establish the wind electronic system, as shown in Figure 8, the wind electronic system consists of wind speed model, blades, permanent magnet synchronous generator, averaged universal bridge converter, MPPT controller, voltage modulation model, machine-side controller and so on, and the main parameters of the wind power system are shown in Table 2.

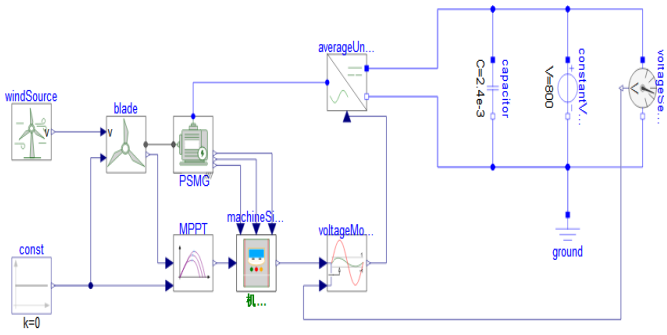

Figure 8. Model diagram of wind electronic system

The system employs a combined wind speed simulation to model the variation of wind speed over time. The wind speed starts from an initial value of 3 m/s and gradually increases to 9 m/s, taking into account both gradual wind changes and random wind fluctuations. The simulation duration is set to 500 seconds.

Table 2. Wind Turbine Parameters

Parameter	Value/Unit
Rated Power P	2 MW
Rated Speed ω	1.93 rad/s
Blade Radius R	40 m
Blade Pitch Angle β	0 °
Air Density ρ	1.293 kg/m^3
Wind Energy Calculation Coefficients	0.70, 150, 0.58, 0.002, 2.12, 13, -18, -0.02, 0.003

The results of the blade wind energy and mechanical power calculations are shown in Figure 9. It can be observed that the wind turbine operates in the constant speed region of the power tracking curve. The pitch angle β is maintained at 0 degrees, indicating normal turbine operation. However, the mechanical power has not reached the rated value, implying that a significant portion of the wind energy is not fully captured. The pitch angle remains unchanged, and the power output is primarily determined by the wind speed and the aerodynamic performance of the blades.

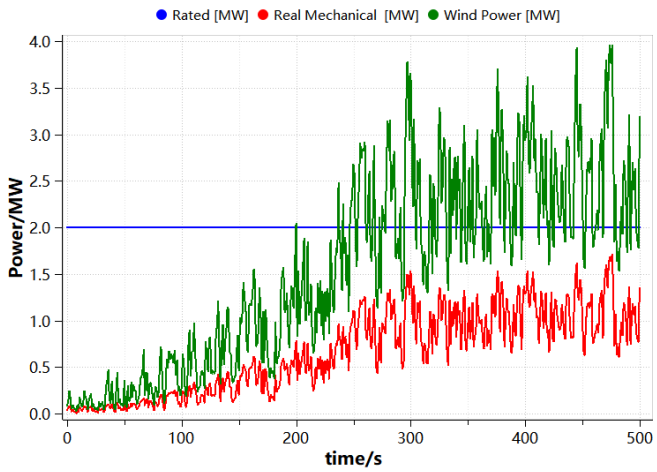

Figure 9. Wind and mechanical power curves

As shown in Figure 10, the tip-speed ratio and power coefficient curve indicate that the system has successfully

implemented Maximum Power Point Tracking (MPPT). The power coefficient has reached its maximum value, and the actual tip-speed ratio of the wind turbine closely approximates the optimal tip-speed ratio corresponding to the maximum power coefficient. The deviation of the tip-speed ratio from its optimal value is attributed to the fact that wind speed is not directly measured. Consequently, the reference signal for the controller (i.e., the rotational speed of the wind turbine) cannot directly respond to wind speed variations.

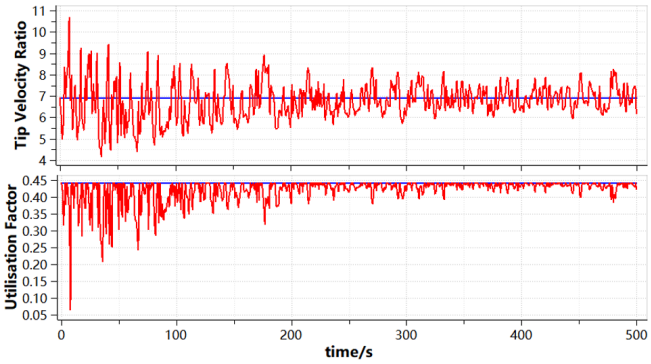

Figure 10. Leaf tip speed ratio curve and wind energy utilisation curve

4.2.2 Photovoltaic System

The photovoltaic (PV) system is established based on Equation 7−Equation 8 and the MPPT control method, as shown in Figure 11. The system comprises environmental models, PV panels, a Boost converter with an MPPT controller, etc. The Boost converter employs an average model and steps up the voltage based on the duty cycle signal output from the voltage regulator.

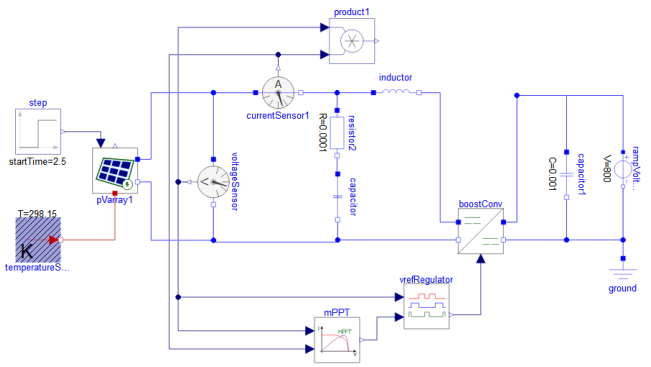

Figure 11. Photovoltaic power generation system

The solar irradiance is set to 1,000 W/m² and steps up to 1,200 W/m² at 2.5 s. The temperature is maintained at 25 °C. Each PV panel has a rated power of 213.15 W, with 10 panels connected in series and 47 panels connected in parallel. The main parameters of the single PV panel are listed in Table 3.

The photovoltaic (PV) MPPT control system can track environmental changes and adjust the output voltage of the PV array to maximize the output power.

Table 3. Single PV Panel Parameters

Parameter	Value/Unit
Maximum Power P_{max}	213.15 W
Number of Cells N_{cell}	60
Open-Circuit Voltage V_{oc_user}	36.3 V
Operating Voltage V_{mp_user}	29 V
Short-Circuit Current I_{sc_user}	7.84 A
Maximum Power Point Current I_{L_ref}	-0.36099 A
Voltage Temperature Coefficient β_{v_user}	0.102 V/K
Current Temperature Coefficient β_{i_user}	0.102 A/K
Series Resistance R_{s0}	0.39381 Ω
Shunt Resistance R_{sh0}	313.0553 Ω

As shown in Figure 12, the output power of the PV array varies with solar irradiance. The simulation results indicate that when the solar irradiance increases from 1,000 W/m² to 1,200 W/m², the output power of the PV panel, controlled by the MPPT controller, increases from 102,169 W to 121,362 W. This demonstrates that the MPPT controller effectively tracks environmental changes and stabilizes the output power at the maximum power point.

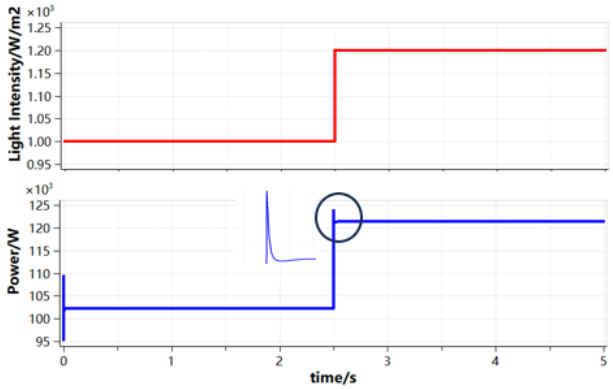

Figure 12. Variation curve of PV array output power with solar irradiance

4.3 Alkaline Electrolyzer

The alkaline electrolyzer model is established based on Equation 10−Equation 18. Considering the high reusability of the electrolyzer model, separate modeling is performed for the cathode, anode, Anolyte, Catholyte and separator within the alkaline electrolyzer. Based on the principles of alkaline electrolysis and considering current flow and material movement, the components are connected via electrolyzer ports and fluid interfaces.

The internal pressure of the electrolyzer is set to 1 bar, with the temperature maintained at 353 K, and temperature variations are considered negligible. A fixed voltage of 2 V is applied to a single electrolyzer cell for electrol-

ysis, with a current density of 1470 A/m^2. The potential differences between the components are listed in Table 4.

Table 4. Potential Differences Between Electrolyzer Components

Component	Potential Difference
Anode	0.57V
Anolyte	0.25V
Separator	0.02V
Catholyte	0.17V
Cathode	0.99V

The hydrogen and oxygen production rates of the alkaline electrolyzer are depicted in Figure 13. The production rates stabilize after 3 seconds. The balance time is influenced by the initial volume of the solution in the electrolyzer and the flow rate of the solution entering the electrolyzer. The hydrogen production rate per cell is 0.1678 Nm^3/h, while the oxygen production rate is 0.0838 Nm^3/h.

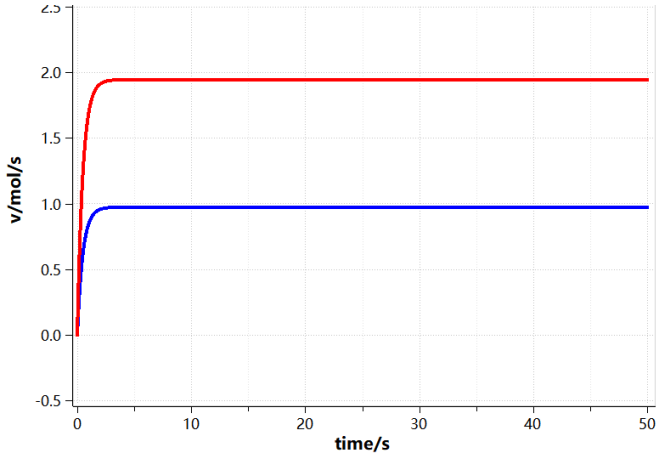

Figure 13. Hydrogen and oxygen production rates

4.4 Wind Power Storage Hybrid System Simulation

To validate the effectiveness of the hybrid wind–photovoltaic–storage hydrogen production system model and its control strategy for an offshore energy island scenario, and to analyze the impact of the wind and PV maximum power point tracking (MPPT) control strategy and the energy storage unit on system reliability and stability, simulations of the wind–PV hydrogen production system were conducted in two scenarios: with and without an energy storage unit.

4.5 Wind-Photovoltaic Hydrogen Production System Simulation

Based on the aforementioned wind power, photovoltaic, and alkaline electrolyzer models and their corresponding control strategies, a hybrid wind–PV hydrogen production system was established. The system comprises 100 series-connected alkaline electrolyzers, with a total rated power of 100 kW. The wind power and PV parameters were appropriately adjusted to match the rated power with the electrolyzer's hydrogen production load. Wind and PV power, as the source side, exhibit significant complementary characteristics in terms of temporal and spatial properties. Variations in wind speed and solar irradiance were simulated to verify the performance of the hybrid wind–PV power generation system under different operating conditions. The system configuration is illustrated in Figure 14.

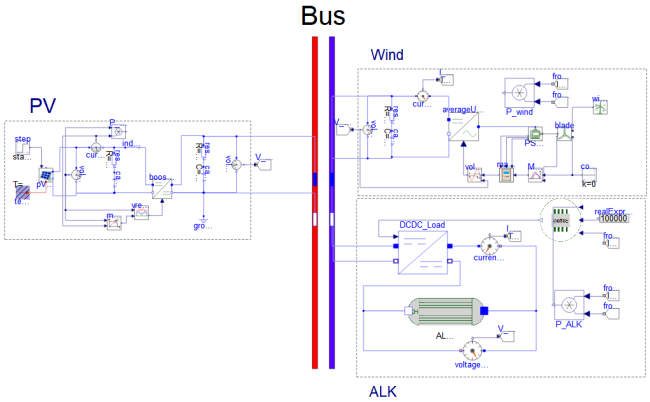

Figure 14. Hybrid Wind-PV Hydrogen Production System Topology

By adjusting the input of solar irradiance and wind speed, the initial solar irradiance was set to 800 W/m^2 and increased to 1000 W/m^2 at 100 s. The wind speed profile incorporated gusts, gradual changes, and random fluctuations.

As shown in Figure 15, the PV MPPT controller rapidly stabilizes the power output at the maximum power point. In the early simulation phase (first 100 s), the alkaline electrolyzers operates at low power due to insufficient wind–PV power generation. After the solar irradiance increase at 100 s, the electrolyzer's power gradually approaches 100 kW. However, as the wind power output further increases during the maximum power point tracking phase, the electrolyzer's power exceeds its rated capacity, posing potential safety concerns.

The fluctuations in wind and PV power generation significantly impact the safe operation of the alkaline electrolyzer. Due to the instability of wind and PV power, the input power to the electrolyzer may experience significant fluctuations, making it challenging to configure the electrolyzer capacity for specific scenarios.

4.6 Wind-PV-Storage Hydrogen Production System Simulation

To address the issues identified in the previous section, an energy storage system is coupled with the hybrid wind–wind-photovoltaic hydrogen production system. The energy storage system adaptively balances the power output

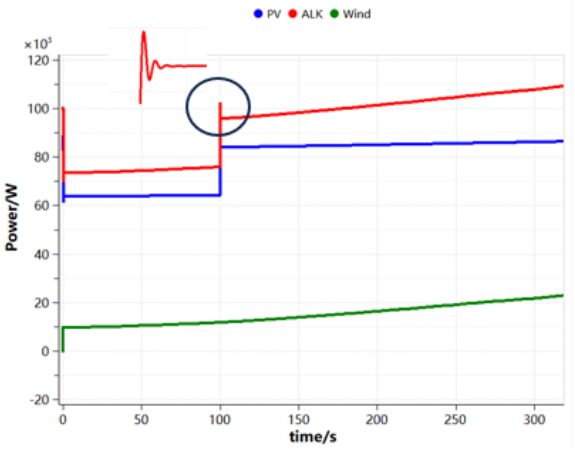

Figure 15. Wind-PV and Electrolyzer Power

from the wind and photovoltaic sources, suppressing fluctuations and stabilizing the DC bus voltage. This ensures that the electrolyzer operates stably at its rated power. The simulation model of the system is shown in Figure 16. The energy storage system is configured with a capacity of 38.4 kWh and an initial state of charge (SOC) of 0.5, and the simulation time is set to 1000 seconds.

The adaptive coordinated control of the energy storage system is based on the DC bus voltage as the power control signal, employing dual-loop voltage and current control. Photovoltaic and wind power, as renewable energy sources, have priority in power output. When the output power is higher or lower than the rated power of the alkaline electrolyzer load, the energy storage system achieves charging and discharging functions through an adaptive coordinated control method. This maintains the balance of the DC bus voltage and ensures the stable and safe operation of the electrolyzer.

In a 1000-second simulation period, the irradiance random perturbation condition was set (irradiance range: 500 - 2000 W/m², step interval: 100 seconds). Figure 17 shows that when an energy storage unit system adaptive coordinated control is activated to maintain the bus voltage at 800 V, small fluctuations in bus voltage occur with each irradiance fluctuation. The magnitude of these voltage fluctuations is related to the extent of irradiance changes. Despite these small fluctuations, the bus voltage remains relatively stable.

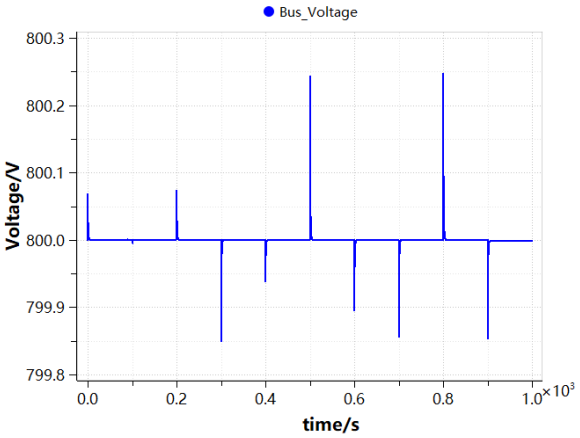

Figure 17. DC bus Voltage

The stable bus voltage enables the alkaline electrolyzer's constant-power controller to operate stably and continuously. The fluctuations in wind and solar power are both smoothed out by the energy storage system, as shown in Figure 18. Within the simulation period, the wind power output increases slowly but remains relatively low, so the system is mainly powered by solar energy. When the solar power output changes abruptly, the en-

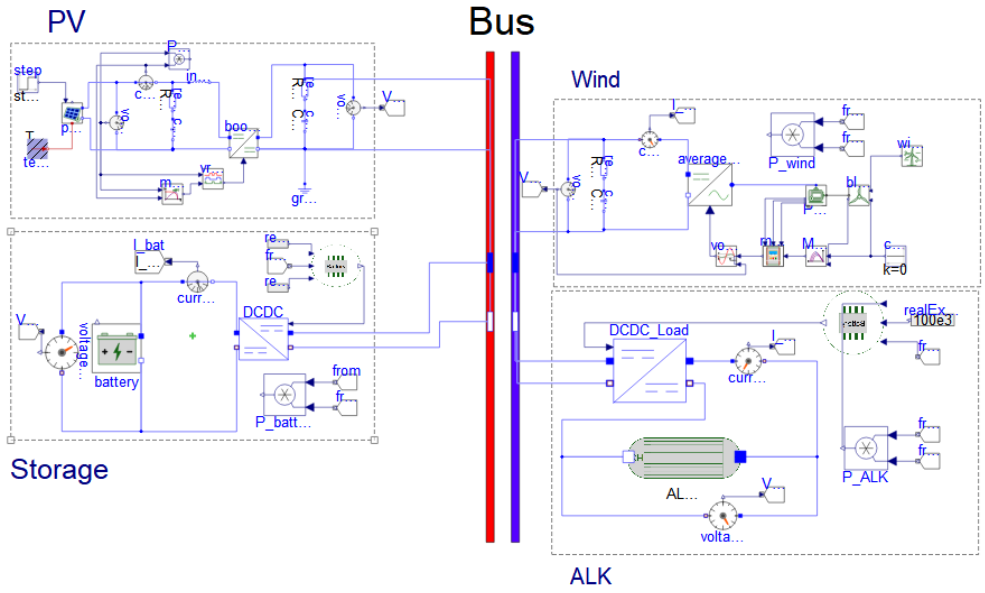

Figure 16. Hybrid Wind-PV-Storage Hydrogen Production System Topology

DOI
10.3384/ecp218909

ergy storage system responds by stabilizing it. The energy storage system's charge or discharge state is determined by the power difference between renewable outputs and the electrolyzer's 100 kW set power. The corresponding state-of-charge (SOC) variation is presented in Figure 19

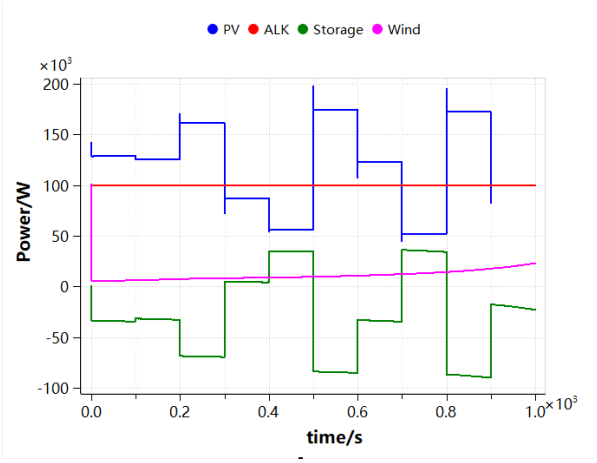

Figure 18. Wind-PV-Storage and Electrolyzer Power

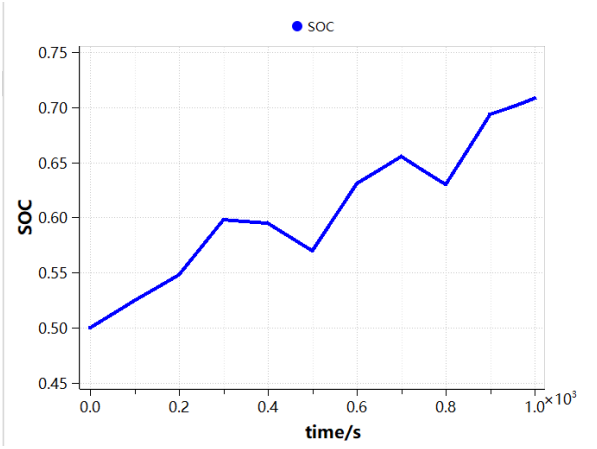

Figure 19. Energy storage SOC

The hydrogen and oxygen production rates of 100 series-connected alkaline electrolyzers with a rated power of 100 kW are shown in Figure 20. Under a current density of 1916 A/m^2 and a cell voltage of 2.087 V, the hydrogen and oxygen production rates are 20 Nm^3/h and 10 Nm^3/h, respectively.

5 Conclusions and Outlook

This paper investigates the dynamic characteristics and control strategies of an offshore energy island system in a hybrid wind–photovoltaic–energy storage hydrogen production scenario through detailed modeling and simulation based on Modelica. The key findings are summarized as follows:

Three modeling methods with different granularities are proposed for the multi-time-scale dynamic response problem of power electronic systems, and continuous and

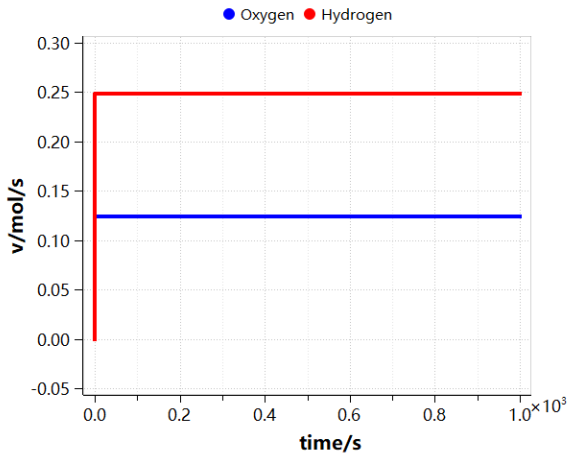

Figure 20. Hydrogen and oxygen production rates

discrete solution algorithms are developed. These approaches significantly enhance simulation efficiency and accuracy.

Subsystem verification shows that the wind power system achieves effective wind energy capture through maximum power point tracking (MPPT) control, and the photovoltaic system.

The energy storage system effectively mitigates the volatility of wind and photovoltaic power generation, maintains DC bus voltage stability, and ensures the safe operation of the electrolyzer.

The research results provide a high-precision simulation support for system parameter optimization and control strategy verification of offshore energy islands, offering significant reference value for practical project implementation. Future work could further explore the system's dynamic behavior across multiple time scales and complex electromagnetic transient processes to enhance the overall performance of offshore energy islands. Additionally, the proposed framework can be extended to include detailed models for hydrogen storage and ammonia/methanol production, bridging the gap between power systems and chemical processes.

Abstract

To address limitations of traditional control methods in complex systems, reinforcement learning (RL) combined with simulation models provides an efficient approach for controller development. In this work, a complete toolchain for developing and deploying RL-based neural network controllers using Modelica system models is presented. Serving as a showcase, a real-world double-inverted pendulum is constructed. The system was modeled in Modelica by combining physics-based and data-driven modeling approaches for efficient development. Coupling simulation with an RL environment is achieved through Functional Mock-up Interface (FMI) standard. Successful training and sim-to-real transfer are demonstrated on a single-pendulum setup, validating the approach for extension to a double-inverted pendulum. This paper provides a reproducible and extensible framework which is well-suited for educational purposes and highlights strengths of Modelica in combination with machine learning approaches.

Keywords: data-driven system modeling, reinforcement learning, sim-to-real transfer, FMI, Modelica, double-inverted pendulum

1 Introduction

Combining reinforcement learning (RL) with system models is a promising approach, as it enables generation of training data using simulations of a system. In this work, a neural network control system is trained using RL coupled with a Modelica system model. After training, the controller is successfully applied to a real system, showcasing challenges and feasibility of this toolchain.

1.1 Motivation

Development of advanced controllers for complex systems requires deep expertise and can even become infeasible with traditional control system methods. This is where RL can fill a gap by learning a control strategy on its own, using a data-driven approach. However, real-world data is limited and costly, which is why generating required training data with a virtual system model is often the only possible path. By combining RL with physics-based simulation models, such as those typically built using Modelica, it becomes feasible to generate efficient training data while ensuring that learned controllers respect underlying system dynamics.

Methods combining RL with physics-based simulation models and sim-to-real transfer of neural network control systems have already been successfully applied in recent studies. Lukianykhin and Bogodorova (2019) introduced a toolbox for integration of Modelica-based models in RL via FMI ('Functional Mock-up Interface', 2014) standard. Heuermann et al. (2023) demonstrated that machine learning surrogate models can accelerate Modelica-based simulations by replacing nonlinear algebraic loops, thereby enabling more efficient training of RL controllers. Lee, Ju and Lee (2025) showcased the use of RL-based neural network control systems and sim-to-real transfer for transition control in a double-inverted pendulum on a cart-pole system, using a model based on Euler-Lagrange differential equations. These successful applications provide a strong foundation for further research that combines these approaches, as pursued in this work. The importance of such methods is expected to grow as systems get more complex in Industry 4.0 and beyond. While alternative approaches, such as *Model Predictive Control* (MPC), which rely on online simulation or optimization, also offer significant benefits, they are often less practical, especially for time-critical applications, due to their substantial computational demands (Morcego et al., 2023). A combination of RL and physics-based simulation models has already been addressed in research projects conducted in collaboration with industry. Among them is *IntelliBake* (INNOSUISSE, 2025), which investigates the application of RL-based neural network control systems for baking processes. Building upon these related efforts, this work contributes to this growing field by providing a demonstrator system and a reusable toolchain for RL-based controller development and deployment.

1.2 Goal

This work demonstrates the development of a neural-network control system trained entirely through RL on a Modelica model. Trained controllers are subsequently transferred to a real-world system, expected to perform a desired control task. This contribution establishes a working toolchain that serves both as proof of concept and as a foundation for future industrial and educational applications. In doing so, it aims to highlight typical challenges and potential solutions associated with following steps:

- System modeling with Modelica for state calculation during RL process.
- Training a neural network control system using RL and Modelica-based simulations.
- Sim-to-Real transfer of a trained neural network control system.

2 Showcase Selection and Setup

The chosen showcase system is a double-inverted pendulum. A motor drives the first pendulum, while the second pendulum is attached via a freely rotating plain bearing. The control task is to swing both pendulums from their initial downward-hanging position to an upright position. This involves two control phases: (1) swinging both pendulums upward by actuating the first joint and (2) stabilizing them in an upright position.

Figure 1. 3D model of the double-inverted pendulum.

This system was selected as a suitable showcase for following reasons:

- *Simple and compact construction:* This system is lightweight, portable, and space-efficient, making it suitable for use in various locations.
- *Demonstrative system for educational purposes:* A double-inverted pendulum allows for direct visual interpretation of control performance, making success and failure immediately apparent.
- *Benchmark character:* A double-inverted pendulum is a well-established benchmark in control theory, enabling direct comparison with related research.
- *Stepwise complexity:* A double-inverted pendulum can be easily simplified to a single pendulum, significantly reducing complexity. This allows initial focus on validation of the toolchain before addressing more advanced control challenges.
- *Challenging sim-to-real conditions:* The System's sensitivity to model inaccuracies (e.g., calibration errors) and a required high control frequency are creating challenges for a sim-to-real transfer, making it ideal for studying transferability.

2.1 System Construction

This mechanical setup features 3D-printed housing and pendulums, a metal flange on the motor mount, and a plain bearing between two pendulums. The assembly is clamped to a table. Physical parameters listed in Table 1 were derived from a computer-aided design (CAD) geometry.

Table 1. Physical parameters of the showcase system

Parameter	*Pendulum 1*	*Pendulum 2*
Mass	0.099 kg	0.061 kg
Length	0.19 m	0.19 m
COM distance from joint center	0.111 m	0.076 m
Moment of inertia	1.9e-3 kg·m^2	7.3e-4 kg·m^2

A brushless DC motor (GB54-2 Gimbal Type 3-6S UAV Drone Motor KV26 by T-Motors) serves as actuator and is controlled via a motor driver (SimpleFOCShield v2.0.4). A hollow motor shaft design allows for internal cable routing, and its permanent magnet rotor enables unrestricted rotation of pendulums. Two 14-bit absolute capacitive encoders (AMT222B by CUI Devices) are used to measure joint angles of both pendulums. These encoders provide direct high-resolution angular measurements for sensor feedback in a control loop. A neural network control system computes a motor voltage in real-time based on sensor inputs. These control signals are transmitted via serial communication to an Arduino Uno R3, which interfaces with electronic components. In this current configuration, the maximum achievable control loop frequency is approximately 250 Hz.

3 System Modeling: Combining Data-based and Physics-based Modeling in Modelica

Successful RL training of a neural-network controller requires an adequately accurate system model. This section outlines the modeling approach for a double-inverted pendulum. Due to the nonlinearity of its governing equations, a double-inverted pendulum exhibits chaotic behavior, making modeling and controlling particularly challenging when using analytical or traditional numerical methods.

This model primarily utilizes components from the `Mechanics` package within the `Modelica Standard Library` (Modelica Association, 2020). An exception is the brushless DC (BLDC) electric motor, which is modeled using a data-driven approach. This method will be described in section 3.1.

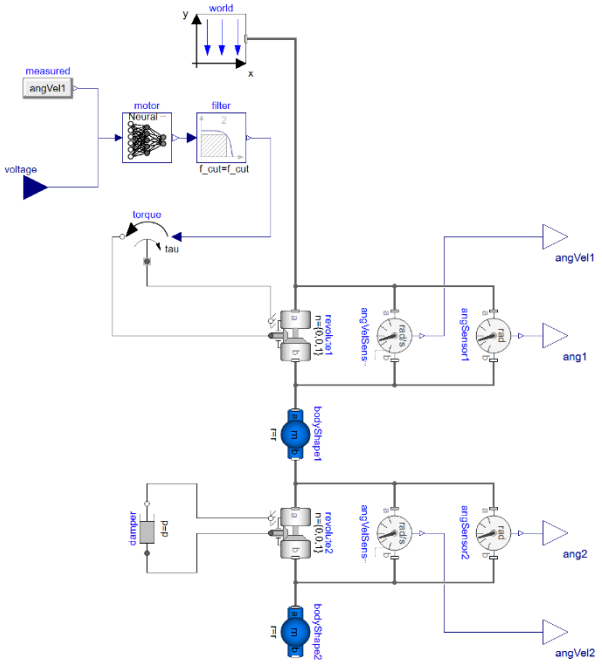

Figure 3. Graphical representation of the Modelica model for the double-inverted pendulum system.

Figure 3 shows a graphical representation of the system model used to train the neural network controller. The model uses two body shape components to precisely model unevenly distributed moments of inertia using a simple method. The pendulums are connected to each other by a joint with a single degree of freedom for rotational motion. Torque is calculated from a data-driven motor model and applied to the first pendulum. For both joints, bearing friction is considered. Friction torque as a function of angular velocity was derived through model calibration using experimental data and mathematical optimization with a Python library called Pygmo. (Biscani and Izzo, 2020). The optimization objective was to minimize normalized root mean squared error (NRMSE) between measurement data and simulation results.

This model has six boundary connectors to interface with an RL environment: two inputs (motor voltage and angular velocity feedback) and four outputs (joint angles and angular velocities of both pendulums). The voltage input is controlled by an RL agent, while angular velocity is required by the data-based motor model to compute torque (see following section). Output signals are used as observations and for reward calculation during training.

3.1 Data-based Methods for Efficient Modeling

A BLDC motor, including its field-oriented control (FOC), requires a specialized modeling approach. Due to its physical complexity, deriving an accurate model from first principles is both challenging and time-consuming. To effectively capture the motor's real-world behavior, a data-driven model was developed. It consists of a feedforward neural network (FNN) trained on measurement data using supervised learning. Available data points primarily cover the motor's static behavior, meaning that transient effects are not fully represented in the training set. To approximate dynamic effects, a Bessel function is included to capture transient torque responses. This approach was deliberately chosen to start with a simple surrogate model. This surrogate model can later be refined, for example by replacing an FNN with a recurrent neural network (RNN), which can leverage time-series information to improve predictions during acceleration and deceleration phases or sudden changes in setpoint speed.

Torque output of a BLDC motor primarily depends on electric current and angular velocity. Since the setup does not permit direct electric current measurement, the motor is controlled using pure voltage input.

For DC motors in general, torque M is proportional to current I, scaled by a torque constant k_m.

$$M = k_m \cdot I \tag{1}$$

Current I can be approximated as proportional to applied voltage U, assuming a constant internal resistance R.

$$I = \frac{U - EMF}{R} \quad \rightarrow \quad I \propto U \tag{2}$$

Therefore, the model assumes that torque M is proportional to input voltage U.

$$U \propto M \tag{3}$$

These assumptions hold for angular velocities near zero, where back- EMF is negligible. Given the motor's application in pendulum control, this simplification is appropriate.

Following on these assumptions, torque values as a function of velocity and input voltage were experimentally determined to develop a motor model. Measurement data was collected for several operational states of a specific BLDC motor. First, no-load operation was recorded across a range of input voltages to establish a zero-torque line in a velocity–voltage plane, with friction effects neglected. Second, the motor's maximum output torque was measured at various input voltages near zero angular velocity. Additionally, data points from runs involving a reversal of rotation direction were recorded along diagonal regions of the plane. Collected measurements are visualized in Figure 4, which displays the motor output torque as a function of angular velocity and input voltage. Measured data points are shown as black dots, while the 3D mesh surface represents the output of the trained feedforward neural network (FNN).

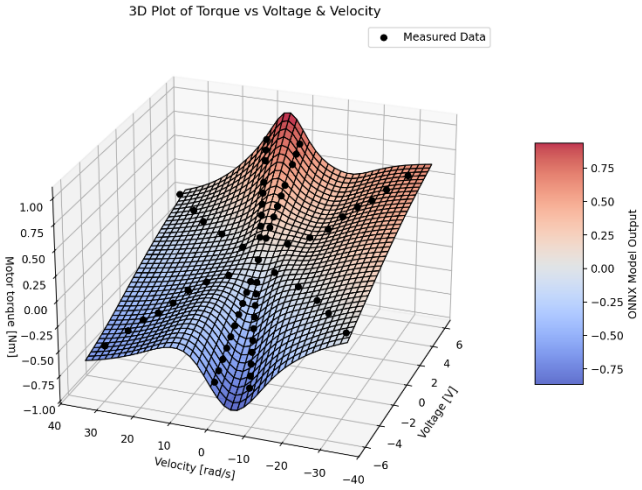

Figure 4. Output visualization of the data-driven motor model.

A supervised learning algorithm was applied to train an FNN. The high-level API `Keras` (Watson et al., 2024), built on top of `TensorFlow` (TensorFlow Developers, 2025), provides a flexible framework for deep learning and enables efficient training of this motor model.

The measured dataset was split into training and test subsets using an 80/20 ratio. This approach allows model performance to be validated on previously unseen data, which is essential for detecting potential overfitting. A Bayesian hyperparameter optimization strategy was employed to efficiently determine a suitable set of hyperparameters (listed in Table 2), after which the FNN was trained for 120 epochs. The resulting model achieved a mean absolute error (MAE) of less than 0.01 Nm on the test dataset. Corresponding mean squared error (MSE) was 0.000095 Nm^2, with a maximum absolute error of 0.038 Nm.

Table 2. Hyperparameters used to train the data-driven motor model.

Parameter	*Value*
Dense Layers	4
Neurons per Layer	80
Learning Rate	0.001
Activation Function	GELU
Optimizer	Adam
Loss	Mean Absolute Error

3.2 Integration of data-driven surrogate models in Modelica

To integrate a data-driven surrogate model of the motor into a Modelica model, the MoONNX (Sergi and Brun, 2024) library has been used. This self-developed library enables execution of Open Neural Network Exchange ('ONNX Project', 2024) models within Modelica environments and is available on GitHub. Currently, it supports Windows 10 (64-bit) and newer Windows operating systems. During simulation, the ONNX runtime library ('ONNX Runtime', 2021), which performs neural network inference, is called with an external function. Resulting outputs can then be used for further computations within the Modelica model.

4 Training Neural Network Controllers using RL and Modelica Simulations

When a system model is available, various methods can be used to develop an optimal control strategy. Neural networks are particularly well suited for implementing complex control policies while keeping real-time computational demands manageable. Discovery of an optimal control policy and training of a neural network are carried out iteratively through RL, involving a resource-intensive upstream training phase, resulting in a neural network controller that can then be executed very efficiently in deployment. When combined with a physics-based system model, it enables rapid and cost-effective generation of large volumes of training data, eliminating need for real-world interaction during training.

4.1 Reinforcement Learning Fundamentals

RL is a subfield of machine learning in which an agent learns to make decisions by interacting with an environment. This process can be modeled as a Markov Decision Process (MDP), defined by a set of *states*, *actions*, *transition dynamics*, and a *reward function*. The goal of an RL algorithm is to find an optimal strategy that maps states to actions in order to maximize cumulative long-term reward. This strategy is typically represented as

DOI 10.3384/ecp218921

a neural network, which can capture complex mappings between state and actions. This can even make high-dimensional, continuous, and partially observed state spaces controllable. Unlike other methods of machine learning, RL does not require pre-collected training data. Instead, an agent learns through trial-and-error interactions with an environment, enabling autonomous data collection and policy improvement.

A basic RL loop consists of an agent selecting an action based on its current policy, applying it to an environment, and receiving a new state and reward based on transition dynamics and reward function. The agent then updates its policy based on the observed outcome. In our setup, state transitions are computed within a Modelica model.

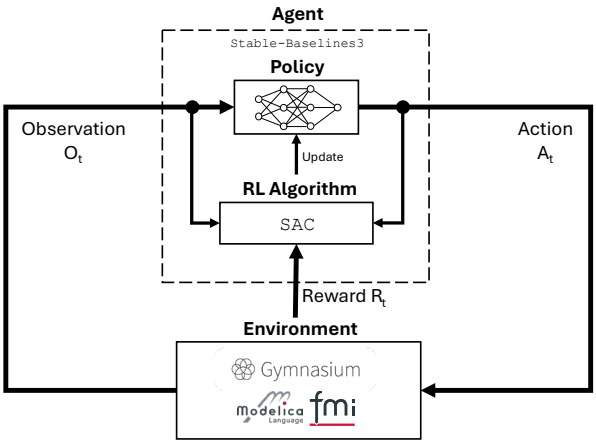

Figure 5. Block diagram of the RL loop, illustrating the interaction between components and the tools applied.

4.2 Coupling RL Environments with Modelica Simulations

Building an RL environment that incorporates physics-based simulations requires integration of multiple software frameworks and standardized interfaces. For this showcase, a training environment was constructed using an RL framework called `Gymnasium` (Mark Towers, Ariel Kwiatkowski et al., 2025), which enables the creation of customized environments via a Python API. `Gymnasium` follows a consistent structure tailored for RL tasks and is compatible with a wide range of existing algorithms, facilitating both development and testing.

The Modelica system model was then exported as a *Functional Mock-up Unit* (FMU), encapsulating relevant simulation equations and parameters according to FMI standard ('Functional Mock-up Interface', 2014). To perform physics-based state updates within an RL loop, the FMU was integrated using the `fmpy` library ('FMPy', 2024). During training, actions chosen by a RL agent are passed to a FMU via model inputs. In turn, FMU outputs are used as observations for an agent as well as values for reward computation. For this work, FMU version 2.0 in Co-simulation mode, which includes an internal solver to ensure stable and reliable simulations, is used. In comparison to Lukianykhin and Bogodorova (2019), the simulation is advanced in each RL step using the `doStep()` function provided by `fmpy`. This enables an RL loop that can be executed efficiently and more quickly, even when model complexity increases.

Listing 1. Illustrative Python code for integrating an FMU into a Gymnasium-based RL environment using FMPy library.

```
# called at beginning of the training
def __init__(…):
        fmu = fmpy.instantiate_fmu(fmu_directory,
        model_description, "CoSimulation")

# called at beginning of each training episode
def reset(…):
        fmu.reset()
        fmu.setupExperiment(startTime=0.0)
        fmu.enterInitializationMode()
        fmu.exitInitializationMode()

# called at each RL step
def step(…):
        fmu.setReal([parameter_names], [action_values])
        fmu.doStep(current_time, step_size)
        observations = fmu.getReal([parameter_names])
```

4.3 RL Agent Setup and Training Configuration

Integration of a RL agent is realized using `stable-baselines3` (Raffin et al., 2021). A library that is fully compatible with `Gymnasium` environments and provides a suite of reliable, state-of-the-art algorithms based on `PyTorch` (Jason Ansel et al., 2024). With only a few lines of code, a neural network is automatically initialized based on defined observation and action spaces and trained using a selected algorithm. Hyperparameters and training settings are freely adjustable to meet specific requirements of a control task.

Primary determinants of a controller's performance are *reward functions*, *observation and action spaces,* and an *environment* (including timestep length, episode termination criteria, initial state, etc.). These elements define an underlying mathematical optimization problem and thereby determine the global optimum. In contrast, the choice of *algorithms*, *hyperparameters*, and *neural network architecture* primarily affects training dynamics, convergence speed, and likelihood of reaching an optimal or near-optimal solution. In practice, especially for complex problems, training often converges only to a local optimum. As a result, these factors still have a significant impact on controllers' performance.

An action selected by an RL agent serves as control input to the system model and is derived from the current state and a probability distribution. In this case, the observable state consists of four state variables, $O_t = \{\theta_1, \theta_2, \dot{\theta}_1, \dot{\theta}_2\}$, representing angular positions and velocities of the

pendulums, respectively. θ_1 is measured relative to the downward vertical, and θ_2 is measured relative to the first pendulum. Thereby, $\dot{\theta}_1$ and $\dot{\theta}_2$ denote their respective angular velocities.

The action space includes the motor voltage, normalized to $-1 \leq a \leq 1$. This normalization improves learning efficiency, as many algorithms in `stable-baselines3` assume a Gaussian action distribution centered around zero.

The *reward function*, which evaluates the quality of the action-state pair at each timestep, is based on the work of Lee et al. (2025) for a double-inverted pendulum on a cartpole. It was adapted to match the system described in this paper and is composed of two components described in Eq. (4) and Eq. (5). A first component that focuses on pendulum position and a second one that focuses on pendulum velocity. As the objective is to stabilize the pendulum in an upright position with minimal angular velocity, an upright pendulum that is not moving yields the highest reward. This reward increases if the pendulum's height gets closer to the target height. Additionally, the reward increases with velocity if the pendulum's height is close to its initial position. However, if the pendulum is close to the target position, the reward increases when its velocity decreases. Unlike the approach taken by Lee et al. (2025), this reward function is specifically designed for a double-inverted pendulum. It ensures a reward path from the initial to the goal position that provides continuously increasing rewards when followed.

$$R_\theta = 0.5 * \sin(\theta_1) + 0.5 * \sin(\theta_1 + \theta_2) \quad (4)$$

$$R_{\dot{\theta}} = e^{\left(-0.02 * \sqrt{(\dot{\theta}_1)^2 + (\dot{\theta}_2)^2}\right)} \quad (5)$$

$$Reward = R_\theta \cdot R_{\dot{\theta}} \quad (6)$$

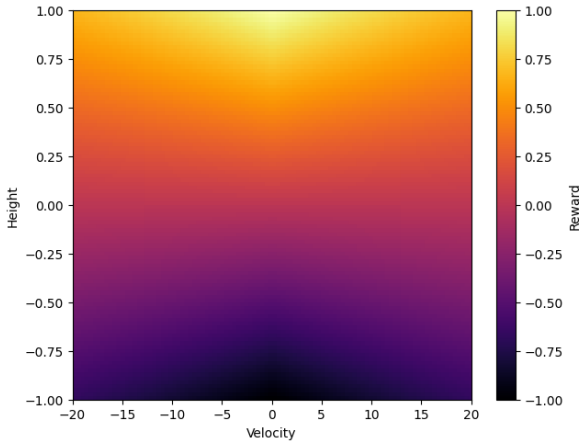

Figure 6. Reward function visualization for the double-inverted pendulum.

The environment is configured with an episode duration of 4 s, allowing the agent to interact with it up to 1'000 times per episode, given a reinforcement learning timestep of 4 ms. At the beginning of each episode, the pendulums are initialized in a downward position with zero angular velocity, corresponding to the natural starting state of a real-world pendulum system.

For training Soft Actor Critic (SAC) (Haarnoja et al., 2018), one of the most widely used modern off-policy RL algorithms, was used. It supports continuous action spaces and demonstrates strong performance in benchmark tests (Haarnoja et al., 2018; Huang et al., 2024). The hyperparameter configuration used in this work is summarized in Table 3.

Table 3. Hyperparameters used for this showcase with the SAC algorithm from stable-baselines3.

Hyperparameter	*Value*
Optimizer	Adam
Learning rate	0.0003
Discount factor (γ)	0.99
Replay buffer size	1e6
Number of hidden layers in critic networks	3
Number of neurons in hidden layers of critic network	512
Number of hidden layers of policy network	2
Number of neurons in 1st hidden layer of policy network	400
Number of neurons in 2nd hidden layer of policy network	300
Minibatch size	256
Nonlinearity	ReLU
Target smoothing coefficient (β)	0.005

Training was conducted on a Windows PC, parallelized across 12 cores of an Intel Xeon W-2275 3.3 GHz CPU. With this configuration, approximately 360 timesteps per second were processed during training.

4.4 Results and Discussion

As an initial step, RL training was conducted on a single-pendulum system. This simpler setup served as a validation of the toolchain by significantly reducing challenges associated with training and sim-to-real transfer. A stepwise increase in system complexity allows for targeted troubleshooting and a structured development approach. RL training for the single-pendulum system converged at a maximum episodic reward of 95%, using the reward function defined in Equation 7, where θ represents the pendulum angle relative to the downward vertical.

$$Reward = \cos(\theta) \quad (7)$$

DOI 10.3384/ecp218921

Convergence was reached after 500’000 timesteps, but training was extended to 1’100’000 timesteps to ensure model stability and robustness. The entire training process was completed in just 52 min. When evaluated with a system model, the trained neural network successfully stabilized the pendulum in an upright position.

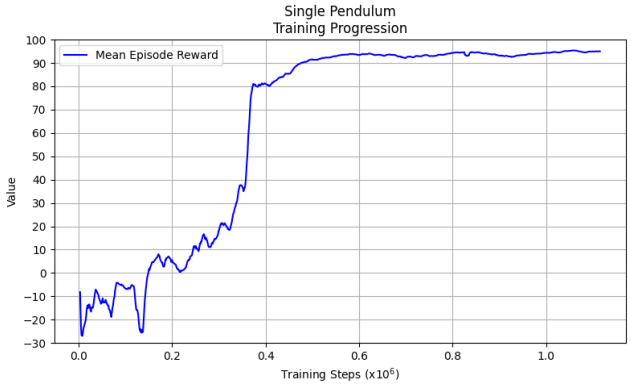

Figure 7. Mean episode reward during training of the single-pendulum system.

To deploy the trained neural network on a real-world system, it was converted into ONNX format, enabling interoperability and execution across different tools. The sim-to-real transfer introduced no additional issues, and the neural network successfully controlled the real-world system with performance comparable to the virtual system. The deployed controller for the single pendulum was also capable of handling external disturbances (e.g., applied forces) and inevitable model inaccuracies, demonstrating robust real-world performance.

Following the successful validation of the toolchain's functionality, it is applied to the double pendulum case. In that the toolchain was used to test various training configurations, each employing different training and pendulum parameters. These trainings have only been successful when system parameters have been chosen carefully. Figure 8 shows the mean reward progress for a representative successful training.

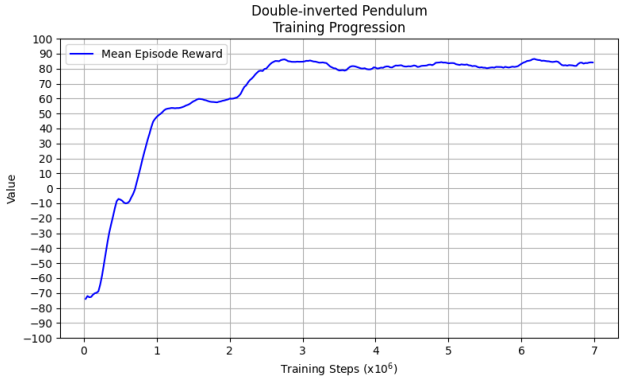

Figure 8. Mean episode reward during training of the double-inverted pendulum system.

In this example, training convergence was reached after 1’100’000 timesteps with a maximum mean episode reward of 86.5%. Despite some successful trainings, a sim-to-real transfer has not yet been achieved. In many cases, the controller could make the real-world double-inverted pendulum swing upwards but failed to balance it.

The conducted grid search indicates that stable control is much more likely when the proportions of the pendulums meet specific conditions. The first observed requirement is an appropriate ratio between the time constants of the motor and second pendulum that must be bigger than 28.5 to ensure stable control. (Eq. 8) The time constant of the second pendulum is determined solely by its geometry and friction, whereas the motor's time constant depends on the geometry of the first pendulum and a small control loop delay. Since this delay is minimal, it can be considered negligible. The second condition is related to the ratio between the damping coefficient D (i.e., the friction in the joint) and the second pendulum's moment of inertia. (Eq. 9) In the trainings, successful controllability could only be observed if this ratio was lower than 3.0.

$$\frac{\tau_{rod,2}}{\tau_{motor}} = \frac{\tau_{rod,2}(I_2, m_2, l_{cm}, D)}{\dot{\tau}_{motor}(\tau_{motor}, I_1)} > 28.5 \tag{8}$$

$$\frac{D}{2 * I_2} < 3.0 \tag{9}$$

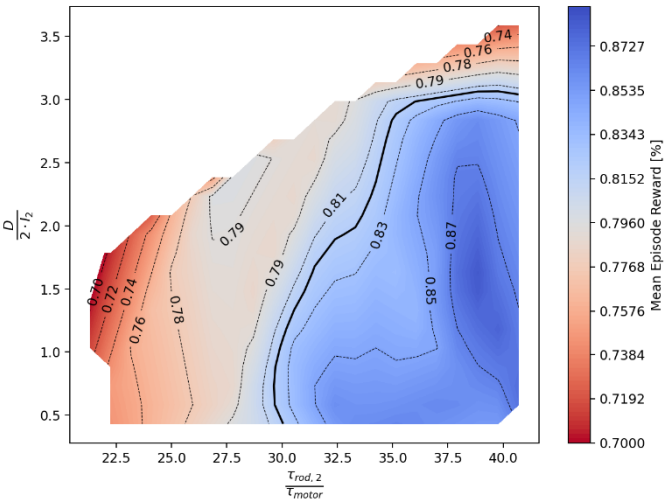

Figure 9. Controllability Analysis for double-inverted pendulum parameters.

Figure 9 visualizes the subset of our sweep that yielded mean rewards > 0.82. Within this empirical region controllability was consistently observed. This region can be accessed through a variety of parameter combinations. A straightforward approach would involve utilization of an electrical motor characterized by a low time constant. It is also plausible to utilize a secondary pendulum with an enhanced time constant. However, this requires a more detailed evaluation due to the dependence of the previously mentioned second condition on properties of the second pendulum.

5 Conclusion and Outlook

This work presents a comprehensive toolchain for training and deploying neural network control systems using reinforcement learning (RL) in combination with physics-based simulations developed in Modelica. A key achievement of this work is the successful transfer of a controller trained entirely in a virtual environment to a real-world system, demonstrating the feasibility of simulation-based training for physical control tasks. By offering a unified and structured workflow, this approach provides an accessible toolchain for both research and educational purposes. The use of well-established tools and frameworks ensures an efficient, reliable, and reproducible development process, laying the foundation for future applications of RL-based neural network controllers in complex, real-time dynamic systems across academic and industrial domains.

The RL training process poses a complex optimization challenge, where success relies heavily on the selected training setup, including algorithm choice, neural network architecture, and reward-shaping strategies. Numerous environment and training parameters, such as hyperparameters, observation augmentation, and initial state distributions, are highly system-specific and interact in intricate ways, adding further complexity to the optimization task. Identifying a configuration that allows a RL agent to reliably converge toward an optimal or near-optimal policy often requires repeated experimentation, with each training run being both time- and computation-intensive. Leveraging prior domain knowledge, heuristics, and insights from previous experiments can help reduce this search space, yet the process remains inherently challenging and iterative.

During the development of this showcase, it became evident that achieving good system controllability is a fundamental yet challenging prerequisite for successful RL training. The controllable region of this system is not intuitively defined, making it difficult to identify suitable configurations, and even a well-designed RL setup cannot compensate for a system that is only partially or poorly controllable. For this double-inverted pendulum case, ensuring controllability requires carefully selecting parameter ratios between the pendulum components, such as their respective moments of inertia, damping coefficients, and lengths, to guarantee that the system can, in principle, be well stabilized. Ongoing work focuses on improving these mechanical design aspects and thereby enabling a sim-to-real transfer of the learned policies. Completing these steps will be essential not only for finalizing the double-pendulum showcase but also for strengthening the reliability, scalability, and educational value of the entire toolchain as a practical teaching and research platform for reinforcement learning in real-world control applications.

5.1 Future Work

The next phase in the development of this showcase focuses on redesigning the physical system to enable a sim-to-real transfer for the double-inverted pendulum. This involves adjusting the system's proportions to align with the empirical guidelines identified in Chapter 4.4.

Optimization efforts will primarily target pendulum components. The first pendulum will be redesigned to reduce its moment of inertia, thereby improving the motor's time constant. In parallel, the second pendulum will be modified to increase its moment of inertia. Since replacing the motor would be significantly more complex, optimizing the pendulum design presents a more practical and effective approach to start with.

Other potential further steps will be focused on:

- *Controller implementation for embedded systems:* Investigating the use of trained neural network controllers on embedded platforms such as industrial PLCs (e.g., Beckhoff SPS)
- *Enhancing controller robustness through system randomization:* Applying randomization techniques during training to improve sim-to-real transfer, increasing resilience to virtual–physical discrepancies, sensor noise, and limitations in the control loop or actuators
- *Educational applications:* The developed showcase can be utilized in lectures to teach reinforcement learning (RL) in an engaging and interactive manner. A possible exercise would involve designing and comparing different reward functions for balancing the pendulums in an upright position. Using this provided toolchain, students can gain practical, hands-on experience with RL training. Furthermore, the most promising neural networks trained in simulation could be deployed on the physical system, enabling a real-world demonstration of RL.

Abstract

The transition from internal combustion engines (ICE) to alternative technologies—such as battery-electric powertrains—in mobile machinery places increased demands on thermal management systems. Cooling requirements below the ambient temperature during the summer, and intensive heating requirements during the winter, lead to holistic but complex integrated solutions where energy efficiency is of high priority. Research into integrated system solutions including heat pumps and waste-heat recovery has been carried out mainly on passenger cars. In this study, mobile machines are considered, and an articulated excavator-loader—also known as backhoe loader—is used as an example. Apart from operating tasks, times, and conditions, the system architecture under the hood differs from architectures usually found in passenger cars, including working hydraulic systems. During the early stages of vehicle development, modeling and simulation of integrated thermal management systems are crucial for proof-of-concept, developing control strategies, and understanding subsystem interactions. These processes rely on data that would otherwise require testing on a complete vehicle. This paper presents a model of a heat recovery system for cabin heating using the DLR ThermoFluid Stream Modelica library, together with input data from previous research based on experiments on a series-hybrid electric machine. The study investigates the initial feasibility and performance of a direct heat recovery system for the architecture of a battery-powered mobile machine. The results show that a simple system design can provide a strong foundation for cabin heating under many of the studied excavating conditions, though it does not fully match the performance of the reference system, which is supplied with heat from an ICE. *Keywords: Thermal management, electric vehicle, heat recovery, cabin heating, mobile machine, ITMS*

1 Introduction

Battery-powered vehicles have become a common sight on the roads. Despite this, the electrification of heavy off-road mobile machines seems delayed in comparison with passenger vehicles. This can be partly explained by small production series and the design challenges arising with varying or unknown duty cycles, in combination with high performance requirements, and end user expectations (Beltrami et al. 2021; Lajunen et al. 2016). Mobile machines are specialized production vehicles designed for specific tasks, where reduced operating costs, minimized downtime, and enhanced performance drive the electrification (Monnay 2017; Lajunen et al. 2016). Battery as an energy storage technology is a main contender in this ongoing transition (Niemelä et al. 2023), where energy density, component costs and demanding operating conditions are some of the major challenges. To mitigate costs for end users and enhance the viability of battery-powered mobile machines, energy efficiency is a high priority—particularly because the cabin requires substantial energy for heating during winter—where thermal management systems play an important role.

Replacing the internal combustion engine (ICE) with electric motors will likely increase the total energy efficiency of the vehicle. However, removing the ICE will also remove a lot of available waste heat, which was previously especially useful during winter to keep the cabin warm and comfortable. Instead, this energy needs to be taken from somewhere else. Ideally, the waste heat previously recovered from the ICE could instead be recovered from the electric motors in a battery-powered mobile machine. On the other hand, the amount of available heat flow from one single source may not always be sufficient to cover the cabin heat demand. Heat sources on these types of vehicles are also specifically dependent on the operating mode of the machine (Lagerstedt et al. 2024). An integrated thermal management system (ITMS)—that enables the collective recovery of heat from multiple components and subsystems within the machine—is therefore a necessary strategy moving forward in order to reduce the energy consumption of the thermal management system and to fulfill the runtime requirements of the machine at lowest possible cost impact on the end user.

Unlike passenger cars, mobile machines are primarily built to perform paid work. In some cases by being stressed to the system limits during a full mission, in others by only occasional peak loads. In both cases, system cost and reliability are key aspects to ensure the profitabil-

ity of the operation. Since the maximum available runtime at high-power utilization is crucial for a mobile machine, the overall vehicle efficiency at these operating points defines the minimum required energy storage needed to reach the lower acceptable runtime—and thus the machine cost. As illustrated in Figure 1, the potential for recovering waste heat is greatest during short runtimes—corresponding to high-utility operation—where effective heat recovery methods are most beneficial, while longer runtimes may require supplementary heating, though this does not necessarily affect the required energy storage if the added energy remains small compared to the high-utility consumption.

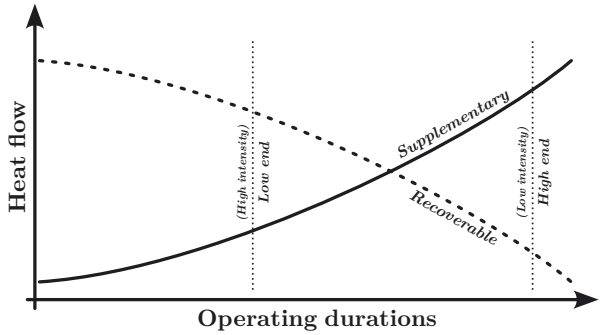

Figure 1. Conceptual representation of the heat flows over operating durations—from a full energy storage to empty—for an electrified mobile machine during cold conditions. At short operating durations—corresponding to high-power utilization—the amount of recoverable heat is high, reducing the need for supplementary energy. As power utilization decreases and operating durations increase, recoverable heat drops, and supplementary heating becomes increasingly necessary. Fictive duration limits, marked as 'Low end' and 'High end' along the horizontal axis, illustrate the design requirement for a supplementary heat source.

Relying solely on waste-heat sources from a battery-electric powertrain may not provide satisfactory heating results in the cabin if the power output from the vehicle is not high enough. To counter this issue, a simple and commonly used method in the history of electrification has been to add resistive heating elements to supplement insufficient heat flow (He et al. 2024). Another solution is to use the existing air conditioning system as a heat pump, which is gaining attention due to the range loss often related to the use of resistive heaters (Kwon et al. 2024). Even if a heat pump system can be designed so that waste heat is recovered from various heat sources in the vehicle, a heat pump is a supplementary heat source requiring energy to power the compressor. Thus, an efficiency limit is introduced which is defined by the energy consumption of the heat pump system. This limit can be passed with a direct heat recovery system, if the amount of waste heat within the system is high enough for the heating demands.

Since the most studied use case within the research of ITMS solutions still is the passenger car (Leoncini et al. 2024), more knowledge is needed regarding mobile machines and the implications of differences in system architecture and duty cycles on the availability of waste heat—and viable methods for recovering it.

1.1 Mobile Machines

In this and previous studies, an articulated excavator-loader—also known as backhoe loader—is used to represent a mobile machine (Lagerstedt et al. 2024; Lagerstedt et al. 2025). The Huddig 1370T, illustrated in Figure 2, is an example of an electric hybrid mobile machine with a specified standard weight of 14.6 t and a top speed of 50 km/h.

Figure 2. Illustration of an articulated excavator-loader, the Huddig 1370T—an example of a mobile machine capable of both road transportation and load handling, featuring a front loader and a rear excavating unit.

Mobile machines in general—and Huddig machines in particular—are multi-purpose vehicles. The main purpose is rarely human transportation—however, many mobile machines still have a physical operator on board with requirements on comfort and visibility. Standardizing mobile machine duty cycles is challenging, due to the variety of functions, capacity and operating conditions. In a previous study, one approach to evaluate thermal loads during extreme, high-utility operation was presented (Lagerstedt et al. 2024). The approach was based on dividing the machine's mode of operation into the two known, most energy-intensive and contrasting modes—transportation and excavating. Combining the operating modes with ambient temperatures, forms a coordinate system of machine operation illustrated in Figure 3. Extreme operating points were selected in each corner and evaluated experimentally on the electric hybrid machine Huddig 1370T to estimate the thermal loads. The thermal loads divided into approximate temperature categories, together with the cabin heating demand, is illustrated in Figure 4.

In this study, a proposed system to recover parts of the available waste heat in order to warm the vehicle cabin is modeled, simulated and evaluated. The proposed system is a direct heat recovery system, meaning that waste heat is transferred to its destination as sensible heat, without phase changes or significant mechanical work on the transport medium. The system covers heat

DOI 10.3384/ecp218931

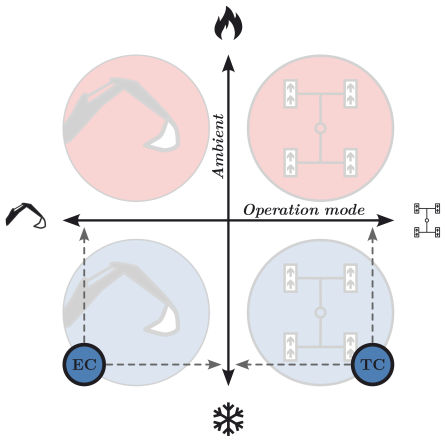

Figure 3. Overview of the operating scenarios for a mobile machine, defined by ambient temperature on the vertical axis and operating mode on the horizontal axis. 'Excavating Cold' (EC) and 'Transportation Cold' (TC) marks operating points previously evaluated by experiments—representing corner cases during cold ambient conditions (Lagerstedt et al. 2024). The dashed lines illustrate the operating point directions of interest to evaluate through simulations in this paper.

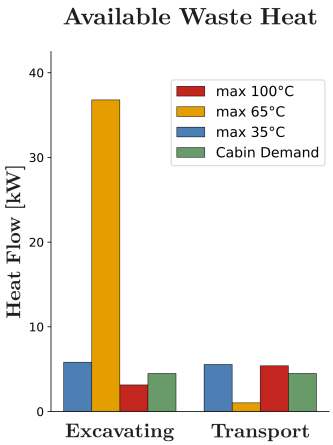

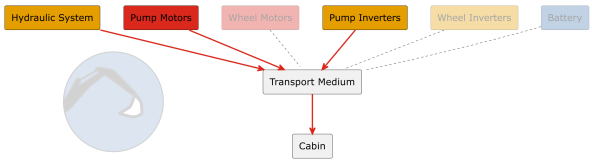

Figure 4. Bar chart from previous work, illustrating available waste-heat flow on a battery-powered mobile machine at worst case operating points during cold ambient conditions—excavating and transportation at –15°C (Lagerstedt et al. 2024).

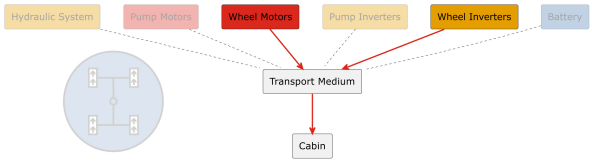

recovery in the two separate operating modes excavating and transportation. During excavating, heat is recovered from the hydraulic system—which is significant for a mobile machine—along with the electric motors and inverters powering the hydraulic pumps. The heat recovery principle for excavating is illustrated in Figure 5a. For transportation, the heat recovery principle is more similar to that of a road transportation vehicle and is illustrated in Figure 5b.

1.2 Contributions

This study investigates the initial feasibility and performance of an ITMS for the architecture of a battery-powered mobile machine. A simple and low-complexity

(a) Heat recovery paths during excavating.

(b) Heat recovery paths during transportation.

Figure 5. Principal overview of the proposed direct heat recovery system during excavating and transportation respectively, as studied in this paper. Heat is recovered from the active subsystems via a transport medium that delivers thermal energy to the cabin. Solid red arrows indicate the active heat flow paths in the respective operating mode, while dashed lines represent inactive heat paths in the ITMS. The heat sources are colored according to the temperature categories used in Figure 4.

system design of a heat recovery system is suggested, adopting the main principle of a traditional heat recovery system—but replacing the ICE with heat sources related to an electrified mobile machine. By the modeling and simulation of the proposed heat recovery system, a wide variety of operating points can efficiently be evaluated, and the effect of control strategies can be understood.

2 Modeling

The models presented in this section were made using the DLR Thermofluid Stream Library (TFS) (Zimmer 2020; Zimmer, Meißner, and Weber 2022), together with the Modelica Standard Library and the modeling and simulation tool OpenModelica v1.22.2. Both the libraries used and the simulation tool are open-source, which was an important reason behind the selected approach. Additionally, ITMSs in electric vehicles can evolve into complex designs with many actively controlled flow routes, where the TFS library can serve as a strong alternative (Zimmer, Meißner, and Weber 2022). Two models were created, where the first model represents a traditional heat recovery system on a vehicle powered by an ICE, in this study acting as a reference system. The second model represents the proposed system, but with two different control strategies. The control strategies refer to the mass flow control of the transport medium—the first maintains the same fixed flow as the reference system, while the second actively controls the flow to keep the electric motors at their maximum temperature.

To evaluate the system models in the different operating points illustrated in Figure 3, two parameters are used—ambient temperature T_{amb} for the vertical axis, and intensity factor X_I for the horizontal axis. The intensity factor

is a simplified representation of both operating mode and degree of operating intensity, where negative and positive values correspond to excavating and transportation respectively, with –1 and 1 both being equal to maximum intensity. The models are evaluated in the temperature range –15 to 15°C.

2.1 Reference System

First, a baseline system was modeled representing a heat recovery system of a traditional vehicle powered by an ICE, and is illustrated in Figure 6. The model consists of two separate circuits—one transport medium circuit delivering heated glycol-mixed water to the heating core in the cabin, and one circuit heating ambient air and delivering it to the cabin.

The transport medium circuit, highlighted with thick blue lines, is modeled as an open circuit with a fixed temperature source of 82°C and a constant flow. The constant flow is modeled with a pump component with input signal from a mass flow regulator, consisting of a PI controller and a limiter. Due to the excessive heat flow available in the ICE, and the thermostat maintaining the engine temperature via an external heat rejection system, the heat supply to the cabin is assumed to be constant. The temperature value was measured in previous work (Lagerstedt et al. 2024).

The second circuit, highlighted with a purple zone, corresponds to the cabin and the fresh air supply, modeled as an open circuit with a fixed air flow—maintained with the same method as the transport medium—corresponding to the maximum possible air flow based on previous measurements (Lagerstedt et al. 2024). The cabin is modeled as a volume component, with the output temperature state representing the cabin temperature in this study. The temperature of the source component is defined with the parameter T_{amb}.

2.2 Proposed System

The system model—covering the hydraulic system, pump motors, pump inverters, wheel motors and wheel inverters—is illustrated in Figure 7, and operates according to the two heat recovery principles presented in Figure 5a and Figure 5b. The system consists of four circuits—two representing the working hydraulic system and its heat rejection system, one transport medium circuit, and a cabin air flow circuit identical to that found in the reference system. Aside from TFS library components described in detail in (Zimmer, Meißner, and Weber 2022), standard Modelica components are used for the control logic and to group the inverter and electric motor models for space-saving purposes. The heat losses rejected by each part of the system are specified in the constants, multiplied with the absolute value of the intensity factor $|X_I|$.

The working hydraulic system, highlighted in a yellow zone in Figure 7, was based on a model used in previous work but with slight modifications (Lagerstedt et al.

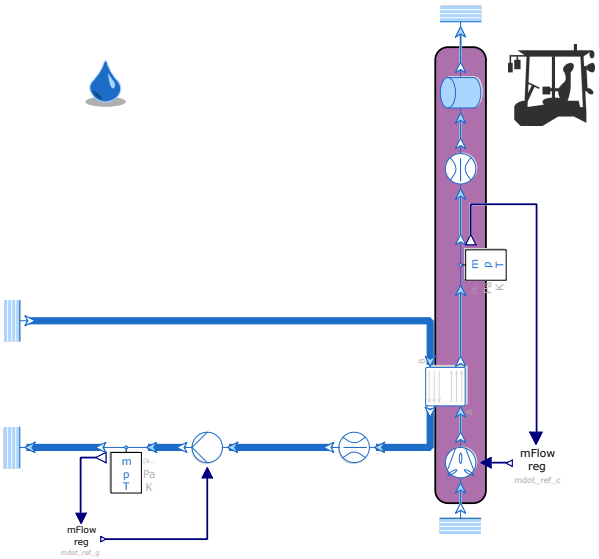

Figure 6. Modelica model of the reference system—aimed to represent a traditional vehicle powered by an ICE—composed of a cabin highlighted in purple and a transport medium circuit modeled as a source with constant flow and temperature.

2025). In this study, a PI controller is used to control the ambient chiller, while constant heat flow and mass flow are used to create a more computationally lightweight model. The hydraulic circuit is modeled as a closed system consisting of a reservoir, a flow restriction, and two heat exchangers—one for heat recovery and one for heat rejection. The circuit leading through the heat rejection exchanger is designed to maintain a maximum allowed temperature of 65°C in the hydraulic reservoir, since the hydraulic heat flow far exceeds the cabin demand. The model represents the return line of the working hydraulic system, transporting the hydraulic heat losses to the ambient chiller. The hydraulic heat losses are modeled as a conduction element and a pump component. The pump component is controlled to maintain a specified hydraulic flow. The conduction element is supplied with a specified heat flow. Both the specified mass flow and heat flow are multiplied with the absolute value of the intensity factor $|X_I|$.

The thick blue lines in Figure 7 highlights the transport medium circuit, creating the integration between vehicle heat sources and the cabin. For each operating mode, the active heat sources are connected in series, while the circuits for the inactive systems are bypassed. The activation and deactivation of systems are controlled by Modelica Standard Library components, together with switching valves from the TFS library. The pump component in the transport medium circuit is controlled by a mass flow regulator—described earlier in the paper—which maintains a fixed flow rate identical to that of the reference system. An alternative control method for the transport medium mass flow rate was also suggested which maintains the active motor temperatures at 100°C—an approximate maximum operating temperature—and is illustrated

DOI
10.3384/ecp218931

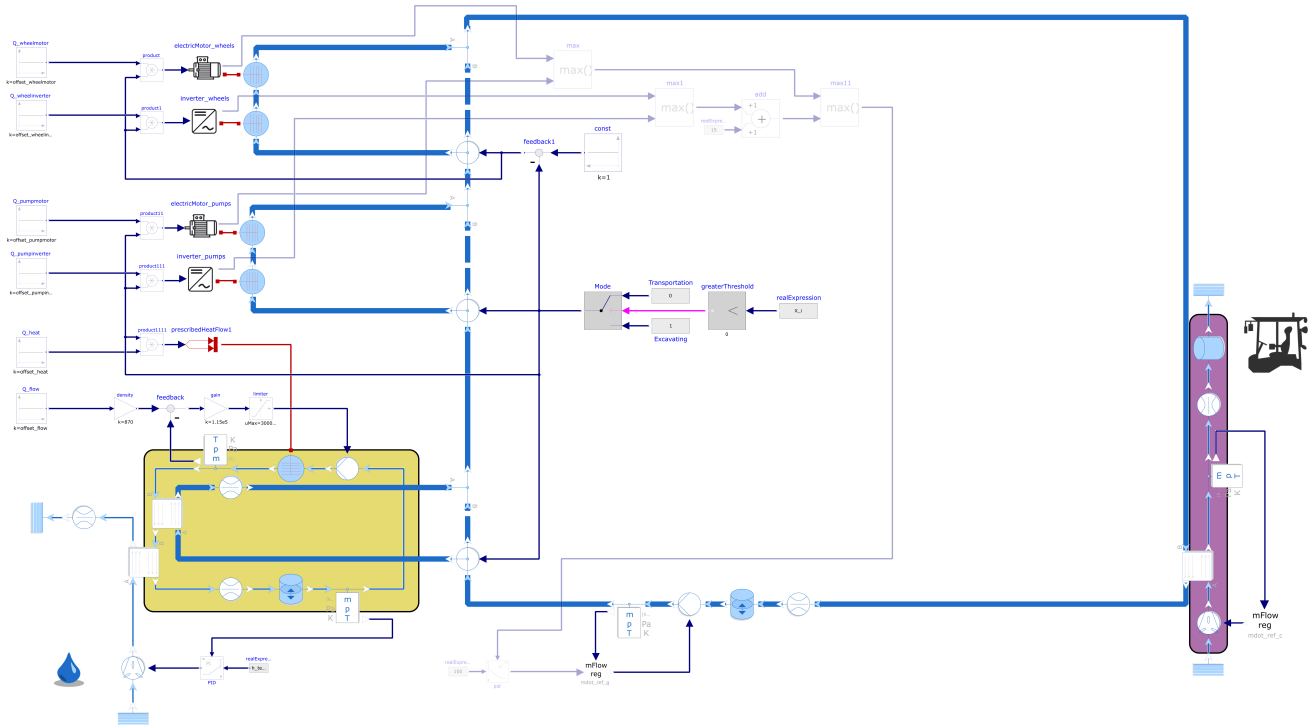

Figure 7. Modelica model of the proposed system, composed of a cabin highlighted in purple, heat sources, and a transport medium circuit highlighted with thick blue lines. The heat sources in the left area of the figure are modeled in series, with loops enabled by switching valves depending on the active operating mode parameter X_I. The hydraulic system, highlighted by the yellow zone, is enabled together with the loop for the inverter and electric motor powering the hydraulic pumps. The transparent lines and components correspond to the alternative mass flow control strategy.

by the transparent components and lines in Figure 7.

To obtain a system model slightly more compact and easier to read, separate but identical models to represent electric motors, and inverters were created, as illustrated in Figure 8. The model converts a real signal into a heat flow, acts as a thermal mass, and converts the temperature state of the heat port into an output value in Celsius. The model is built using Modelica Standard Library components, and the only difference between the motor and inverter models is the icon.

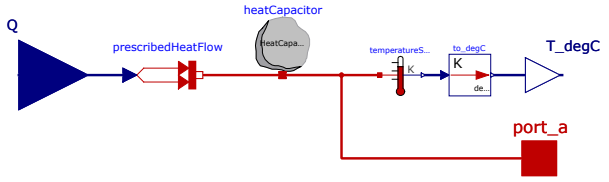

Figure 8. Modelica model of the inverter and electric motor—used to improve the readability of the system model—composed of a prescribed heat flow, a heat capacitor, and a temperature conversion component. The only differences between the inverter and motor models are the icon and the heat capacity parameter value.

3 Results

In this section, simulation results from the reference system and the proposed direct heat recovery system for a battery-powered mobile machine are presented. The reference system represents a conventional cabin heating system based on heat recovery from an ICE. The proposed system adopts the main principle of the reference system—but with heat recovery from alternative sources—and is evaluated using two different strategies. First, with the transport medium mass flow rate fixed at the same level as in the reference system—and second, with the mass flow rate controlled to maximize the electric motor temperature. The two strategies are evaluated in comparison with the reference system and with one another. Contour plots are used to illustrate performance across different operating modes, ambient temperatures, and operating intensities.

In Figure 9, the simulated cabin temperature from the reference system is shown, using the maximum available heating power. The straight contour lines illustrate how the traditional cabin heating performance is independent of operating mode and intensity. The different cabin temperatures are an effect of the intake air temperature varying with the ambient temperature on the y-axis. The high absolute temperature values observed are a consequence of the system's passive exposure to ambient temperatures not being included in the model. This result is used as a baseline for comparison with the proposed system.

Figure 10 shows the simulated cabin temperature from the proposed heat recovery system with a fixed transport

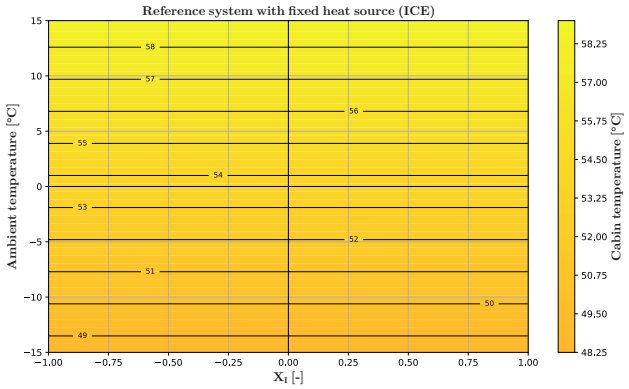

Figure 9. Resulting contour plot of the simulated cabin temperature using the reference system at maximum heating power, with fixed transport medium mass flow rate and temperature. Ambient temperature is represented on the y-axis and intensity factor on the x-axis, where negative and positive values correspond to excavating and transportation, respectively.

medium mass flow rate—relative to the reference system results shown in Figure 9. The mass flow rate is the same as that of the reference system. Negative values of cabin temperature difference means that the cabin temperature is lower compared to the reference system, which is true for all simulated operating points. The cabin temperature is generally higher in excavating mode—denoted by negative values of X_I in the plot—compared to transportation mode, denoted by positive values, as indicated by the smaller cabin temperature differences.

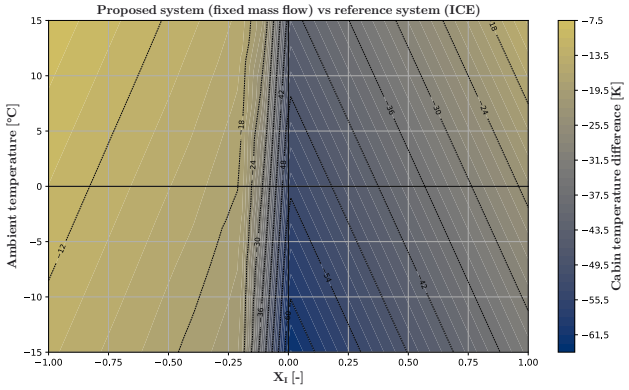

Figure 10. Resulting contour plot of the simulated cabin temperature using the proposed system at maximum heating power—with fixed transport medium mass flow rate—shown relative to the reference system results. Ambient temperature is represented on the y-axis and intensity factor on the x-axis, where negative and positive values correspond to excavating and transportation, respectively.

Simulation results for the proposed system, but with active control of the transport medium mass flow rate is seen in Figure 11. Compared to the results with a fixed mass flow rate, the cabin temperature is more similar between the operating modes—excavating and transportation. The cabin reaches slightly higher temperatures during medium to high intensity transportation, while the opposite is true across all intensities of excavating.

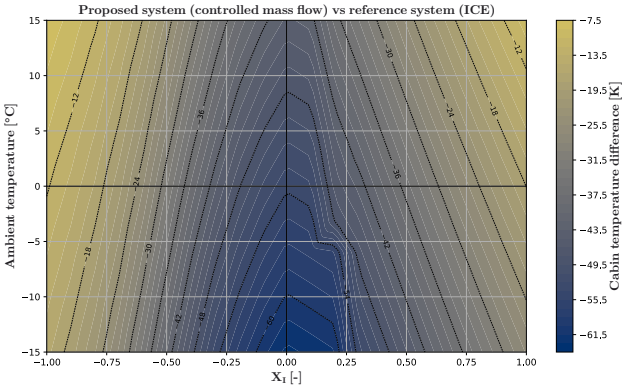

Figure 11. Resulting contour plot of the simulated cabin temperature using the proposed system at maximum heating power—with controlled transport medium mass flow rate—shown relative to the reference system results. Ambient temperature is represented on the y-axis and intensity factor on the x-axis, where negative and positive values correspond to excavating and transportation, respectively.

To better understand the results in Figure 11, a comparison between the two strategies is shown in Figure 12, where the cabin temperature achieved with controlled transport medium mass flow rate is shown relative to the fixed flow rate case. It is observed that the cabin temperature during transportation increases with the control strategy, but decreases during excavating. One exception to the improved performance during transportation is observed at intensities $0 \leq X_I \leq 0.2$, where the electric motors do not reach their maximum temperature and therefore do not demand an increased mass flow rate. During excavating, the strategy of controlling the mass flow rate solely to maintain the electric motors at 100°C results in reduced heat recovery from the working hydraulic system. Even though a significant amount of waste heat is available in the hydraulic system at most operating points, the recovered heat depends on—and is limited by—the transport medium mass flow rate, as the hydraulic system temperature is maintained at 65°C by the ambient chiller.

In Figure 13, the recovered heat flow from each subsystem and the cabin's heating performance are shown for the worst-case operating points during excavating and transportation—indicated by 'EC' and 'TC' in Figure 3. Apart from confirming the earlier presented results—that the heating performance of the cabin with the proposed heat recovery system is lower than for the reference system—it is shown that all the available waste heat from the motors and inverters are recovered in both operating modes. However, during excavating only a fraction of the available hydraulic waste heat is recovered. As already mentioned, this is due to the temperature limit in the hydraulic system, here set to 65°C to protect the oil from degrading.

Figure 13. Simulated heat flows in the worst case operating points, marked as 'EC' and 'TC' in Figure 3. The categories on the horizontal axis refer to the subsystems in the studied heat recovery systems. The gray bars correspond to the measured values of available waste heat and cabin heat demand, illustrated in Figure 4. The red bar is the cabin heating performance in the reference system. The yellow and green bars show recovered heat from working hydraulics, motors and inverters, and the cabin heating performance for each control strategy respectively.

4 Discussion

The purpose of this paper was to investigate and understand the potential of direct heat recovery for warming the cabin of a battery-powered mobile machine—and to what extent the heat source of an ICE can be replaced by multiple alternative sources. A proposed direct heat recovery system was modeled and simulated using two different control strategies, and the results were compared with a reference system. The focus of this study was to understand the initial feasibility of the direct heat recovery system principle. Even though previously measured data has been used within the model, some uncertainty remains regarding component parameters. Therefore, the results are compared between models with equal uncertainty, and absolute values should be interpreted with caution.

The results suggest that the heat recovery system and control strategies as presented in this paper do not match the performance of the reference system—despite the available waste heat shown in Figure 4, where the heat exceeds the cabin demand. However, it is demonstrated that a simple system design can warm the cabin while keeping the included system components within their temperature limits. The results further indicate that the heating performance can be improved by the selection of control strategy—especially in order to maximize the heat recovery from the working hydraulic system during excavating. Even though the performance in the reference system is not reached, there is room for further improvement, including solutions to close the performance gap. To improve the heat recovery during excavating, the transport medium flow could be divided into two parallel circuits, with the power electronics in one circuit, and the hydraulic system in the other. This way, maintaining the electric motor at 100°C will not negatively affect the heat recovery from the working hydraulic system. Including the battery in the heat recovery system is also a possible option, but it would likely increase system complexity due to its low nominal temperature. To close the heating performance gap, stored electric energy in the battery could be used when needed—either through the implementation of a heat pump or via resistive heating.

A direct heat recovery system is—as indicated by the results—dependent on the actual temperature on the individual heat sources. In this study the results are presented during steady state, after 8 hours continuous operation. In a product application, the heat-up time before heat can be effectively recovered becomes important, and should be considered in a comparison with alternative systems designs or principles.

The presented models are simplified such that the ambient effects on the system are not considered, other than the

simulation starting temperature, and the intake air temperature of the cabin heating core. This makes the resulting cabin temperatures only valid in relation to the reference system, where the same simplifications are used. Additionally, a cabin on a vehicle commonly uses an air recirculation system, not included in the models presented here. The absence of air recirculation leads to an overestimation of the modeled heating power, which can be observed in Figure 13, and an underestimation of the cabin temperatures—however, the same applies to both systems, keeping them comparable.

Finally, using the cabin performance powered by an ICE as a reference system and a baseline to determine whether a proposed system design is 'good enough' may not be entirely relevant—due to the fact that cabins on traditional vehicles are not designed for limited heat sources and high energy efficiency. However, it can serve as a useful benchmark for evaluating the specific performance of a chosen design and control strategy—particularly in future assessments aimed at closing the heating power gap.

5 Conclusions

Direct heat recovery from inverters, electric motors, and the working hydraulic system is not sufficient on its own to replace the heat delivered by an ICE—but it can provide a significant foundation for cabin comfort management during excavating, offering low system complexity.

Abstract

This paper presents a dynamic, physics-based Modelica model for simulating solar-powered, off-grid cold storage systems used to preserve perishables. A preliminary component library, developed using the Modelica Standard Library, supports modular modeling of photovoltaic (PV)-powered chillers, thermal loads, and latent thermal energy storage (LTES), which maintains cooling during non-solar hours. The library is applied to a 200 m³ cold room in Xingalool, Somalia, designed to stay at 5 °C. A case study simulating 500 kg of crop loading at 8:00 and unloading at 17:00 demonstrates the system's dynamic behavior under realistic solar and ambient conditions.

Keywords: Off-Grid, Cold Storage, Digital Twin, Agriculture

1 Introduction

Post-harvest losses of perishable crops remain a pressing challenge, particularly in low- and middle-income countries. In regions such as sub-Saharan Africa and South Asia, up to 50% of harvested fruits and vegetables are lost due to the absence of proper cold storage near farms (Amjad et al. 2023). These losses not only reduce farmer income and worsen food insecurity but also contribute significantly to greenhouse gas emissions (de Souza Garcia et al. 2024).

To mitigate these issues, solar-powered off-grid cold storage systems are increasingly seen as promising solutions for remote agricultural communities (Natarajan et al. 2023). However, their design is inherently complex due to the fluctuating nature of solar energy, variable cooling demands, and the need for reliable energy storage (electrical or thermal) for maintaining the desired temperature in the cold room continuously when the sun light is not present. Dynamic modeling provides a way to calculate system performance under varying conditions and improve design and operation (Purcell et al. 2023). Modelica, a physics-based, equation-oriented modeling language, offers a powerful framework for capturing such multi-domain, dynamic behavior and guiding performance-driven design (Modelica Association 2017).

In this research, a dynamic Modelica model of a solar-PV-powered off-grid cold storage system for perishables is developed for the first time. The system integrates a vapor compression chiller and a latent thermal energy storage (LTES) unit using water/ice to extend cooling during periods without sunlight. The model captures dynamic processes on both demand (e.g., product loading/unloading, wall and infiltration loads) and supply sides (e.g., PV variation, LTES charging/discharging). This work lays the foundation for a digital twin capable of scenario testing, optimization, and real-time analysis.

2 Modelica Modeling Approach

A preliminary component library was developed in Modelica with open-source Modelica Standard Library (MSL) to represent the thermal behavior of solar-powered, off-grid cold storage systems for perishables. The library enables modular and object-oriented construction of system models, simplifying configuration and simulation using reusable components.

In this paper, the library is applied to simulate a representative system in Xingalool, Somalia, consisting of a 200 m³ cold room maintained at 5 °C with time-dependent cooling loads such as product entry and removal, product respiration, wall and infiltration heat gains, and lighting. A vapor compression chiller with a variable-frequency drive (VFD) compressor is powered directly by photovoltaic (PV) panels. The compressor speed adjusts with available solar power, delivering variable cooling capacity. To ensure reliable operation during low or no solar input, a latent thermal energy storage (LTES) unit is incorporated, using roll-bond heat exchangers for energy exchange.

The model focuses on thermal energy transfer through heat ports and omits fluid flow dynamics to maintain computational efficiency. Figure 1 illustrates the three-stage energy flow: during sunlight hours, PV electricity drives the chiller to cool the cold room directly and any surplus power charges the LTES unit; once solar input falls below chiller demand (e.g. at dusk or under cloud), the stored latent thermal energy becomes the sole

cooling source, sustaining the cold-room temperature until PV power resumes.

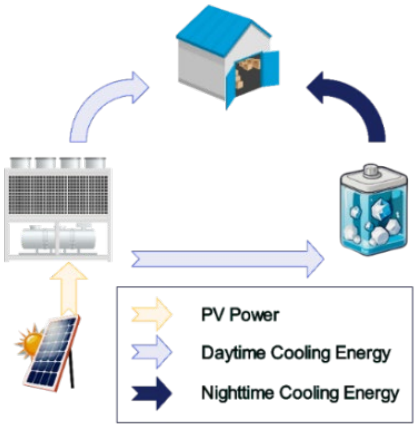

Figure 1. Thermal Model Energy Flow

3 Component Modeling

This section describes the dynamic modeling approach for key components in the cold storage system.

Cold Room and Cooling Loads: The cold room, sized at 200 m³ (4 m × 11 m × 4.6 m), is modeled as a single-node control volume, assuming uniform air temperature throughout, which justifies a lumped capacitance assumption due to well mixing of air in the room. The space is maintained at 5 °C and insulated from direct solar exposure, and is assumed to be filled to 50 % capacity with perishable crops. Cooling demand is dynamically driven by both internal and external loads, including crop loading/unloading, wall heat transfer, infiltration, lighting, and occupant presence.

- Product Sensible Heat Load: To capture the dynamic thermal impact of crop handling, a simplified discretization approach is used. The product mass is divided into two tanks to approximate the first-in-first-out (FIFO) behavior during cooling and storage. Fresh crops enter the first tank at 8:00, exchange heat with the cold room air, and are transferred to the second tank once their temperature converges with that of the second tank. Crops are assumed to be removed at 17:00. This method captures the transient sensible load from crop cooling and removal throughout the day. The logic of the proposed approach is presented in Figure 2 and Equation (1), where Tm_1 and Tm_2 denote the temperatures of the product masses m_1 and m_2 in the first and second tanks, respectively; ε is an infinitesimal tolerance (ε→0).

$$if\ T_{m_1} = T_{m_2} \pm \varepsilon\ \ (\varepsilon \to 0)\ then$$
$$m_1 \to 0; m_2 = m_1 + m_2 \quad (1)$$

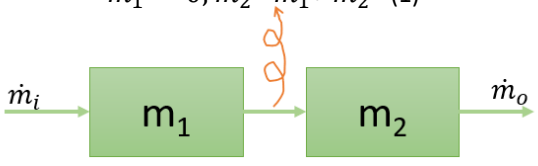

Figure 2. The logic of product sensible heat load model

- Additional Cooling Loads: Time-dependent cooling loads are included to reflect realistic system behavior. Wall heat transfer is modeled using an R-C approach with a U-value of 0.125 W/m²·K, and material properties accounting for thermal mass. Respiration heat from stored crops is computed based on cold room temperature and total product mass dynamically (Blumenthal et al. 2023). Infiltration gains arise from air leakage through a 1.4 m × 2.4 m door and vary with ambient conditions. Occupant heat is modeled using a fixed schedule with two persons entering the room for 2 hours in the morning and afternoon. Lighting is triggered by occupancy and set at 6 W/m².

PV Power Generation: On the supply side, the model accounts for variations in solar irradiance and ambient temperature, which affect PV output. A temperature-dependent efficiency model is used to convert solar input into electrical power, capturing realistic system behavior under varying environmental conditions. (Olukan and Emziane 2014).

Latent Thermal Energy Storage (LTES): To maintain cooling during non-solar hours, a latent thermal energy storage system using roll-bond heat exchangers (RHXs) is integrated. The LTES tank is filled with phase change material (PCM) and connected to a heat transfer fluid (HTF) circuit that charges or discharges the PCM based on energy availability and cooling demand. In the simplified thermal energy-based Modelica model the heat transfer to or from LTES is carried out via a heat port rather than directly involving fluid medium.

Figure 3 shows the LTES tank as a rectangular prism filled with water/ice, into which identical roll-bond heat-exchanger plates are inserted in parallel at 31 mm center-to-center spacing.

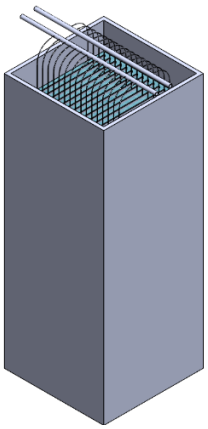

Figure 3. 3D schematic of LTES

Because empirical correlations for natural convection during PCM melting and solidification over a vertical roll-bond heat exchanger are lacking, heat transfer within the PCM has been assumed to occur solely by one-dimensional conduction. A single roll-bond plate plus the half-spacing of PCM is thus defined as the "base unit." A lumped-capacitance assumption for the entire PCM domain in the base unit would introduce large errors due

DOI
10.3384/ecp218939

to steep temperature gradients during phase change; consequently, the PCM thickness of each base unit is discretized into multiple control volumes (Figure 4).

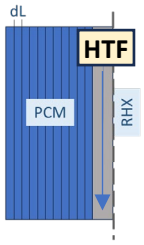

Figure 4: Base element of the LTES model

Within each volume, transient heat storage and transfer are represented by a thermal capacitance and a conduction resistance, whose governing equations are presented in Equations (2)–(7).

PCM Heat Capacity:

$$m.C.\frac{dT}{dt} = Q_{flow} \tag{2}$$

$$C = \begin{cases} C_{ice} & T < T_s \\ \dfrac{h_{sl}}{T_l - T_s} & T_s \le T \le T_l \\ C_w & T > T_l \end{cases} \tag{3}$$

$$f_{liq} = \begin{cases} 0 & T < T_s \\ \dfrac{T - T_s}{T_l - T_s} & T_s \le T \le T_l \\ 1 & T > T_l \end{cases} \tag{4}$$

PCM Heat Transfer:

$$Q_{flow} = G.(T_{hot} - T_{cold}) \tag{5}$$

$$G = \frac{K_{eff}.A}{d} \tag{6}$$

$$K_{eff} = K_{ice}.(1 - f_{liq}) + K_w.f_{liq} \tag{7}$$

In these equations, m is the mass of PCM in each control volume, C the specific heat capacity of the PCM, T the local PCM temperature, Q_{flow} the heat flow into or out of the PCM, f_{liq} the liquid fraction of the PCM, G the thermal conductance between hot and cold faces, A the heat-exchange area, d the conduction path length, K_{eff} the effective thermal conductivity, The solidus and liquidus temperatures, T_s and T_l, are specified as 272.85 K and 273.15 K, respectively. A CFD conduction-only charging simulation was conducted with the roll-bond boundary held at 259.15 K, and the Modelica model was run under the same condition; the validation comparison is presented in Figure 5.

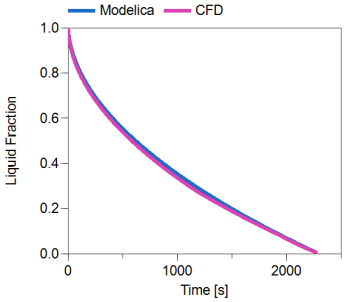

Figure 5: CFD validation results for liquid fraction

4 System Integration and Case Study Results

With all key components developed, the system is now ready for integration under a coordinated control logic. The initial control strategy, shown in Figure 6, distinguishes between normal and cloudy days. On normal days, energy from the PV is first used to cool the cold room. Once the cold room reaches the desired temperature, excess energy is redirected to charge the LTES. On cloudy days, if solar radiation is insufficient to run the chiller, the LTES is discharged to maintain the cold room temperature.

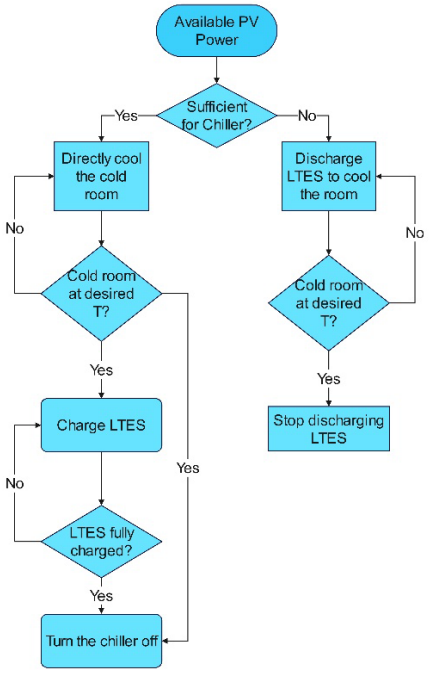

Figure 6: Control Strategy for Normal and Insufficient PV Power Conditions

Representative simulation results are provided for Xingalool, Somalia. Figure 7a shows the cold room temperature during a typical sunny day. The blue line indicates how crop loading in the morning introduces a heat disturbance, prompting the chiller to cool the products. Later, door opening in the afternoon causes another rise in temperature due to infiltration of warm air. The temperature zig-zagging in the cold room is due to the hysteresis mechanism considered for the chiller to avoid chattering and unlimited on/off cycles. To demonstrate the role of LTES in mitigating temperature fluctuations, two consecutive cloudy days were simulated (Fig. 7b), showing how the LTES supports temperature regulation when solar power is unavailable. It can be seen that LTES with 20 roll-bond heat exchangers is not capable of maintaining the cold room temperature under normal loading conditions in two consecutive cloudy days. Hence, in case this occasion is going to be repeated, either the LTES capacity should increase or loading behavior should change when sun light is absent.

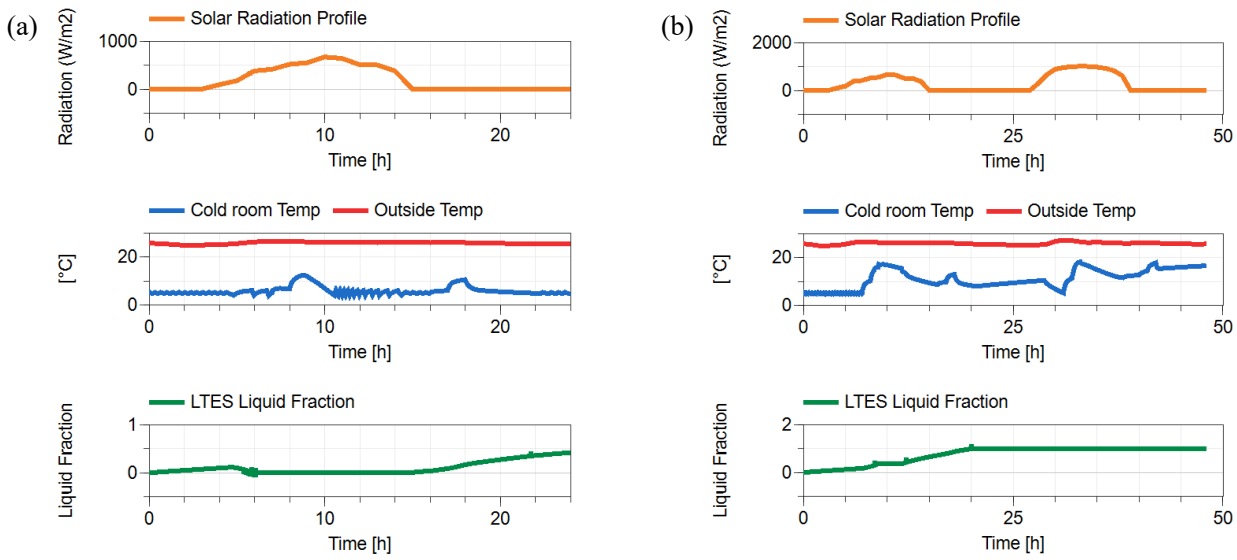

Figure 6: Represantative results for (a) normal sunny day, (b) two consecutive cloudy days

5 Conclusion

This work presents a dynamic, physics-based Modelica model for simulating solar-powered, off-grid cold storage systems for perishables. By leveraging Modelica's object-oriented, equation-based framework, a modular component library was developed that can be readily extended or reconfigured for alternative system variants, such as different PCM geometries, chiller types, or control strategies, without rewriting core equations. The library was applied to a 200 m³ case study in Xingalool, Somalia, demonstrating accurate capture of time-dependent thermal behavior under realistic solar and load profiles. These results underscore Modelica's strengths in rapid prototyping, and parameterized system variation, for sustainable cold-storage design and optimization..

Selective Evaluation of RHS during Multi-Rate Simulation

Philip Hannebohm [1] Bernhard Bachmann [1]

Abstract

Modeling across physical domains can lead to coupled systems that operate on different time scales. Moreover, spatially discretized models can have dynamic behavior on only a small portion of the whole system, while that portion might move over time. With a single rate solver like DASSL, the step size is restricted to fast dynamics of a few states while the others could do much larger time steps, degrading the overall simulation speed. Recent development of the Generic Bi-rate ODE (GBODE) solver within the OpenModelica simulation environment addresses these models. It allows for adaptive partitioning of slow and fast states and progresses these partitions with different time steps. However, substantial performance improvements were not yet observed, in part because of the rigid evaluation structure of the generated code. During each small step only the derivatives of fast states are required, but all derivatives are computed. This paper demonstrates the use of selective equation evaluation to reduce the computational cost of multi-rate integration as shown on a scalable example of a distributed heating system. Further uses for selective evaluation during the simulation process are discussed and a complexity analysis is given.

Keywords: Equation-based modelling, Multi-rate simulation, Structural analysis

1 Introduction

In computer science strategies like partial or lazy evaluation are used to improve computation speeds. This paper introduces a similar approach for use in the simulation of equation-based models. These models are commonly represented as one coupled differential algebraic equation system (DAE), so for the purposes of this paper we consider the equation

$$0 = F(x, \dot{x}, u) \tag{1}$$

which is solved for $\dot{x}$ at each integration step assuming knowledge of all the states x. Further inputs u may influence the system dynamics as well.

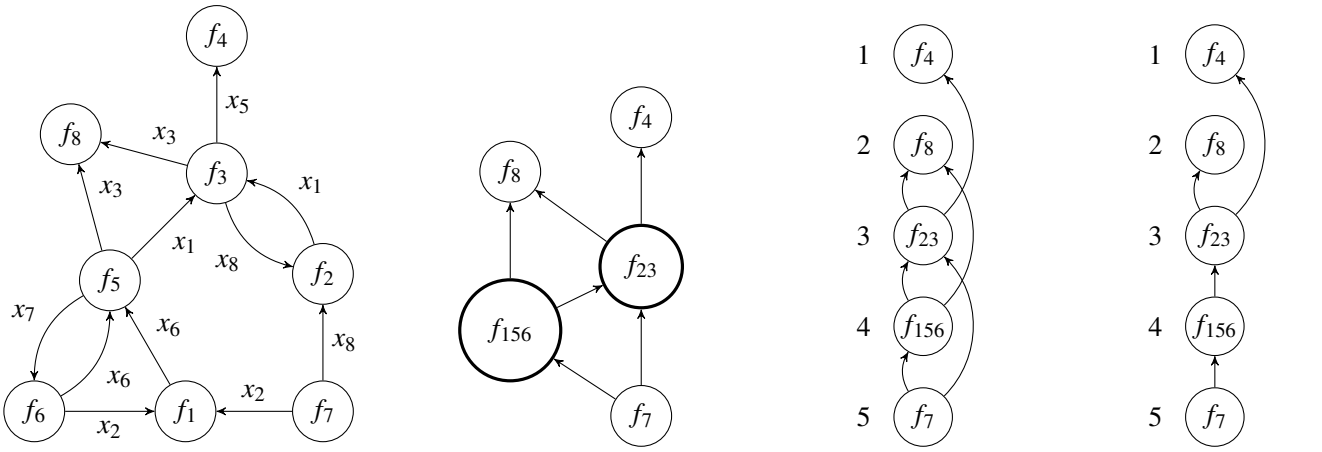
Multi-rate integration methods are suited for systems with dynamics on multiple time scales (Thiele, Otter, and Matsson 2014). Furthermore, for models where a subsystem A undergoes rapid changes while another subsystem B stays relatively stationary during some interval of the simulation time, at a later time B may have dynamic changes while A does not. In these scenarios adaptive multi-rate simulation is clearly superior to statically partitioned multi-rate or even single-rate simulations. One such adaptive multi-rate solver is GBODE which stands for Generic Bi-rate ordinary differential equation (ODE) solver and is a generic implementation for any Runge-Kutta (RK) scheme (Bachmann 2023; Bonaventura et al. 2025). As a case study, our method is applied to the GBODE solver of OpenModelica.

During a multi-rate simulation step a subset of fast states is identified. For these states several small steps are taken while the remaining states take only one large step. At each fast step only a subset of $\dot{x}$ needs to be computed. Thus, computing the whole right-hand side (RHS) means superfluous calculations.

For efficiently evaluating parts of a model without evaluating the whole RHS, it is necessary to have a fast and flexible way to evaluate only a selected subset of equations. We demonstrate how this can be easily done within the OpenModelica Compiler (Fritzson, Pop, Abdelhak, et al. 2020). For the relatively newly developed GBODE solver this feature is crucial in providing improved simulation performance compared to other integration schemes.

2 Evaluation Structure

This section builds up the notation used in this paper. A general system of equations can be given in residual form as



$$\begin{aligned} 0 &= f_1(x_{I_1(1)}, \ldots, x_{I_1(d_1)}) \\ &\vdots \\ 0 &= f_n(x_{I_n(1)}, \ldots, x_{I_n(d_n)}) \end{aligned} \tag{2}$$

where d_k is the number of variables occurring in equation k and $I_k(1), \ldots, I_k(d_k)$ are their corresponding indices.

If this system is given symbolically, or the incidence is given explicitly by the $I_1, \ldots, I_n$, Equation (2) can be transformed into semi-explicit form. The OpenModelica Compiler does this via the following steps.

A *perfect matching* between variables and equations is found (Pantelides 1988). The result can be interpreted as a directed graph with matched pairs of variables and equations as nodes and edges from equations to variables used in the equation.

In the context of this paper it is advantageous to define the edges in the opposite direction such that $f_i \to f_j$ when f_i depends on f_j, instead of the usual definition where we would have $f_j \to f_i$ as f_j influences f_i.

(a) Directed graph based on the given matching.

(b) DAG constructed by contracting the SCCs $f_{23} = \{f_2, f_3\}$ and $f_{156} = \{f_1, f_5, f_6\}$.

(c) Topologically sorted DAG.

(d) Transitive reduction of the DAG in (c).

Figure 1. Structure of the system in Equation (3).

As an example take the following system of equations and assume the equations are matched to the underlined variables:

$$\begin{aligned} 0 &= f_1(\underline{x_2}, x_6) & 0 &= f_5(x_1, x_3, \underline{x_6}, x_7) \\ 0 &= f_2(x_1, \underline{x_8}) & 0 &= f_6(x_2, x_6, \underline{x_7}) \\ 0 &= f_3(\underline{x_1}, x_3, x_5, x_8) & 0 &= f_7(x_2, \underline{x_4}, x_8) \\ 0 &= f_4(\underline{x_5}) & 0 &= f_8(\underline{x_3}) \end{aligned} \tag{3}$$

Figure 1a shows the graph resulting from Equation (3).

All *strongly connected components* (SCCs) of the graph are contracted into single nodes resulting in a *directed acyclic graph* (DAG). This DAG is the basis for evaluating the RHS of any ODE. The nodes of a DAG can be *topologically sorted*, i.e. they can be labeled with integer indices in such a way that $i > j$ for every edge $i \to j$. One such choice of indices is shown in Figure 1c. A valid order of execution is obtained by progressing from nodes with lower index to nodes with higher index. These two steps, contracting SCCs and topological sorting, are done simultaneously (Tarjan 1972).

There is a map $\mathscr{M}$ from variable to index corresponding to the node that computes the variable. This can be seen as a modification of the matching where variables solved in the same SCC are given the same index. For the system of Equation (3) this would be

$$\begin{aligned} &\mathscr{M}(x_1) = \mathscr{M}(x_8) = 3 \\ &\mathscr{M}(x_2) = \mathscr{M}(x_6) = \mathscr{M}(x_7) = 4 \end{aligned} \qquad \begin{aligned} &\mathscr{M}(x_3) = 2 \\ &\mathscr{M}(x_4) = 5 \\ &\mathscr{M}(x_5) = 1 \end{aligned} \tag{4}$$

Similarly, a modified incidence map $\mathscr{I}$ from index to variable sets can be constructed based on the I_k as defined in Equation (2) and the contraction of SCCs. The variables solved in the respective SCC are removed so only its dependencies remain. For Equation (3) this would be

$$\begin{aligned} &\mathscr{I}(1) = \mathscr{I}(2) = \{\} && \mathscr{I}(4) = \{x_1, x_3\} \\ &\mathscr{I}(3) = \{x_3, x_5\} && \mathscr{I}(5) = \{x_2, x_8\} \end{aligned} \tag{5}$$

Applying $\mathscr{M}$ to each element of $\mathscr{I}(k)$, we get the direct dependencies of the SCC with index k. This corresponds to the direct children of node k. In general we get the direct dependency map $\mathscr{D}$ as

$$\mathscr{D}(k) = \{\mathscr{M}(x) \mid x \in \mathscr{I}(k)\}. \tag{6}$$

Again, for Equation (3) the direct dependencies are

$$\begin{aligned} &\mathscr{D}(1) = \mathscr{D}(2) = \{\} && \mathscr{D}(4) = \{3, 2\} \\ &\mathscr{D}(3) = \{2, 1\} && \mathscr{D}(5) = \{4, 3\} \end{aligned} \tag{7}$$

Note that the indices in $\mathscr{D}(k)$ are all smaller than k. This is by construction of the topological ordering.

3 Selective Evaluation

The goal is to only evaluate the minimal part of the system that is needed to compute values for a set X of selected variables.

3.1 Computing Reachability

Finding all dependencies of X is equivalent to computing the reachability of the corresponding nodes in the DAG. Since the DAG is topologically sorted, the reachability can be found without the need for depth-first search. This is done in Algorithm 1 by going through the nodes from last to first according to the topological order and on each selected node k marking its direct dependencies $\mathscr{D}(k)$ as selected. All nodes in $\mathscr{D}(k)$ are smaller than k and their direct dependencies will be selected once the outer loop in line 3 gets to them. In this way the deeper paths are marked automatically by later loop iterations. The

DOI 10.3384/ecp218943

Algorithm 1 mark reachability by backwards loop

1: **for** $x \in X$ **do**
2: select $\mathscr{M}(x)$
3: **for** $k = N, \ldots, 1$ **do** ▷ backwards
4: **if** k is selected **then**
5: select all $j \in \mathscr{D}(k)$ ▷ $j < k$

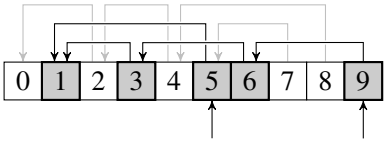


Figure 2. Example of reachability computation exploiting the topological ordering of the DAG.

complexity of Algorithm 1 is $O(|X| + |V| + |E|)$ where $|E| = \sum_k \mathscr{D}(k)$ is the number of edges in the DAG and $|V| = N$ is the number of vertices.

This is demonstrated in Figure 2 with a small example. First, nodes 5 and 9 corresponding to fast states are selected, then direct dependencies of selected nodes are selected going from right to left, so the order of selection is: $9 \to 6$, $6 \to 3$, $5 \to 1$, $3 \to 1$.

3.2 Transitive Reduction

The *transitive reduction* R of a DAG G is a subgraph of G which has the same reachability relation but minimal number of edges (Aho, Garey, and Ullman 1972). If there is a longer path from i to j then a direct edge $i \to j$ can be removed, keeping the overall reachability the same. Figure 3 shows the simplest scenario where the edge from 3 to 1 can be removed because dependency is still given through 2. The cost of computing R is $O(|V||E|)$ for sparse graphs (Goralčíková and Koubek 1979).

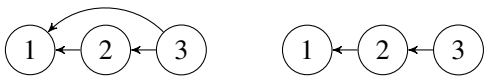

Figure 3. One step of transitive reduction.

Using R instead of G we can reduce the amount of work in line 5 of Algorithm 1 because fewer nodes are in direct dependencies. Since R needs to be computed only once in a preprocessing step, its cost is negligible when doing a reachability analysis many times during simulation. In highly connected systems this might improve the overall performance significantly. For the example system in Equation (3) this removes two out of six edges as depicted in Figure 1d.

3.3 Implementation

Prior to our changes the simulation code generated by the OpenModelica Compiler had the following flat structure:

```
void functionODE()
{
  eqFunction_1();
  // [...]
  eqFunction_N();
}
```

While very simple and efficient, the code does not allow for partial evaluation. One way to achieve this is by giving each `eqFunction_i` a flag to tell whether or not it should be evaluated. However, this would still lead to $O(N)$ operations. Replacing the function with the following evaluation scheme gives the desired flexibility with minimal overhead:

```
void functionODE()
{
  static f_ptr eqFunctions[N] = {
    eqFunction_1,
    // [...]
    eqFunction_N
  };
  for (int i = 0; i < evalN; i++)
    eqFunctions[evalI[i]]();
}
```

Here `evalI` is an array of SCC indices and `evalN` is the length of `evalI`, whereas `eqFunctions` is an array of function pointers `f_ptr`.

During simulation, `evalI` needs to be recomputed via Algorithm 1 each time X changes. If there is a rapid swap between two unchanging sets X_s and X_f, as is the case for GBODE bi-rate integration, the corresponding `evalI` can be buffered to avoid recomputation.

Some additional overhead can be expected from making equation evaluation flexible in this way because of the additional pointer indirection and as a consequence the less efficient cache handling. However, this overhead should be negligible for large systems when only a fraction of equations needs to be evaluated.

4 Preliminary Results

A modified version of GBODE was tested on the model `HeatingSystem` from the ScalableTestSuite Modelica Library (Casella 2015). It has the following equations:

```
Text = 278.15 + 8*sin(2*pi*time/86400)"f1";
Cd*der(Td) = Qd - sum(Qh)             "f2";
Qd = sat(Kp*(Td0 - Td),0, Qmax)       "f3";
for i in 1:N loop
  Qh[i] = Gh*(Td - Tu[i])*u[i]        "f4";
  Que[i] = Gu*(Tu[i] - Text)          "f5";
  Cu[i]*der(Tu[i]) = Qh[i] - Que[i]   "f6";
  der(x[i]) = a*hist(x[i], Tu0 - Tu[i],
                     Teps)            "f7";
  u[i] = sat(b*x[i], -0.5, 0.5) + 0.5 "f8";
end for;
```

Its equation structure, depicted in Figure 4, is well suited to selective evaluation when solving for fast states. There are no algebraic loops involved and thus every variable can be computed explicitly. Because of this, each node corresponds exactly to one variable.

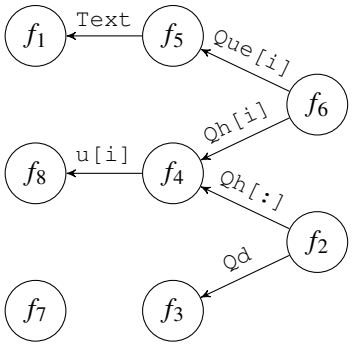

Figure 4. DAG of `HeatingSystem`. Arrays and for-loops are kept as single nodes for better readability.

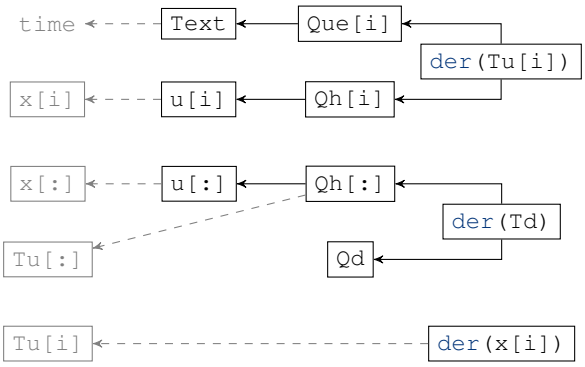

Figure 5. Sub-DAGs of `HeatingSystem` for each state derivative. In dashed are dependencies on states that may need to be interpolated. Self-dependencies are omitted for readability.

The various sub-DAGs for computing single derivatives are shown in Figure 5. Here variables are used as names for the nodes to make the structure easier to recognize. There is some overlap between the dependencies of each of the `der(Tu[i])` and `der(Td)` due to `Qh`.

We performed a simulation of `HeatingSystem` with the solver settings `-s=gbode -gbratio=0.5`. Each time a new set of fast states was identified, the fraction of equations needed to evaluate the derivatives was determined by Algorithm 1 and logged. The top row of Table 1 shows the number of equations to evaluate. The bottom row shows how often these many equations were needed to evaluate the new set of fast states. In most cases the number of equations needed is less than 7 out of a total of 64, which is about 11%. More than half of the time only two equations (3%) were needed, while the number never went beyond 17 (27%).

Table 1. Number of phases that require evaluation of `evalN` equations for fast states. Entries not in the table have a count of zero.

`evalN`	2	4	6	13	15	17
#	365	184	75	4	3	3

5 Conclusions and Future Work

We showed that selectively computing parts of the equation system of a DAE is practically possible and most of the work needed is already done by Modelica compilers. We also demonstrated that it would be desirable for multi-rate simulation of at least some models. Selective evaluation is also used to compute only needed parts of the Jacobian when solving fast states with implicit methods. In particular for the `HeatingSystem` there are significant savings in computational load. This is not a direct measure of performance gain, but it gives a rough idea that selective evaluation should lead to significantly faster simulations.

The technique of selective RHS-evaluation and the corresponding dependency analysis can be used even more broadly. During event search of hybrid DAE simulations only the zero crossings need to be computed in order to narrow down the exact event time. Then during event iteration only parts influenced by discrete changes need to be recomputed iteratively. For this the dependency analysis needs to be extended on discrete variables and a slightly different selection mechanism needs to be developed. This will be investigated in future works.

Acknowledgements

This work was conducted as part of the OpenSCALING project (Grant No. 01IS23062E) at the University of Applied Sciences and Arts Bielefeld, in collaboration with Linköping University. The authors would like to express their sincere appreciation to both the OpenSCALING project and the Open Source Modelica Consortium (OSMC) for their support, collaboration, and shared commitment to advancing open-source modeling and simulation technologies.

Abstract

This publication presents a Modelica library developed to investigate absorption thermodynamic cycles, with special attention to the absorption heat exchanger (AHE). The library includes models for different absorption cycles at various levels of detail, most of which have been validated against literature values. The AHE concept and the main components used to develop a dynamic AHE model, together with validation results based on laboratory measurements, are described in detail. The library is available at `https://github.com/carlesRT/Absolut`.

Keywords: Modelica library, Absorption thermodynamic cycles, Absorption heat exchanger, H_2O/LiBr

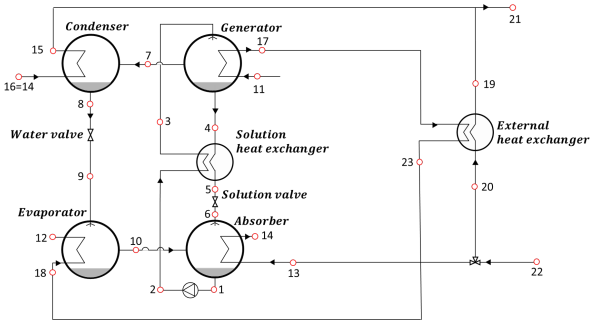

Figure 1. Schematics of an absorption heat exchanger. Numbers indicate the positions of referenced variables.

1 Introduction

1.1 The absorption heat exchanger

The absorption heat exchanger (AHE) concept involves the integration of an absorption heat pump (AHP) with a conventional heat exchanger (HEX), see Figure 1. The main advantage of this configuration is the lower return temperatures achieved on the primary (hot) side compared to standard solutions, such as water-water counterflow heat exchangers. The AHE concept was originally introduced and discussed in (Fu et al. 2010), (Li et al. 2011) and (Yin Zhang, Shi, and Yinping Zhang 2014).

The primary supply stream at temperature T_{11} first passes through the generator, where it provides heat to produce the refrigerant vapor. It then enters the external heat exchanger, and subsequently flows into the evaporator, where it can be cooled to a temperature lower than the secondary return temperature ($T_{12} < T_{22}$). On the secondary side, the return stream is heated by the external heat exchanger, the absorber, and the condenser. Various configurations are possible (e.g. absorber, condenser and HEX arranged in parallel). In the configuration shown in Figure 1, the secondary stream is split into two branches; one flows through the external heat exchanger, while the other passes through the absorber and then the condenser.

The AHE concept is applied mainly in China, with a notable project located in Taiyuan-Gujiao, China (Hu, Jiang, and Xie 2009). In this project, an AHE is integrated into a 50 km long district heating line connecting a CHP plant to the city center to increase heat transport capacity. Through this integration, the system can deliver 3.2 GW of heat at 130°C/20°C, demonstrating the significant reduction in return temperature achievable with this technology. Interest in the AHE concept within the district heating sector is also growing in Europe (G. Beckmann, F. Schittl, G. Piringer, D. Rixrath, R. Krotil, J. Krail 2019; Yang, Mirl, and Schmid 2020; Zotter, Eberhöfer, and Seidnitzer-Gallien 2023).

1.2 Open-Source Modelica models

The modeling language Modelica (Modelica Association n.d.) was selected to develop the necessary models for conducting various studies within the Absolut project and upcoming studies on future energy concepts within the TREASURE[1] project.

Before initiating the modeling process, a literature review was conducted, which included testing available open-source models, to assess their suitability for the planned work. Commercial libraries such as TIL (*TIL Suite* n.d.) and in-house models (e.g. (Cudok 2021; Corrales Ciganda et al. 2016; De La Calle et al. 2016; Wernhart et al. 2022)) were excluded from this review. The review identified three primary libraries. The key findings are summarized in Appendix A.

The review of open-source models for absorption machines yields the following conclusions.

- Compatibility with other Modelica libraries: The use of standardized interfaces (e.g. `fluidPort`) enables a modeling approach that leverages validated models from multiple sources and facilitate interoperability. This approach has been adopted by the authors to enhance the usability of their models within the broader Modelica ecosystem.

[1]TREASURE project: www.treasure-project.eu

- Object-oriented modeling approach: The DCOL library (Febres et al. 2017) adopts an object-oriented approach, with separate models for key components (e.g. absorber, generator), which supports modularity, ease of development, and maintainability. The same approach is followed in this work, with DCOL models serving as a reference for the implementation of the dynamic models.
- Initialization Challenges: Some evaluated models encountered difficulties during initialization and execution, highlighting the importance of a robust model structure and well-defined initial values to improve usability. The models developed in this work include runnable examples, which also serve as a reference for troubleshooting newly created or modified models.
- Fluid Property Implementation: Although fluid property correlations are available, inconsistencies in their implementation may lead to numerical instabilities. Existing libraries would benefit from a more consistent and reliable representation of fluid properties.

1.3 The Absolut library

A wide range of models at varying levels of complexity has been implemented. Given the number of Modelica models publicly available compared to those described in the literature (see section 1.2), we believe that the open-source community can benefit from this contribution. The provided library offers a reliable set of simplified models suitable for case studies or as a foundation for further development. However, it should be noted that the implementation work was primarily focused on the dynamic modeling of the absorption heat exchanger (AHE).

The Absolut library includes models for absorption heat pumps at three main levels of detail: basic (zero-order), static, and dynamic models. The left side of Figure 2 provides a view of the main package structure. Most of the models have been validated using examples from (Herold, Radermacher, and Klein 2016). The static and dynamic models use H_2O/LiBr as the working pair, for which thermophysical correlations have been implemented (see section 2.2). The use of alternative working pairs is subject to two main conditions: first, the compatibility between the models and the implemented fluid property correlations; and second, the validity of the model assumptions (e.g., the assumption of a pure refrigerant at the generator outlet). Mention that some modifications will be most likely required due to the use of some non-standard functions such as `temperature_Xp()` on the mixture side (H_2O/LiBr). These can be addressed by adding missing functions to the new working pair package or better adapting the models to use more standardized functions, e.g. `temperature(setDewState())`. Similar compatibility issues might also arise on components using pure-refrigerant.

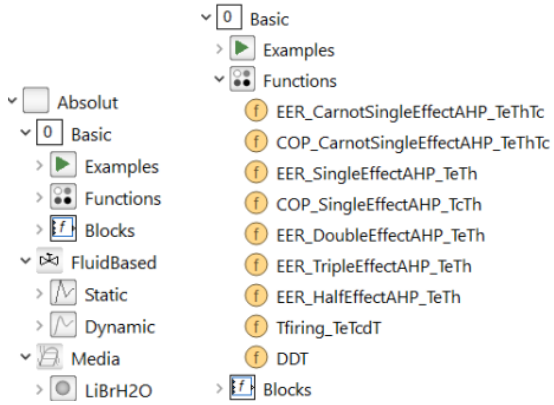

Figure 2. Overview of main packages structure (left) and Basic package (right).

Usability has been confirmed primarily in Dymola (*Dymola* 2024), with partial testing performed in OpenModelica (*OpenModelica* 2024) to ensure usability with purely open-source environment.

2 Description of models

2.1 Ideal models

The `Basic` package contains models based on an idealized representation of the thermodynamic cycle for absorption machines. The core models are implemented as functions, which are encapsulated in blocks with input/output interfaces to facilitate their use via the graphical user interface. All the available functions are shown in the right side of Figure 2. The application of these functions and blocks is demonstrated through several examples.

The provided examples are adapted from (Herold, Radermacher, and Klein 2016) and are used to verify the correctness of the implementation. In addition, `.mos` scripts are included with each example to facilitate automated simulation and visualization of results.

Most of the models included in the `Basic` package are based on the Carnot cycle (reversible process). By combining the Carnot cycle for power generation with a refrigeration cycle, the efficiency of a single effect absorption heat pump can be derived. This principle forms the basis of the functions `EER_CarnotSingleEffectAHP_TeThTc` and `COP_CarnotSingleEffectAHP_TeThTc`, as well as their corresponding blocks. The Carnot-based functions are further refined to account for the primary source of irreversibility in absorption cycles, which is associated with heat transfer between the cycle and its surroundings (Herold, Radermacher, and Klein 2016). This refinement is achieved by introducing a thermal resistance between the external and internal temperatures, resulting in a temperature difference. It is important to note that the internal cycle of the AHP is still assumed to be reversible. This assumption, along with the assumption that the tempera-

DOI
10.3384/ecp218949

ture difference between the condenser and the generator is equal to that between the condenser and the evaporator, forms the basis of the so-called zero-order model (Herold, Radermacher, and Klein 2016). This models is used to derive the functions `EER_SingleEffectAHP_TeTh` and `COP_SingleEffectAHP_TeTh` to calculate the cooling and heating efficiency respectively of a single effect absorption heat pump. Similar functions are implemented to calculate the cooling efficiency of double effect, triple effect and half effect absorption heat pumps.

The main practical application of the basic models is to quickly estimate the expected efficiency - and thereby the feasibility - of an absorption cycle for given operating temperatures. Conversely, they can be used to estimate the required driving temperature needed to deliver heat at a target temperature (e.g. `Absolut.Basic.Blocks.Tfiring`). Notice that the use of input/output interfaces is in line with the intended use of the models. However, this approach restricts the use of the blocks, as, for example, `EER_CarnotSingleEffectAHP` cannot be used to determine the driving temperature `Th` given the desired efficiency (`EER`) and the temperatures `Tc` and `Te`. Nevertheless, this result can be obtained by using the function `EER_CarnotSingleEffectAHP_TeThTc` directly, as both Dymola and OpenModelica are capable of interpreting and manipulating the function to solve for the input temperature `Th`.

2.2 Fluid properties

The static and dynamic models use pure water as a refrigerant, specifically employing the implementation based on the IAPWS/IF97 standard provided in the Modelica Standard Library (MSL) (Modelica Association 2024). The thermodynamic correlation for the working pair H_2O/LiBr is based on the formulation from (Yuan and Herold 2005) and has been implemented in Modelica.

This correlation follows a global approach to ensure improved consistency across properties. Rather than fitting individual thermodynamic properties separately, a fundamental function - in this case Gibbs free energy - is selected. All relevant properties are derived from this function using thermodynamic relationships (e.g. entropy is obtained from the partial derivative with respect to the temperature of the Gibbs free energy). The correlation expresses the Gibbs free energy as a function of temperature, pressure, and lithium bromide mass fraction. All available thermodynamic data are then used simultaneously to determine the main coefficients of the fundamental function. The correlation obtained gives good accuracy over the full range of liquid concentrations from pure water up to the crystallization line and from 5°C to 250°C (Yuan and Herold 2005). Examples verifying the implementation are included in the `Media.LiBrH2O.Validation` package.

2.3 Static models

The `...FluidBased.Static` package contains models for components such as valves, pumps, primary heat exchangers (absorber, generator, evaporator, and condenser) and solution heat exchangers. These component models can be combined to assemble various thermodynamic absorption cycles.

Several cycle configurations have already been implemented, including single effect and double effect absorption heat pumps (AHP), absorption heat transformer (Type II AHP), absorption heat exchanger (AHE) and resorption cycle. In some cases, multiple variants of a given cycle are provided, for example AHE model with the absorber and condenser arranged in parallel, and a version with all flows in parallel. These models can be used to roughly assess the required size, or better said the required UA value, for a given application (temperatures, heating capacity, configuration), while disregarding process dynamics. As a result, their use is limited when analyzing control strategies.

Most of the models implemented have been verified using examples from (Herold, Radermacher, and Klein 2016). The corresponding verification models are included in the respective `Validation` packages. Some results are included in Appendix B.

2.3.1 Heat exchangers

A detailed description of the main heat exchanger models (evaporator, etc.) is omitted here, and only a few remarks are provided on the available models.

All primary heat exchangers, and consequently the thermodynamic absorption cycles, are modeled using the standard `fluidPort` interface for external fluid connections. This allows the models to be integrated with their respective heat sources and sinks. However, for the single effect absorption heat pump, simplified versions of the models are also provided without a heat exchanger (`Static.SingleEffect_intern`). These omit the external fluid interfaces and are intended for simulations under prescribed operating conditions (e.g. given pressure and LiBr concentration at the generator and absorber) that can be used to easily evaluate a prescribed thermodynamic cycle and to provide reference values for initializing more complex models.

Models that consider the heat exchanger and have `fluidPort` interfaces calculate the total heat transfer using the commonly applied simplified method, which is based on the product of the overall heat transfer coefficient (UA) and the logarithmic mean temperature difference (LMTD), as described in (Herold, Radermacher, and Klein 2016). As the calculation of LMTD might be problematic, the `NoEvent` operator is included to avoid division by zero. Furthermore, the approximation of the LMTD proposed by Chen (Chen 1987) is also implemented, see `...Static.BaseClasses`. As reported in Petterson (Pettersson 2008) the deviation between the LMTD and Chen expression is very small. Either the LMTD method or Chen's approximation can be selected,

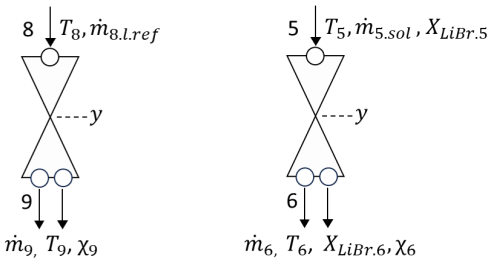

Figure 3. Schematics of the valve model: Refrigerant side (left) and solution side (right).

with LMTD used as the default.

Some relevant limitations and weak points of the current implementation, in addition to the fact that the models are static, includes the use of constant UA values (defined as parameters) and the limited use of `extends` clause, which leads to code duplication and consequently increases the risk of errors and maintenance effort.

Additionally, three heat exchanger models from the Buildings library, `PartialEffectivenessNTU`, `PlateHeatExchangerEffectivenessNTU` and `ConstantEffectiveness`, have been incorporated into the library using the `extends` clause (see package `...Static.Components.HEX`). An additional parameter has been introduced to later facilitate model substitution via the `redeclare` keyword. In the context of the static models, these models are intended to be used to model the solution heat exchanger. The simplest ones are `simpleHX`, which `extends PartialEffectivenessNTU` and fixes the UA value, and `ConstantEffectiveness` which assumes a constant effectiveness. `PlateHeatExchangerEffectivenessNTU` is a more complex model with a variable UA value.

2.3.2 Valves

Both the solution valve and the refrigerant valve are modeled assuming isenthalpic expansion and with no mass accumulation. The incoming fluid may undergo flashing, therefore the valve model calculates the outlet vapor quality, χ, defined as the mass fraction of vapor at the outlet. State points are numbered for ease specific location in the system, see Figure 3. Additionally, subscripts are used to further specify variables, as detailed in the nomenclature section. Subscripts are separated by a dot. For flow related variables (e.g. mass flow rate), a positive value indicates inflow into the component, while a negative value indicates outflow. This sign convention has already been incorporated into the governing equations, consequently, flow variables should be considered in terms of their absolute values. The common mass and energy balance equations for the refrigerant and solution valve are:

$$0 = \dot{m}_j - \dot{m}_k \quad \text{where } (j,k) \in \{(8,9),(5,6)\} \tag{1}$$

$$\chi_j = \frac{\dot{m}_{j.v}}{\dot{m}_j} \quad \text{where } j \in \{9,6\} \tag{2}$$

$$h_j = (1-\chi_j)\cdot h_{j.l} + \chi_j \cdot h_{j.v} \quad \text{where } j \in \{9,6\} \tag{3}$$

An additional mass balance equation for lithium bromide is required for the solution valve,

$$0 = \dot{m}_{5.l.sol} \cdot X_{LiBr.5} - \dot{m}_{6.l.sol} \cdot X_{LiBr.6} \tag{4}$$

The mass flow rate is determined by Equations (5) and (6). It is modeled as being proportional to the valve opening signal y, the pressure difference across the valve, and a constant based on nominal operating conditions. Specifically, the nominal mass flow rate $\dot{m}_{nom}$ is defined for a fully open valve ($y = 1$) and a specified nominal pressure difference dp_{nom}. The pressure levels correspond to the pressures in the respective vessels. For example, in the case of the refrigerant valve, the pressure difference is calculated using the pressure in the condenser p_c (position 8) and the pressure in the evaporator p_e (position 9).

$$\dot{m}_{8.l} = y \cdot (p_c - p_e) \cdot \frac{\dot{m}_{nom}}{dp_{nom}} \tag{5}$$

$$\dot{m}_{5.l} = y \cdot (p_g - p_a) \cdot \frac{\dot{m}_{nom}}{dp_{nom}} \tag{6}$$

2.3.3 Pumps

Equation (7) used to obtain the electrical power consumption of the solution pump W_{el} is obtained assuming incompressible flow and isentropic compression. It is defined as the ratio of the hydraulic work W_h, to the pump efficiency η. The hydraulic work is determined as the product of the mass flow rate at the pump inlet, the specific volume v, and the pressure difference between outlet and inlet. For a single effect AHP, this pressure difference corresponds to the pressure at the generator (high pressure) and the absorber (low pressure).

$$W_{el} = \frac{W_h}{\eta} = \frac{(p_g - p_a)\cdot v \cdot \dot{m}_{1.l}}{\eta} \tag{7}$$

The hydraulic work is added to the fluid as an enthalpy increase. Fluid properties, such as the specific volume, are evaluated at the pump inlet conditions. The same modeling approach is applied to the water pump, which is required in certain configurations, such as for simulating an absorption heat transformer.

2.4 Dynamic models

Up to this point, the dynamic models have been focus on the single effect absorption heat pump, which serves as the core component of the AHE. The dynamic model of the absorption heat pump is implemented in an object oriented manner, utilizing modular component models for pipes, valves, pumps, the solution heat exchanger, and the main

DOI 10.3384/ecp218949

heat exchangers (i.e. absorber, generator, evaporator and condenser) among others.

Key modeling assumptions are summarized below. These assumptions are commonly adopted in the literature (Herold, Radermacher, and Klein 2016).

- The refrigerant is assumed to be pure water.
- The condenser and generator operate at the same pressure, as do the evaporator and absorber, i.e. no pressure loss between them is considered.

Some of the component models such as valves, pumps and the solution heat exchanger have already been introduced (see section 2.3). Additional models, including pipes and various auxiliary components (e.g. sources), are taken from the MSL (Modelica Association 2024).

The primary work in the dynamic modelling involve the main heat exchangers. Several modeling approaches have been implemented, with a key distinction related to how heat exchange between the internal and external fluids and thermal inertia is handled.

The simplest approach utilizes an internal heat exchanger and it is analog to the static model formulation, where a fixed UA values is defined and the heat transfer rate is calculated using the logarithmic mean temperature difference. The process dynamics in this model are mainly limited to inertia related to the inner volumes of the vessels. The alternative approach models the heat exchanger externally, using a discrezited structure. For comparison, models ending in `_heatport` and `_internalHEX` within the `FluidBased.Dynamic.Components` package illustrate the effects of the difference of the modelling approach. More specifically, the models `AHPse_Dyn_internalHEX` and e.g. `AHPse_Dyn_heatport_nocp` within the package `...Components.Validation` provide a direct contrast between these two approaches.

Within the external heat exchanger modeling strategy, several versions have been developed. These include models that account for the thermal capacity of the heat exchanger itself, such as `...Dynamic.AHP.AHP`. Furthermore, some models are also capable of representing heat losses, whether radiative, convective, or both.

Some implementations incorporate a two-stage heat exchange process, with an additional heat exchanger between the external fluid and the entering solution in the absorber and generator; such models end in `_hex_extended`. This modification is motivated by the specific design of the AHP under study (WEGRACAL® SE 15), whose handbook indicates that the liquid solution coming from the absorber is evenly distributed within the generator and includes a sprayer in its schematics. A similar configuration is shown for the solution path from the absorber to the generator. In this context, incorporating an additional heat exchanger provides a straightforward way to reflect this design feature. However, it should be noted that the models do not include recirculation within the heat exchanger, which would be required to faithfully model the evaporator. This represents a limitation of the current models.

Further extensions include configurations that incorporate an additional solution pump transferring fluid from the generator back to the absorber, as implemented in `...Dynamic.AHP.AHP_pump`. This modification is again based on the WEGRACAL® SE 15 handbook, which explicitly states that the solution with a high lithium bromide concentration is pumped back to the absorber.

As with the static models, some code duplication exists in the current implementation, which complicates code review. This limitation will be addressed by introducing base classes and using the `extends` clause, by enabling feature toggling through if-conditioned component declarations. On the other hand, some of the dynamic models offer increased flexibility, compared to the static models, through the use of variable UA values in certain configurations, such as `...Dynamic.AHP.AHP_hex_extended`. In summary, the different versions result from a step-by-step implementation process that progressively increased model complexity and incorporated specific design features of WEGRACAL® SE 15, the device employed for model validation purposes. A clear conclusion about which model is preferable cannot yet be drawn, as no detailed analysis comparing the versions in terms of results and performance has been conducted.

2.4.1 Generator and Absorber

In general, the version with an externalized heat exchanger is preferred due to its greater flexibility. This modeling approach is applied to both the generator and the absorber, which are described in more detail below.

The same general modeling strategy is used to model the absorber and the generator. The main differences them lie in the direction of the vapor flow (compare the flow at position 7 and 10) and in the thermodynamic states of the entering fluid streams, see for example, the differences between the states at position 3 and 6 (refer to Figure 4).

The internal mass balance equations define the total mass within the component as the sum of the vapor and liquid phase masses. The total must equal the combined mass of refrigerant and lithium bromide solution, as formulated in Equations (8) to (10).

$$m = m_{ref} + m_{LiBr} = m_v + m_l \tag{8}$$

$$m_{ref} = m_v + m_l \cdot (1 - X_{LiBr}) \tag{9}$$

$$m_{LiBr} = m_l \cdot X_{LiBr} \tag{10}$$

The total mass is contained in a vessel of volume V, which is composed of contributions from both the vapor and liquid phases.

$$V = \frac{m_v}{\rho_v} + \frac{m_l}{\rho_l} \tag{11}$$

A vapor-liquid equilibrium is assumed between the liquid phase (H_2O/LiBr solution) and the vapor phase (pure

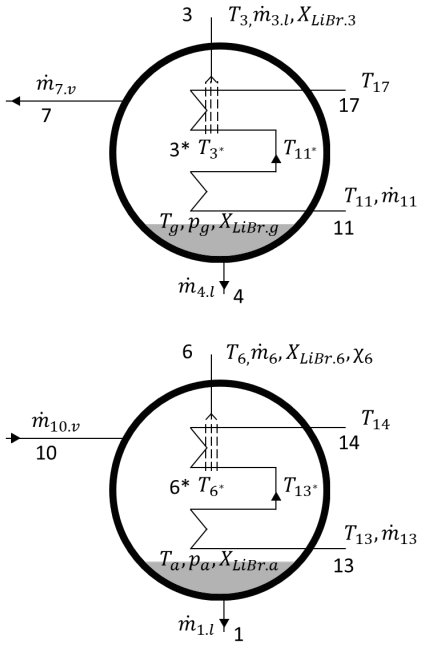

Figure 4. Schematics of the generator (top) and absorber (bottom).

refrigerant). Phase equilibrium is maintained by requiring the chemical potential of water to be equal in both phases, as expressed in Equation (12).

$$\mu_{l.ref} = \mu_v \tag{12}$$

The mass balance for the refrigerant in the generator and absorber is described by Equations (13) and (14) respectively. For example, the change in refrigerant mass within the generator is determined by the net mass flow: it is equal to the mass flow rate of the refrigerant entering from the absorber $\dot{m}_{3.ref}$, minus the mass flow rate of vaporized refrigerant exiting into the condenser $\dot{m}_{7.v}$, and minus the portion of liquid refrigerant returned from the generator to the absorber $\dot{m}_{4.l.ref}$.

$$\frac{d(m_{g.ref})}{dt} = \dot{m}_{3.l.ref} - \dot{m}_{7.v} - \dot{m}_{4.l.ref} \tag{13}$$

$$\frac{d(m_{a.ref})}{dt} = \dot{m}_{6.l.ref} + \dot{m}_{10.v} - \dot{m}_{1.l.ref} \tag{14}$$

Similarly, the mass balance for the solution in the generator and absorber is described by Equations (15) and (16) respectively.

$$\frac{d(m_{g.LiBr})}{dt} = \dot{m}_{3.l.LiBr} - \dot{m}_{4.l.LiBr} \tag{15}$$

$$\frac{d(m_{a.LiBr})}{dt} = \dot{m}_{6.l.LiBr} - \dot{m}_{1.l.LiBr} \tag{16}$$

With respect to the energy balance, the mass within the generator gains energy from three main sources: heat transfer from the external fluid, which provides the driving heat for refrigerant vaporization $\dot{Q}_g$, heat exchange with the surroundings, accounting for possible heat losses or gains $\dot{Q}_{g.loss}$ and enthalpy carried by the mass flows $\dot{H}_g$. The corresponding energy balance is defined by Equation (17).

$$\frac{d(U_j)}{dt} = \dot{H}_j + \dot{Q}_j - \dot{Q}_{loss.j} \quad \text{where } j \in \{g,a\} \tag{17}$$

The heat losses or gains to the environment are modelled using a constant thermal conductance and are assumed to be proportional to the temperature difference between the internal temperature of the vapor liquid equilibrium mixture, denoted as T_g for the generator and T_a for the absorber, and the ambient temperature T_{amb} (T_{amb} is now fixed to 25°C). This relationship is defined by Equation (18).

$$\dot{Q}_{loss.j} = UA_{j.amb} \cdot (T_j - T_{amb}) \quad \text{where } j \in \{g,a\} \tag{18}$$

The contribution of the enthalpy flow rate $\dot{H}$ to the energy balance in the generator and absorber is defined by Equations (19) and (20) respectively. It is expressed as the sum of enthalpy flows, i.e. the product of each entering (positive) and leaving (negative) mass streams and their respective associated specific enthalpies.

$$\dot{H}_g = \dot{m}_{3.l} \cdot h_{3^*.l} - \dot{m}_{7.v} \cdot h_{7.v} - \dot{m}_{4.l} \cdot h_{4.l} \tag{19}$$

$$\dot{H}_a = \dot{m}_6 \cdot h_{6^*} + \dot{m}_{10.v} \cdot h_{10.v} - \dot{m}_{1.l} \cdot h_{1.l} \tag{20}$$

Note that the enthalpies $h_{3^*.l}$ and $h_{6^*.l}$ correspond to the thermodynamic states at positions 3* and 6* respectively. These represent the "pre-heated" and "pre-cooled" streams, i.e. streams that have already exchanged heat with the external fluid. As a result, the heat transfer from the external fluid to the vessel contents is modeled in two stages.

The first stage involves heat transfer between the incoming external fluid (at position 11 and 13) and the internal vapor-liquid mixture within the generator or absorber, maintained at temperature T_g or T_a. The second stage involves heat exchange between the cooled external fluid (at positions 11* and 13*) and the fluid entering from the external circuit, initially at temperature T_3 or T_6, which is then heated and cooled to T_{3^*} and T_{6^*} respectively. This additional heat transfer step is specific to model versions identified by the suffix `hex_extended`.

The first stage corresponds to the main heat exchanger. In this model, the thermal capacity of the solid structure of the heat exchanger is explicitly considered. Both the external fluid and the solid parts are spatially discretized into n elements to capture transient behavior accurately (see Figure 5). The total heat flow entering the generator and absorber is defined by Equation (21).

$$\dot{Q}_j = \sum_{n=1}^{n} UA_j \cdot (T_{j.s.i} - T_j) \quad \text{where } j \in \{g,a\} \tag{21}$$

DOI
10.3384/ecp218949

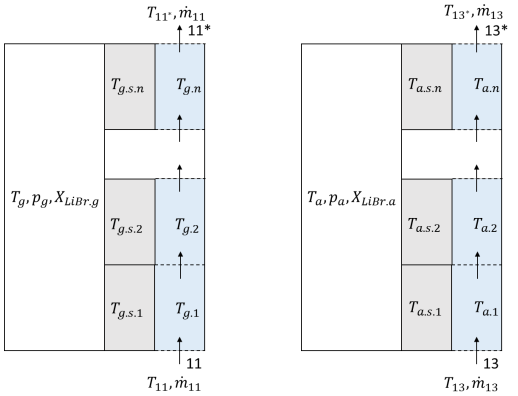

Figure 5. Schematics of internal heat exchanger model of generator (left) and absorber (right).

The energy balance of the solid part of the heat exchanger is defined by Equation (22) for each discretized section i. Here, C denotes the heat capacity of the solid in each section, expressed in Joules per Kelvin, and is calculated as $C = c \cdot m$, where c is the specific heat capacity and m is the mass of the solid in the corresponding section.

$$C\frac{d(T_{j.s.i})}{dt} = UA_j \cdot (T_j - T_{j.s.i}) + UA_j \cdot (T_{j.i} - T_{j.s.i}) \quad (22)$$

where $j \in \{g,a\}$ and $i \in \{1,2,\ldots,n\}$

The external fluid is modeled using the `DynamicPipe` model of the MSL. The static head is set to zero. The pressure loss coefficients are set to a negligible value. Changes in density are expected to be low. The energy balance equations for the external fluid are defined by Equations (23) and (24). $\dot{m}_{j.ext}$ and $h_{j.i}$ are used to indicate the entering (*in*) and leaving (*out*) mass flow rate and specific enthalpy at each volume i.

$$\frac{d(U_{j.i})}{dt} = \dot{H}_{j.i.ext} - UA_j \cdot (T_{j.i} - T_{j.s.i}) \quad (23)$$

$$\dot{H}_{j.ext} = \dot{m}_{j.ext.in} \cdot h_{j.i.in} - \dot{m}_{j.ext.out} \cdot h_{j.i.out} \quad (24)$$

where $j \in \{g,a\}$ and $i \in \{1,2,\ldots,n\}$

With regard to the second stage of heat transfer from the external fluid to the entering fluid at the main vessel, represented by $\dot{Q}_{hex}$, (corresponding to positions 11*, 17, 3 and 3* for the generator, and positions 13*, 14, 6 and 6* for the absorber), it is important to note that the thermal capacity of the solid structure is neglected in this part of the model. The model used is based on `PartialEffectivenessNTU`[1]. In this model, the overall heat transfer coefficient-area product (UA value) is assumed to be constant. The heat transfer is defined as the product of the maximum possible heat flow rate $\dot{Q}_{hex.max}$ and the heat exchanger effectiveness ε, as shown in Equation (25). The effectiveness ε is a function of the number of transfer units ($NTU = UA/\dot{C}_{min}$) and the thermal capacities of the internal and external streams, $\dot{C}_{int}$ and $\dot{C}_{ext}$, respectively, where $\dot{C} = \dot{m} \cdot c_p$. More specifically, ε depends on the ratio of the minimum to the maximum capacity rate, $\dot{C}_r = min(\dot{C}_{int}, \dot{C}_{ext})/max(\dot{C}_{int}, \dot{C}_{ext})$, as described in Equation (26). The maximum possible heat transfer rate $\dot{Q}_{hex.max}$ is defined as the product of the minimum thermal capacity rate and the temperature difference between the two entering fluid streams (e.g. temperatures at position 11* and 3 in the case of the generator), as shown in Equation (27).

$$\dot{Q}_{hex} = \dot{Q}_{hex.max} \cdot \varepsilon \quad (25)$$

$$\varepsilon = \frac{1 - e^{-NTU \cdot (1 - \dot{C}_r)}}{1 - \dot{C}_r \cdot e^{-NTU \cdot (1 - \dot{C}_r)}} \quad (26)$$

$$\dot{Q}_{hex.max} = \dot{C}_{min} \cdot (T_j - T_k) \quad (27)$$

where $(j,k) \in \{(11^*,3),(13^*,6)\}$

2.4.2 Evaporator and condenser

The primary difference in the modeling of the evaporator and condenser, compared to the generator and absorber, lies in the treatment of heat transfer and the working fluid. In the evaporator and condenser, only pure refrigerant is present, and the heat exchange between the vapor–liquid equilibrium mixture and the external fluid is modeled in a simplified manner. Specifically, only a single main heat exchanger is used in these components—no extended or two-stage heat exchanger configuration is applied.

The equations that describe the mass balance of the evaporator and condenser are equivalent to Equations (8) to (12) assuming $X_{LiBr} = 0$. Equations (13) and (14) need to be substituted by Equations (28) and (29).

$$\frac{d(m_{c.ref})}{dt} = \dot{m}_{7.v.ref} - \dot{m}_{8.l.ref} \quad (28)$$

$$\frac{d(m_{e.ref})}{dt} = \dot{m}_{9.l.ref} + \dot{m}_{9.v.ref} - \dot{m}_{10.v.ref} \quad (29)$$

Regarding the energy balance, Equations (18), (22), and (23) apply under the assumption that $j \in \{c,e\}$. Furthermore, Equations (19) and (20) must be replaced by Equations (30) and (31).

$$\dot{H}_c = \dot{m}_{7.v} \cdot h_{7.v} - \dot{m}_{8.l} \cdot h_{8.l} \quad (30)$$

$$\dot{H}_e = \dot{m}_9 \cdot h_9 - \dot{m}_{10.v} \cdot h_{10.v} \quad (31)$$

As mentioned above, the two-stage heat exchanger configuration is not applied in this case. Consequently, Equations (25) to (27) are not relevant to the evaporator and condenser models.

[1] Model Fluid.HeatExchangers.BaseClasses.PartialEffectivenessNTU of the Buildings library (Wetter et al. 2014)

3 Absorption heat exchanger (AHE) model validation

3.1 Model description

An AHE model has been developed based on the `PlateHeatExchangerEffectivenessNTU` model for the external heat exchanger and the `Dynamic.AHP.AHP_pump_hex_extended` model for the AHP. This model has been validated using experimental measurements obtained within the framework of the Absolut project (Eberhöfer 2022; Zotter, Eberhöfer, and Seidnitzer-Gallien 2023). For detailed information about the experimental test rig, the reader is referred to (Eberhöfer 2022).

The measurement data are used as input for the model, particularly the inlet mass flow rates and temperatures at the absorber, external heat exchanger, and generator. These measurements correspond to the sensor locations at positions 13, 20, and 11, respectively (see Figure 1).

In regard of the parametrization and setup,

- Based on estimation heat loss coefficients from (Eberhöfer 2022), the parameter `U_amb` is fixed to 3 W/K for each main heat exchanger. Heat losses due to radiation are not considered.
- Details on the internal control of the absorption heat pump (e.g. solution pump) are not known. The mass flow rate from the generator to the absorber has been fixed to 0.12 kg/s. The mass flow rate from the absorber to the generator is adjusted to keep the volume at the generator at a constant level.
- The volume of each vessel is estimated to be 70 liters.
- The sum of heat capacity per section C used in Equation 22 is set to 5 kJ/K for all main heat exchangers. The values in Table 1 of (Kohlenbach and Ziegler 2008) are used as reference values. The values of the heat exchanger tube bundles (assuming 100% weight) vary from 3.9 kJ/K to 6.1 kJ/K.
- The external heat exchanger SWEP B25Tx41/2P is parametrized directly based on expected performance obtained with the manufacturer software.

In regard of the model calibration, the main work is related to the estimation of appropriate values for the 6 unknown UA values of the AHP heat exchangers. The calibration is performed manually through stepwise adaptation of the parameters, using approximately 90 stationary points from various experiments as benchmarks. The UA value for each element n required for Equation (22), which are the same values used in Equation (23) are obtained with Equation (32) and are defined based on nominal operating conditions by two parameters ($\dot{m}_{nom}$ and UA_{nom}). The mass flow rates $\dot{m}$ and $\dot{m}_{nom}$ are referred to the external fluid, i.e. positions 11, 13, 16 and 18.

$$UA_j = \frac{UA_{nom}}{n} \left(\frac{\dot{m}}{\dot{m}_{nom}} \right)^{0.6} \quad \text{where } j \in \{g, a\} \tag{32}$$

The values after calibration are summarized in Table 1. Additionally, the fixed UA in W/K values used for the solution heat exchanger, and the second stage heat exchange at the generator and absorber, see Equations (25) to (27), are set respectively to 350, 100 and 400 W/K.

Table 1. Parametrization of main heat exchangers after calibration.

Heat exchanger	UA_{nom} **in kW/K**	$\dot{m}_{nom}$ **in kg/s**
Evaporator	1.2	0.045
Generator	1.5	0.045
Absorber	3.9	0.35
Condenser	3.9	0.35

To analyze the dynamic behavior of the model, simulation results covering 14 hours of experimental operation are compared with measurement data. The measurement uncertainty of the temperature sensors is estimated at $\pm$ 0.2 K as reported in (Zotter, Eberhöfer, and Seidnitzer-Gallien 2023). The comparison primarily focuses on the outlet temperatures of the main heat exchangers. To assess the model's accuracy under steady-state conditions, data points identified as quasi-stationary- according to the criteria outlined in (Eberhöfer 2022) are used. These points correspond to periods in which the system operation is assumed to have stabilized.

Results from a single experimental run are presented here. The boundary conditions used in the simulation are summarized in Figure 6. Points at which the operation is considered to have reached steady-state are marked with circles. For this analysis, the evaluation period spans from hour 1 to hour 15 of regular operation.

3.2 Validation results

Simulation results at positions 12, 14, 15, 17, 19 and 21 (see Figure 1) over the evaluation period of the experiment are presented in Figure 7 alongside the corresponding measurement data and the calculated deviations. The model predicts the outlet temperature behavior with generally good accuracy. A total of 841 values (one every minute) are used for calculate the deviation at the given instant and used for the evaluation, see Table 2. Most monitored temperatures, specifically T_{14}, T_{15}, T_{17}, and T_{21}, show low average deviations in the range of -0.4 K to 1.3 K, with deviations spanning from -2.7 K up to 3.2 K. In contrast, the outlet temperature of the external heat exchanger T_{19} and the outlet temperature of the evaporator T_{12} exhibit a higher average deviation of 2.7 K and 1.6 K with a maximum deviation (underestimated temperature) of 8.3 K and 3.1 K respectively.

When evaluating temperature deviations under steady-state operating conditions, the average deviations are comparable to those observed over the entire duration of the

DOI 10.3384/ecp218949

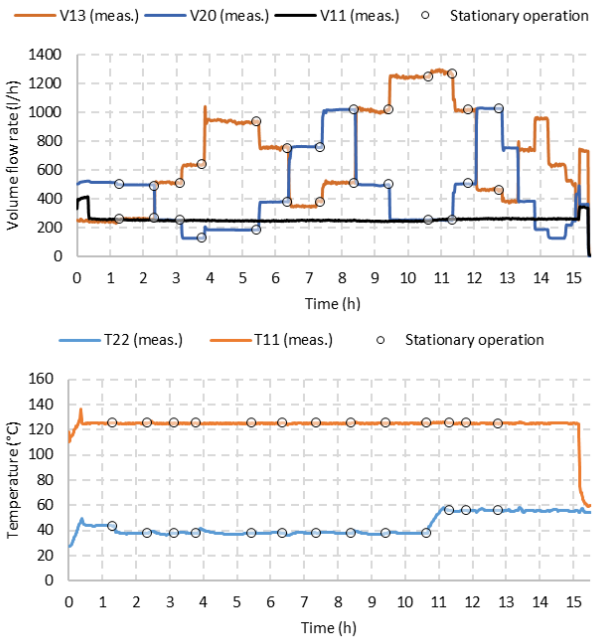

Figure 6. Measured data (meas.) used as boundary conditions for the model validation. Volume flow rates (top) and temperatures (bottom). Volume flow rate and temperature entering the generator V_{11} and T_{11}. Volume flow rate entering the absorber V_{13} and the external heat exchanger (secondary side) V_{20} and their temperature T_{22}.

experiment (cf. Table 2 and Table 3). It is noteworthy that the large temperature deviations previously observed at the external heat exchanger outlet (T_{19}) during transient conditions are reduced once the system reaches steady-state. Under these conditions, the deviations at T_{19} range from a minimum of 0.74 K to a maximum of 5.5 K, with an average deviation of 2.6 K across the thirteen steady-state data points - the highest average deviation among the six evaluated temperatures.

4 Conclusions

The presented Absolut Modelica library includes both static models, which have been verified against literature

Table 2. Average, maximum and minimum temperature deviations (in Kelvin) defined as the reference value (measurement) minus the calculated values (simulation result) for 14 hours evaluation period.

	Temperature deviation in K		
Temperature	**Average**	**Maximal**	**Minimal**
T_{14}	−0.26	1.42	−2.73

T_{21}	−0.07	0.65	−1.38

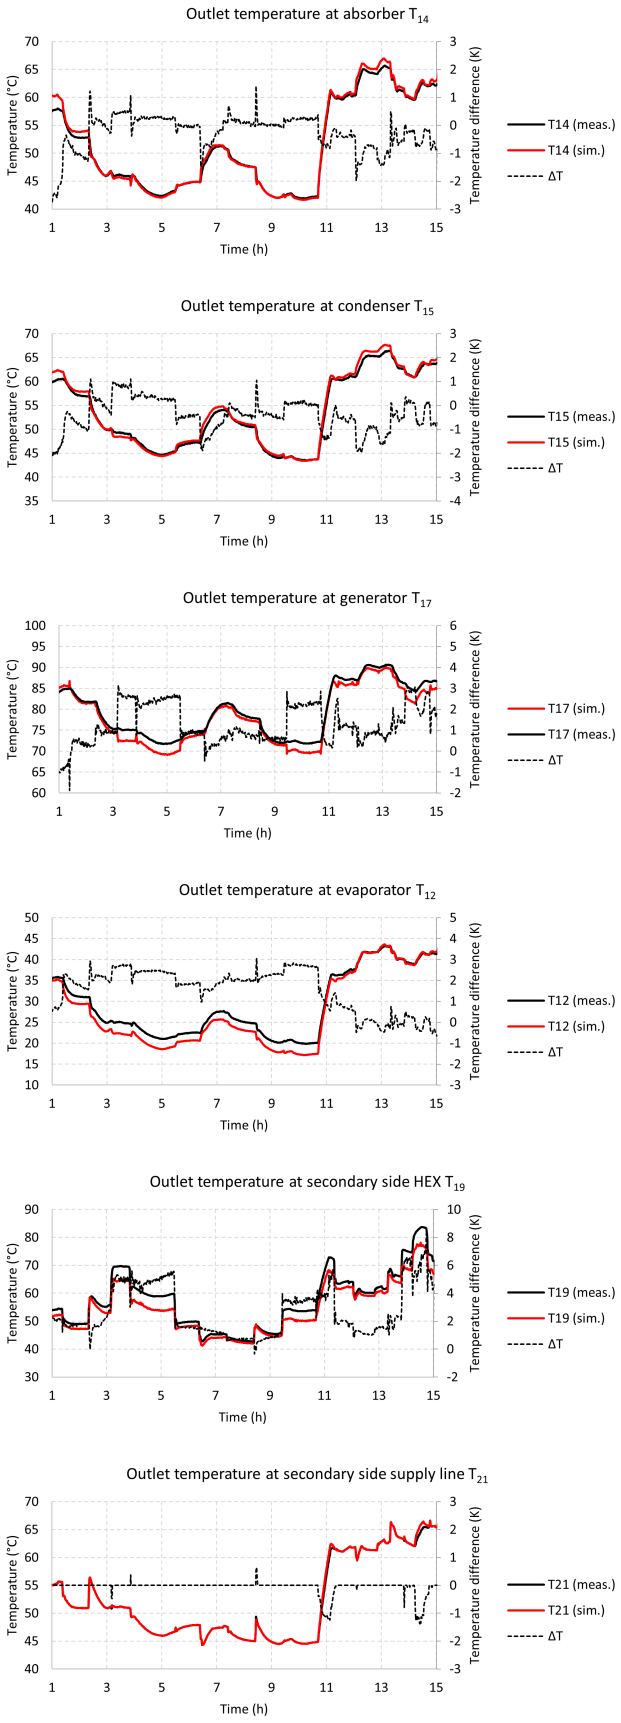

Figure 7. Temperature difference (ΔT) in K between measurements (meas.) and simulation results (sim.) at outlet of main heat exchangers.

Table 3. Average, maximum and minimum temperature deviations (in Kelvin) defined as the reference value (measurement) minus the calculated values (simulation result) for monitored positions under steady-sate operating conditions.

Temperature	Temperature deviation in K		
	Average	**Maximal**	**Minimal**
T_{14}	−0.29	0.53	−2.11
T_{15}	−0.43	0.7	−1.66
T_{12}	1.2	2.61	−0.79
T_{17}	1.72	2.74	−0.01
T_{19}	2.58	5.49	0.74
T_{21}	0.0	0.0	−0.05

values and are suitable for preliminary analysis of absorption thermodynamic cycles, and dynamic models. Despite the current limitations - such as the use of simplified heat exchanger models and uncertainties related to internal control - the simulation results of the dynamic models show good agreement with experimental data. Both the dynamic and static models utilize the implemented correlations for the H_2O/LiBr working pair. Overall, the library provides a solid foundation for the analysis of absorption thermodynamic cycles, offering basic yet reliable models for further study and development. As an open-source resource (available at `https://github.com/carlesRT/Absolut`), it is intended to be extended and refined by the community to address current limitations and support broader applications.

Nomenclature

Table 4. Description of subscripts and symbols.

Subscript	Description
a	Absorber
amb	Ambient / Surroundings
c	Condenser
e	Evaporator
el	Electric
ext	External fluid
g	Generator
h	Hydraulic
hex	Heat exchanger
l	Liquid state
LiBr	Lithium bromide
Loss	Heat losses
max	Maximal
min	Minimal
p	constant pressure
r	Ratio between minimal and maximal
ref	Pure refrigerant
s	Solid state
sol	Solution, i.e. LiBr-water mixture/solution
v	Vapor state
$1, 2, 3, \ldots$	Position of the variable in the AHE

Symbols	Description
C	Heat capacity (J/K)
$\dot{C}$	Capacity rate (W/K)
c	Specific heat capacity (J/(kg.K))
$\dot{H}$	Enthalpy flow rate (W)
m	Mass (kg)
$\dot{m}$	Mass flow rate (kg/s)
NTU	Number of transfer units (-)
p	Pressure (Pa)
$\dot{Q}$	Heat flow rate (W)
T	Temperature (K)
U	Internal energy (J)
UA	Heat transfer coefficient times area (W/K)
V	Volume (m^3)
W	Work (W)
X	Mass fraction (kg/kg)
y	Valve opening (-)
ε	Heat exchanger effectiveness/efficiency (-)
η	Pump efficiency (-)
μ	Specific chemical potential (J/kg)
ν	Specific volume (kg/m^3)
ρ	Density (m^3/kg)
χ	Vapor quality (-)

Appendix A: Review of open source models

The ThermoSysPro library (EDF LAB CHATOU PRISME Department 2024; El Hefni 2019) includes a model for an absorption chiller (`AbsorptionRefrigeratorSystem`). This model employs non-standardized interfaces rather than the standard Modelica fluid interface `FluidPort`, limiting compatibility with other Modelica libraries. The model provides interfaces for the external fluids of the evaporator and generator, while the condenser and absorber are connected in series using idealized internal sources and sinks. This modeling approach restricts the flexibility of the model, requiring modifications for more generic applications. The H_2O/LiBr fluid functions in `Properties.WaterSolution` are sufficient for using the provided model but are constrained to a few equations with ambiguous references to the underlying data.

The District Cooling Open-Source Library (DCOL) is an open-source library that provides parametric thermo-fluid dynamic models for components of District Cooling Systems (Febres et al. 2017). It includes two absorption chiller models: a standard model and a simplified version that eliminates the need for control signals for internal valves. Both models share core components, namely the absorber, evaporator, generator, condenser, and pump, and utilize standard interfaces based on the Modelica Standard Library (Modelica Association 2024). The models are dynamic, accounting for vessel volumes and the mass of heat exchangers. Several examples simulations are provided, the simplified model runs successfully, while the standard model fails to initialize. The library also implements fluid property functions for the H_2O/LiBr working pair. However, inconsistencies have been observed in the definition of some thermodynamic functions, particularly a mismatch that can lead to numerical issues. For example, given a pressure `p`, temperature `T` and concentration `X` the result of `temperature(setState_phX(p,h,X))`, where the enthalpy `h` is obtained via `specificEnthalpy(setState_pTX(p,T,X))` will differ slightly from the original input temperature `T`.

The Buildings library (Wetter et al. 2014) includes a model of an indirect steam-heated absorption chiller, that uses performance curves and is adapted from the EnergyPlus Absorption:Indirect model[1]. It employs standard interfaces from the Modelica Standard Library (Modelica Association 2024). The model uses six functions to predict key performance metrics, including cooling capacity, pump power consumption, generator heat flow rate, and condenser heat flow. These functions rely on performance data stored in a `record`. Several example simulations are provided to demonstrate the model's functionality.

Appendix B: Additional validation results

In this section validation results of selected static models are presented. The results are used to confirm the correct implementation of the models and, indirectly, that of the fluid property correlations as well.

Identification and Elimination of Instabilities During Simulation of Highly Stiff Vehicle Electrical Power System Models

Robert Weber[1] Staša Gejo[1] Rainer Gehring[1] Lars Mikelsons[2]

[1]BMW Group, Germany, {robert.we.weber, stasa.gejo, rainer.gehring}@bmw.de

Abstract

In vehicle electrical power system simulations, reliable models are required, especially for critical use cases such as inrush currents, short circuits, and load dump scenarios. These switching scenarios involve rapid changes in resistance and result in stiff models due to the fast dynamics. Instabilities are observed immediately after switching, highlighting significant numerical challenges. In this study, we investigate the origins of these inaccuracies and propose robust solutions through improved electrical models and advanced numerical integration techniques with optimized error tolerance settings. The suggested decoupling approach employs physical and signal filtering techniques to replace the variable resistor used to simulate the fuse switching process. The nominal value strategy involves establishing an appropriate baseline value. The methods discussed yield stable and accurate simulations when implemented with appropriately adapted model-specific parameterizations.

Keywords: stiff model simulation, vehicle electrical system simulation, numerical instabilities, decoupling method, nominal value

1 Introduction

The importance of the electrical power system for vehicle operation and safety is ever-increasing, due to the growing complexity and reliance on integrated assistance and safety functions in modern vehicles. As the automotive industry moves towards increased automated and autonomous driving functions, new challenges arise in achieving functional safety (Schwimmbeck, Buchner, and Herzog 2018).

New electronic fuses play a vital role in ensuring the safe operation of power distribution units by implementing protection mechanisms like overcurrent, overtemperature, undervoltage, and wire protection algorithms. These functions guarantee the reliable supply of safety-critical consumers even in error conditions, through the quick and selective isolation of faults (Baumann, Abouzari, et al. 2023). To ensure the reliability and availability of these safety-critical systems, it is crucial to perform highly dynamic simulation tests, such as inrush current, short circuit, and load dump scenarios, visualized in Figure 1. Short circuit tests are performed adjacent to the load to evaluate the fuse's fault isolation capability. Moreover, inrush current tests assess the immediate electrical response upon fuse closure, while load dump scenarios simulate the transient overvoltage conditions, resulting from the abrupt load disconnection via the fuse.

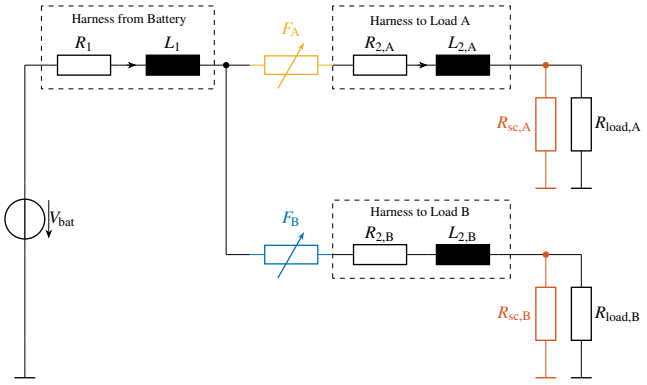

Figure 1. Simplified model of the vehicle electrical power system visualizing the different test cases: short circuit scenarios via small resistors $R_{sc,A}$ and $R_{sc,B}$ (marked in orange) connected to ground, load dump scenario by opening fuse F_A (marked in yellow) and closing fuse F_B for the inrush current scenario (marked in blue).

Evaluating the vehicle electrical power system functionality and simulation results is challenging, as discontinuities and steep gradients can lead to numerical artifacts. The time constants of the circuit elements can vary by several orders of magnitude, so the effective time constant changes as the resistance varies during switching. This change in resistance alters the dynamic behavior of the system, which is why it is considered *stiff*. Highly stiff or hybrid stiff systems – i.e., systems with discontinuities and Boolean functions that alter the mathematical model description – can be computationally expensive to solve. Moreover, their results are sensitive to solver settings, which poses a challenge for safety-related investigations (Liu, Felgner, and Frey 2010).

One of the common problems encountered during the simulation of electronic fuses in vehicle electrical systems is the appearance of deviations from a physically correct behavior. These deviations manifest as uneven sawtooth disturbances in the voltage across the fuse or as a single exaggerated spike caused by integration instability, rather

than by physical phenomena. Such voltage behavior can be critical, as it serves as an input for additional components – such as the diodes connected in parallel with the fuse. Diodes alone may pose numerical challenges, and an unstable voltage input can introduce further complications in the numerical simulation. They are employed as a protective measure to limit the voltage across the fuse. Furthermore, the fuse trigger limits can be incorrectly breached, leading to erroneous simulation model behavior (e.g. undervoltage). All these aspects can have a significant negative impact on the numerical stability and functionality of simulation models. The goal of this work was to find the sources of numerical instabilities in these models and to resolve them by means of physical remodeling or by using more advanced integrator settings.

Chapter 2 discusses the properties of the vehicle electrical power system. Chapter 3 characterizes the non-physical numerical artifacts observed in the simulation, examining their causes and consequences. The practical remodeling approaches are presented and discussed in Chapter 4. Integrator settings as well as the error estimation and tolerance, and their effect on the simulation results are covered in Chapter 5. Lastly, Chapter 6 compares the presented methods applied in two different models and sets the ground for future research and improvements.

2 Vehicular Electrical Power System Simulation Models

The models examined in this chapter represent key elements of vehicular power systems, consisting of voltage and current sources, variable resistors, and signal conditioning circuits, used to represent the behavior of switched electronic fuses and other protective devices. These models can be used to capture transient effects previously mentioned under inrush currents, short-circuit events, and load dump conditions, covering a broad range of time constants.

Such highly dynamic systems are usually also *stiff*. There is no unique definition of stiffness; however, according to Lambert (1992) and Cellier and Kofman (2006), there are several criteria which can be used to recognize or define a stiff system. The two criteria important for this work are:

- Statement A: "A linear constant coefficient system is stiff if all of its eigenvalues have negative real part and the stiffness ratio is large."
- Statement B: "A system is said to be stiff in a given interval of time if in that interval the neighboring solution curves approach the solution curve at a rate which is very large in comparison with the rate at which the solution varies in that interval."

According to Statement A, a linear electrical system is considered stiff if the real parts of its eigenvalues differ by several orders of magnitude.

Let us look at an example of an interconnected load model, consisting of a line, load input impedance, and closed switch found in Baumann, Weissinger, and Herzog (2019), shown in Figure 2. Its eigenvalues are $\lambda = \{-1.43 \cdot 10^{10}, -5.88 \cdot 10^{4} \pm j\, 4.01 \cdot 10^{4}, -4.45 \cdot 10^{-3}\}$, whose ratios of real parts go from 10^{6} up to 10^{13}. This type of circuit is omnipresent in the vehicle electrical power system, though in slightly varying input impedance topologies but with similar order of magnitude of its parameters. These circuits connect numerous consumers (small motorized components, heaters, wipers, and ventilators) with the supply, converters, and power distributors. System stiffness arises from the input impedance, cable, and parasitic effects in complex components which can create states with vastly different time constants (referring to Statement B). Additionally, fuse switching causes the total resistance value to change, amplifying variations in time constants and eigenvalues over time. Consequently, this alteration introduces a change in the stiffness of the system. Another cause of numerical issues and instabilities can be discontinuities, as well as nonlinear components and signals.

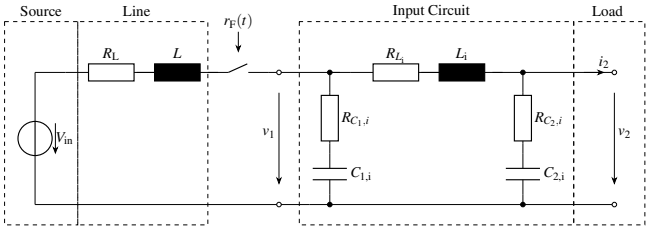

Figure 2. Interconnected load model adapted from Baumann, Weissinger, and Herzog (2019).

The problem of numerical integration for stiff problems has persisted for decades, and no integration method is able to solve every stiff problem. Various integrators can be used for stiff applications, such as Radau, LSODAR, CVODE, and DASSL, as well as a whole range of ESDIRK methods (Liu, Felgner, and Frey 2010; Cohen, Hindmarsh, and Dubois 1996; Blom et al. 2016). These integrators can be classified as either single-step methods, which rely only on the current integration step, or multi-step methods, which use several previous steps to compute the next time step. In addition, the methods differ in the order of integration. Four solvers, including DASSL and RADAU IIA, were compared in a stiff system simulation in Liu, Felgner, and Frey (2010), which showed that DASSL had a higher number of calculated points and a higher solver efficiency for a stiff continuous and stiff hybrid model. However, the study showed a lack of accuracy in all compared solvers for the stiff hybrid system. It is important to note that accuracy and efficiency always depend on the simulated model and cannot be generalized. This work will use DASSL for all the models, as it is well-suited for stiff systems due to its implicit multi-step properties.

DOI 10.3384/ecp218961

3 Model Analysis

"Stability" is a broad concept used to define the behavior of a system. *Analytical* stability, in simplified terms, refers to the property of the system to achieve a steady state after a transient or to remain asymptotically bound. On the other hand, the lack of *numerical* stability (Cellier and Kofman 2006), or rather a *discretization* instability (Ardourel and Jebeile 2021), refers to the lack of ability of the system to numerically reproduce the exact solution. The reason for it lies in the small differences between the original differential equation and its implemented discretized version in the applied numerical method. In other words, a system is numerically unstable if, however small the step size is, a significant deviation arises between the exact solution and the numerical solution (Ardourel and Jebeile 2021).

An additional problem of numerical integration is inaccuracy due to round-off, truncation, and accumulation error. Reducing the step size improves the accuracy but also increases the computational cost. A good balance between error and cost can be achieved by the use of variable-step integration algorithms which utilize specific step-size control algorithms. (Cellier and Kofman 2006)

If a variable-step solver is used, the estimated local error at a given simulation step is controlled to satisfy the following condition (*Dymola Full User Manual* 2022):

$$|\text{local error}| < \text{tol}_{\text{rel}} \cdot |x_i| + \text{tol}_{\text{abs}} \tag{1}$$

By default in Dymola, the relative and absolute tolerances of the simulation are equal, reshaping the Equation 1 into Equation 2, where "tol" denotes the available tolerance input in the setup.

$$|\text{local error}| < \text{tol} \cdot (|x_i| + 1) \tag{2}$$

Dymola Full User Manual (2022) roughly defines the relative tolerance as the approximate definition of the "number of expected true digits in the solution". Meaning, if the value of the state x at a time step i is close to zero, the value of absolute tolerance will determine the limits of the local error. The role of the $+1$ operation in the brackets in Equation 2 and the settings that change its value, affecting the error calculation, will be discussed in Chapter 5.

Consider the example from Figure 3, which is used to examine the instability in the fuse voltage when inductance is present. The resistor R_{load} represents a simple resistive load with no input circuit. The fuse is connected to the source and load via wiring harness models. The fuse is modeled as a simplified component that switches off by acting as a variable resistor, with its resistance changing according to the adapted sigmoid function defined in Equation 3. A key element of these simulations is the detailed representation of the resistance change dynamics of the fuse, closely approximating the behavior observed in the physical fuse. Such modeling provides a more accurate insight into the fuse's effect on the vehicle electrical system.

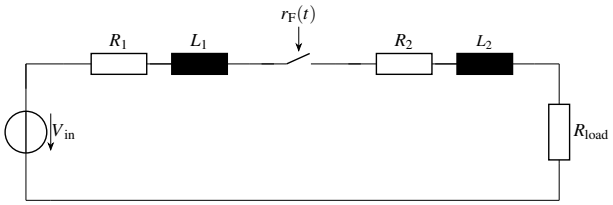

Figure 3. A simple circuit used to investigate the fuse voltage instability in the presence of inductance. The circuit comprises a source, a fuse with upstream and downstream wiring harness models, and a simplified load.

$$r_F(t) = -\frac{R_{F,off}}{1 + e^{k\cdot(t - T_{sw})}} + R_{F,off} + R_{F,on} \tag{3}$$

The switching time T_{sw} is the defined time instant where the switch between the "on" and "off" states is at a halfway point; k is the rate of change of the exponential element. The "on" and "off" state resistances are $R_{F,on} = 1\,\text{m}\Omega$ and $R_{F,off} = 10\,\text{M}\Omega$. The off state is chosen to approximate "open-circuit" conditions. The simulation is run with the DASSL solver, using different tolerance values ranging from 10^{-5} to 10^{-8}. The artifact visible in fuse voltage, as illustrated in Figure 4, indicates a numerical error rather than an actual system response.

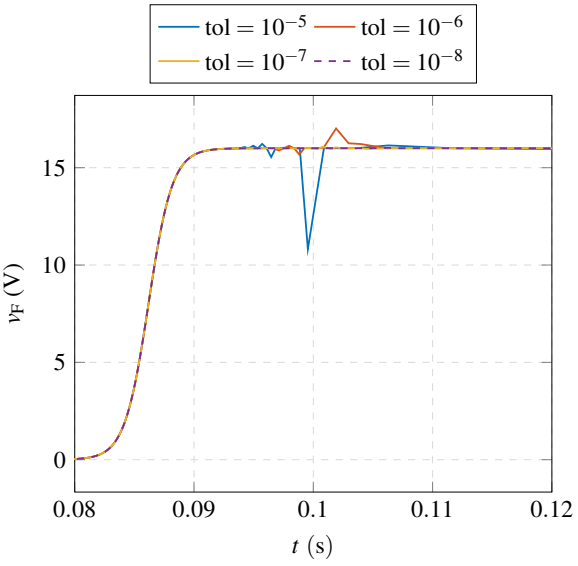

Figure 4. Instability in fuse voltage across different relative error tolerance values.

Such a sharp, triangular deviation is not characteristic of the passive electrical elements under a continuous switching function. It is shown to be a consequence of numerical inaccuracy, as reducing the relative error tolerance by one order of magnitude to 10^{-8} eliminates any visible disturbance in the signal. In order to see what causes such

a spike after the voltage transition seemingly ends, an additional plot was generated that marks every simulation step, as depicted in Figure 5.

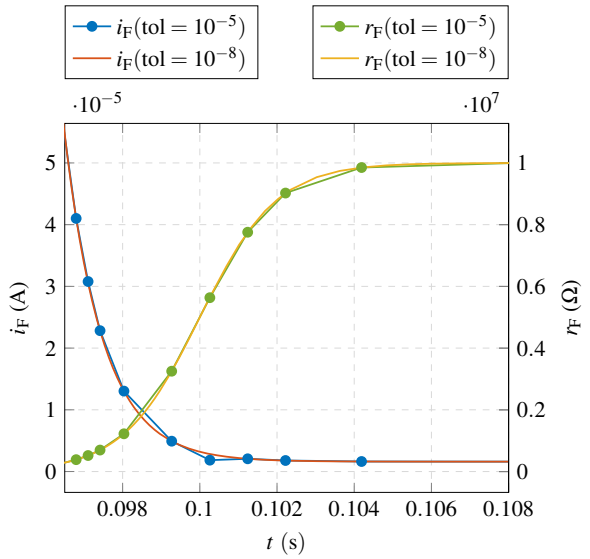

Figure 5. Current and resistance of the variable resistor across different relative tolerance values are plotted. Additionally, the solver steps for tol $= 10^{-5}$ are marked.

As the fuse resistance keeps rising and reaching 5 MΩ, the voltage approaches the value of the source voltage $V_{\text{in}} = 16\,\text{V}$. The "off" current is already in the order of microamperes, which means that the relative error tolerance is insufficient to maintain calculation accuracy. Further calculations in the integration algorithm for the ODE problem involve both very small (µA) and very large quantities (MΩ). However, the disparity in the orders of magnitude between these quantities induces a significant error amplification, ultimately resulting in voltage deviations in the order of several volts. This deviation can be seen in the fuse current plot, where i_F is a result of simulation using relative tolerances of tol $= 10^{-5}$ and tol $= 10^{-8}$. At time $t = 0.100256\,\text{s}$, the current value at tol $= 10^{-5}$ is deviating from the "expected" current at tol $= 10^{-8}$, leading to an error magnification to the voltage level. Using a smaller value for the relative tolerance helps keep the step size small enough to avoid any error escalation. Only at tol $= 10^{-8}$ is the inaccuracy not present.

Equations 4 to 11 present the causal system of equations for the model generated by Dymola. The integration inaccuracy is evident in the voltage signals of both inductors (v_{L_1}, v_{L_2}) as well as in the voltage across the fuse (v_{r_F}) in the circuit shown in Figure 3.

When the error occurs in the integration of the differential equation of the current in Equation 9, it is propagated through the calculations of all the voltages, including the negative potential on R_1 in Equation 7. These voltage values are subsequently fed back into the derivative of the current in Equation 9, which can further exacerbate the error.

$$v_{R_2} = L_2 \cdot i \tag{4}$$
$$v_{r_F} = r_F \cdot i \tag{5}$$
$$v_{R_1} = L_1 \cdot i \tag{6}$$
$$v_{R_1}^{-} = V_{in} - v_{R_1} \tag{7}$$
$$v_{R_{\text{load}}} = R_{\text{load}} \cdot i \tag{8}$$
$$\frac{\mathrm{d}i}{\mathrm{d}t} = -\frac{1}{L_1 + L_2}\left(v_{R_2} + v_{r_F} - v_{R_1}^{-} + R_{\text{load}}\right) \tag{9}$$
$$v_{L_1} = L_1 \cdot \frac{\mathrm{d}i}{\mathrm{d}t} \tag{10}$$
$$v_{L_2} = L_2 \cdot \frac{\mathrm{d}i}{\mathrm{d}t} \tag{11}$$

It shall be noted that, although this is a simple example, the same effect can be observed in more complex circuits, e.g. in the model below and generally in the vehicular power system simulations as well. The model developed by Baumann, Abouzari, et al. (2023) is a slightly expanded version of the previously shown model in Figure 3. In this model, additional consumers are added to the single supply line (with one fuse), each equipped with individual input circuits and resistive load elements, as illustrated in Figure 6.

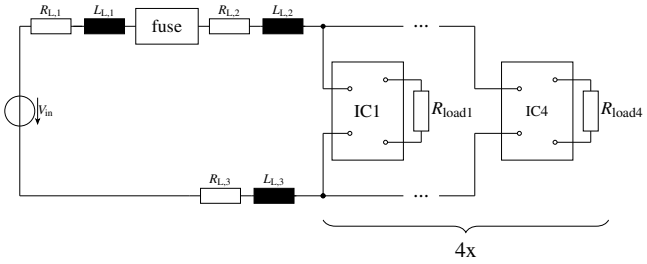

Figure 6. Simple multi-load model with a source and one resistive fuse element, interconnected with cables. Each resistive load has an input circuit (IC) block.

This time the fuse variable resistor is controlled with a more advanced dynamic switching function, developed by Baumann, Abouzari, et al. (2023). The fuse is switching the load "off" from the supply at $t = 0.1\,\text{ms}$. As shown in Figure 7, the numerical accuracy is present even after the significant change in fuse voltage. A very small current and a very large changing resistance are unfavorable for the integration algorithm. When the relative and, consequently, the absolute tolerance of the simulation are reduced, the errors observed in the previous case are resolved.

However, such a low relative tolerance value is too low for the highly stiff large-scale systems required in the design of vehicular electrical systems. It can cause a complete simulation failure during switching or even at the very start of the simulation. Hence, an alternative solution was explored that does not involve a direct limitation of the global relative tolerance.

4 Simulation Approaches for Switched Electronic Fuses

In the following, a signal and a physical filtering approach is proposed to mitigate instability. The variable resistor is remodeled and the circuit is split, yielding an equivalent model referred to as decoupling. This serves as a necessary preparatory step for the implementation of the filtering approaches.

4.1 Decoupling

The main idea behind the decoupling is to use controllable current and voltage sources. This allows for the implementation of a custom control function rather than using a variable resistor. Its resistance directly affects the system matrix and variations in its value modify the system eigenvalues. Therefore, an indirect way of securing the same voltage behavior was required to construct an equivalent system with the use of the closely available physical quantities. Among the decoupled attempts with different source combinations, the best implementation was found in the combination of the controlled current source on the primary (supply) side and a controlled voltage source on the secondary (output or load) side. This configuration is presented in Figure 8.

Equations (12) and (13) were implemented to control the respective sources using the mathematical expression for the desired resistance change of the fuse, the measured secondary current $\hat{i}_y$ and the measured primary voltage $\hat{v}_x$. The measured current from the secondary circuit is fed to the current source on the primary side, ensuring identical conditions as in the original model, whereas the secondary voltage was controlled indirectly via the shown expressions. Voltage was measured between the positive nodes of the two decoupled sides v_{xy} to obtain the equivalent of

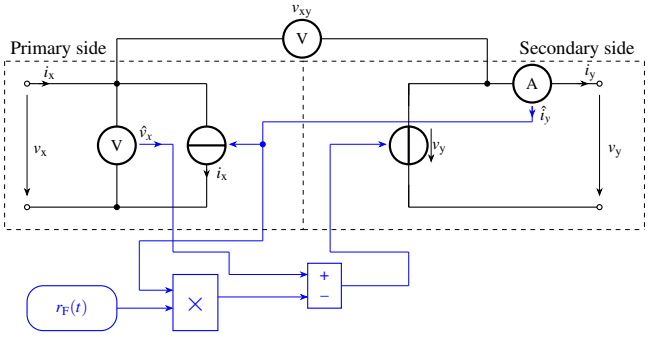

Figure 8. Decoupling implemented with a combination of a controlled current and voltage source (CV).

the fuse voltage. The notation CV will be used to denote this implementation in the subsequent text.

$$v_y(t) = \hat{v}_x(t) - \hat{i}_y(t) \cdot r_F(t) \tag{12}$$

$$i_x(t) = \hat{i}_y(t) \tag{13}$$

An option that was explored as well included two controlled voltage sources (further denoted as VV), whose inputs are shown in Equations (14) to (16).

$$v_y(t) = \hat{v}_x(t) - \hat{i}_x(t) \cdot r_F(t) \tag{14}$$

$$v_x(t) = \hat{v}_y(t) + \hat{i}_y(t) \cdot r_F(t) \tag{15}$$

$$i_x(t) = i_y(t) \tag{16}$$

This approach has certain disadvantages due to its structure. The most significant problem is the occurrence of a division by zero in one of the differential equations of the simulation model. Therefore, to avoid the division by zero a correction factor is defined to only slightly differ from the original factor in the addition block. However, this very small value in the denominator had a negative impact on the stability of the model. Apart from these VV drawbacks, no other significant differences between the two approaches that could affect the stability of the model were observed.

Since the secondary current is measured and fed to the primary, the sensitive state can be accessed directly. Due to the previous comparison of the two approaches, the decoupled CV was subsequently used for further investigation.

4.2 Signal Filtering

Decoupling the system offers a significant advantage of transforming a purely electrical model into a signal-based switching system. This approach enables modifying the signals for both the controlled signal current on the primary side and the controlled signal voltage on the secondary side. Since it is known that instabilities arise from even minimal inaccuracies in the current, which are amplified by large resistance values, the idea was to smoothen the entry to the controlled signal voltage. This can be achieved by employing a filter, as shown in Figure 9.

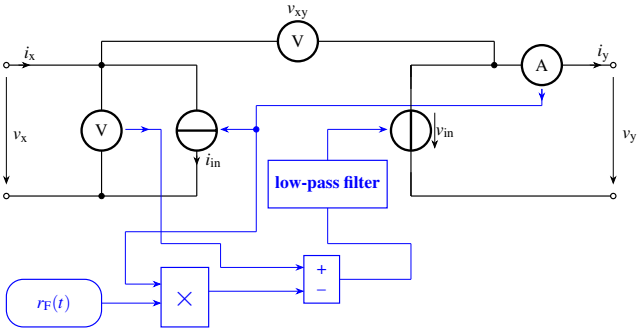

Figure 9. Decoupled model with an integrated low-pass filter.

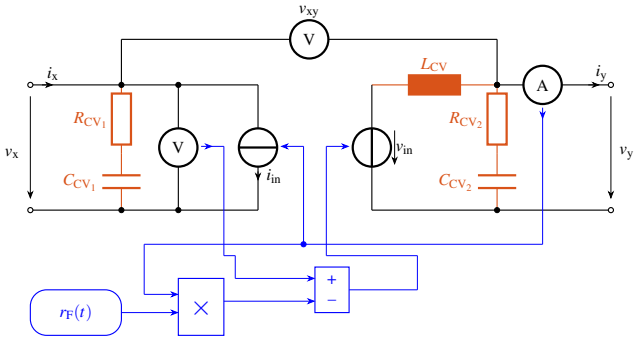

Figure 10. Decoupled model with an implemented physical filter approach. The components needed for the filter are highlighted in orange.

Such an implementation can achieve a smoother transition during switching operations. When it comes to the primary side, filtering the current directly is neither necessary nor effective, as the current response itself has no evident sawtooth disturbances. Additionally, primary and secondary currents must remain equal, in order to retain the equivalence to the original circuit (Equation 13).

Various strategies can be employed to smoothen the signal input for the secondary voltage source, with a first-order element serving as the simplest form of signal-based filtering (Equation 17).

$$\tau \cdot \frac{y_{\text{filter}}(t)}{\mathrm{d}t} + y_{\text{filter}}(t) = K \cdot u_{\text{filter}}(t) \tag{17}$$

It is crucial to have a precise understanding of the expected voltage behavior in the circuit before implementing any filters to avoid suppressing significant electrical effects. Additionally, it must be noted that such components influence the system dynamics by introducing a delay and altering the signal's response based on the chosen time constant. It is advantageous to select a very small time constant (e.g., $\tau < 10^{-7}$ s) to minimize switching delays and preserve the original electrical characteristics of the signal. The effects of different time constants are discussed in more detail in Chapter 6. The preset gain factor should be set to $K = 1$.

4.3 Physical Filtering

In addition to the previously introduced signal filter, a physical filter approach is presented. The most promising variant included the RC branch parallel to the controlled sources and an additional inductor on the secondary side. This configuration is illustrated in Figure 10.

Table 1. Parameter values used in the decoupled CV with inaccuracy compensation.

Primary side		**Secondary side**		
R_{CV_1}	C_{CV_1}	R_{CV_2}	C_{CV_2}	L_{CV}
$10^4\,\Omega$	$10^{-9}\,\mathrm{F}$	$10^4\,\Omega$	$10^{-9}\,\mathrm{F}$	$10^{-9}\,\mathrm{H}$

This circuit has shown the ability to compensate the numerical error and provide accurate results for the example in Figure 11. The parameters of the additional circuit elements are set to very high resistance values and very low inductance and capacitance values, so as to avoid introducing undesired dynamics into the system. A parametrization example is shown in Table 1.

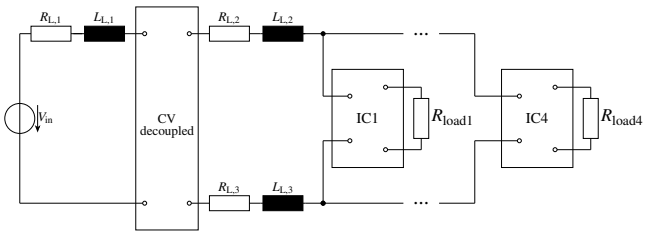

Figure 11. Power system model with decoupled block.

When this implementation is applied to the simplified system with multiple loads with their input circuits, the behavior was stable and accurate. However, if the circuit tends to be predominantly inductive, the shown solution still exhibits inaccuracies. One such example is the small model from Figure 3. Its inductive characteristic causes numerical instability with every possible RC and RLC combination, except in the case with the RC branch only on the secondary side, without an inductor, where the instability is only reduced but not eliminated. Since the RLC components of the physical approach may also represent parasitic effects of the wiring harness, it is possible to investigate whether a more detailed modeling of the wiring harness could lead to a more accurate simulation and reduce instabilities. This could be addressed in future research.

5 Elimination of Instabilities by Focusing on the Absolute Tolerance

A *nominal* value indicates the magnitude of a specific state and influences the absolute tolerance. This nominal value is specified in the textual description of the component (*Modelica - Language Specification* 2023).

Listing 1 shows an example in which the current i of an inductor is assigned a nominal value of 10^{-4}.

Listing 1. Nominal value definition for a component

```
L2(i(nominal=1e-4), L=0.75e-6)
```

Equation 18 demonstrates how error tolerance is effectively distributed using this setting. If the value of the state itself is higher than the defined nominal value, the relative tolerance will dominate the error calculation. Conversely, a higher nominal value shifts the dominance toward the absolute tolerance. But what does it mean in practice?

$$|\text{local error}| < \text{tol} \cdot (|x_i| + \text{nominal}(x_i)) \tag{18}$$

"A simple way of understanding tolerance is that the relative tolerance sets the number of significant digits to be calculated using:

$$\text{significant digits} = -\log_{10}(\text{tol}),$$

(when $|x_i|$ is larger than the nominal value). And the absolute tolerance sets the number of decimal places:

$$\text{decimal places} = -\log_{10}(\text{tol} \cdot \text{nominal}(x_i)),$$

(when $|x_i|$ is less than the nominal value)" (Fish 2019).

Therefore, it is desirable to use a nominal value of the same order of magnitude as the lower value of the state in which the inaccuracy occurs. Decimal places are used for large values and significant figures for very small ones. It ensures that the step size remains sufficiently small for precise calculations when the state falls below the nominal. This is a crucial point in these switching models because exactly when the current becomes too small for the integrator to keep the accuracy, the large resistance comes into play. This way, the strict accuracy mode is "turned on" only when the state is below the nominal value. Otherwise, the system follows the relative tolerance constraints.

An investigation of the small model in Figure 3 with preset relative tolerance of 10^{-5} reveals that defining an appropriate nominal value for the state leads to immense improvements in the voltage characteristics. This change is illustrated at the bottom of Figure 12.

The simulation analysis performed in Dymola provided access to information on integrator order, step size, and various error indicators and markers. In the upper plot of Figure 12, this small example shows that using the nominal setting (dashed red) results in an extended period of reduced step size compared to the default (dashed blue), thereby enabling more accurate calculations at the end of the switching period. This change is reflected in the integration order remaining at higher values over that extended duration. The step size is reduced as a consequence of more frequent step rejections compared to the simulation with the default settings, as shown by the dots in Figure 12.

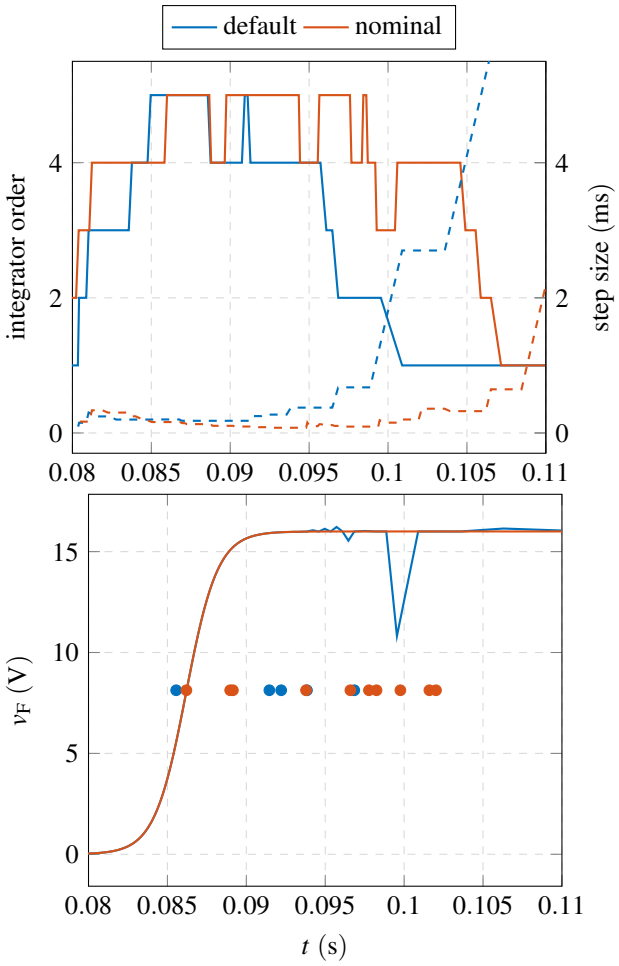

Figure 12. Numerical analysis of the small model without (default, nominal = 1) and with a nominal value of 10^{-4}. The upper plot shows the integration order in full line and step size comparison in dashed. The plot below depicts the change in fuse voltage as well as the solver rejected steps as full dots.

6 Results and Discussion

To evaluate the performance of these approaches, two simulations are presented. Firstly, the results from the small-scale power system model are shown, followed by those from a large-scale simulation. Finally, the similarities and differences between the results of these approaches are compared.

6.1 Small-Scale Power System Simulation Model

This vehicle electrical system model was previously introduced in Figure 6. The model consists of four loads with integrated input circuits, one fuse, and a corresponding wiring harness. The fuse is switched off at $t = 0.1\,\text{ms}$ changing its resistance from 1 mΩ to 1 MΩ. The function describing the change in resistance during switching off was developed by Baumann, Abouzari, et al. (2023). As a consequence of switching the fuse, the voltage over the resistor changes from 28 mV to 16 V. Preset tolerance of the simulation is $\text{tol}_{\text{rel}} = 10^{-5}$.

Figure 13 displays the voltage across the fuse resistor for the default simulation (shown in blue). Additionally, the previously introduced methods for physical filtering (yellow) and signal filtering (violet), as well as the nominal value (orange), are visible. The parameters for the physical filtering are the same as in Table 1. For signal filtering, a time constant of $\tau = 10^{-8}$ s is used. The trace of the default simulation shows instabilities occurring between 0.4 ms and 0.8 ms. These sawtooth disturbances exhibit a maximum voltage deviation from the equilibrium state of 10.71%. As visualized in the zoomed-in area (**A**) of Figure 13, the simulation results indicate that both filtering approaches and the nominal setting produce identically smooth voltage outputs.

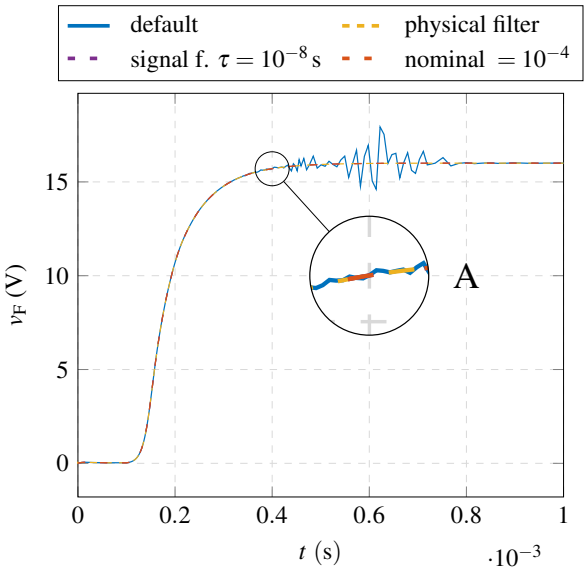

Figure 13. Differences in voltage response v_F across the fuse of the models from Figure 6 and Figure 11 at $\text{tol}_{\text{rel}} = 10^{-5}$ (default).

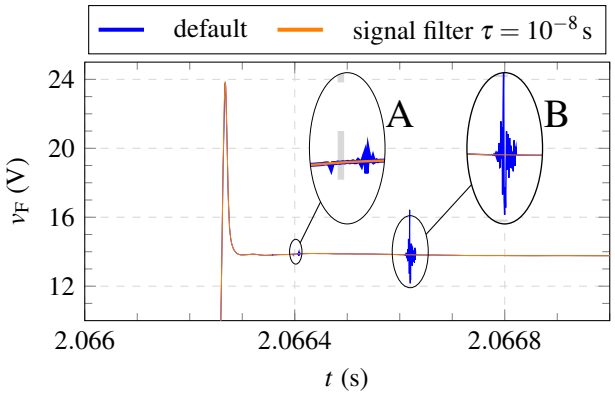
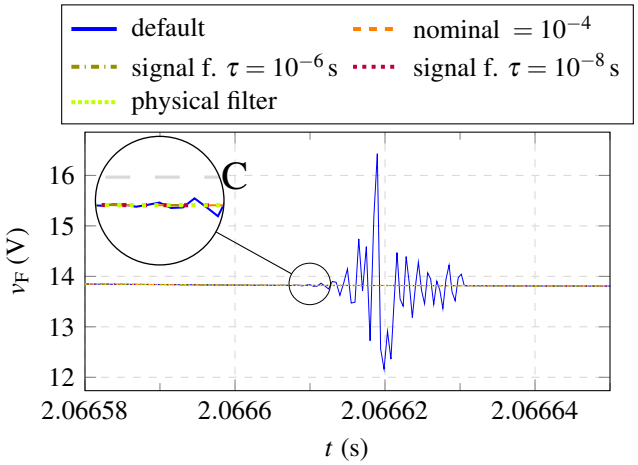
Further tests have shown that a sufficiently small time constant is $\tau < 10^{-6}$ s. Since the fuse switches within a time interval of up to 10^{-5} s, the first-order filter can effectively resolve numerical inaccuracies without introducing significant delays in the voltage value. In addition, no negative side effects of the approach can be identified. For the physical approach, adding the RLC and RC branches before and after the variable resistor is also a viable option, yielding results similar to those of the decoupled system with a signal filter. The filter CV models typically do not exhibit a reduced step size compared to the original model, as the filtering elements do not dominate the solver's error estimation. Defining the nominal state value (highlighted in orange) further improves stability at minimal implementation cost, without requiring detailed knowledge of the circuit parameters. The only information necessary to properly set the nominal value is the state that causes numerical disturbances and the precision required to mitigate them. The nominal attribute employs a stricter error tolerance for very small currents. In this example, the approach results in more rejected steps and a smaller step size, as demonstrated in the previously shown example, illustrated in Figure 12.

6.2 Large-Scale Power System Simulation Model



In the following, the stability of the approaches is evaluated using an electrical power system simulation model developed at BMW. This full model includes all components of the vehicle's electrical consumers, a battery model, the entire wiring harness, and the above-mentioned fuses. In addition, each component contains complex control and monitoring logic. The simulation model is comprised of approximately 1,800 states and about 230,000 equations. In this simulation at $t = 2$ s, a short circuit is initiated, causing the fuse to switch off in accordance with the characteristics described in Chapter 6.1. Despite the preset tolerance ($\text{tol}_{\text{rel}} = 10^{-7}$) being relatively strict, instabilities are still observed. The fact that we observe such disturbances, even with the tight tolerance, indicates that they occur in almost every power system simulation after switching the fuse. Vice-versa, this contradicts the findings in Figure 5 that instabilities are no longer visible at a preset tolerance of $\text{tol}_{\text{rel}} = 10^{-7}$ or stricter. Investigations show that the potential of the deviations is reduced with a tighter tolerance, but it is not guaranteed.

Figure 14 shows the voltage across the fuse resistor, where the same signal filtering technique is applied using two different time constants. Furthermore, the physical approach is presented using the same parameter set as in the initial model described in Table 1, while the nominal approach again employs a value of 10^{-4}. During the switching of the fuse, the voltage across it leads to a voltage peak due to the up- and downstream inductors at time 2.066 26 s. After the voltage peak, the instabilities occur at 2.066 32 s and 2.0668 s. The maximum deviation is about 15.89 % at 2.066 62 s. As visualized in the zoomed-in areas (**A**) and (**B**) in Figure 14a, the characteristic sawtooth disturbances are consistent with those observed in Figure 4.



The signal filter curve ($\tau = 10^{-8}$ s) demonstrates significant improvements in stability at the time when the inaccuracies in the default simulation model arise. These enhancements occur without any observable change in the electrical system dynamics. Figure 14b presents the zoomed voltage traces and illustrates both the instability characteristics and the results of the implemented approaches. Overall, these simulation results indicate that all introduced and applied methods have effectively eliminated the observed instabilities. Compared to the small model filtering result ($\tau = 10^{-6}$ s), the large model result ($\tau = 10^{-8}$ s) also does not exhibit any observable differences after the voltage peak. The effects of different signal filter time constants throughout the complete simulation duration are explored next.

Figure 15 illustrates the same simulation with default settings alongside the signal filtering applied with two dif-

ferent time constants at $t = 2\,\text{s}$, where a maneuver is initiated. This occurs before the fuse is switched off. In this context, maneuvers refer to vehicle-specific events that change the load on consumers, such as electric power steering. The large-scale simulation shows that a large time constant (definition of "large" relative to the simulation model) leads to oscillations starting at $t = 2\,\text{s}$ with a maximum amplitude of 0.21 V. These oscillations can reduce the step size and affect simulation stability. Therefore, the time constant for the filtering approach must be carefully selected.

6.3 Discussion of the Approaches

The implementation of the previously introduced approaches in the two simulation models, which differ significantly in numerical complexity, revealed notable variations in the simulation results. The following discusses these similarities and differences in detail.

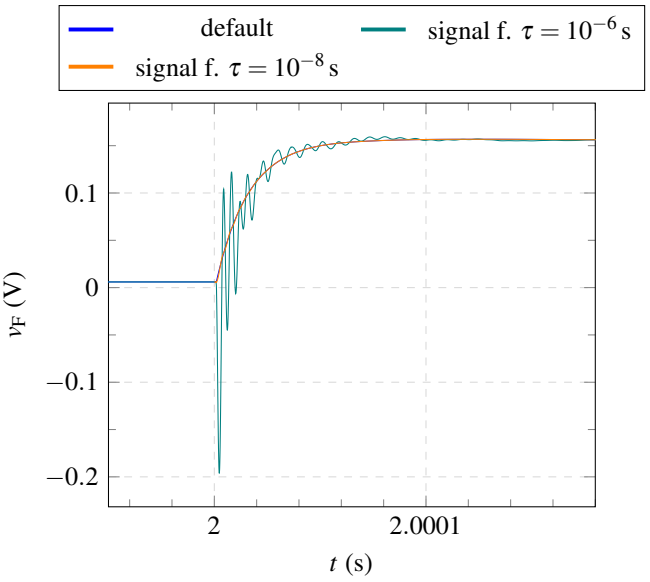

Figure 15. Effects of the signal filter with different time constants on the voltage across the fuse resistor at the start of the maneuver in the power system simulation.

6.3.1 Nominal Approach

The nominal approach is attractive due to its straightforward implementation. The simulation results indicate that the instability issues were minimized. Residual ripples may persist, but they typically do not affect simulation stability. The models presented above generally exhibit different behavior with regard to step size. While in the first small-scale simulation the step size is reduced – thereby increasing the simulation time – the large-scale model demonstrates a reduction in simulation time. This effect in the large-scale model is due to the constantly low step size, caused by the remaining states, as well as state and time events of the overall simulation model. As a result, the step size is controlled in a different manner compared to the small-scale model, which can positively affect the simulation time. However, this relationship cannot be determined in advance, as it depends on the individual model and its dynamics. As already mentioned in Chapter 5, the nominal value should be chosen to be of the same order of magnitude as the low state value at which the inaccuracy occurs.

6.3.2 Signal Filtering Approach

By decoupling the system, continuous controllability of the voltage was achieved throughout the simulation. In both models, the implementation of a first-order filter in the voltage path resulted in significant improvements by smoothening the voltage. Importantly, overall simulation performance remained unchanged compared to the original simulation, regardless of the time constant employed. However, large time constants that depend on the simulation model lead to oscillations in both voltage and current. In particular, the current as a state variable further compromises simulation performance and stability. These ob-

servations underscore the critical importance of carefully selecting the time constant in the filtering approach. For the demonstrated simulation scenarios, it is recommended to select time constants τ between 10^{-7} s and 10^{-9} s. Previous investigations have shown that these values do not cause any noticeable negative effects.

6.3.3 Physical Filtering Approach

Physical filtering is another approach in which different states are integrated before and after the switching element. By using a high resistance and a low capacitance and inductance, instabilities can be eliminated without significantly changing the dominant error or the step size. Both simulation models presented earlier, despite their differences in complexity, have demonstrated that this approach reliably eliminates instabilities. However, the natural delay in the RC circuit in an electrical system can lead to oscillations if the parameters of the components are chosen improperly. When using this approach, it is recommended to employ the previously used parameter values for inductance, resistance, and capacitance. If necessary, these parameters may be reduced by an order of magnitude without compromising stability.

7 Conclusion

A decoupling approach with filters has been introduced as a substitute for the challenging variable resistor element under highly dynamic switching in stiff electrical power system models. On the other hand, an alternative error tolerance setting – nominal – has been explored and compared to the default settings. Decoupling is essential for the signal filtering approach, as it enables the removal of numerical disturbances in a manner analogous to physical filtering. This strategy provides direct access to the perturbed voltage value, which can then be stabilized. Both filter variants successfully achieve their intended purpose without reducing the global relative tolerance. However, the first-order block in the signal variant is considerably simpler to implement. With a sufficiently small time constant, it is also more robust against unwanted voltage instabilities. The application of the physical filtering solution is the more complex method, which involves tuning of the RLC and RC branches to achieve the desired output.

It can be concluded that the fastest and most reliable solution to the problem is the use of the nominal setting in the problematic state, in the magnitude of its low value. However, this method still exhibits a minor error, although in the order of less than a percent of the expected value. The authors advise a thorough understanding of the circuit characteristics, as it is essential to identify the problematic state and subsequently implement a suitable approach.

For future studies, it is recommended to investigate how the various approaches with different parameter sets affect the runtime of the models. Furthermore, it is important to understand the performance implications for different fuses in the power system simulation, given its complexity and size.

An alternative approach to achieve the desired voltage-switching characteristic is to use a series-connected controllable voltage source instead of a variable resistor. This configuration replicates the voltage-switching behavior of the electronic fuse rather than relying solely on resistance. Moreover, this approach avoids dependency on the current and high resistance by applying a direct voltage requirement. This solution requires further research and testing to determine potential disadvantages.

Abstract

Common Requirement Modeling Language (CRML) is a language designed to express requirements in an intuitive manner, in this paper we present the recent advancements in tool support for the requirement modeling and verification workflow in OpenModelica and illustrate this on the Traffic Light use-case.
Keywords: CRML, Requirements, Verification, Complex Systems, Digital Engineering

1 Introduction

Systems Engineering is *a transdisciplinary and integrative approach to enable the successful realization, use and retirement of engineered systems* (INCOSE Fellows 2019).

Thanks to an approach centered on requirements, its main benefits lie in better consideration of the system's environment (in terms of coordination of the various stakeholders, support of associated constraints and interfaces with other systems). It also provides an iterative approach making it possible to guide choices towards solutions "just needed" throughout the life cycle of the system. Impact analyses of some changes during the system development cycle (e.g. coming from regulatory tightening, partner entry and/or withdrawal, etc.) can be performed early in the design process and knowledge can be better capitalized to refine the product strategy in its whole from one implementation project to another.

Despite numerous success stories, in particular, in the most advanced systems engineering industries such as defense and aerospace, many industries still struggle to implement systems engineering practically (Bretz, Kaiser, and Dumitrescu 2019; Kiniry et al. 2022).

In addition to budgetary and socio-organizational difficulties linked to change management, one of the major pitfalls often encountered is to limit the management of requirements to the documentary aspect. Technical contributors then perceive requirement management as an additional task to their usual engineering activities and with a relatively poor added value at the very limited time scale of their responsibility in the project compared to the lifespan of the system or even the company. In the worst case, this can generate a certain disillusionment and at least partial disengagement of some of the contributors.

When verification and validation of requirements are taken into account correctly in the organization and in the projects, the second flaw lies in the difficulty of finding "off-the-shelf" software solutions to handle requirements "from end to end" during the system lifecycle. In particular, beyond documenting the traceability of requirements and their theoretical correspondence to design elements (such as requirement management tools like IBM Doors, Polarion, etc.), using requirements as a guide for the development process requires the ability to capitalize this kind of industrial constraints in the form of models to make this knowledge usable by a computer (i.e. calculable) and to allow the automation of a certain number of tasks such as checking the consistency of a set of requirements, verifying the compatibility of a solution with a set of regulations, studying the impact of changes in the specifications or in the design, etc.

As defined by INCOSE in (SEBoK v2.11 2024), a requirement is a "*statement that identifies a system, product, or process characteristic or constraint, which is unambiguous, clear, unique, consistent, stand-alone (not grouped), and verifiable, and is deemed necessary for stakeholder acceptability*" and six verification methods are usually acknowledged:

1. *Inspection* requires a human sense or a simple measurement method to examine the object studied once it exists.
2. *Test* consists in performing some verifications on the existing object, often with dedicated instrumentation, and under specific controlled conditions.
3. *Demonstration* checks the desired characteristics of the existing object under its *classical* operating conditions.
4. *Sampling* tests also characteristics, but not only on one realization of the object studied but on a sample of several realizations.
5. *Analogy* uses the similarity of the object studied with elements for which the desired characteristics have already been proven.
6. *Analysis* shows theoretical compliance of the object studied using analytical evidence based on mathematical reasoning (calculation, modeling and / or simulation).

The article focuses here on the verification method based on analysis, which is the only option one can have for checking objects early in their design process or when testing or demonstration in real-life conditions is not possible (e.g. for cost reasons) or even not desirable (e.g. for safety reasons). Several approaches already exist in the literature to formalize requirements and their verification such as LTL (Linear Temporal Logic) and CTL (Computation Tree Logic) (Baier and Katoen 2008) , timed (Alur 1999) and hybrid (Henzinger 2000) automata or UML/SysML state behavioral diagrams (OMG 2017; OMG 2025b). (Bouskela, Buffoni, et al. 2023) explains why existing solutions are not really suitable for complex systems with strong physical aspects, the origin of the Common Requirement Modeling Language (CRML) from ITEA MODRIO project previous work's on the FORM-L language and how such a new language separate from Modelica could be a possible solution. In short, the existing formal requirements modeling methods have the following disadvantages: they lack of object-orientation, have difficult mathematical syntax, often do not deal with probabilistic aspects and, most importantly, tend to use abstractions of the system in the form of state machines, which already express a kind of a behavior and is not appropriate to correctly deal with systems with strong physical aspects that evolve continuously over time.

The novelty of the current paper is to show the recent progress made for supporting CRML in OpenModelica and how this new feature can practically help newcomers automating the verification of some temporal requirements with the use of Modelica/FMI (or more largely black box) models.

Section 2 briefly presents the CRML language and the associated methodology to verify requirements through the simulation of solution models. Section 3 provides details on how the continuous- and discrete-time domains are handled to express dynamic requirements in CRML. Section 4 introduces the Traffic Light System (TLS) used as a common thread example to illustrate the CRML approach. Section 5 describes the current tooling in OpenModelica. Section 6 concludes with some perspectives for improving the overall toolchain and its potential integration into a larger (Model-Based Systems Engineering) MBSE framework.

2 CRML in a Nutshell

CRML is a language for verifying temporal requirements on systems with strong physical concerns and for which the dynamical interactions with its environment and interfaced systems are of most importance.

The main goal of CRML is to be a high-level language enabling the definition of requirements in quite readable but computable expressions and serving as a pivotal format capable of targeting different verification engines either by simulation (as documented here with its integration in OpenModelica) or by formal proof (future work not documented here about connection with model checking approaches).

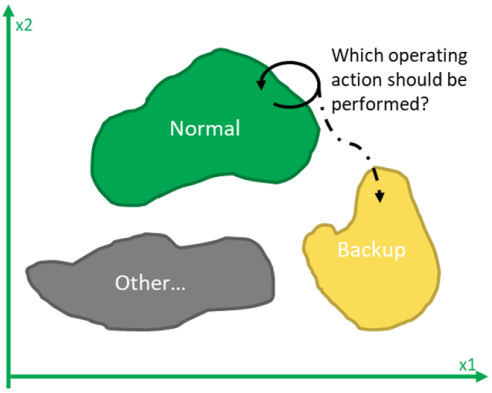

Figure 1. A typical realistic dynamic requirement.

The following paragraphs briefly recap how a requirement could be expressed and verified using CRML. Appendix gives a quick overview of the CRML built-in elements and most useful operators. Interested readers can refer to the online tutorial (Buffoni et al. 2023) and the language specifications (CRML v1.2 2023) for more details.

2.1 Requirement Expression

A requirement in CRML is defined as an expression combining up to 4 items:

- a **condition** to be checked;
- a **spatial locator** indicating on which object the condition has to be verified;
- a **time locator** defining when the condition has to be satisfied;
- (optionally) a **statistical target** to indicate with which performance the condition has to be satisfied.

A CRML requirement is therefore of a "special" Boolean built-in type, here called Boolean4 stating that a requirement value at instant `t` can vary among the set `{true, false, undefined, undecided}`. This is illustrated with the Traffic Light System example of Section 4. The theoretical rationale for introducing these 4 values could be found in (Bouskela and Jardin 2018) where a new temporal logic algebra is defined to rigorously compute the value of requirement over continuous-time periods and to enable the combination of requirements together.

One may consider that checking requirements for physical systems always amounts more or less to checking whether main variables of interest do not exceed thresholds. The main difficulties that make the handling of requirements more complex are as follows:

DOI 10.3384/ecp218971

Table 1. CRML pattern for a typical realistic dynamic requirement.

Req.	*Natural Language*	*CRML Formalization*
r1	During operation, the system should stay within its normal domain.	`Requirement r1 is 'during' inOperation 'ensure' inNormalDomain;`

r2	If the system fails to stay within its operating domain, then it should not stay outside of its normal domain for more than x minutes.	`Requirement r2 is 'during' inOperation 'ensure' (not inNormalDomain 'implies' r2_outside);`
		`Requirement r2_outside is 'during' [inNormalDomain 'becomes false', inNormalDomain 'becomes false' + x mn] 'check at end' b;`
		`Boolean b is inOperation 'implies' inNormalDomain;`

r3	The system should not go outside its normal domain more than n times per year.	`Requirement r3 is 'count' ((b 'becomes false') on [b 'becomes false', b 'becomes false' + 1 year]) <= n;`
r4	If (r1 and r2 and r3) fail, then the system should go to its backup domain within y minutes as soon as the failure is detected.	`Requirement r4 is not (r1 and r2 and r3) 'implies' 'during' [(r1 and r2 and r3) 'becomes false', (r1 and r2 and r3) 'becomes false' + y mn] 'check at end' inBackupDomain;`
R	(**The "real" complete requirement:**) During system operating life, r1 and r2 and r3 and r4 should be satisfied with a probability of success of p.	`Real prob is estimator Probability (r1 and r2 and r3 and r4) at inSystemOperatingLife 'becomes false';` `Requirement R is 'during' inSystemOperatingLife 'check at end prob' > p;`

- The authorized values vary dynamically depending on the system operating modes and the periods of time.
- Time response and/or probabilistic criteria should be added to make the requirements achievable by real systems.
- The number of requirements is rapidly growing (due to the number of stakeholders, the complexity of the system/subsystems/components, and the possible evolution over the system lifespan).

The CRML language enables alleviating these problems by allowing the formal expression (Table 1) of realistic dynamical requirements (Figure 1).

Listing 1. Example of user-defined operator in CRML

```
Operator [ Periods ] 'during' Boolean b =
    Periods [ new Clock b, new Clock not b
    ];
```

The user can enhance the readability of CRML statements by defining his own operators with a chosen syntax simply by combining built-in operators. For example, the `during` operator in Table 1 has been defined as a time period constructor from a Boolean input (Listing 1). This `during` operator is part of a library known as FORM-L used in CRML to define time periods and conditions constructors that are frequently encountered (see Appendix for more examples of custom operators).

2.2 Requirement Verification

As stated above, a CRML requirement is a Boolean4 variable. Its value is: `true` (resp. `false`) if the condition is satisfied (resp. violated) for the defined time locator, `undefined` if the time locator has not been tested over the test scenario, `undecided` if the test scenario has finished before a decision could be made (i.e., before the condition has been violated or before the end of the time locator).

The value of a CRML requirement is computed from verification models made of four different kinds of model (Figure 2):

- the *behavioral model* capturing the behavior of design solutions;
- the *requirement model* defining envelopes of acceptable behaviors;
- the *binding model* mapping the variables of the two previous models and processing the required conversions (the functional variables mentioned in the requirements could have different naming convention and units than the physical quantities computed in the behavioral model);
- the *test model* specifying the operating scenarios to be studied.

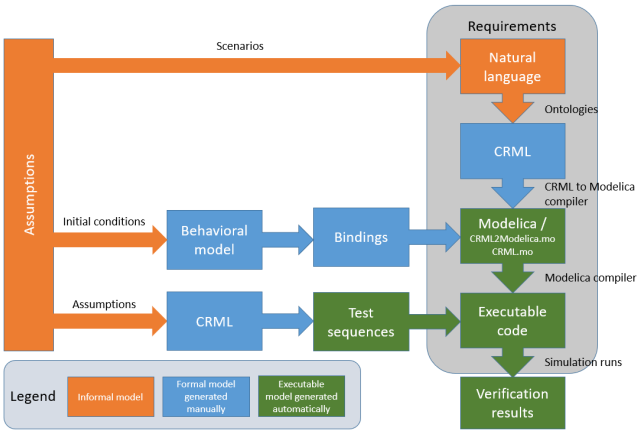

Figure 2. Requirement verification workflow.

3 Time Management in CRML

The main temporal constructs in CRML are Clock, Event, Period and Periods.

The CRML2Modelica library contains the definitions of basic types in CRML, including events and periods. These definitions are split into two parts, a record structure that can then be passed along an argument in subsequent equations, and a model containing the equations for the record.

In Modelica Events are represented by a trigger (a 4-valued boolean) and a time of occurrence.

A single period, as shown in Listing 2 is defined by opening and closing events, while a set of periods is defined by clocks or sets of opening and closing events (leading to possibly overlapping time periods).

For example, a new Period instance is generated and instantiated as follows:

Listing 2. Period instance creation in Modelica

```
record CRMLPeriod
 Boolean isLeftBoundaryIncluded "If true,
     the left boundaries of the time
     periods are included";
 Boolean isRightBoundaryIncluded "If true,
     the right boundaries of the time
     periods are included";
 public
  Types.Event start_event;
  Types.Event close_event;
  Boolean is_open;
end CRMLPeriod;

model CRMLPeriod_build
 CRMLPeriod P;
 equation
 P.is_open =
  if( (CRMLtoModelica.Functions.
      Event2Boolean (P.start_event) ==
      Boolean4.true4) and not (
      CRMLtoModelica.Functions.
      Event2Boolean (P.close_event)==
      Boolean4.true4))
  then true else false;
```

```
end CRMLPeriod_build;
```

4 Traffic Light Use-Case

The purpose of the Traffic Light example is to illustrate how CRML could be used in the OpenModelica framework from the requirement formalization phase to verification by simulation and analysis phases.

This example was chosen to show, on a system known to all, how some realistic requirements could be handled in a very practical way with CRML and OpenModelica. It is deliberately simplified to focus on the software tooling part.

The mission of the Traffic Light System (TLS) is to avoid accidents and fluidize traffic by minimizing congestion. The main functions are, respectively: F1) give clear instructions to each vehicle and F2) prioritize crossing durations based on road traffic. The corresponding requirements could therefore check that *"at most only one light should be on"* and *"the time spent in a light mode must be between two limits"*. A possible formalization in CRML is given in Listing 3.

Listing 3. Requirements on the Traffic Light System

```
model TrafficLightSpecification is
 // Import of libraries
 flatten {ETL, FORM_L}
 union {
 // List of external variables
 Boolean red is external;
 Boolean yellow is external;
 Boolean green is external;

 Boolean operation is external;
 Boolean night_mode is external;
 Boolean day_mode is not night_mode;

 // Definition of requirements
 // req0: "During operation, no more than
    one light should be on (a flashing
    mode could be specified later)"
 Boolean{} lights is {red, yellow, green};
 Integer n_lights_on is card { filter
    lights (element == true) };

 Requirement req0 is
  ('during' operation) ('check anytime' (
     n_lights_on <= 1) );

 // Day_mode
 // req1: "After green, next step is yellow
    "
 Requirement req1 is
  (( 'after' ( green 'becomes true' ) '
     before' ( yellow 'becomes true' ))
     while day_mode)
  ('check count' (red 'becomes true') '=='
     0);

 // req2: "Step green should stay active
    for at least 30 seconds"
 Requirement req2 is
  (( 'after' (green 'becomes true') 'for'
     30) while day_mode)
  ('ensure' green);

 // req3: "After green becomes active + 30
    seconds, next step should turn yellow
    within 0.2 seconds"
 Requirement req3 is
  (( 'after' (green 'becomes true' + 30) '
     for' 0.2) while day_mode)
  ('check at end' yellow);

 // Night_mode
 // req4: "During night, yellow should only
    be used"
 Requirement req4 is
  ('during' night_mode)
  ('check count' ( (red or green) 'becomes
     true') '==' 0);
 // req5: "During night, yellow should
    flash every 2 seconds"
 Requirement req5a is
  ('during' night_mode)
  ('check count' ( yellow 'becomes true') '
     <>' 0);
 Requirement req5b is
  ('after' ( yellow 'becomes true') 'within
     ' 2) while night_mode)
  ('ensure' yellow);
 Requirement req5c is
  ('after' ( yellow 'becomes true') 'for'
     2) while night_mode)
  ('check at end' not yellow);
 Requirement req5 is req5a and req5b and
    req5c;
};
```

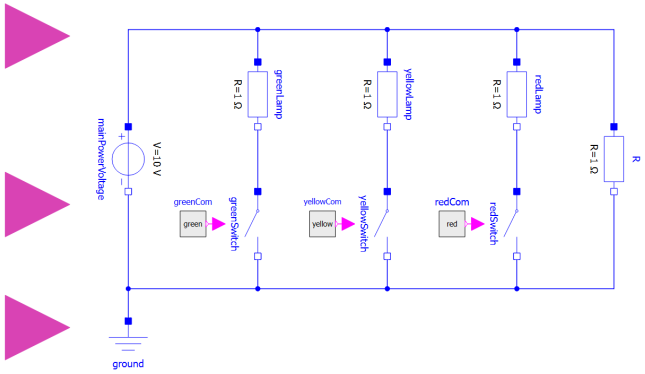

Figure 3. Traffic Light implementation as a circuit.

The physical behavior of TLS could be modeled as an electronic circuit that activates three different lights (Figure 3). The control part of TLS could be modeled in two different ways: either as a grafcet or as a finite-state machine using the synchronous built-in operators of the Modelica language as shown in Figure 4.

4.1 CRML Compilation

The CRML2Modelica compiler is a proof of concept compiler written in Java. It is open source and available on

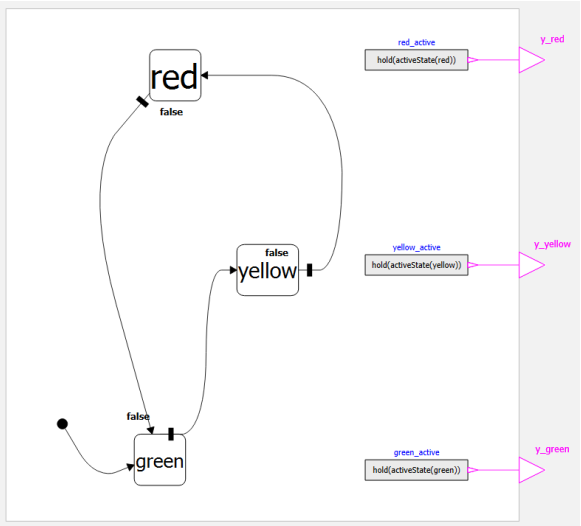

Figure 4. Traffic Light control implemented as a state machine.

GitHub [1]. Currently it supports almost all the Extended Temporal Library (ETL) library blocks which define all the operators required for computing Boolean4-status of a requirement.

The CRML2Modelica compiler goes through the CRML file once first, to retrieve all signatures of user-defined operators and category's definitions and then a second time translating all the definitions. In addition to temporal aspects, three CRML features require special handling: Boolean4, categories and sets.

Boolean4

Boolean4 is defined in Modelica as an enumeration as shown in Listing 4.

Listing 4. Boolean4 translation in Modelica

```
type Boolean4 = enumeration(undefined,
    undecided, false4, true4);
```

Categories

Categories are applied directly to the operator definitions, and the corresponding operators are replaced. For example, the operator `set to false` in Listing 5 is translated to Modelica as shown in Listing 6 and the operator `id` is replaced by `cte_false` as specified by the category `varying1`.

Listing 5. Category in CRML

```
Operator [ Boolean ]  'id'  Boolean b = b;
Operator [ Boolean ]  'cte_false'  Boolean
    b = false;
Category varying1 = { ('id', 'cte_false')
    };
Operator [ Boolean ] 'set to false' Boolean
     b = apply varying1 on ( 'id' b );
        ...
Boolean b_varying1_on_id_true is 'set to
    false' b_true; // value should be false
```

[1] https://github.com/OpenModelica/CRML

Listing 6. Category translation to Modelica

```
model 'set to false'
 output CRMLtoModelica.Types.Boolean4 out;
 input CRMLtoModelica.Types.Boolean4 b;
 'cte_false' 'cte_false0'(b=b);
 equation
 out ='cte_false0'.out;
end 'set to false';
```

Sets

Sets are handled as fixed size arrays in the current implementation, for sets with a known number of elements, the array size is set accordingly, for sets with an unknown size, the array size is set to a predefined buffer size. Periods are a special case of this and are currently mapped to a record with an array with a static size, but if a larger number of events is expected, the buffer size can be increased with a flag to the compiler.

In our Julia-based OpenModelica framework (Tinnerholm, Pop, and Sjölund 2022) we support automatic recompilation during simulation and one can increase/shrink the size of an array or change any other aspect of the model. An example of a `when` equation triggering such a change is given in Listing 7. Using this functionality in the future, we can make the translated Modelica code more flexible and more efficient as resizing can be tailored to the needs of each variable.

Listing 7. Dynamic Array Resize

```
when requestedSize > N then
  // Recompilation on parameter change
  recompilation(N /* what to change */,
      requestedSize + 100 /* value */);
end when;
```

4.2 Requirement Verification

A requirement model is verified for a behavior model and a scenario. In this paper we focus on Modelica, but as a requirement model can be exported as an FMU, it could be verified against any other FMU representing a behavioral model.

In order to identify the inputs from the behavioural model, CRML uses `external` variables, that are variables that do not need to be instantiated within the model. A list of external variables can be exported during compilation into a file. This list can then be fed into a semi-automated bindings algorithm for mapping requirements to the behavioural model.

A verification scenario that instantiates the requirement and behavioural models and connects them together can then be simulated and the results analysed.

The code generated for requirements is composed together with the unmodified Modelica model and the external variables in the CRML are bound to the Modelica variables. Usually this results in a balanced Modelica model but is certain cases, usually with badly specified CRML it might be possible to build invalid models.

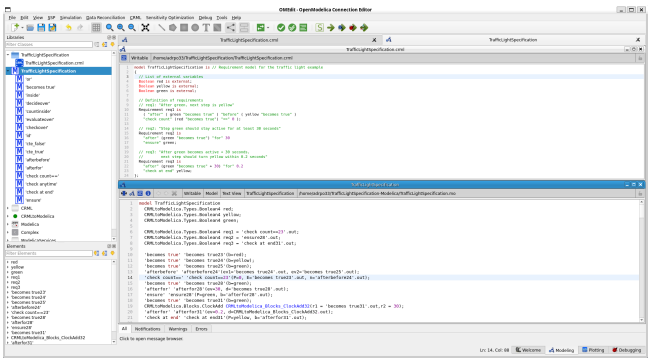

Figure 5. CRML file display in OMEdit and its Modelica translation.

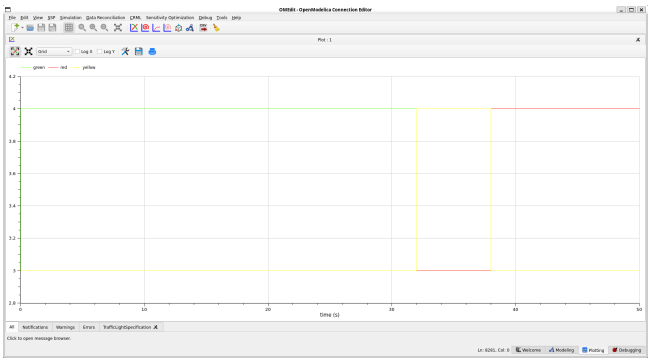

Figure 6. Simulation of the generated Modelica file corresponding to the original CRML file.

5 CRML Support in M&S tools

We have started integrating the CRML tools into OpenModelica. The CRML files can be loaded in the OpenModelica Connection Editor (OMEdit) and the text displayed with syntax highlighting, see Figure 5, top part. It is also possible to load entire directories containing CRML files.

The CRML files can be translated to Modelica from OMEdit via menu actions (via right click) and the translated .mo files are automatically loaded into OMEdit, see Figure 5, bottom part.

As expected, the generated Modelica files can also be simulated, as in Figure 6.

To tell OMEdit where it can find the tools and required Modelica libraries for the CRML translation a settings dialog is used, see Figure 7. If additional Modelica libraries are needed, one can specify them here.

The CRML compiler also specifies a test suite with about 150 test cases based on the ETL and FORML library blocks as well as more complex use-cases. This test suite can be run command line or from OMEdit and generates a test report that allows to evaluate coverage progress. Currently around 30% of the tests are successful as the test suite also includes features that are not yet supported in the compiler.

Using CRML files as text is only the first integration step in OpenModelica. Work is ongoing to support a

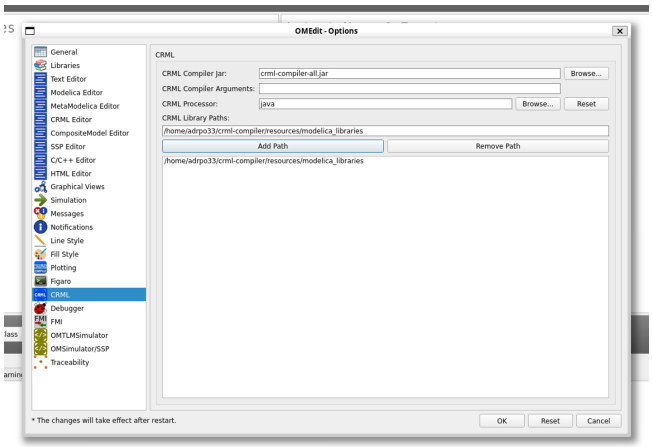

Figure 7. CRML tools settings in OMEdit.

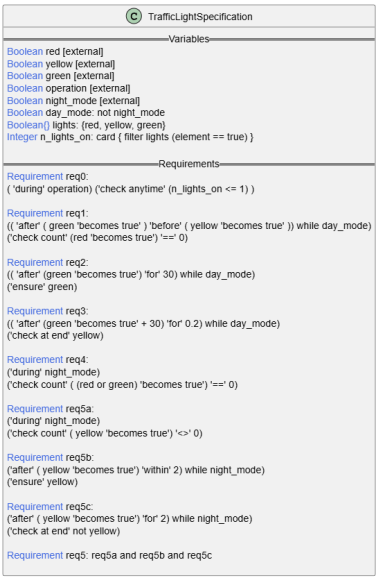

Figure 8. A graphical representation for CRML for the given example.

graphical representation language for CRML similar to UML as proposed by (Mazurié 2023), see Figure 8.

6 Conclusion and Future Work

CRML tooling is progressing to enable the formalization of realistic dynamic requirements of complex systems. Integration into OpenModelica enables a first step towards an easy access for the Modelica/FMI community to check requirements with simulation means. In order to be applicable to industrial-level use cases, future work plans to improve the toolset in several areas:

- Improvement of the user interface to visualise requirements simulation results as dashboards and structured html pages.
- Integration with the ReqIF standard (OMG 2025a) to provide a native gateway to the requirements management and traceability tools. This is in particular

needed to handle the metadata associated with the lifecycle of each requirement, coordinate the teams issuing requirements and deduce which set of requirements is valid and must be verified at a given point in time during the project.

- Alignment with the emerging SysML v2 standard (OMG 2025b) to structure and better visualise a large volume of requirements.

Other work is also planned, notably on the use of structural analysis techniques to statically verify consistency between CRML requirements and the introduction of the concept of Assume/Guarantee contract to facilitate the generation of test scenarios from CRML constraints.

7 Acknowledgements

The CRML initiative has initially been supported by the ITEA3 EMBrACE project, as well as National Research, Development and Innovation Fund of Hungary, financed under the [2019-2.1.1-EUREKA-2019-00001] funding scheme. It is continued and improved within the Open Source Modelica Consortium partly through EDF funding.

Key Concepts

Requirements

A requirement is a `Boolean4` combining up to 4 items:

```
R = (Where) (When) (What) [How well]
```

Multiple requirements can be combined according to the algebra defined on the `Boolean4` type.

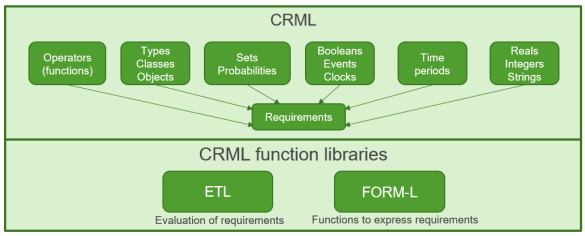
b	true	false	undecided	undefined
not b	false	true	undecided	undefined

b1 and b2	**true**	**false**	**undecided**	**undefined**
true	true	false	undecided	true
false	false	false	false	false
undecided	undecided	false	undecided	undecided
undefined	true	false	undecided	undefined

Syntax

Notation

```
[ expr ] ..... optional expression
{ expr } ..... expression repeated
expr_1 | ... | expr_n .... n expressions
'char' ..... character
"string" ..... string
```



Expressions

```
[ [type] ident is] [ value |
external ] [ ; | , ] ..... expression
// This is single-line ..... comment
/* This is a multi-line */ .. comment
```

Keywords

Special values: false, true, undecided, undefined, time
Special characters: (,),[,], {, }, ,, ;, ., ", ', E, e, //, /*, */, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9
Operators: =, +, -, *, /, <, <=, >, >=, ==, <>, ^, acos, alias, and, asin, associate, at, card, constant, cos, duration, element, else, end, estimator, exp, extends, external, filter, flatten, forbid, if, integrate, is, log, log10, mod, new, not, on, or, parameter, partial, proj, redeclare, sin, start, then, tick, time from, union, variance, while, with

Architecture

Real Operators

`Real x is decimal_value ....` constructor
`Real x is new Real n ...` constructor from *Integer n*
`x1 + | - x2 .....` binary addition | subtraction
`+ | -x1 ..........` unary addition | subtraction
`x1 * x2 .....` multiplication
`x1 / x2 .....` division
`x1^x2 .....` exponentiation

`if b then x1 else x2 ..........` if-clause
`x1 at c .....` value at *Clock c*
`duration b on P .....` duration during which *Boolean b* is true over a *Period P*
`e2 - e1 ...` elapsed duration between two *Event*
`time frome e1 ...` elapsed time from an *Event*

Integer Operators

`Integer n is integer_value` constructor
`Integer n is new Integer x` constructor from *Real x*
`n1 + | - n2 .....` binary addition | subtraction
`+ | - n1 .....` unary addition | subtraction
`n1 * n2 .....` multiplication
`n1 / n2 .....` division
`n1^n2 .....` exponentiation

`if b then n1 else n2 ..........` if-clause
`n1 at c .....` value of *Integer n1* at *Clock c*
`card c .....` number of ticks of *Clock c*
`card S .....` number of elements of *set S*

String Operators

`String s is string_value ...` constructor
`String s is new String x ...` constructor from *Real* | *Integer* | *Boolean* x
`s1 + s2 .....` concatenation

Boolean Operators

`Boolean b is true | false | undecided | undefined .....` constructor
`Boolean b is new Boolean c` constructor from *Clock c*
`b1 and b2 .....` conjunction
`b1 or b2 .....` disjunction
`not b .....` negation
`b1 * b2 .....` filter
`b1 + b2 .....` accumulation
`integrate b1 on P` integration over a *Period*
`b1 == b2 .....` equality
`if b then b1 else b2 ..........` if-clause
`b1 at c .....` value at *Clock c*
`x1 > x2` strictly greater than for *Real* | *Integer xi*
`x1 < x2 ...` strictly less than for *Real* | *Integer xi*
`n1 >= | <= n2 .....` comparison of *Integer ni*
`n1 <> n2 .....` different from for *Integer ni*
`x1 == x2 .....` equality for *Integer* | *Type xi*
`e1 < | <= e2 ....` (strictly) before for *Event ei*
`e1 > | >= e2 .....` (strictly) after for *Event ei*

Event Operators

`Event e is new Event b .` constructor from first occurence of *Boolean b*
`e1 proj c .....` projection on ticks of *Clock c*
`e1 proj(d) c ..` projection for duration *Real d*
`e1 + d .....` delay of *Real d*
`tick c .....` current tick of *Clock c*
`p start .....` opening event of *Period p*
`p end .....` closing event of *Period p*

Clock Operators

`Clock c is new Clock b .` constructor from *Boolean b*
`c1 proj c2 ....` projection on ticks of *Clock c2*
`c1 proj(d) c2 .` projection for duration *Real d*
`c1 + d .....` delay of *Real d*
`c1 filter cond tick .....` filter

`c1 and c2` ..... conjunction
`c1 or c2` ..... disjunction

Period and Periods Operators

`Period P is [|] e1, e2 [|]` constructor from *Event*
`Periods P is {P1, P2, ..., Pn}` . constructor from a set of *Period*
`Periods P is [ | ] c1, c2 [ | ]` constructor from *Clock*
`P2 while P1` ..... filter

Probability Operators

`Probability px is new Probability b` ..... constructor from *Boolean b*
`Probability px is new Probability b at c` ..... constructor at ticks of *Clock c*
`estimator px` ..... estimator
`estimator variance px` . variance estimator

Sets Operators

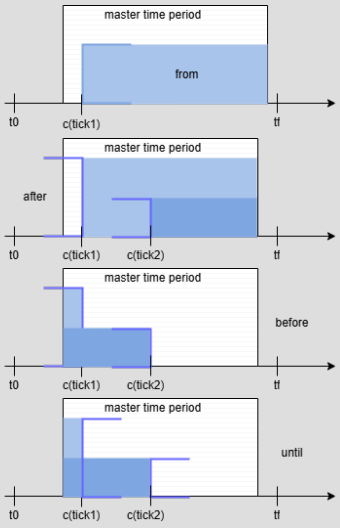
`[T{} S is]{u1,...,un}` .. non-empty typed set
`[T{} S is]{}` ..... empty typed set of type T
`T{} S is {expr}` special set with elements of different types (=*class, model, library, or package*)
`S1 union S2` ..... union of sets
`flatten S1` ..... flattening of a set
`filter(S1 cond (element))` ..... filter

Customisation

Type Constructors

`type T2 is (T1 x is value(a1,..., an)){Type D1, ...Dn; D1 a1 [is value];...}` ..... custom type
`partial type T is value` .... partial type
`T1 alias s` .... renaming type T1 with *String s*
`T1 forbid f1,...,fn` forbidding operators *fi*

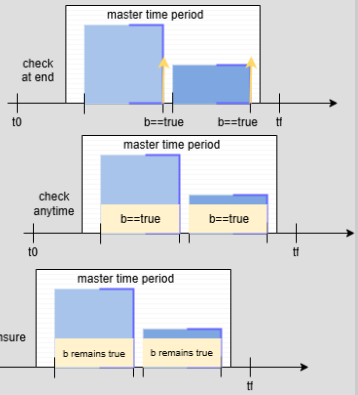
Operator Constructors



`Operator [T] 'w1' T1 u1 ... 'wn' Tn un = expr` .. custom operator 'w1w2wn' on inputs ui of type Ti
`Template w1 u1 ... wn un = expr` .... custom operator 'w1w2wn' on *Boolean*

Libraries

ETL Operators for Evaluating Booleans



`c 'inside' p` .....
`b 'becomes true'` .....
`b 'becomes false'` .....
`b 'becomes true inside' p` .....
`b 'becomes false inside' p` .....
`'count' c 'inside' p` .....
`'decide' b 'over' p` . decision event, could be violation of *Boolean b* or end of *Period p*
`'evaluate' b 'over' p` accumulated value over a *Period p*
`'check' b 'over' P` accumulated value over a set of *Periods*

FORML Operators for Expressing Periods

`'from' c` .....
`'after' c` ....
`'before' c` ..
`'until' c` ....
`'during' b` .....
`'when' c` .....

FORML Operators for Expressing Conditions

`'check at end'`

Abstract

This article presents the development of a synthetic thermal digital twin designed to reproduce the temperature distribution within the asphalt layers of a pavement system. At the core of the digital twin is a numerical model that solves Fourier's heat conduction equation using a finite difference method, enabling the simulation of transient heat transfer across multiple material layers.

The digital twin architecture is organized into three modular layers: the physical twin, which includes real-time temperature measurements from embedded sensors (synthetically simulated in this study); the twinning layer, which synchronizes physical and virtual data through feedback control using proportional-integral (PI) controllers; and the virtual twin, which integrates material properties, heat fluxes, and environmental conditions to replicate pavement thermal behavior.

The numerical model was validated using climate data and surface temperature measurements collected over a one-year period from a reference instrumented pavement in Costa Rica. In addition to radiative, convective, and conductive heat fluxes, the model accounts for the cooling effects of rainfall and subsequent evaporation—factors that are particularly relevant in tropical climates. The results demonstrate the capability of the digital twin to capture both long-term thermal trends and short-term responses to environmental events.

Keywords: Digital Twin, Asphalt Concrete, Pavement, Heat transfer

1 Introduction

1.1 Background

Digital transformation has changed the way infrastructures are designed, built and maintained (Barricelli, Casiraghi, et al. 2021). This transformation has been made possible by the integration of cyber-physical systems, which have paved the way for the development and use of digital twins (DTs). DTs are virtual replicas of physical assets that facilitate real-time data monitoring and analysis, thus enabling performance optimization and early detection of potential problems before they become critical issues. This transformative process has been enhanced by the rapid advancement of cutting-edge technologies, including advanced sensors, Internet of Things devices, artificial intelligence and big data analytics. These technologies empower DTs to provide highly accurate and predictive information on critical infrastructure performance and maintenance requirements.

The digitization of physical transportation infrastructures is currently in its early stages compared to other civil engineering infrastructures (Torzoni et al. 2023), facing several challenges that hinder its progress. One of the main obstacles encountered in the digitization process is the scarcity of comprehensive sensor data available for existing road network. This lack of data poses a major barrier to the creation of accurate DTs that can faithfully reproduce real road conditions. In addition, the absence of accurate numerical models further compounds the problem, as it can lead to erroneous predictions and impede the overall effectiveness of digitization efforts.

However, despite these challenges, digitization of transportation infrastructure holds immense potential to revolutionize the entire lifecycle of road systems, from design and construction to ongoing maintenance. The implementation of digital twins and the use of real-time data can enable proactive maintenance strategies, allowing early detection and resolution of potential problems before they escalate. This can improve safety, reduce downtime and increase operational efficiency. In addition, the digital transformation of roads facilitates optimized resource allocation through data-driven decision making, resulting in cost savings and improved sustainability.

1.2 Digital twin concept for road infractructures

The concept of a DT for road infrastructure is centered around the physical asset, which in this case is the pavement structure. Pavement structures can be classified into

two main categories: flexible pavements, which are constructed using asphalt concrete (AC) materials, and rigid pavements, which are made with cement-based materials. The present work, however, focuses solely on flexible pavements.

The structural integrity of flexible pavements is significantly influenced by the dynamic stresses and strains induced by vehicular traffic and environmental loads, such as temperature fluctuations, moisture, and precipitation. Furthermore, the materials utilized in flexible pavement construction undergo aging processes that can lead to a modification of their mechanical properties over time. Hence, the physical characteristics of AC pavements are time-dependent and can experience substantial variations in response to changes in external factors. Therefore, to ensure the integration of the pavement structure into a DT, it is crucial to incorporate embedded sensors capable of continuously monitoring and detecting changes in critical parameters. These parameters may include vibrations, strains, humidity, temperature, and other relevant variables that affect the structural performance of the pavement.

The data stream derived from the sensors provides a fundamental foundation for creating a physics-based computational model, commonly referred to as the digital twin model (DTM) or virtual twin. The DTM closely replicates the real-time state of the physical structure. The concept of DT involves creating a dynamic feedback loop between the physical twin and its corresponding virtual twin.

In order to facilitate the continuous feedback process between the physical and virtual systems in a DT, it is necessary to establish a physical-to-virtual connection. This connection utilizes the data collected by sensors and applies it to update the parameters of the DTM. This process enables the DT to remain in synchronization with the physical system, allowing for a deeper understanding of the system's behavior and the ability to predict and prevent potential issues.

Figure 1 illustrates the digital twin concept for asphalt pavements. The physical twin (i.e., physical asset) on the left represents the real-world pavement infrastructure equipped with sensing technologies, while the virtual twin on the right corresponds to the computational model, developed using data-driven, numerical, or hybrid modeling approaches. The cyclic interaction—referred to as twinning—establishes the physical-to-virtual connection, enabling the virtual model to continuously reflect changes in the physical system.

1.3 Objective and Methodology

The objective of this paper is to demonstrate the feasibility of implementing a thermal digital twin for asphalt pavements using the Modelica language. The focus lies on the development of a numerical model capable of accurately reproducing the transient thermal behavior of a multi-layered pavement structure. This model is a key component of a broader modular digital twin framework

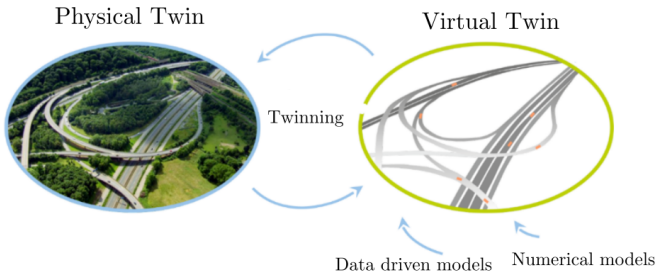

Figure 1. Digital twin concept of an asphalt pavement.

designed to integrate both thermal and mechanical aspects of pavement systems. In the present study, only the thermal subsystem is considered, which has been fully implemented in OpenModelica. The mechanical component—developed separately in Fortran and coupled to the thermal model via a Python wrapper—is acknowledged but remains outside the scope of this paper.

The thermal model is based on the one-dimensional form of Fourier's heat equation and is solved using a finite difference scheme with small time steps to capture transient heat flow through the pavement layers. The model receives surface and environmental heat fluxes as input and outputs the internal temperature distribution.

A proportional-integral (PI) controller forms the core of the twinning mechanism. It dynamically adjusts the surface albedo to minimize the error between the measured and simulated surface temperatures. This feedback process enables real-time synchronization between the physical twin—comprising embedded surface sensors—and the virtual thermal model.

Model validation was performed using data from a reference pavement located in the central region of Costa Rica. Surface temperature measurements collected over a one-year period were compared against simulation outputs. The model was further applied to forecast temperature distributions and to assess the thermal response of the pavement under typical tropical conditions. Special attention was given to the cooling effects produced by rainfall events, which were modeled through the inclusion of advective and evaporative heat transfer mechanisms.

2 Thermal digital twin architecture

The proposed architecture consists of three interconnected layers: the *physical twin*, the *twinning layer*, and the *virtual twin*. This multi-layer structure enables real-time synchronization between physical measurements and numerical simulations. Figure 2 illustrates the high-level system layout, highlighting the interaction among the three layers and their respective components.

The Digital Twin is implemented herein as a purely synthetic system. Both the Physical and Virtual Twins are modeled within the same simulation environment. Since no real hardware is involved in this implementation, communication protocols and latency are not relevant to the

DOI
10.3384/ecp218981

current setup. However, in a future deployment involving real pavement sensors, the communication interface between the physical system and the Modelica-based Virtual Twin would become crucial. Although thermal systems generally evolve slowly, latency could still impact the effectiveness of control recommendations or predictive maintenance alerts derived from the twin.

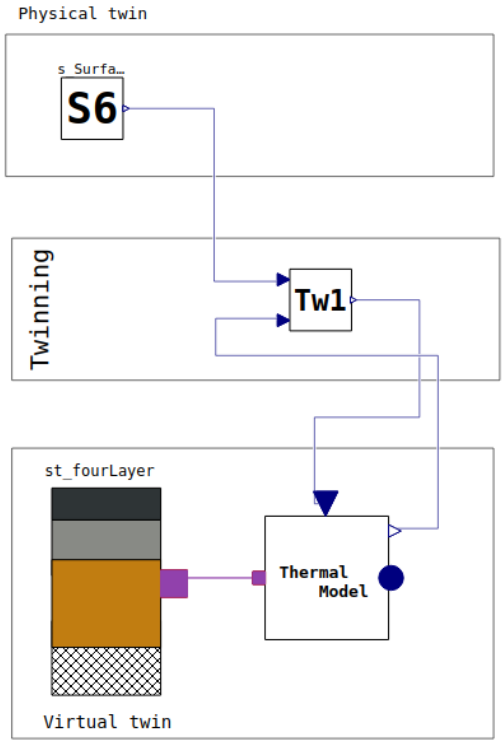

Figure 2. High-level architecture showing the physical twin, twinning layer, and virtual twin.

The model architecture has been developed in a modular fashion, enabling users to easily configure or extend the framework with their own use cases, as demonstrated in the package structure shown in Figure 3. It can be seen that the top-level package `DigitalTwinRoad` contains several subpackages, each dedicated to a specific aspect of the modeling framework, including sensors, numerical models, pavement structure, materials, traffic, and twinning logic.

This modular organization allows users to define and manage each component independently. For instance, the present example utilizes elements from the `Sensors` package to create six different environmental and pavement-related input components, including ambient temperature, solar radiation, vapor pressure, wind speed, cloud coverage, and surface temperature sensors. This flexibility supports a broad spectrum of applications, including academic experimentation, applied research, and real-world deployment scenarios.

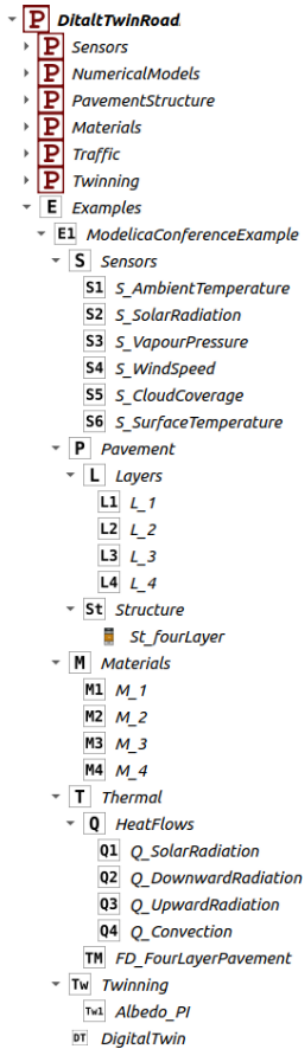

Figure 3. Modelica package structure of the digital twin road framework.

2.1 Physical Twin

The physical twin comprises sensors embedded in or positioned on the pavement structure. In this study, the primary physical input is provided by the `S6` component, which may be either a surface-mounted temperature sensor or a thermal camera. This device measures the real-time surface temperature of the pavement and transmits the data to the digital twin system for synchronization.

2.2 Twinning Layer

The twinning layer serves as the intermediary interface between the physical and virtual twins, enabling closed-loop communication and real-time synchronization. This layer is implemented using a Proportional-Integral (PI) controller. The PI controller receives two inputs: the measured surface temperature from the physical sensor (`S6`) and the corresponding temperature calculated by the virtual twin. It computes the error between these two values and generates an output signal (`outputSignal`) that is used to dynamically adjust the surface albedo, which di-

rectly influences the calculation of solar heat input to the pavement surface and controls the energy absorbed in the thermal model. This feedback mechanism minimizes discrepancies and ensures that the virtual twin consistently aligns with the behavior of the real pavement system.

2.3 Virtual Twin

The virtual twin is responsible for simulating the internal thermal behavior of the pavement system. It consists of two primary components: (1) the pavement structure model and (2) the numerical model for heat transfer.

2.3.1 Pavement Structure

The pavement structure is represented using a layered configuration defined in the `PavementStructure` and `Materials` packages. Each layer corresponds to a physical segment of the pavement—such as surface, binder, base, and sub-base—and is characterized by specific material properties including thermal conductivity, density, specific heat capacity, and thickness. These parameters define the thermal inertia and conduction capacity of each layer, forming the physical foundation for the thermal simulation.

2.3.2 Numerical Thermal Model

The second component of the virtual twin is the thermal model, which numerically solves the one-dimensional transient heat conduction equation using a finite difference method. The model is based on the Fourier differential heat equation without internal heat generation (Adam et al. 2023):

$$\frac{\partial^2 T}{\partial z^2} = \frac{\rho \cdot c}{k} \frac{\partial T}{\partial t} \tag{1}$$

where T is the temperature within the pavement (K), z is the pavement depth (m), t is time (s), k is the thermal conductivity ($\mathrm{W \cdot m^{-1} \cdot K^{-1}}$), ρ is the density ($\mathrm{kg \cdot m^{-3}}$), and c is the specific heat capacity ($\mathrm{J \cdot kg^{-1} \cdot K^{-1}}$).

Figure 4 shows the Modelica implementation of this thermal model. The core numerical solver is encapsulated in the `FD4` block, which receives as inputs four distinct surface heat fluxes:

- `Q1`: Solar radiation (Alavi, Pouranian, and Hajj 2014)
- `Q2`: Downward longwave radiation (Hall et al. 2012; Bliss 1961)
- `Q3`: Upward longwave radiation
- `Q4`: Convective heat transfer (Wolfe, Heath, and Colony 1983; Vehrencamp 1953; Bentz 2000)

Owing to the modular design of the model architecture, additional heat flux components—such as latent heat losses due to evaporation or heat exchange caused by rainwater infiltration—can be seamlessly integrated into the thermal model.

These heat fluxes are summed and applied at the surface boundary of the finite difference grid. The model outputs the surface temperature (`T_surface`), which is compared against physical sensor data to drive the feedback mechanism in the twinning layer.

Additionally, the model computes the coefficients of a fifth-degree polynomial used to approximate the in-depth temperature distribution within the pavement. This polynomial expression takes the form:

$$T(z) = a_0 + a_1 z + a_2 z^2 + a_3 z^3 + a_4 z^4 + a_5 z^5 \tag{2}$$

where z is the depth (m) and a_0 through a_6 are coefficients determined dynamically during simulation, provided as output via the `aCoeffs[5]` port.

The fifth-degree polynomial was chosen to ensure proper fitting of the in-depth temperature distribution within the pavement structure. This level of polynomial provides sufficient flexibility to capture the nonlinear temperature gradients that develop due to surface heating and thermal diffusion through layered materials.

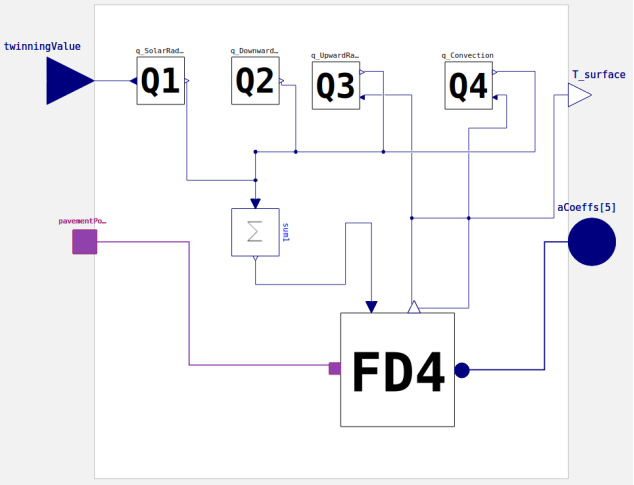

Figure 4. Modelica implementation of the thermal model using finite difference approximation in the `FD4` component.

3 Example Application: Instrumented pavement in Costa Rica

This case study presents the application of the proposed digital twin model to a real asphalt pavement structure located along Route 35 in the canton of San Carlos, Alajuela province, Costa Rica (Figure 5).

3.1 Pavement structures, climatic conditions and material properties

The pavement structure consists of four layers: the top layer is a polymer-modified asphalt concrete with a thickness of $d_1 = 60$ mm. The second layer is a conventional (unmodified) asphalt concrete with a thickness of $d_2 = 70$

DOI 10.3384/ecp218981

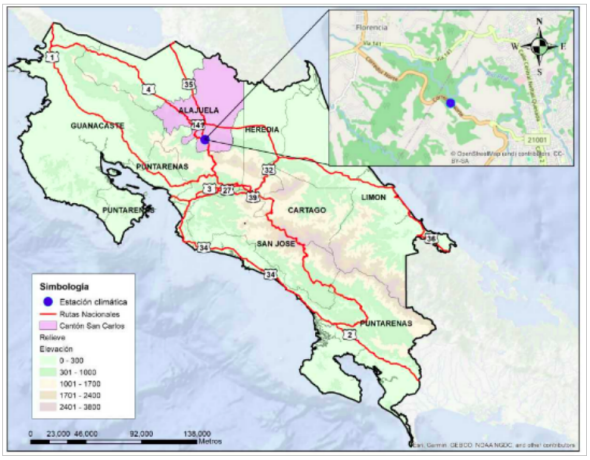

Figure 5. Location of the reference pavement along Route 35, San Carlos, Alajuela, Costa Rica.

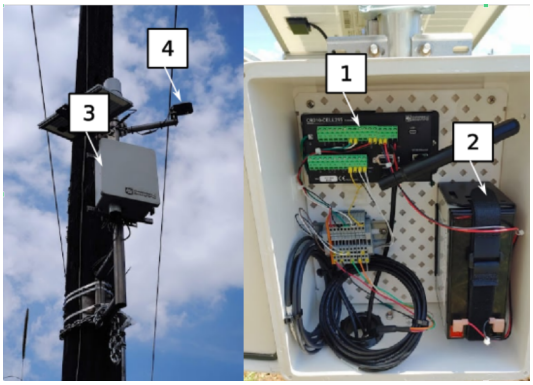
mm. The third layer is a hydraulically stabilized granular base with a thickness of 240 mm, and the fourth is a granular sub-base with a thickness of 300 mm.

Meteorological data required for the numerical thermal model were obtained from a weather station installed on the roadside adjacent to the test section (Figure 6). The station is equipped with a data acquisition system capable of managing multiple sensors, configuring capture frequencies, and handling data storage and access.Additionally, the station supports cellular network communication, enabling remote configuration management and real-time data retrieval. This setup ensures that the digital twin model receives continuous and reliable boundary condition data for accurate thermal simulation.



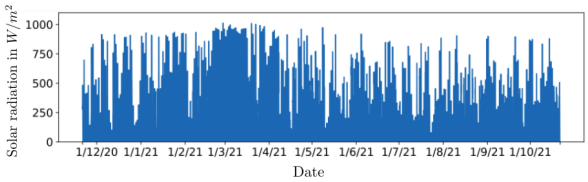


Figure 6. Meteorological station setup for data acquisition. (1) CR310 datalogger with 3G remote connectivity, (2) backup battery, (3) solar panel for system power, (4) CLIMA VUE 50 multiparameter sensor.

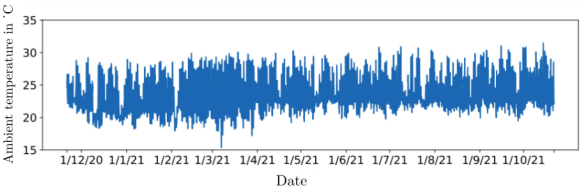
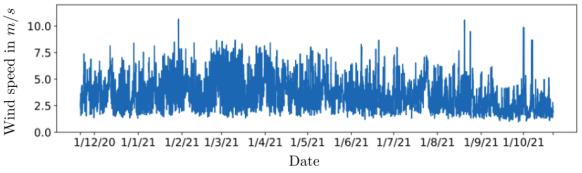
The collected data included hourly measurements of solar radiation, wind speed, air temperature, relative humidity, and precipitation. These values were linearly interpolated to generate input data at 10 minutes intervals.



The heat transfer due to advection, which in this case refers to the thermal exchange caused by rainfall and its temperature difference with the pavement surface, was calculated according to the method described by Yavuzturk and Ksaibati (Yavuzturk and Ksaibati 2006).

Additionally, it was assumed that rainwater drains immediately from the pavement surface, forming a thin film from which evaporation occurs. The heat transfer due to evaporation was determined following the approach proposed by Van Buren (Van Buren et al. 2000).



Climatic data from an 11-month period (from November 20, 2020, to October 20, 2021) are presented in Figure 7. As shown, air temperature varied approximately between 15°C and 32°C. Solar radiation reached a maximum of 1012.0 W·m^{-2}, while wind speed peaked at 10.7 m/s with an average of 3.5 m/s.

(b) Air Temperature

(c) Wind Speed

(d) Relative Humidity

(e) Precipitation

Figure 7. Hourly climatic variables measured at the roadside weather station over the 11-month period.

The thermal properties assigned to each pavement layer in the model include density, thermal conductivity, and specific heat capacity. For the asphalt layers (Layers 1 and 2), these properties were experimentally measured at

Technische Universität Dresden using an ISOMET 2114 device, applied to materials similar to those used in the Costa Rica test section. The granular layers (Layers 3 and 4) were characterized using values obtained from published literature.

Layer 1 has a density of 2530 kg/m^3, thermal conductivity of 1.46 W/m·K, and specific heat capacity of 654.13 J/kg·K. Layer 2 has a slightly higher density of 2560 kg/m^3, thermal conductivity of 1.33 W/m·K, and specific heat capacity of 648.61 J/kg·K. For the granular layers, Layer 3 has a density of 1800 kg/m^3, thermal conductivity of 1.0 W/m·K, and specific heat capacity of 900 J/kg·K, while Layer 4 has a density of 1700 kg/m^3, thermal conductivity of 0.8 W/m·K, and the same specific heat capacity of 900 J/kg·K.

3.2 Thermal Model Validation

To validate the thermal model, simulated temperature values were compared with field measurements obtained from a thermometer installed at a depth of 40 cm along the roadside. Figure 8 shows the results of the numerical simulation overlaid on the field-measured temperatures. As observed, the model is capable of replicating both the overall shape and magnitude of the thermal history with reasonable accuracy.

The average absolute difference between the simulated and measured temperatures was 1.08 °C. While this is a modest error, it should be considered in the context of the relatively narrow temperature range (∼20 °C to 28 °C). Furthermore, localized differences greater than 4 °C were observed during some transient periods, such as around January 9, 2021.

These discrepancies are attributed to two main factors: (1) the thermal properties used in the model were not site-specific, and (2) the field measurements were taken at a depth of 40 cm, beneath the surface and at the pavement edge. At this depth, thermal variations are attenuated and phase-shifted relative to the surface, making direct alignment with surface-driven simulations inherently challenging. Nevertheless, the model captures the overall thermal trends and magnitudes with sufficient fidelity for Digital Twin calibration purposes.

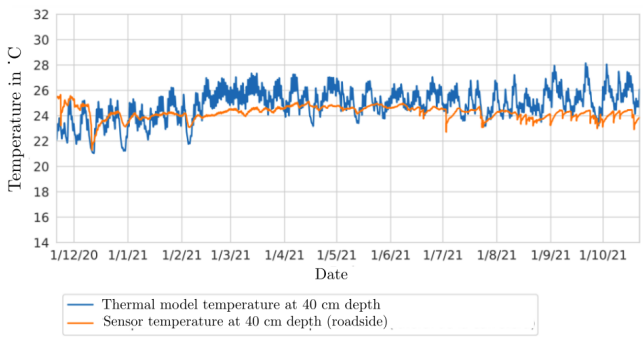

Figure 8. Comparison between measured and simulated temperatures at 40 cm depth over the validation period.

4 Numerical Results

4.1 Surface Temperature of the Asphalt

Figure 9 shows the simulated surface temperature of the asphalt pavement in comparison with the ambient air temperature over the 11-month period. As expected, surface temperature variations are significantly larger than those of the ambient air due to the combined effects of solar radiation, convective heat transfer, and thermal inertia of the pavement structure.

While ambient temperatures remained within a relatively narrow range (typically between 18° C and 32° C), surface temperatures frequently exceeded 40° C, with peaks reaching nearly 50° C under high solar radiation. This highlights the importance of modeling radiative and conductive mechanisms when predicting thermal loads on pavement surfaces, particularly in tropical environments.

Such elevated surface temperatures can increase the risk of temperature-related distresses such as rutting and fatigue cracking, even though low-temperature cracking is unlikely to occur in this climate.

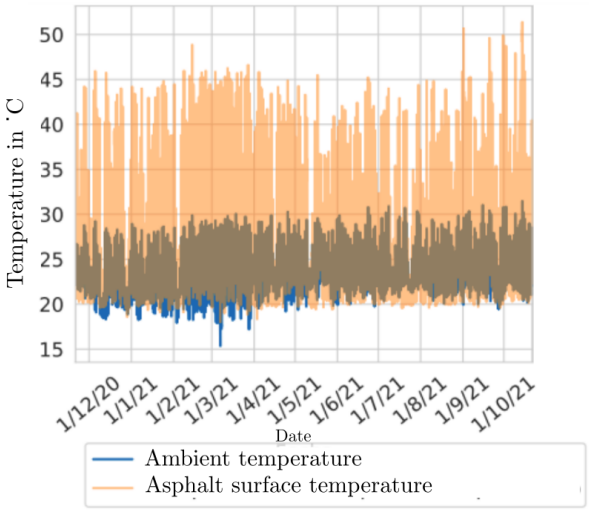

Figure 9. Simulated asphalt surface temperature compared to ambient air temperature from November 2020 to October 2021.

4.2 Cooling Effect of Rainfall on Pavement Surface

For a country like Costa Rica, incorporating the effects of rainfall into the thermal model is essential. Due to its tropical climate, Costa Rica experiences substantial precipitation throughout the year. In this context, the evaporation of rainwater serves as a key cooling mechanism that significantly influences pavement surface temperature.

Figure 10 shows the simulated surface temperature distribution over a two-day period, including a rainfall event during the night of January 2, 2021. The figure clearly illustrates that the onset of precipitation, followed by evaporation, produces a noticeable cooling effect on the asphalt surface.

DOI
10.3384/ecp218981

With the inclusion of rainfall effects in the model, surface temperatures are approximately 2–3°C lower than they would be without accounting for this phenomenon. This result highlights the importance of modeling transient environmental events to improve the realism and predictive capability of digital twin systems for pavements in tropical climates.

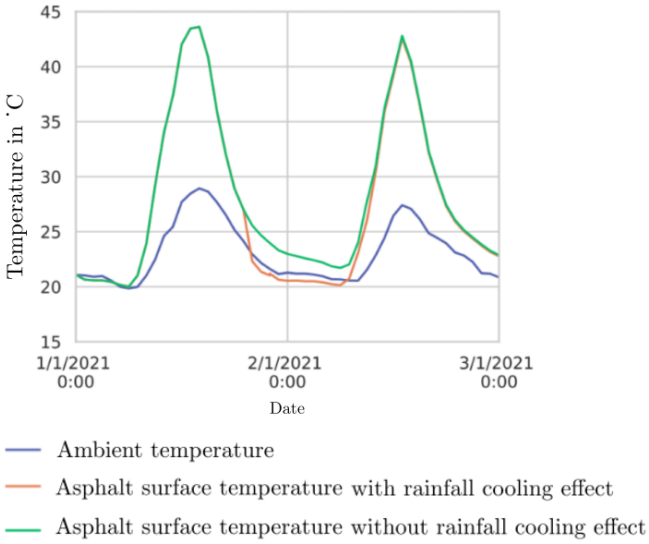

Figure 10. Simulated effect of rainfall on asphalt surface temperature during a two-day period including a nighttime rain event on 02.01.2021.

4.3 Temperature Distribution Within the Asphalt Layers

Figure 11 presents the simulated temperature distribution across the asphalt layers (Layers 1 and 2) over a 48-hour period, from January 1, 2021 at 00:00 to January 3, 2021 at 00:00. As expected, asphalt temperatures peak around midday, coinciding with the maximum solar radiation.

During the daytime, a clear thermal gradient can be observed between the top and bottom of the asphalt layers, with surface temperatures significantly higher due to direct solar exposure. Conversely, nighttime conditions lead to more uniform temperatures across the asphalt layers, typically close to the ambient air temperature of around 20° C.

This thermal behavior reflects the dominant heat transfer mechanisms, particularly conduction from the surface downward. A noticeable thermal lag is observed, with a delay of approximately 1.5 hours between the peak surface temperature and the temperature observed at the bottom of the asphalt layers. This lag is characteristic of heat diffusion in materials with thermal mass and indicates the importance of time-resolved simulation in capturing pavement response to environmental loads.

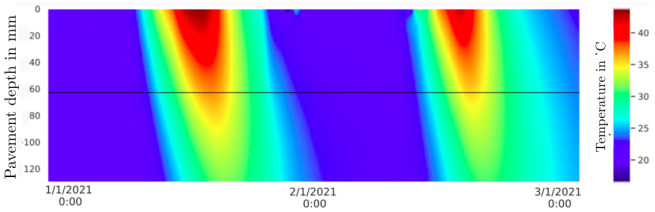

Figure 11. Simulated temperature distribution in asphalt layers (1 and 2) over a 48-hour period from 01.01.2021 to 03.01.2021.

5 Conclusions

This study demonstrates the development and application of a synthetic thermal digital twin for asphalt pavements using the Modelica language and the OpenModelica platform. The model captures transient heat conduction through a multilayer pavement structure by solving Fourier's heat equation with a finite difference scheme. Real-time synchronization between the physical and virtual twins is achieved through a PI controller that adjusts surface albedo to minimize temperature discrepancies.

The digital twin was applied to a case study in Costa Rica, where the model was validated using field temperature data collected over an 11-month period. The model showed good agreement with measured values, with an average absolute error of 1.08° C. The inclusion of rainfall and evaporation effects proved critical in accurately simulating surface cooling events, demonstrating the value of incorporating site-specific environmental conditions.

Results also highlighted the thermal behavior of asphalt layers under daily and seasonal cycles, revealing surface temperature peaks exceeding 50° C and internal thermal lags of about 1.5 hours. These conditions, typical in tropical climates, suggest that pavement distress mechanisms such as rutting and fatigue cracking may be more relevant than thermal cracking.

Finally, the modular architecture of the Modelica-based framework enables easy integration of additional environmental inputs and control strategies. This flexibility supports further development of comprehensive digital twins capable of coupling thermal and mechanical behavior for improved pavement performance prediction and infrastructure management.

In a real-world implementation, the Digital Twin would transmit predicted in-pavement temperature data from the virtual model to the physical road system. This information flow is essential for enabling proactive pavement management strategies. Forecasts of temperature at various depths can inform decisions such as optimal timing for de-icing, preventative maintenance to reduce thermal cracking, and adaptive load management during extreme heat or cold events. By delivering this predictive insight, the Virtual Twin supports data-driven interventions that can reduce operational costs, extend pavement lifespan, and enhance roadway safety. Although this study focuses on a synthetic case without direct communication to a

physical system, the proposed architecture is designed to support such bidirectional data exchange in future deployments.

Abstract

The TransiEnt Library is an open-source Modelica Library originally developed at the Hamburg University of Technology. It is a flexible framework for modelling and analysing the dynamic behaviour of coupled energy systems under current and future scenarios. With the addition of three new members to the TransiEnt Library consortium, namely Fraunhofer UMSICHT, Gas- und Wärme-Institut Essen e.V. and XRG Simulation GmbH, the TransiEnt Library has expanded its portfolio of models and methods for investigating the challenges in energy systems. Building upon the previous status report, this article presents the latest developments in the TransiEnt library, highlithing its extended capabilities to model and simulate large, complex energy systems. The recent developments include the automatic generation of aggregated models at district and regionals levels, as well as the modelling of medium- and low-voltage electrical distribution networks. In addition, new concepts for the representation of large-scale heating networks have been developed and are presented alongside illustrative use cases.

1 Introduction

Due to climate change, energy systems are in the midst of a transformation from using fossil fuels to a sustainable energy production. Large, centralized plants are being replaced by many small, decentralized ones. As energy production becomes predominantly renewable, various energy systems formerly based on heat or gas are increasingly electrified, resulting in enhanced interconnectivity and rising electricity demand through power to x technologies. In addition to the growing demand for electricity, the decentralized and small-scale systems in the electricity grid are leading to bi-directional power flows, which are putting a particular strain on the distribution grids (Greve et al. 2021). The intermittent nature of renewable energy generation from wind and solar on hourly and seasonal time scales leads to a growing need for short-term and long-term storage with different capacity and performance requirements. The digitalization of energy systems also makes it possible to control generation and consumption in real time.

This transformation process is leading to significantly more complex and interconnected energy systems that need to be assessed in terms of economic efficiency, sustainability, reliability and resilience. The economic design of storage systems, the investigation of flexibility through increased interconnection, and the resilience of grids require the investigation of dynamic processes.

The modelling language Modelica is ideally suited for simulating the dynamic behaviour of multi-domain systems. There are several open-source Modelica libraries that specialize in different areas of energy system modelling (Modelica Association 2025). The AixLib (Maier et al. 2024) and the buildings library (Wetter et al. 2014), for example, are two very comprehensive libraries that focus on the modeling of building energy systems at different levels of detail, from individual buildings to district level. The DisHeatLib library (Leitner et al. 2019) is a useful tool for simulating heating networks. However, to the authors' knowledge, no large-scale heating networks have been simulated with it yet. The library also does not take coupled networks into account. The ClaRa library (Vojacek et al. 2023) enables the analysis of power plant processes. Nevertheless, owing to its level of detail, it is not appropriate for simulating large networks. However, the TransiEnt library is designed for analyzing large-scale, coupled energy systems. Building upon the previous status paper (Senkel, Bode, Heckel, et al. 2021), this paper

focuses on simulations of large-scale energy networks. In the following, the context of the library, its scope and structure are described, before three more detailed considerations of larger energy systems are given, that are enabled by the new models in the library. At first, the modeling of large energy systems at regional level using the superstructure model is explained. Then, the modeling of large medium and low voltage distribution grids is presented. Finally, the modeling of large district heating networks is discussed. The paper concludes with a summary and an outlook on future developments.

2 Overview of Library

2.1 Context of TransiEnt Library

Experience from the development of the libraries *HKSim* (Wischhusen, Lüdemann, and Schmitz 2003) and *ACLib* (Pfafferott and Schmitz 2003) as well as a research focus on climate-friendly energy and environmental technology at the Hamburg University of Technology (TUHH) led to the idea of a Modelica library for the simulation of integrated energy systems, which resulted in the research project TransiEnt.EE from 2013 to 2017. First results and the relevance of dynamic consideration of integrated energy systems in the calculation of CO_2 emissions for different conversion paths were presented at the Modelica conference in 2015 (Andresen, Dubucq, et al. 2015) and led to the first release (version 1.0.0) of the Transient Library in 2017. The main focus was on the analysis of costs and CO_2 emissions of energy systems, facilitating the evaluation of efficiency measures.

The library was further developed in the follow-up project ResiliEntEE from 2017 to 2021. The focus here was on applying the Transient Library for large-scale simulations through numerically efficient modelling and evaluating the resilience of energy systems. As a new partner, the Institute of Electrical Power and Energy Technology at the TUHH made a significant contribution to the development of electrical power systems and grids (Heckel and Becker 2019). The resulting changes to the library were presented at the Modelica conference in 2021 (Senkel, Bode, Heckel, et al. 2021).

At the same time, the TransiEnt Library was also used and further developed outside the TUHH, in particular in the IntegraNet project (2016 - 2019). The project partners Fraunhofer UMSICHT, Gas- und Wärme-Institut Essen e.V. investigated sector coupling at the distribution system level, supported by XRG Simulation GmbH. Consequently, new models for gas and heating networks were developed, as well as the GridConstructor for complex district modelling (Benthin, Heyer, et al. 2019).

The follow-up project IntegraNet II (2019-2023) has led to new developments, including the introduction of an electric vehicle model to represent electromobility in local energy systems. Moreover, the coupling of the electricity and transport sectors has been facilitated, and heating network models have been revised to reduce computation time.

Due to many years of cooperation and parallel development of the TransiEnt library, a consortium was formed with TUHH and the Integranet project partners in April 2021 to combine their activities and support further developments. Together they released version 2.0.0 with extensions in the domains of large-scale simulations and resilience at the transport system level, in addition to novel models for the underlying distribution system level. After the alliance was founded, the development of the library was moved to GitHub in favor of better access and community collaboration (TransiEnt-official/transient-lib).

Components of the TransiEnt library have also been used in the project CyEntEE (2021 – 2024) to develop novel dynamic integrated low and medium voltage grid models with the goal to optimize flexibility and develop congestion management strategies. Additionally, the ongoing EffiziEntEE project (2022 - 2025) further utilizes and enhanced those models. Furthermore in EffiziEntEE heat models, which enable the numerically efficient simulation of large-scale district heating networks, were developed. The models from CyEntEE and EffiziEntEE are part of the release for this publication. The new release also contains the latest improvements in the automation of model creation at district and regional level. The next chapter provides a detailed insight into the improvements and innovations of the TransiEnt library.

2.2 Scope of TransiEnt Library

The TransiEnt Library serves as a comprehensive Modelica library specifically designed for the dynamic modeling of integrated energy systems with a high share of renewable energy (RE). It facilitates the representation of interactions among the domains of electricity, heat, and gas, thereby addressing the complexities inherent in present and future energy systems.

The primary objective of the TransiEnt Library is to provide a versatile framework that can be applied across various areas of energy research and analysis. Through documentation and the provision of check models, the library aims to ensure accessibility for researchers and engineers engaged in the dynamic modeling of integrated energy systems.

The applications of the TransiEnt library extend from district-level analysis to regional investigations, comprising industrial, commercial and residential sectors. This integration facilitates the interactions between producers (power plants and decentralized units), consumers, storage systems, and the infrastructures of the gas, heat, and electricity sectors.

The existing models of the TransiEnt library allow the modeling and simulation of complex integrated energy systems and can therefore be used to study the effects and opportunities of increased integration of electricity, heat and gas from RE into existing structures, such as the deployment planning of combined heat and power plants (cf. Peniche and Kather 2015) or the use of conven-

DOI 10.3384/ecp218989

tional power plants per se (cf. Dubucq and Ackermann 2015). The library also ensures the investigation of the potential and integration of green hydrogen in industry (cf. Andresen and Schmitz 2016; Andresen, Bode, and Schmitz 2018) or the volatile nature of RE on the stability of the electricity grid and possible flexibility options (cf. Dubucq and Ackermann 2017; Heckel, Möws, and Becker 2022). By providing models for the interconnection of the sectors, i.e. power-to-heat (PtH) and power-to-gas (PtG) technologies, issues related to flexibility between the individual sectors, such as the use of surplus electricity in PtH units (Bode and Schmitz 2019) or voltage stability in coupled grids (cf. Heckel and Becker 2020; Heckel, Steffen, and Becker 2022), can be investigated. In particular, the introduction of a resilience index in coupled grids (Senkel, Bode, and Schmitz 2021; Heckel and Becker 2019) can be used to assess the resilience of energy grids to disturbances (cf. Bode, Senkel, and Schmitz 2020; Heckel, Senkel, et al. 2022). Furthermore, uncertainties regarding the economic evaluation of future investments in building energy systems can be addressed through real options analysis using simulated energy flows (Glombik and Fromme 2024).
Moreover, the TransiEnt Library offers aggregation models, such as `GridConstructor` and `Superstructure`. These models empower users to model entire districts or large energy systems at the transport grid level with simple parameterizations. For instance, the `GridConstructor` can be used to analyze the physical impact of vehicle-to-grid communication attacks on low-voltage grids (Zhdanova et al. 2022).

While the TransiEnt Library offers robust modeling capabilities and ensures large-scale simulations, it is important to note its inherent limitations. The optimization of energy systems cannot be performed with the models in Dymola itself, but must be implemented via interfaces such as Matlab or Python. Furthermore, the library is not designed as a high-level designing tool; rather, it allows dynamic simulations of given system designs to analyze their impacts on the energy system.

2.3 Structure of TransiEnt Library

The TransiEnt Library provides models for components of gas, heat and electrical systems (generators, storage facilities, infrastructure, consumers) as well as various system models. Some basic models, particularly in the area of heat and gas, as well as basic modeling principles have been adopted from the ClaRa Library. This freely available model library was developed by TLK-Thermo GmbH and XRG Simulation GmbH and contains models of power plant components for the simulation of power plant systems.
As shown in Figure 1, the current version of the TransiEnt library consists of eight top level packages. Since the last status paper, the package `SystemGeneration` has been added, which supports the automated generation of energy systems on a city and regional level: `GridConstructor` and `Superstructure`. Please refer to Benthin, Heyer, et al. (2019) for information on how the `GridConstructor` works. The modeling of regional energy systems with the `Superstructure` is presented in subsection 3.1.

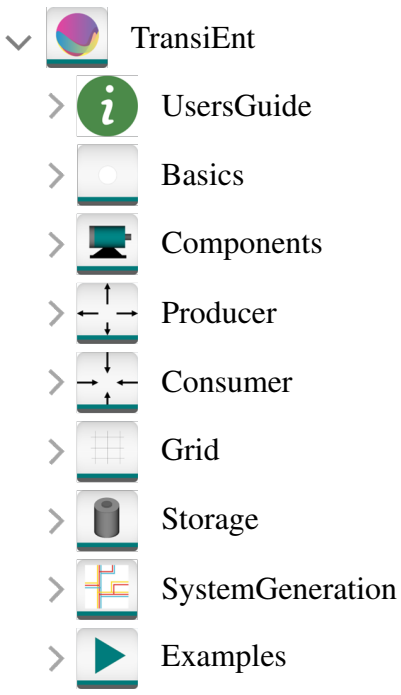

Figure 1. Icons of the relevant top level packages inside the TransiEnt Library

3 Exemplary Developments and application examples

The focus of this chapter is to present the most important developments in the TransiEnt library. First, the automated model creation through the `Superstructure` model is presented. Second, the developments in modeling medium and low voltage networks are explained. Finally, two modeling approaches for large heating networks are introduced.

3.1 Cellular Energy Systems with the Superstructure

Modeling of large energy systems can include large structural data sets and may require a substantial amount of manual work and is error prone. Script based automated model generation can be a solution. However, generating Modelica code for detailed energy systems from scratch can become very complex, as completeness of the equation system in the generated code needs to be ensured. The superstructure model of the TransiEnt Library enables the

user to create checkable models of energy systems at the scale of coupled regions or more generally, coupled energy cells by choosing available technologies and setting (structural) parameters.

As shown on the left of Figure 2, the superstructure contains for each cell (region) subsystems for (1) the heating Grid including thermal storages, (2) electrical storages of different types, (3) gas storages, (4) power to gas, (5) CO_2 capture and storage, (6) available power plants of different types, (7) local renewable power generation and (8) local demand. The technologies available in each of these subsystems can be specified by the user with a replaceable package called technology portfolio. Here all technologies available in the TransiEnt Library as well as user specific models may be added by extending the existing base package.

All subsystems and their sub components are connected to the sectors they involve (electricity, heat, gas), e.g. power to gas is connected to electricity and gas. For the electric and gas sector, each cell provides a connector to the outside as well as three bus connectors for input, control and output signals. At present there is no outside connector for the district heating network (DHN). It is assumed that each DHN is located entirely inside its cell. The technical reason behind this is the lack of an automated DHN model generation, entirely from structural parameters, similarly to the electric grid connector in Figure 3. This may change in the near future, since the new modeling approach of section 3.3 offers more flexibility for model initialization and simulation performance.

In order to resolve larger spatial scales, an array of cells (regions) can be used consisting of `nRegions` cells. This is done in the so called portfolio mask model (Figure 2, center). For each of the `nRegions` cells (regions), its local energy system can be specified through structural parameter records: instance records can be used to disable technologies through conditional components in order to to adapt the energy cell model to a specific configuration, for example, to set up the available generation technologies. Enabled technologies can be further specified by parameter records, by setting e.g. the total power of each individual renewable generation technology or storage capacities of a given energy cell. For each technology an individual number of plants in a cell with their specific properties may be specified.

By construction the portfolio mask model provides an array of `nRegions` gas and electric grid connectors as well as a collection of all cell-buses in a master bus.

In order to model a scenario (Figure 2, right), the different cells of the portfolio mask model need to be connected by an electric and gas grid. Furthermore a control algorithm for the system has to be provided.

For constructing a simple electric grid model just from parameters, the `GridConnector` model can be used. There, as shown in Figure 3, an incident matrix specifies how many lines exist between two given regions.

Each line can be individually parametrized with respect to its voltage level, cable type, length and cross sectional area. For the gas grid a lumped model is used by default, however more detailed models may be provided by the user.

By using the masterBus, the control of the overall system is separated from the physics based cell models: all status information of the different cell components ("measurements") are aggregated towards the controller and the controller signals are propagated down to the individual cell component.

3.2 Integrated Electric Distribution Grids

The ongoing electrification of consumers in the electrical grid is one of the central consequences of the energy transition. This particularly affects consumers and producers in the distribution grid at medium- and low-voltage level, i.e. electric heat pumps (EHP), battery electric vehicles (BEV) and battery energy storage systems (BESS) as consumers and photovoltaic generators (PVG) as producers. These electrified components represent not only large additional loads or generators, but can also provide flexibility for the operation of the electrical grid, if according control and communication strategies are implemented. As these components couple the sectors, slower dynamics from the heat and mobility sectors are integrated into the electricity grid. To represent those dynamic effects of interest in grid simulations at system level, the library was expanded by several components. In order to be able to carry out simulations at system level, a scenario generator was developed that maps consistent development scenarios by parameterizing different low- and medium-voltage grid models on the basis of the SimBench data sets topologies (Meinecke et al. 2020; Wiegel et al. 2023). With the help of the scenario generator, a set of 17 preconfigured exemplaric grid models, 15 low voltage and 2 medium voltage, were implemented and added to the library. For the electric grid the RMS simulation approach was chosen. For all underlying novel component models, numerical efficiency was considered so that simulations of large non-aggregated grid models are feasible. The most important developments are briefly described below.

Building Heating System Building heating systems are increasingly being electrified by replacing gas or oil heating systems with heat pumps. The electrical energy demand of heat pumps is primarily dependent on the heat flow required to maintain a defined room temperature and for the provision of hot water. For this purpose, a building model was created in accordance with the enveloping surface method of DIN EN 12831, which calculates the heat flows occurring through walls, windows, floor and ceiling. The heat transfer coefficients required for this were taken from the current design standards for buildings. In addition to conductive heat transfer, the mass-bonded enthalpy exchange through room ventilation is also taken into account.

In order to perform system simulations using the developed model, numerical efficiency competes with model

accuracy. Fluid dynamic simulations are therefore not useful at the system level for modeling of larger systems of decentralized heating units. Therefore, the behavior of the EHP in the system is mapped by a gray-box controller model. The basic structure of the model consists of a PID controller, a power splitter, and various components that represent the operating state under real-world conditions. The controller parameters were measured and validated on a real test facility as part of the European ERIGrid 2.0 project at the SYSLAB of the Technical University of Denmark (DTU). Part of the measurements are steady state operation and dynamic state changes. In addition to system simulation under regular operation, the behavior under external influence, for example by the grid operator when the load is reduced or limited, can be investigated using these models. Another use case is aggregators that use the flexibility of the components for energy trading on the electricity exchange.

Battery Electric Vehicles BEVs are characterized by two main aspects from the perspective of the electrical grid: availability according to the charging behavior and the electrical properties of the on-board charger. An empirical profile generator was therefore developed as part of the scenario generator, which maps the presence and driving behavior of individual owners. The electrical behavior of the on-board charger was investigated as part of the ERIGrid 2.0 project. This mainly affects the efficiency of the charger and the reactive power behavior. Moreover, the grid voltage dependency of the parameters and the dynamics of operating point shifts were analyzed and derived into the newly developed models (Steffen et al. 2024).

Battery Electric Storage System BESSs are usually controlled in such a way that self-consumption is maximized. This is achieved by measuring the load at the grid connection point and setting the operating point of the BESS according to the available power. Measurement takes place via a smart meter, which also takes measurement uncertainties into account.

Grid-level simulations The scenario generator developed allows system configurations to be created on the basis of parameters derived from the TYNDP scenarios to estimate future developments (Wiegel et al. 2023). These are automatically converted into an executeable Modelica model using a Python script. The modular structure allows the parameters to be adapted to the users individual needs. The electric grid simulation is based on a complex root mean square approach, since the fast electromagnetic transient effects are not in the scope of this modelling approach. The dynamic effects included originate from the models described above.

Use Case With the previously introduced component models, large distribution grid scenarios can be modelled and simulated. An example, a medium voltage ring based on the urban distribution grid model, named MV-urban-6, from the benchmark topology *1–MV-urban–6-no-sw* published by SimBench (Meinecke et al. 2020) is simulated. The medium voltage ring consists of in total 18 low voltage grid models, whereby 12 are different semiurban and 6 are urban low voltage grid topologies, in a future scenario. In total, over seven thousand individual component models contribute to this simulation.

Table 1 shows the share of included components. For the simulation the C-variable-coefficient ordinary differential equation solver (CVODE) with fixed integration step size of 60 seconds and tolerance of 10e-4 was used. 7 days of winter weather data for the location Berlin in

Table 1. Overview of grid components and their number in different topologies

Battery Energy Storage System (BESS)	1	4	4	69
Photovoltaic Generator (PVG)	5	15	18	278

January 2024 where chosen as input data sources. The data was acquired by the German Weather Service (DWD) (Reinert et al. 2025). The simulation time is close to 17 hours on an Intel I9 13900k CPU. The results are given in figure 4 and show the maximum loaded cables, node deviations and the power consumption of the low voltage grids connected to the medium voltage ring as well as the maximum cable load from the medium voltage grid. One can see, that the medium voltage grid in terms of line load is usually less loaded than the low voltage grid. The daily rising loads and falling voltages can be justified by the increased probability of BEV arriving in the late afternoon of a day. Additionally the influence of the electric heating within the BHS is noticeable with a slower dynamic due to the falling temperatures in the middle of the simulated week.

3.3 Simulation of large-scale district heating networks

In the following section, the developments of the heat components in the TransiEnt Library are described. There are two main use cases for the heat models of the TransiEnt library:

- the simulation of dwelling heating systems and
- the simulation of district heating networks (DHN).

Modelica is a suitable modeling language for DHN simulations because of its acausal character allowing physical modeling and easy model adaption. Moreover, it enables dynamic simulation, which allows the investigation of thermal inertia.

Until now, large-scale simulations using the TransiEnt Library have only been performed for electricity and gas grids. In contrast, the simulation of heating grids has been limited to a few components. This absence of large-scale examples has also been mentioned in literature (e.g. Schweiger et al. 2017). For this reason, the emphasis of recent developments has been on the simulation of large-scale DHN. Therefore, new modeling concepts for the simulation of DHN have been developed. Within the TransiEnt library two different approaches regarding the consideration of thermal dynamics in DHN are available - Euler and Lagrange. The Euler approach focuses on fixed locations inside a fluid field while the Lagrange approach is about tracking an individual fluid particle inside a fluid field. Both approaches are valid and have their flaws and assets.

The first one is described by (Westphal, Brunnemann, and Speerforck 2025) and is based on the discretization of the balance equations of momentum, mass, and energy. The presented modeling concept can be categorized as shown in Figure 5. DHN simulations are often categorized with regard to simulation type, calculation method, loop method, software environment, and control strategy. The modeling concepts consider thermal dynamics but neglect the hydraulic dynamics inside the network.

To achieve an efficient simulation performance and scalability for larger models, three key points were discovered and implemented in the component models using the Euler approach:

1. Avoidance of implicit non-linear systems of equations through a suitable consumer model and the strategic use of mass flow states, which is partly based on Zimmer (2020).
2. Discretization of only the energy balance to enable the use of a sparse solver.
3. Avoidance of unnecessary equations and function calls by assuming constant or fitted curves for the fluid properties.

The new models have been presented by (Westphal, Brunnemann, and Speerforck 2025) and used by (Vieth, Westphal, and Speerforck 2025). Further explanations regarding the modeling concept and how to achieve an efficient simulation can be found in (Westphal, Brunnemann, and Speerforck 2025).

The second concept is based on a plug flow Lagrangian approach and is used in the models `SinglePipe_LX` and `DoublePipePair_LX`. The same approach is used in the IBPSA library, which is, for instance, integrated into the Buildings library (Heijde et al. 2017). For the TransiEnt library, the model was adapted within the project IntegraNet (Benthin, Hagemeier, et al. 2020) based on the work of (Hägg 2016) and (Heijde et al. 2017) to enable usage within the TransiEnt framework. The model `SinglePipe_LX` comprises submodules for heat loss,

DOI 10.3384/ecp218989

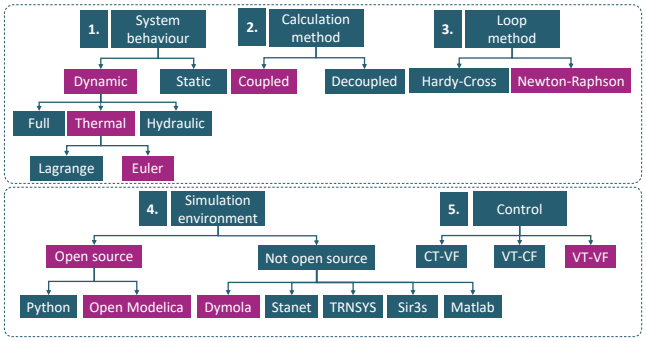

Figure 5. Categorization of modeling concepts for district heating networks based on the literature review of Kuntuarova et al. (2024)

residence time, pressure drop, and volume. It contains two heat loss components, one for the nominal flow and one for the reverse flow. Each of them implements the plug flow approach in a different flow direction. In the plug flow approach, thermophysical properties are evaluated solely at the pipe inlet and outlet, significantly reducing numerical complexity.

The heat loss rate $\dot{Q}$ is calculated as a function of the mass flow $\dot{m}$, the heat capacity of the medium c_p and difference of the inlet temperature T_i and the outlet temperature T_e:

$$\dot{Q} = \dot{m} \cdot c_p \cdot (T_\mathrm{e} - T_\mathrm{i}). \tag{1}$$

The outlet temperature T_e is calculated as shown in Equation 2 as a function of the residence time τ, the inlet temperature T_i, the ambient temperature T_a, the thermal resistance R, and the heat capacity of the heat carrier per meter C:

$$T_\mathrm{e} = T_\mathrm{a} + (T_\mathrm{i} - T_\mathrm{a}) \cdot e^{\frac{-\tau}{RC}}. \tag{2}$$

A key feature of the model is the physically consistent representation of the residence time, which is essential for capturing transient thermal effects in pipe systems. The residence time required for the heat loss calculation is determined in the residence time component using the `spatialDistribution()` function as described in (Heijde et al. 2017). The pressure drop across the pipe is computed using the Darcy-Weisbach equation, linearized for small mass flows.

The plug flow approach facilitates initialization by allowing initial values for physical parameters such as temperatures to be less precise. The approach itself does not account for delays in temperature changes due to the carrier pipe. Therefore, an optional volume component is added (Benonysson 1991; Hägg 2016; Heijde et al. 2017). Another module, `Pipe-Parameter`, provides a centralized interface for setting initial conditions and defining the geometric parameters of the pipe.

3.3.1 Use case: Using the piping network as a short-term storage

To prove the applicability of the component models, a dynamic simulation of a large-scale DHN with 2167 substations and a network length of 140 km is performed. The scope of the simulation is to use the piping network as a short-term storage to reduce peak heat production. This can be done by adapting the supply temperature of the network shortly before peak loads appear.

In Westphal, Brunnemann, and Speerforck (2025) the DHN topology used for this study has been introduced. Heat is generated by one large-scale heat producer, and the network is configured in a meshed topology. The main topology is derived from Frederiksen and Werner (2013) who classified different DHN based on the position of the heat producers. Distribution topologies have been based upon the work of Benthin, Hagemeier, et al. (2020) and designed with assumed heat fluxes. By combining the suggested main topology with the designed distribution topologies, a realistic heating network is created (see Figure 6). The mass flows are calculated by the consumer models with the use of a P-Controller, whose output depends on the room temperature.

To prove a decrease of peak heat production the heat flows required by the consumers are increased manually over a time span of four hours. In Figure 7, the generated heat flows can be seen for two scenarios. The blue graph describes the reference scenario where the supply temperature is held constant during the whole simulation. Therefore, the generated heat increases simultaneously with the heat load. The orange graph describes a scenario where the supply temperature was increased shortly before the peak load. It can be seen that the produced heat is increased when the supply temperature is raised. However, after a while, the produced heat starts to decrease again. The reason for this is that the increased temperature starts to reach the consumers with a time delay. Because of the higher supply temperature, the consumers need less mass flow and the generated heat flow starts to decrease. As a result, heat generation is decoupled from the heat load.

It can be concluded that the maximum peak generation is decreased due to the supply temperature adaptation. Therefore, peak generation can be avoided by using an advanced control strategy for the supply temperature and thus using the piping network as a short-term storage. This could, for example, be used for DHN operators to avoid costly peak generations like gas boilers and use more base load generation like combined heat and power plants (CHP).

3.3.2 Use case: Analysing future developments of a district heating network

The pipe models using the plug flow approach were used within the project IQDortmund (Gas- und Wärme-Institut Essen e.V et al. 2023) to simulate and analyze the district heating network of the city of Dortmund. This includes the assessment of the current state, as well as expansion and transformation scenarios for the period up to 2045. Using detailed simulations in combination with GIS-based modelling, several neighborhoods were evaluated in terms of future heating infrastructure development. A detailed model of the heating network with approximately 56 km of pipeline was created for simulating dynamic network behavior and future scenarios. To ensure robust initialization and improve numerical convergence in such a large-scale simulation, a node model is inserted between pipe segments. This model dampens rapid transients and decouples adjacent sections by introducing a time constant in the mass flow and energy balance equations.

The overall system model enables the investigation of changes in the system infrastructure like different heat sources or an expansion of the district heating network and their effects on the loading of the pipe infrastructure and resulting pressure losses. In the current state of the district heating network evaluated, a CHP plant serves as the primary heat source. In a future scenario, waste heat from a source located in the northern area becomes the main supply. Natural gas boiler plants are replaced by hydrogen boiler plants and a biomass heating plant. For larger potential waste heat sources, two heat pumps are installed. The shift in the primary heat generator results in a changed pressure distribution within the network (as shown in Figure 8), leading to increased loads of specific pipeline sections. Due to the intensified use of waste heat, a significant portion of the thermal energy has to be transported from the northern area to the rest of the network. As illustrated in Figure 8, this causes increased loading on two pipelines that are critical for connecting the northern section to the remaining network. For more details and further analyses on the district heating in Dortmund please refer to the final report (Gas- und Wärme-Institut Essen e.V et al. 2023).

4 Summary and Outlook

The transformation of energy networks and their requirements for economic efficiency, sustainability, reliability and resilience require dynamic simulations of energy systems with a large number of components at different levels. With the `GridConstructor` and the `Superstructure` two models are available in the TransiEnt library, which can be used to **easily** create aggregated energy systems at city or regional level. The focus of the GridConstructor is on simulating coupled energy grids at the district level. On the other hand, the Superstructure is used for simple modeling of coupled energy systems at the regional and supra-regional levels. While in recent years the focus of electrical modeling has been on extra-high voltage networks, new models are now available in the TransiEnt library, such as electrical prosumers, which are an integral part of medium and low voltage distribution grid. These models are capable of integrating the dynamic effects associated with the residential heating and mobility sector into electric grid simulations. In the specific use case, the utilization of a medium voltage network

DOI 10.3384/ecp218989

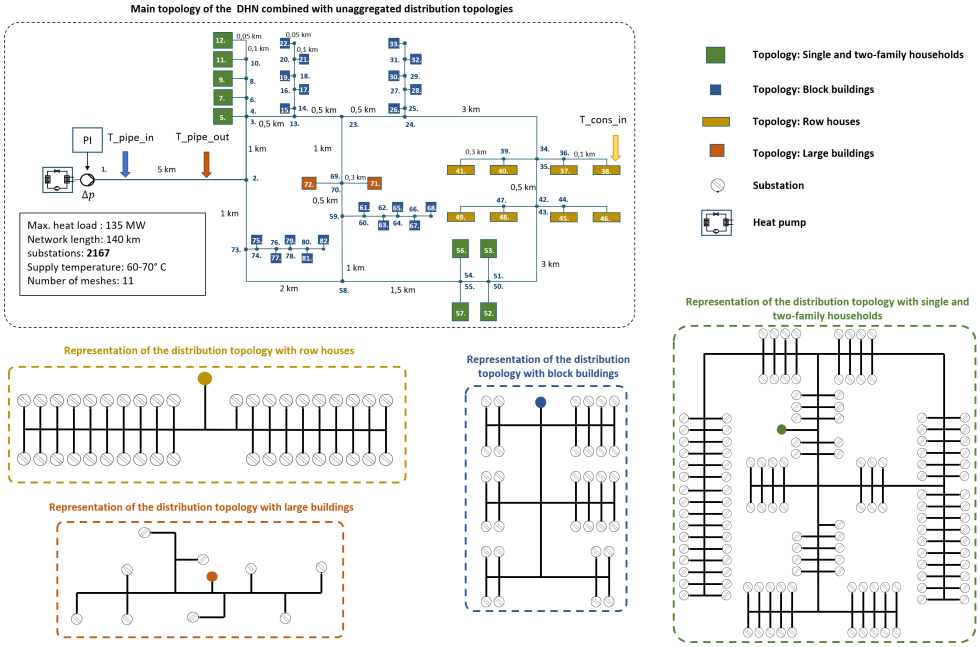

Figure 6. Topology of the investigated DHN from (Westphal, Brunnemann, and Speerforck 2025)

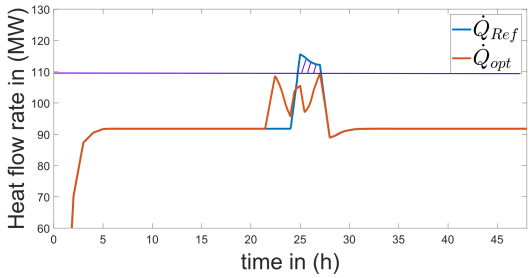

Figure 7. Heat flows of the producer for the reference scenario (blue) and the scenario with an adapted supply temperature (orange)

with over 7000 components is investigated.

Until now, the TransiEnt library has shown weaknesses in the simulation of large heating networks. With the two presented models, based on conservation equations on the one hand and the plug-flow approach on the other hand, large heating networks with e.g. over 2000 transfer stations and a network length of over 140 km can be simulated.

In addition to the standard extension of models, the future development of TransiEnt will also focus on enabling the use of the library with the OpenModelica platform. Furthermore, the documentation of the models is to be improved, access to the library simplified through tutorials and the exchange with the user community strengthened. In addition, hybrid models from Modelica and AI are to be given greater consideration.

The current version and Release 2.1.0 can be downloaded from the GitHub repository at `https://github.com/TransiEnt-official/transient-lib`. It is freely available under the terms of 3-clause BSD license. Further information about the library can also be found on the website `https://www.tuhh.de/transient-ee`.

Abstract

Efficient and cost-effective hydrogen storage necessitates quick compression across significant pressure ranges (usually up to 700 bar), while keeping heat generation to a minimum during the process. This can be achieved by improved understanding of gas-to-wall heat transfer enhancement in hydrogen compression systems, careful design and operational optimisation. In this context, the present paper introduces a 0D/1D lumped numerical model of a liquid piston compressor for hydrogen applications. Heat transfer is considered as (i) convective at the liquid-gas interface, (ii) conductive within the gas volume based on a 1D approach accounting for thermal stratification, and (iii) as conjugate at the gas-to-wall interface. To achieve a pressure ratio of 30 (from 15 to 450) bar, at a power density of approximately $65 kW/m^3$, the compression energy cost reaches $1.85 kWh/kg$. Further, various standard pressure vessels materials with different thermal and mechanical properties are considered, highlighting the potential compromise between lightweight and thermal efficiency.

Keywords:liquid-piston compressor, hydrogen, conjugate heat transfer

1 Introduction

Hydrogen holds great promise as an energy carrier that can progressively transition energy systems from relying on limited fossil fuels to utilizing sustainable renewable sources. It seeks to replace natural gas for domestic space heating and hot water, and enable long-range clean transportation. A major hurdle is achieving high-density hydrogen storage, particularly for hydrogen-powered vehicles that need to compete with the quick refueling and extensive range of traditional liquid fuel engines. A significant technical and economic obstacle for the transportation sector is the need to develop affordable compression, storage, and dispensing (CSD) stations outfitted with high-pressure compressors. Ideally, the hydrogen compression process should be isothermal, both to reduce the input work required and maintain the hydrogen delivery temperature very low (close to -40^oC). With limited heat transfer from the gas, this however comes at the expense of power density. Piston compressors are typically used in CSD stations as they are able to achieve high pressure ratios. In order to optimise simultaneously the piston compressors efficiency and power density, a compromise must be found.

Various methods have been developed to achieve near-isothermal compression in piston systems. Saadat et al. have concentrated on optimizing compression and expansion processes and maximizing heat transfer (Saadat, P. Li, and Simon 2012). Spraying liquid droplets can also enhance heat transfer by increasing the surface area between the gas and a secondary cooling fluid (Sapin et al. 2018). However, the energy required for injecting liquid droplets rises significantly with pressure. Another approach involves using phase change materials (PCMs) in the reservoir walls, where the heat from gas compression is stored isothermally as latent heat (Mazzucco et al. 2016). Recent focus has been on liquid-piston compressors, which replace the traditional reciprocating solid piston with a column of liquid, typically water, driven by a hydraulic pump. These systems offer excellent sealing and compatibility with heat transfer enhancers (Van de Ven and P. Y. Li 2009). An example of such enhancers is porous metal foams with high thermal inertia, which increase the heat transfer surface area when placed in the tank (Wieberdink et al. 2018). Finally, Specklin et al. investigated the potential of heat transfer augmentation with forced internal convection (Specklin et al. 2022).

In this paper, a comprehensive dynamic model is derived and used to investigate the role of the conjugate gas-to-wall heat transfer in the final energy cost of high pressure hydrogen compression. The model is based on the combination of 0D zonal approaches and a 1D discretization technique of the gas volume using elements from the Modelica Standard Library (MSL) (*MSL* 2023), in order to account for the different energy balances. The effect of different materials' thermal properties onto the heat transfer efficiency is put in parallel with their mechanical properties, especially the density, in order to give insight on potential optimal configurations. The study is introduced by presenting the composition and operation of a dual system of liquid piston compressors. Then, the main sub-models with their inherent governing equations are detailled. Finally, the thermodynamical behaviour of the system is hilighted and the final energy costs are assessed for different

wall materials.

2 Modeling methodology

The current numerical model is constructed following the same principle as the full scale setup described in (Solai, Specklin, and Deligant 2025), originally working with air. A simple zonal 0D approach was proposed and used to assess the system compression efficiency through uncertainty analysis. This approach is extended here, the main improvements being:

- mimicking the dynamic behavior of the full test bench which includes a dual system of liquid piston,
- adapted for hydrogen gas,
- proposing a 1D discretization of the time-varying hydrogen gas volume accounting for temperature gradients,
- based on an innovative extension of the thermal components of MSL.

This modeling strategy is implemented and tested with OpenModelica (*OpenModelica* 2023).

2.1 Liquid piston compressor system

The present liquid piston compressor is designed with a dual system of pistons, which facilitates the compression-expansion operation. The full system is represented in a schematic diagram in Figure 1. The liquid piston compressor is operated via the control of four solenoid valves. The opening of the valves is cyclic and the switch is determined based on the water level. The solenoid valves operate in parallel by pairs, as water from one tank is pumped into the other one. The check valves at the top of the reservoirs allow to bound the internal pressure between the two extrema given by the boundary conditions. Hence, as the water level increases in one of the cylindrical tank, the gas is being compressed. Once the final (or maximum) pressure is reached during compression, the corresponding check valve opens and the compressed gas is discharged. During the expansion process, the water level decreases and consequently the pressure too. Similarly, if the initial (or minimum) pressure is reached, the opening of the check valve occurs and the tank is filled with gas at this minimum pressure.

The liquid-piston system model shown in Figure 1 is constructed from components from MSL and from the in-house developed library based on MSL components (*MSL* 2023). Check valves, solenoid valves and the volumetric pump are considered as ideal. The thermodynamic behaviour of both left and right liquid piston cylinders are described in the next section.

2.2 Components modeling and governing equations

The liquid piston gas-spring arrangement, described in Figure 2, is initially filled with hydrogen at $P_0 = 15$ bar

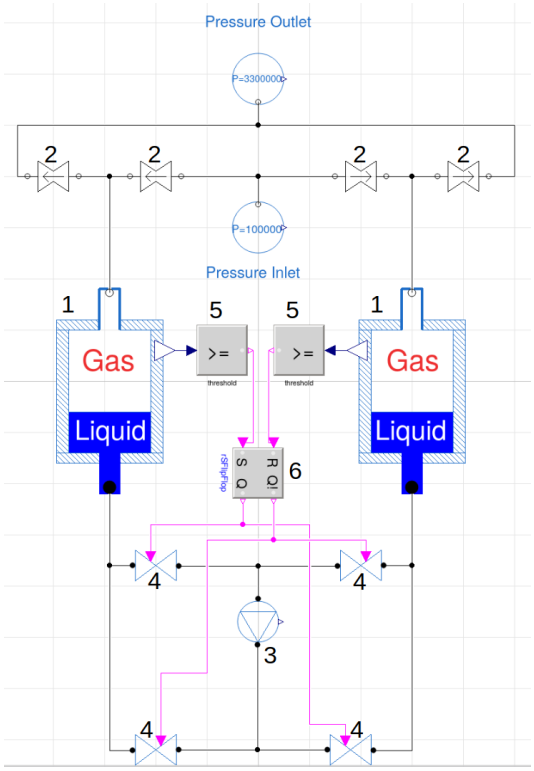

Figure 1. Schematic view of the experimental setup. 1) liquid piston tanks. 2) check valves. 3) volumetric pump. 4) solenoid control valves. 5) level threshold. 6) logical Reset-Set flipflop.

and at $T_0 = 20$ °C. Water is injected to compress the gas contained within the cylinder up to a pressure of 450 bar, which corresponds to a pressure ratio of 30. During compression, the hydrogen is heated up by the boundary work applied by the liquid piston motion, while being cooled down by the gas-to-solid and gas-to-liquid heat transfers. Further, heat transfer by conduction within the hydrogen gas is considered in the vertical direction.

The liquid piston cylinder model is composed of two sub-models, one for both time-varying gas and liquid volumes, as illustrated in Figure 3. Conjugate heat transfer is considered with two half thermal resistor and a heat capacitor representing the thermal inertia of the wall.

The outer half resistance includes both conductive thermal resistance through half thickness of the solid wall and the convective thermal resistance with the ambient. The inner half resistance includes the same conductive resistance and convective thermal resistances with the gas volume and the liquid volumes. The conductive resistances consist of resistances due to the lateral cylinder surface (Patil, Acharya, and Ro 2019). The convective thermal resistance with the ambient is governed by a heat transfer coefficient fixed to a standard value of $5W.K^{-1}.m^{-2}$ for natural convection. Finally, the inner convective resistances associated to both fluids are time-dependent and their inherent heat transfer coefficients are computed based on Reynolds-Prandtl correlations:

DOI 10.3384/ecp2181001

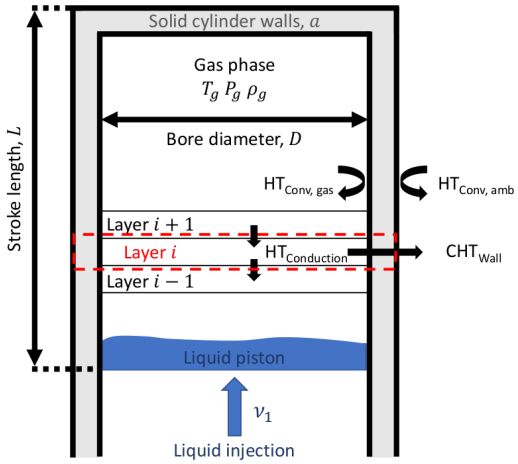

Figure 2. Schematic view of the liquid-piston cylinder involving 1D discretization of the gas volume.

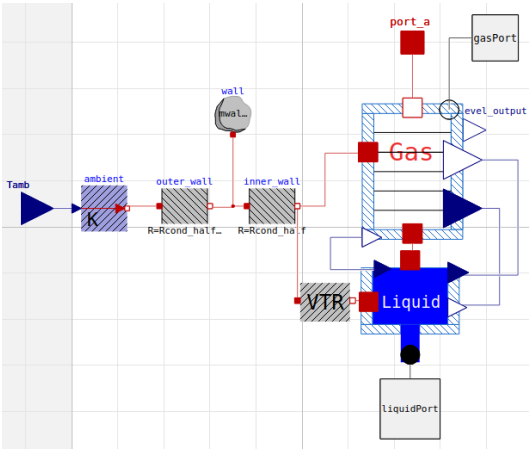

Figure 3. Schematic diagram of the liquid-piston cylinder model and its sub-models. The following variables are transfered between the sub-models of the gas and liquid volumes: the gas pressure P_g, the liquid volume V_l and the gas-to-liquid heat transfer coefficient h_{gl}.

$$Nu = aRe^b Pr^c \tag{1}$$

where Nu is the Nusselt number. More specifically, for the liquid-to-wall heat transfer, a, b and c coefficients are fixed considering standard correlation for forced convection in laminar regime over a flat plate. As for the gas-to-wall heat transfer the coefficient values are adjusted based on the uncertainty quantification approach described in (Solai, Specklin, and Deligant 2025) for the same piston liquid system operating at similar conditions, yet with air. Both Reynolds Re and Prandtl Pr numbers are computed based on the instantaneous values of the thermophysical gas properties, which are all obtained with the hydrogen ideal gas media from MSL.

The volume of the gas is further decomposed by an array of layers that encompass the internal convective heat transfer described above. This 1D approach allows to account for the thermal gradient in the vertical dimension.

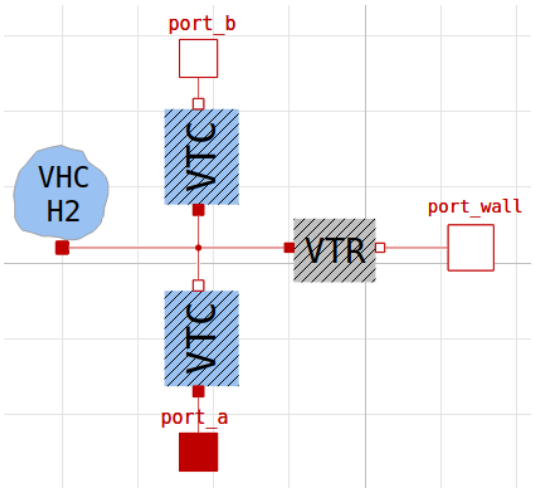

Figure 4. Schematic diagram of the gas layer element which includes convective thermal resistance with the adjacent wall. VHC stands for Variable Heat Capacitor, VTC stands for Variable Thermal Conductor and VTR stands for Variable Thermal Resistor.

A gas layer is thus made of the following element: a heat capacitor for the mass of hydrogen, two thermal conductors for conduction with the bottom and top gas layers, and the thermal resistor accounting for gas-to-wall heat transfer. The layer composition is shown in Figure 4. This is a modeling approach typically used for wall elements (Şeren and İpek 2023). In order to obtain a 1D discretization of the gas volume, these elements are defined as an array and connected successively. Another possibility lies in the direct resolution of the 1D partial differential equation such as in (Maccarini et al. 2023). In the present paper, the gas layer elements account for the time variation of the gas volume and thermodynamical properties during compression, expansion, discharge and admission stages. Hence, the different thermal components are extended versions of the MSL equivalent components with time-varying inputs governing their thermodynamical properties.

The variable heat capacitors defining the gas layers are adapted to satisfy the first law of thermodynamics:

$$\frac{dU_g^i}{dt} = \dot{m}_g^i \mathbf{h_g^i} - P_g^i \frac{dV_g^i}{dt} \tag{2}$$

where U_g and $\mathbf{h_g}$ are respectively the internal energy and the specific enthalpy of the hydrogen gas at pressure P_g and for a volume V_g. During the compression or the expansion stage strictly, the first term of right hand side in Eq. 2 depending on the mass flow rate $\dot{m}_g$ is null as the valves are closed. The superscript i stands for the i-th gas layer. Heat transfer by conduction with the adjacent layer is taken directly into account with the two thermal conductors, while conjugate heat transfer through the solid wall is taken into account through the thermal resistor. Thus equation 1 is layer dependent.

Heat transfer between the highest gas layer and the top wall surface is neglected due to the higher thickness of the

tank there. At the interface between the lowest gas layer and the liquid volume, heat transfer $\dot{Q}_{gl}$ is defined as:

$$\dot{Q}_{gl} = S_p h_{gl}(T_l - T_g) \tag{3}$$

S_p is the piston area and h_{gl} is coefficient of gas-to-liquid heat transfer, also estimated with a Reynolds-Prandtl correlation.

The number of gas layers n is fixed to 20, which has shown to be sufficient to predict the temperature gradient and to achieve independence of the results on n. The layers are defined with identical hydrogen mass at all time, and their volumes can thus be different depending on the thermodynamical properties of the gas within the layer. To ensure that the pressure is identical in all layers, a stable dynamics procedure is implemented such as in (Srivatsa and P. Y. Li 2018), which depends on a small positive number λ and reads:

$$\frac{d(P_g^{i+1} - P_g^i)}{dt} = -\lambda(P_g^{i+1} - P_g^i) \tag{4}$$

Here, $\lambda = 1e^{-4}$ is sufficient to force the pressure to be equal in all gas layers. As for the liquid volume finally, a 0D zonal approach is used, for which the volume follows the first law of thermodynamics:

$$\frac{dU_l}{dt} = \dot{m}_l \mathbf{h_l} + \dot{Q}_{lg} \tag{5}$$

where $\dot{Q}_{lg} = -\dot{Q}_{gl}$ and $\mathbf{h_l}$ is the specific enthalpy of water. Due to the high thermal inertia of liquid water, its temperature increase remains much below 1^oC in all present simulations, however considering a fixed inlet temperature within the volumetric pump.

2.3 Material selection

Four materials were selected, representing both standard pressure vessels materials and materials with both high thermal effusivity and thermal diffusivity. Commercially available high-pressure vessels are all based on the use of aluminium, steels and carbon fiber reinforced plastics. The study focuses on structures based onto those three main types of materials. In the current study, both the thermal and mechanical properties of materials are considered, a priori, with the same level of importance regarding their impact on the compression energy consumption. Hence, best performing grades of steel and aluminium were chosen in terms of thermal effusivity and diffusivity and in terms of yield strength to density ratio (21.2.0 n.d.): AISI 316L, an austenitic stainless steels, and Al 7068, a 7000 aluminium series. To complete the selection, as metal hybrids and composites are also good material candidates for application as high-pressure vessels (Solazzi and Vaccari 2022) (Bhattacharyya, El-Emam, and Khalid 2022) (Liu et al. 2012), the following two materials are also investigated: a metal matrice composite (MMC), based on an aluminium matrix filled with carbon fibers, and a carbon fiber reinforced polymer (CFRP),

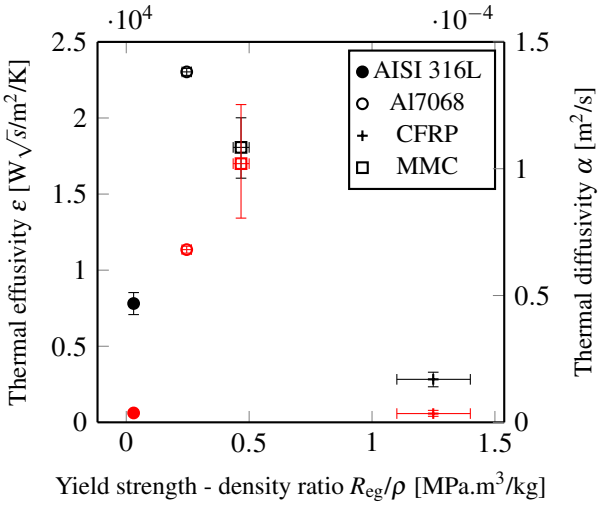

Figure 5. Variations of the selected materials thermal and mechanical properties. Thermal effusivities are represented in black while thermal diffusivities are represented in red.

based on an epoxy matrix reinforced by high strength unidirectional carbon fibers.

The mean thermal and mechanical properties of the four materials are presented **Table 1** and **Table 2**, respectively. **Figure 5** presents the variations of the thermal diffusivity and effusivity of those materials as a function of the ratio between the material yield strength and its density, thus relating the thermal and the mechanical properties of interest for this study.

For each material selected, the minimum wall thickness is determined by both the size of the reservoir and the targeted maximum gas pressure $P_{g,max}$. Thickness and diameter of the pressure vessels are the two main design criteria to ensure strength (Vullo et al. 2014). In the present study, the diameter of the vessel is fixed by the volume of gas that it must contain. Therefore, following recent ISO standard 9809-1:2019 for high pressure gas cylinder (*ISO 9809-1:2019: Gas cylinders - Design, construction and testing of refillable seamless steel gas cylinders and tubes - Part 1: Quenched and tempered steel cylinders and tubes with tensile strength less than 1 100 MPa* 2019), the cylinder wall thickness is obtained from the Lamé von Mises formula. It varies linearly with the vessel diameter D following:

$$a = \frac{D}{2}\left(1 - \sqrt{\frac{10FR_{eg} - \sqrt{3}P_{g,max}}{10FR_{eg}}}\right), \tag{6}$$

where R_{eg} is the minimum guaranteed value of yield stress and $F = min(\frac{0.65}{R_{eg}/R_{mg}}, 0.85)$ is a safety factor which depends on both R_{eg} and R_{mg}, the minimum guaranteed value of tensile stress. Assuming a perfect cylindrical shape for the piston, which is a general simplification of the real design of pressure vessel, the volume of material required is directly deduced, and so is the total mass required. Figure 6 shows this mass normalized by the max-

imum mass of gas (where the gas density ρ_g is taken at the initial baseline conditions). It highlights that the decrease of the piston thickness compensates the supplementary material needed for smaller piston. Hence, looking strictly only at the material mass required, the smaller the piston, the better it is.

3 Results

The conjugate thermal model described in the previous section has been used to predict the compression work required and heat production (through the effective temperature ratio) during the compression strokes. Salient results are presented in this section. First, time-resolved data are inspected in a baseline configuration. The influence of the stroke speed on the thermal gradient within the gas volume and compression work required are investigated. Second, the sentivity of the energy compression cost to the wall material is assessed.

The energy compression cost $\bar{C}$ is defined based on the energy requirement of the hydraulic pump. Further, it is

Table 3. Geometrical, initial, and operating conditions of the liquid piston system.

Geometrical conditions	
Cylinder bore (internal)	240 mm
Cylinder stroke	1 m
Initial conditions	
Initial hydrogen pressure	15 bar
Initial hydrogen temperature	20 ^oC
Initial water level	0.4 m (L) & 0.6 m (R)
Initial water temperature	20 ^oC
Operating conditions	
Overall pressure ratio	30
Injection flowrate	0.8 L/s
Ext. ambiant temperature	20 ^oC
Ext. heat transfer coefficient	3 $W.K^{-1}.m^{-2}$

defined per unit of mass of hydrogen discharged at the targeted pressure. The cost thus reads:

$$\bar{C} = \frac{\int Q_v |P_{g,left} - P_{g,right}|}{\int (q_{m,left} + q_{m,right})} \tag{7}$$

where q_m are the mass flow rates through the two exhaust check valves. The energy compression cost is assessed when the thermal transient behaviour of the system is over and a purely periodic state is reached. A final water level threshold of $99,5\%$ of the stroke length is considered, triggering the switch from the discharge stage to the expansion stage. This level corresponds directly to a dead volume of $0,5\%$ within both cylinder tanks. To sum up, Table 3 lists the geometrical, initial, and operating conditions of the present system in the baseline scenario.

3.1 General results

Figure 7 presents the evolution of different thermophysical variables for fixed regime of pump operation, corresponding to a water flow rate of $Q_v = 0.8L/s$. Pressure rise is shown for both cylinders, as well as the temperature evolution of the left cylinder wall, and, bottom and top gas layers. Vertical delimiters separate the four stages of the compressor system: (i) a long compression stage higlighting the polytropic evolution of pressure and temperature, (ii) a short discharge stage where hydrogen is ex-

hausted at constant pressure and fluctuating temperature, (iii) a short expansion stage where the remaining mass of hydrogen within the dead volume is expanded until the piston pressure reaches the inlet pressure, and finally (iv) a long admission stage where the hydrogen is filled again at constant inlet pressure, and which corresponds to the compression and discharge stage of the other piston. Pressure and temperature are normalized by their initial values (15bar, 20^oC). Aluminium is considered for the material wall, its maxium temperature reaching 35.6^oC at the end of the compression, i.e an extra 15^oC. As for the gas, the temperature ratio reaches 2.11 in the highest gas layers. This finally leads to a compression cost of $1.85kWh/kg$. Due to the heat conduction within the gas volume, the hydrogen temperature is not uniform as shown by the lower temperature obtained in the first layer ($R_T = 1.73$ at maximum).

Figure 8 shows how reducing the pump flow rate allows for more time to cool down the gas during compression, and reduces the vertical temperature gradient. In the second configuration, the flow rate has been divided by a factor height, and so is the power density which is proportional to the stroke duration. The temperature ratio reaches 1.88 at maximum at the end of the compression in this case. It corresponds to an energy cost of compression of $1.73kWh/kg$, representing a 8% cost reduction in comparison to the high flow rate scenario.

3.2 Sensitivity to the cylinder material

In this section, the energy cost of compression obtained with the present model is compared for the four different wall materials considered. The results are shown in Figure 9 along with the associated maximum temperature ratio at the end of the compression stage. Two scenarios are considered. For the first scenario, the internal gas-to-wall heat transfer is modeled with the Reynolds-Prandtl correlation calibrated for this specific liquid piston system in (Solai, Specklin, and Deligant 2025). Results (in light grey in Figure 9) highlight the negligible influence of the wall material in these conditions. The maximum relative difference for the compression cost is below 0.3%. Although the materials exhibit different thermal properties, the relatively short stroke time (around $56s$) and low gas-to-wall convective heat transfer coefficient (at maximum $340W/m^2/K$ at the end of compression and $100W/m^2/K$ in average) do not allow for the wall to affect the temperature rise within the cylinders.

In the second scenario, the heat transfer coefficient has been increased and fixed to $1500W/m^2/K$. This high value corresponds to what can be achieved when aiming at heat transfer enhancement through forced convection, as detailed in (Specklin et al. 2022) where the presence of a high speed fan in the cylinder is modeled. With the present model, this forced convective cooling reduces the energy cost of compression from $1.85kWh/kg$ to approximately $1.55kWh/kg$. Further, in this configuration, the influence of the wall material type becomes visible. Hence, a 2% difference is found in the energy cost of compression between the stainless steel and the carbon fiber reinforced polymer. Their thermal diffusivities and effusivities being relatively close, it shows that it is the thermal inertia which actually drives the energy cost among the material properties. The CFRP heat capacity is 16 folds smaller than the AISI 316L heat capacity, due to its high strength properties that allows for thinner wall and thus lower mass. Hence, after a thermodynamic periodic state being reached, the CFRP wall experiences temperature variations from 27^oC to 62^oC during a stroke, while the stainless steel wall only exhibits temperature periodic oscilations from 40^oC to 42^oC only.

To conclude, although it seems low, a 2% difference in the energy cost of compression can quickly add-up for expensive processes such as high pressure hydrogen compression. This result suggests then that there may be an interesting trade-off between the material cost for the compression system and the energy cost of the compression process.

4 Discussion

The results obtained with the present model can be put in perspective with those from the CFD investigations from (Specklin et al. 2022). In the latter, a lower energy cost of compression was obtained, $1.67kWh/kg$ at a power density of $540kW/m^3$, for an identical hydrogen compression configuration. There are however two differences in the modeling techniques that all lead to an overestimation of the cost in the present case or an underestimation in (Specklin et al. 2022). First, a Nusselt-Peclet correlation is used in (Specklin et al. 2022) for the unsteady gas-to-wall heat transfer, leading to higher coefficent values than the Reynolds-Prandtl correlation used in the present case. Second, Specklin et al. neglected the conjugate heat transfer and assumed an isothermal conditions for the internal wall which could slightly overestimates its cooling power. In our future studies, the Nusselt-Peclet correlation, together with a real gas media or Equation Of State, will be implemented in Modelica and will be used to bridge the modeling gap. Finally, a common limitation to both lumped model and CFD approaches is the omission of the liquid to vapor phase change during the process. The significance of this phenomena has yet not been clearly quantified in literature (Specklin et al. 2022) and certainly depends on gas nature and operating conditions. With air at low pressure ratio, the impact of evaporation seems to have a limited influence on the energy cost of compression (Solai, Specklin, and Deligant 2025). At high pressure ratio, it was shown theoretically by (Srivatsa and P. Y. Li 2018) that mass transfer between liquid water and vapor can significantly affect the maximum temperature reached during compression, and thus the energy cost. However, Wieberdink et al. (Wieberdink et al. 2018) did not mention this issue for instance during the operation of their liquid-piston system for air compression at similar ratio

DOI 10.3384/ecp2181001

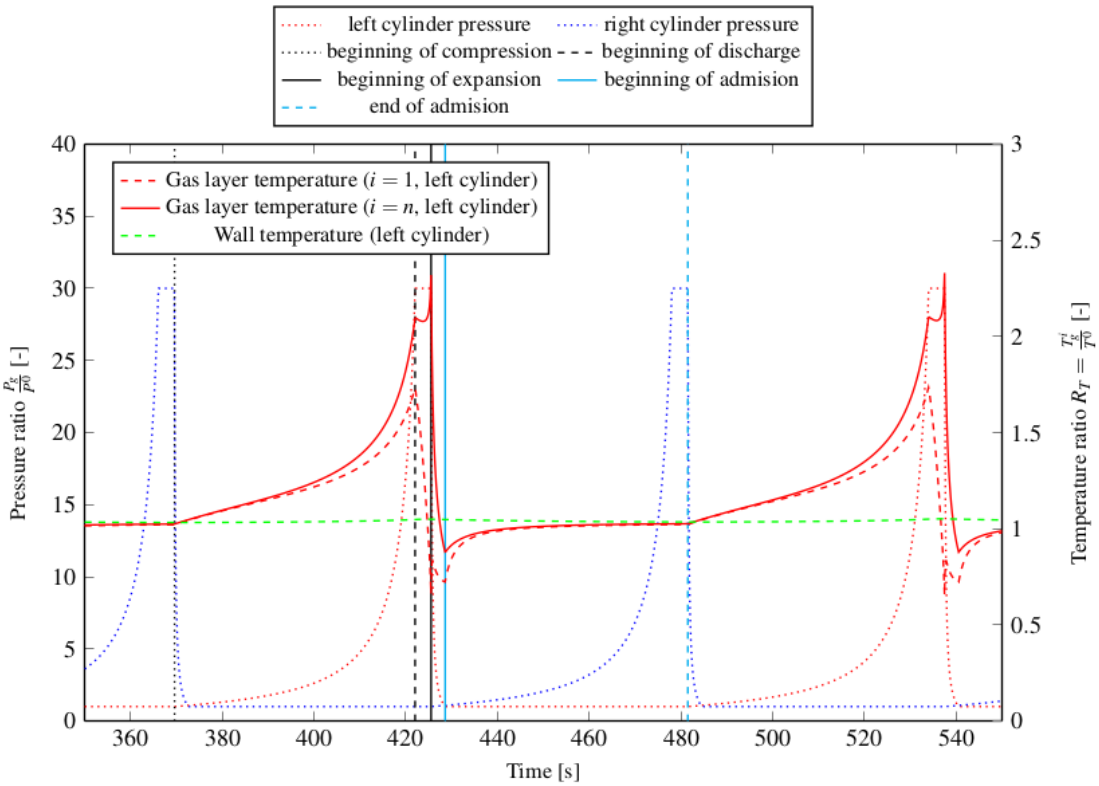

Figure 7. Evolution of pressures and temperatures obtained for $Q_v = 0.8L/s$ with aluminium wall.

and maxima of pressure. To avoid this issue, ionic liquid can be used to compress the gas, as they do not have a vapor pressure (Wang et al. 2018), or additional separator technologies to recover the purity of the materials but with additional costs.

5 Conclusion

In this paper, an object-oriented modeling methodology using the Modelica Programming Language has been presented for a high pressure liquid piston compressor system. The model is based on an existing experimental test bench using air, and has been extended for hydrogen gas. The modeling strategy involves considering the temperature gradient within the compressed gas, using a 1D discretization technique based on MSL elements. Further, conjugate heat transfer through the piston wall is considered and a specific attention is paid to the material choice. In its present state, the lumped model overestimates the energy cost of compression, in comparison to figures obtained with more accurate numerical investigations. However, the developed dynamic model is able to respond to changes in operating conditions and wall material types, and by means of this, it could be used for optimizing processes. In particular, promising insights can be expected from possible trade-off between material cost and energy cost, which could be investigated in full Life Cycle Analysis (LCA) or eLCC (environmental Life Cycle Costs) studies.

Abstract

We present Rumoca, a translator written in Rust that forms the basis of a symbolic toolchain, automatically converting Modelica models into a variety of target algebraic modeling languages. Rumoca is demonstrated on three models and translated into two different algebraic representations: CasADi and SymPy. Designed for generalizability, Rumoca has the potential to accommodate increasingly complex Modelica models and additional target languages.

Keywords: Modelica, symbolic computation, algebraic modeling, cyber-physical systems, Model Translation, CasADi, SymPy

1 Introduction

Cyber-physical systems (CPSs) are designed using a variety of modeling languages and tools, each with its own advantages (Amrani et al. 2021). However, interoperability between these tools remains limited. Porting models across platforms often requires manual conversion or unverifiable code generation techniques, such as those based on large language models (LLMs), which is both time-consuming and error-prone (Liu et al. 2020). To address this, we present Rumoca, a translator written in Rust that converts Modelica models into various algebraic modeling backends, enabling symbolic manipulation, automatic differentiation, and optimization (Jakob Andersson et al. 2019).

The long-term vision for Rumoca is to provide a flexible, extensible compiler infrastructure for hybrid systems modeling and analysis. It targets full coverage of a flattened Modelica representation—stripped of class hierarchies as defined later in this paper—and currently supports SymPy and CasADi backends. By exposing a lightweight abstract syntax tree (AST) and a modular templating engine, Rumoca makes it easy to develop additional code generation backends.

1.1 Modeling and Compiler Languages

Modelica was selected as the source language due to its concise semantics for modeling CPSs and its precise mapping to differential-algebraic equations (DAE) as defined in the language standard (Henriksson et al. 2011). These characteristics make it more verifiable than general-purpose languages like Python and C++, while availability of graphical editors and a large user community further support its adoption.

Rumoca is implemented in Rust, which offers significant benefits for compiler construction. The language provides strong static typing and memory safety without garbage collection, helping to eliminate entire classes of bugs while maintaining runtime performance. Modern features like pattern matching, algebraic data types, and expressive traits support the creation of robust and maintainable translation infrastructure (Klabnik and Nichols 2019; Matsakis and Klock 2014; Jung et al. 2018).

1.2 Target Languages

In designing Rumoca, CasADi and SymPy were selected as the primary languages for translated Modelica models. These languages were chosen because of their strengths in symbolic and numerical computation and optimization.

CasADi is a symbolic framework for algorithmic differentiation and numeric optimization, particularly well-suited for control and estimation in dynamic systems (Jakob Andersson et al. 2019). It represents expressions as directed acyclic graphs (DAGs), which allows for efficient symbolic manipulation and code generation. This structured representation offers significant advantages for optimization tasks compared to black-box models, such as those commonly encapsulated in Functional Mock-up Units (FMUs). CasADi is widely used in optimal control, parameter estimation, and nonlinear programming, especially in embedded applications where runtime performance and gradient computation are critical. By translating Modelica models into CasADi expressions, Rumoca enables users to perform gradient-based optimization, sensitivity analysis, and simulation leveraging high-performance solvers.

A key advantage of using CasADi is its close integration with numerical solvers like IPOPT (Biegler et al. 2009) and C code generation. This makes it highly suitable for deploying optimized controllers or estimators on embedded platforms. A disadvantage of CasADi is its lack of object-oriented features, which makes it difficult to scale to larger, more sophisticated models. However, since object-oriented design is a strength of Modelica, CasADi

is a strong candidate for serving as the backend of the symbolic toolchain enabled by Rumoca.

SymPy, in contrast, is a general-purpose computer algebra system written entirely in Python (Meurer et al. 2017). It supports a broad range of symbolic operations including simplification, equation solving, symbolic differentiation and integration, and matrix algebra. SymPy is especially useful for verifying model structure, performing symbolic manipulations, and producing readable mathematical expressions. These capabilities make SymPy an ideal target when the goal is to inspect or manipulate equations algebraically.

Although SymPy lacks the high-performance optimization and solver integration features of CasADi, it excels in educational, research, and verification settings. SymPy's strength lies in its ability to express mathematical models symbolically and perform analytical transformations, including the computation of Jacobians, Laplace transforms, or simplification of symbolic DAE systems. Its integration with Jupyter and Python's scientific stack makes it highly accessible and extendable. As an immediate application of the SymPy backend, we intend to leverage these computational features to construct reachability proofs.

1.3 Related Work

Numerous tools exist for compiling or translating Modelica models, each with distinct design goals. Rumoca distinguishes itself by acting as a *translator*–focused on high-level symbolic representation and model interoperability–rather than as a compiler generating low-level machine code.

The most mature open-source option is OpenModelica, which supports the Modelica Standard Library and offers a graphical user interface via OMEdit ((OSMC) 2025). While well-suited for simulation and code generation, OpenModelica does not currently support symbolic backends such as CasADi or SymPy. Since the OpenModelica compiler does support multi-code generation backends, it is possible it could be extended to these languages. Rumoca, however, offers unique advantages by being implemented in Rust, having algebraic modeling languages in mind.

Marco is a high-performance Modelica compiler written in C++ and based on LLVM (Agosta et al. 2023). It targets efficient simulation of large-scale models, prioritizing speed and robustness. However, Marco is focused on generating C code and does not offer translation into symbolic frameworks, limiting its utility for applications involving algebraic transformation or formal analysis.

In constrast to traditional Modelica compilers that focus on simulation and code generation, Rumoca is designed as a translator–targeting symbolic and algebraic frameworks. Its purpose is not to compete on execution speed or complete language coverage, but to facilitate workflows involving optimization, model verification, and hybrid system analysis. We envision a workflow that utilizes OpenModelica or Marco, by using these compilers to convert Modelica models to an intermediate representation that could be handled by Rumoca. The clear candidate would be the ongoing effort to define a BaseModelica language specification, which is a simplified subset of Modelica.

While Rumoca may not be able to handle a complex model directly, the model could first pass through a compiler such as Marco or OpenModelica, removing its object-oriented structure, and produce the model in BaseModelica. The BaseModelica version could then be processed by Rumoca. This proposed workflow is shown in Figure 1.

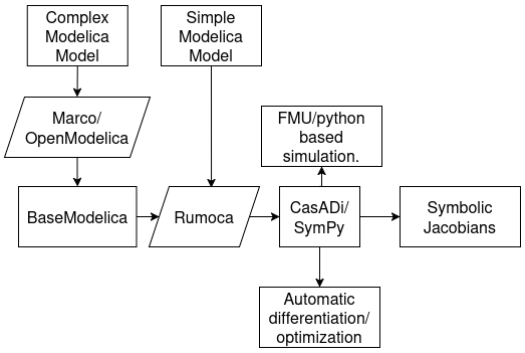

Figure 1. Proposed workflow utilizing compilers for generation of BaseModelica. Rumoca is a translator that takes simple Modelica models to target algebraic modeling languages. Complex models could first be passed through a more extensive compiler, removing the object oriented structure, before being processed by Rumoca.

Another notable effort is Pymoca, an open-source translator written in Python and based on ANTLR. It shares similar goals with Rumoca and provides a Pythonic interface for model transformation (Contributors 2025). Pymoca benefits from accessibility and ease of use, especially for Python developers. However, it suffers from significant performance limitations due to Python's speed and the use of un-typed ASTs. The lack of strong typing and the slow parsing pipeline–where the source is first converted into a parse tree before AST generation–makes Pymoca less suitable for handling large-scale models efficiently.

1.4 Overview

The remainder of the paper is structured as follows. Section 2 explains the details of Rumoca, including modifications to the Parol parser, structure of the AST, and use of Jinja2 templates for the generator code. Section 3 describes some changes that were made to the CasADi library to more easily accommodate the Modelica structure. Section 4 demonstrates Rumoca on three example systems, converting them from Modelica to Sympy and CasADi. Section 5 provides a summary and direction for future work on the Rumoca translator.

DOI 10.3384/ecp2181009

2 Rumoca Details

The compiler pipeline can be understood in terms of four components. First, the automatically generated parse tree is overwritten to a customized IR format. Second, this AST is flattened, removing class hierarchies. Third, the flattened IR is lowered into a DAE representation, consistent with the semantics defined by the Modelica specification. Finally, the DAE system is rendered into the target language using a template engine.

2.1 Parser

For parsing, Rumoca is using the Parol parser (Singer 2025). Parol is a Rust based parser generator, similar to ANTLR. Given an EBNF grammar file, Parol can automatically generate a parser. While we evaluated other parser generators such as ANTLR and LALRPOP, we found that Parol was best suited for the project. ANTLR handles EBNF grammar well, but does not have a native Rust implementation, and lacks the capability to significantly modify the automatically generated parser code. ANTLR does however support (LR*) grammar with arbitrary look-ahead which simplifies grammar handling.

The LALRPOP parser generator, which handles LR(1) grammar, we found to be limiting, and the compilation times for the compiler slowed our development cycle. LALRPOP did provide an easy mechanism for modifying the generated parser tree at runtime so that a second pass over the parser tree was not generated to obtain an abstract syntax tree.

Finally, Parol was selected as it had the advantage of supporting EBNF grammar and allowing for customization of the parse tree at parse time. When customization of the parse tree is necessary to obtain a desirable abstract syntax tree to be used as an internal representation, it is useful to selectively re-implement the parse tree generation for specific language elements. The automatically generated parsing functions may then be leveraged when customization is not necessary. Parol has a fast compile time, similar to ANTLR, and is a LL(k) parser. LL(k) means that the EBNF grammar is analyze for the largest look-ahead necessary. We were able to implement the Modelica language specification with a look-ahead of 3 tokens (k = 3). In order to simplify the implementation of the Modelica language parser, we requested several features to be added to Parol, and they were quickly implemented.

2.2 Language Coverage

While the Parol parser automatically generates a parse tree for the entire Modelica language grammar, the steps converting it to the intermediate representations require significant customization. For this reason, Rumoca only supports a portion of the Modelica language. Independently, there is an ongoing effort to define a BaseModelica language specification, which is a simplified subset of Modelica. It is our goal to have Rumoca work for the entirety of the BaseModelica features. Table 1 shows a preliminary draft of the features that may be included in BaseModelica, and which are currently supported by Rumoca. The features listed were taken from the BaseModelica meeting notes (Modelica Association 2023). We envision that compilers such as OMC or Marco will compile to BaseModelica, so that by chaining the tools any Modelica model could be handled by Rumoca.

Table 1. Rumoca support for selected Modelica features

Modelica Feature	*Supported*
Scalar types (e.g., `Real`, `Integer`)	Yes
Record and enum types	No
Arrays (decl. & indexing)	Partial
Component decl.	Yes
Equations and algorithms	Yes
Source location metadata	No
Documentation strings	Yes
Vendor-specific annotations	No
All variabilities (no param eval)	Yes
Params treated as const	Yes
Preserve values of inlined constants	Yes
Relaxed record field access	No
Relaxed array subscripting	Partial
Naming of intermediate vars	No
Alias expressions (ref & sign)	No
Used function declarations	Yes

In addition to the features listed, we have added support for simple class structures. This is because we intend to use Rumoca for hierarchical reachability proofs which require nested components.

2.3 Generator Code

Jinja2, a widely used text templating engine for Python, is employed to construct the generator code. With millions of downloads per month and integration into major frameworks such as Flask and Ansible, Jinja2 benefits from a large and active user base (Index 2024; Projects 2024; Red Hat 2024). In Rumoca, each Jinja template defines how the symbolic expressions described in the AST are rendered into source code. Due to the common DAE structure of the AST, templates can be created and modified for specific target languages with relative ease. This gives Rumoca the advantage of being extendable to a variety of backends with minimal effort and expertise. This allows for end-users to create custom backends. Examples and documentation for writing custom templates are available online.[1]

An example of how a template defines the handling of model parameters is shown below. Listing 1 presents a portion of the template for rendering the CasADi repre-

[1] `https://github.com/CogniPilot/rumoca/blob/main/tests/templates`

sentation, while Listing 2 displays the corresponding rendered code.

Listing 1. Jinja2 template for parameter handling

```
{%- elif var == 'p' %}
    # Declare {{ var }}
    {% for c in dae[var] -%}
    {{ c.name }} = dae.add('{{ c.name }}',
        'parameter', 'tunable', dict(start
        = {{ render_expression(c.start) }})
        )
    {% endfor -%}
```

Listing 2. Rendered code for parameter declarations

```
# Declare p
e = dae.add('e', 'parameter', 'tunable',
    dict(start = 0.8))
h0 = dae.add('h0', 'parameter', 'tunable',
    dict(start = 1.0))
```

3 CasADi Additions

In this work we leverage and extend CasADi's DaeBuilder class (Joel Andersson 2024), which can be used for both import of Modelica in both symbolic form and in the form of exported FMUs adhering to FMI 2.0 and 3.0. In the recent CasADi 3.7 release, the DaeBuilder class was refactored to use a representation of model variables that closely resembles the representation of model variables in the FMI standard. The same release also saw a new refactored high-level interface for symbolically defining model equations, now including model equations with event dynamics, compatible with the recently added support for analytic derivative calculations for dynamic systems with events (Joel Andersson and Goppert 2025). Another important update is an extension of CasADi's support for FMI export, which can now be used for systems with events. We refer to the updated CasADi user guide for details on this support.

4 Examples

This section demonstrates the use of Rumoca on three representative examples: a simple bouncing ball, a mass-spring-damper system, and a more complex quadrotor model. For each case, Rumoca takes the corresponding Modelica model and translates it into either a SymPy or CasADi representation, depending on the selected backend template. These examples illustrate the class of systems that Rumoca currently supports, ranging from basic hybrid dynamics to nonlinear multibody systems.

In addition to translation, further analyses are performed to highlight some of the benefits of the target symbolic languages. Specifically, an optimal disturbance attack is computed for the mass-spring-damper model, leveraging CasADi's directed acyclic graph (DAG) structure and automatic differentiation. For the quadrotor, the Jacobian matrix is extracted using SymPy's symbolic differentiation capabilities, which enable exact analytical expressions for sensitivity analysis and control design.

Rumoca is accessed through a command-line interface. Listing 3 shows the help menu output. As shown, Rumoca requires two inputs: a Modelica model and a code generation template specifying the target language. Each example uses a distinct Modelica file and a corresponding template—either for SymPy or CasADi—to produce the desired output.

Listing 3. Rumoca Help Menu

```
Rumoca Modelica Translator

Usage: rumoca [OPTIONS] --template-file <
    TEMPLATE_FILE> --model-file <MODEL_FILE
    >

Options:

      model file to compile
  -v, --verbose
      Verbose output
  -h, --help
      Print help
  -V, --version
      Print version
```

4.1 Bouncing Ball

As a first example, consider the classic bouncing ball model. Listing 4 shows this in Modelica.

Listing 4. Bouncing Ball model in Modelica

```
model BouncingBall "The 'classic' bouncing
    ball model"
  parameter Real e=0.8 "Coefficient of
      restitution";
  parameter Real h0=1.0 "Initial height";
  Real h = 5.0 "Height";
  Real v "Velocity";
  Real z;
equation
  z = 2*h + v;
  der(h) = v;
  der(v) = -9.81;
  when h<0 then
    reinit(v, -e*pre(v));
  end when;
end BouncingBall;
```

The bouncing ball model above is processed by Rumoca using the CasADi template, which generates a corresponding Python script. Listing 4.1 shows the command used to run this transformation via the command-line interface.

```
rumoca BouncingBall.mo -t casadi.jinja >
    bouncing_ball_ca.py
```

This generated script, here called "bouncing_ball_ca.py", contains a class with several methods. A portion of this code is shown in Listing 5.

Listing 5. A portion of the casadi code generated by rumoca (bouncing_ball_ca.py)

DOI 10.3384/ecp2181009

```
def c0():
    return (h < 0.0)

# ============================================
# Define reset functions: fr
def c0_fr():
    return dae.reinit("v", -((e * pre_v)))
dae.when(c0(), [c0_fr()])
# ============================================
# Declare x_dot
der_h = dae.der(h)
der_v = dae.der(v)
# ============================================
```

The example in Listing 6 demonstrates how to simulate the bouncing ball using the generated CasADi class, the result of which, is Figure 2 .

Listing 6. Simulation of the bouncing ball model using CasADi backend

```
import bouncing_ball_ca
import matplotlib.pyplot as plt

model = bouncing_ball_ca.Model("
    bouncing_ball")
tgrid, res = model.simulate(t0=0, tf=8, dt
    =0.01)

plt.plot(tgrid, res['xf'].T, label=model.
    dae.x())
plt.grid()
plt.legend()
plt.show()
```

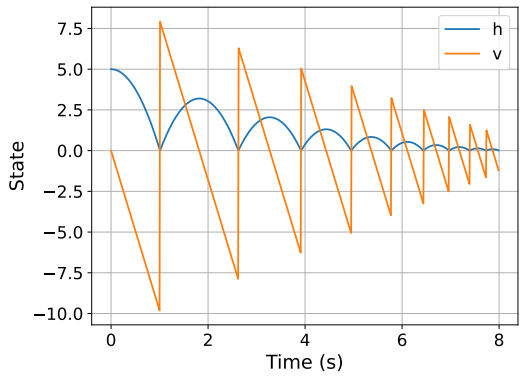

Figure 2. Height (m) and velocity (m/s) of a bouncing ball as a function of time. The simulation was done using the automatically generated CasADi script.

Consider now the example of using Rumoca on the bouncing ball model with the SymPy template. Here, the generated code is a script "bouncing_ball_sympy.py." As with the CasADi generated script, this code contains a class with several methods. A portion of this code is shown in Listing 7.

Listing 7. A portion of the SymPy code generated by rumoca ("bouncing_ball_sympy.py")

```
# Define Reset Functions: fr
def __fr_c0(x):
    pre_h, pre_v = self.x
    h, v = self.x
    v = -((e * pre_v))
    return [
        h,
        v]
self.fr_c0 = sympy.lambdify([self.x, self.p
    ], __fr_c0(self.x))

#
    ============================================

# Define Condition Update Function: fc
self.fc = sympy.Tuple(*[
    (h < 0.0)])
self.f_c = sympy.lambdify(
    args=[self.time, self.x],
    expr=self.fc,
    modules=['numpy'])
```

Listing 8 demonstrates running the bouncing ball simulation with the SymPy script, adjusting the initial height and velocity as well as the coefficient of restitution parameter. The corresponding plot can be seen in Figure 3.

Listing 8. Simulation of the bouncing ball model using SymPy backend

```
import bouncing_ball_sympy
import matplotlib.pyplot as plt

model = bouncing_ball_sympy.Model()
model.solve()
model.x0['h'] = 10
model.x0['v'] = 5
model.p0['e'] = 0.7
res = model.simulate(t0=0, tf=8, dt=0.01)

plt.plot(res['t'], res['x'].T, label=model.
    x0.keys())
plt.legend()
plt.grid()
```

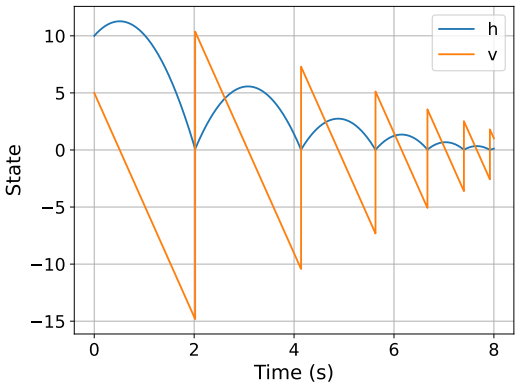

Figure 3. Height (m) and velocity (m/s) of a bouncing ball as a function of time. The simulation was done using the automatically generated SymPy script.

4.2 Mass-Spring-Damper

As an example of leveraging CasADi optimization, consider the simple mass spring damper system in Modelica

with a disturbance force shown in Listing 9.

Listing 9. Mass-spring-damper system

```
model msd "Mass spring damper"
  parameter Real k=1.0 "Coefficient of
      spring";
  parameter Real c=1.0 "Coefficient of
      damper";
  parameter Real m=1.0 "mass";
  Real x = 0.0 "Position";
  Real v "Velocity";
  input Real u "Disturbance";
equation
  der(x) = v;
  der(v) = -(k/m)*x - (c/m)*v - (1/m)*u;
end msd;
```

Once the model is processed by Rumoca using the CasADi template, the system can be optimized using familiar CasADi features. Consider the problem of optimizing a bounded disturbance for the MSD system such that it causes the mass to deviate as far as possible from equilibrium. This problem is solved using CasADi optimization tools, and the result is shown in Figure 4. This was done with the system only ever written in Modelica.

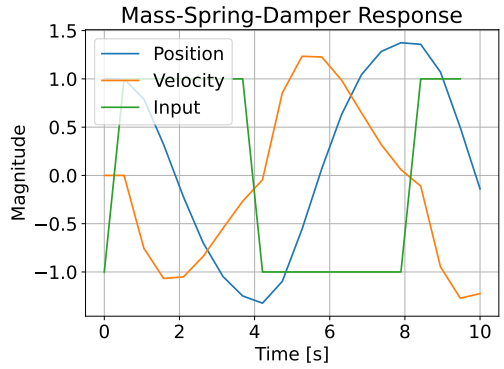

Figure 4. The optimized bounded control input to maximize disturbance from equilibrium. This was found using CasADi tools, having only written the system in Modelica.

4.3 Quadrotor

Rumoca is also capable of handling more complex models, including some with a hierarchical structure. The quadrotor model shown in Listing 10, extends a rigid body model and makes use of a separate motor model. Automatic generation of the corresponding CasADi and SymPy code are shown and demonstrate handling control inputs and using Sympy to linearize the model.

Listing 10. Quadrotor model definition in Modelica

```
model Quadrotor
    extends RigidBody6DOF;
    parameter Real l = 1.0;
    parameter Real mix_a = 1;
    parameter Real mix_e = 1;
    parameter Real mix_r = 10;
    parameter Real mix_t = 32.0;
    Motor m_1, m_2, m_3, m_4;
    input Real a "aileron";
    input Real e "elevator";
    input Real r "rudder";
    input Real t "throttle";
equation
    // body forces
    F_x = -(m*g)*sin(theta);
    F_y = (m*g)*sin(phi)*cos(theta);
    F_z = (m*g)*cos(phi)*cos(theta) -
          (m_1.thrust + m_2.thrust + m_3.
              thrust + m_4.thrust);

    // body moments
    M_x = l*(-m_1.thrust + m_2.thrust - m_3
        .thrust + m_4.thrust);
    M_y = l*(-m_1.thrust + m_2.thrust + m_3
        .thrust - m_4.thrust);
    M_z = m_1.moment + m_2.moment - m_3.
        moment - m_4.moment;

    // motor equations
    m_1.omega_ref = t*mix_t - a*mix_a + e*
        mix_e + r*mix_r;
    m_2.omega_ref = t*mix_t + a*mix_a - e*
        mix_e + r*mix_r;
    m_3.omega_ref = t*mix_t - a*mix_a - e*
        mix_e - r*mix_r;
    m_4.omega_ref = t*mix_t + a*mix_a + e*
        mix_e - r*mix_r;
end Quadrotor;
```

4.3.1 CasADi Quadrotor Simulation

Upon running Rumoca for the quadrotor model using the CasADi template, the "quadrotor_casadi.py" python script is generated. Listing 11 demonstrates how the control input can be adjusted and the quadrotor simulated. In this case, the throttle is set to a constant value. The resulting position of the quadrotor upon running the CasADi simulation is shown in Figure 5.

Listing 11. CasADi simulation setup for the quadrotor model

```
model = quadrotor_casadi.Model("quad")
states = model.dae.x()
params = model.dae.p()

x0 = model.dae.start(states)
param_vals = model.dae.start(params)

# Set control input: aileron, elevator,
    rudder, throttle
inputs = np.array([0, 0, 0, 0.5])

# Set initial height of quadrotor to 10 m.
x0[states.index('h')] = 10
tgrid, res = model.simulate(t0=0, tf=10, dt
    =0.01, f_u=inputs, x0=x0)
```

4.3.2 SymPy Quadrotor Linearization

Rumoca's SymPy output enables the generation of symbolic expressions for the Modelica model. Eq, displays a portion of the 16×16 linearized state matrix for the quadrotor automatically generated by Sympy from the

DOI

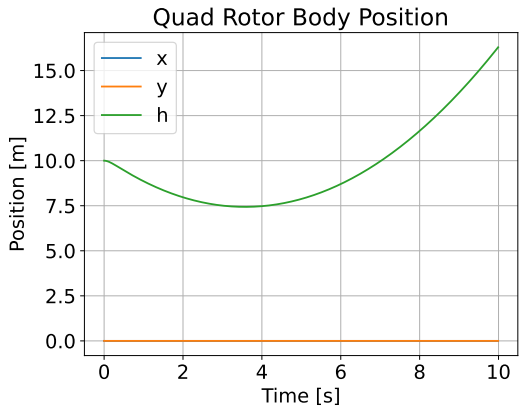

Figure 5. Quadrotor position from CasADi simulation.

Modelica model, illustrating the power of using SymPy as a back-end.

$$\begin{array}{ccc} \frac{J_x J_{xz} Q - J_{xz} J_y Q + J_{xz} J_z Q}{\Lambda} & \frac{J_x J_{xz} P - J_{xz}^2 R - J_{xz} J_y P + J_{xz} J_z P + J_y J_z R - J_z^2 R}{\Lambda} & \frac{-J_{xz}^2 Q + J_y J_z Q - J_z^2 Q}{\Lambda} \\ \frac{-J_x R - 2J_{xz} P + J_z R}{J_y} & 0 & \frac{-J_x P + 2J_{xz} R + J_z P}{J_y} \\ \frac{J_x^2 Q - J_x J_y Q + J_{xz}^2 Q}{\Lambda} & \frac{J_x^2 P - J_x J_{xz} R - J_x J_y P + J_{xz}^2 P + J_{xz} J_y R - J_{xz} J_z R}{\Lambda} & \frac{-J_x J_{xz} Q + J_{xz} J_y Q - J_{xz} J_z Q}{\Lambda} \end{array} \tag{1}$$

Linearizing the system in SymPy, the root locus and Bode plots can be quickly computed in Python. These are shown in Figure 6 and 7 respectively for the transfer function relating the motor throttle command to the altitude of the quadrotor.

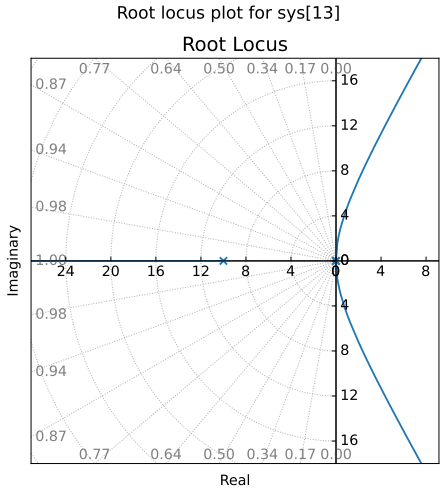

Figure 6. Root locus plot for linearized quadrotor.

5 Summary and Future Work

This paper introduces Rumoca, a Rust-based translator that automates the conversion of Modelica models into a variety of target algebraic modeling languages. Demonstrated through the translation of three models into two algebraic representations—CasADi and SymPy—Rumoca showcases its ability to bridge Modelica and common

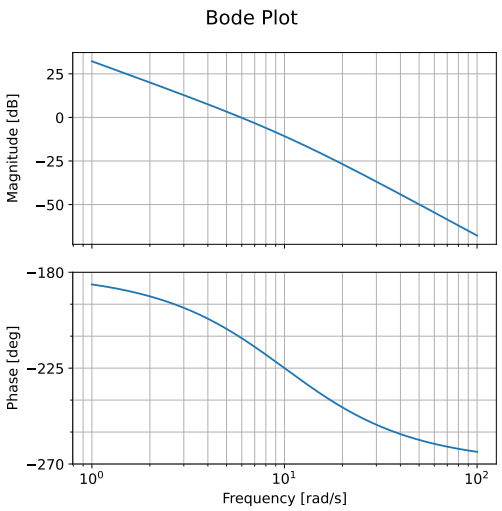

Figure 7. Bode plot for linearized quadrotor.

computational tools. While still in active development, future enhancements to Rumoca aim to expand its capabilities to handle a broader range of Modelica features. Additionally, future work may include the creation of Jinja templates to integrate with other back-ends, such as JAX for machine learning applications, Pycollimator for an intuitive graphical user interface, and Gazebo for simulations.

Safe and Efficient Control of a Brayton Cycle Heat Pump Using Reinforcement Learning

A. Phong Tran[1] Fatma Cansu Yücel[1]

[1]German Aerospace Center (DLR), Institute for Low-Carbon Industrial Processes, Germany,
{Phong.Tran,Fatma.Yuecel}@dlr.de

Abstract

Decarbonizing industrial process heating will increasingly depend on high-temperature heat pumps. In particular, Brayton cycle heat pumps, which can reach temperatures above 250 °C, are viewed as a promising technology. However, ensuring safe operation and optimal control remains challenging. This study presents an experimentally validated dynamic model of a Brayton cycle heat pump, a system with multiple control inputs for regulating its thermal output. Using this model as a training environment, several control concepts integrating Reinforcement Learning (RL) and traditional PI controllers were implemented to achieve desired heat supply at target temperatures. Domain randomization was employed to improve the controller robustness against model uncertainties in preparation for deployment on the physical system. The results demonstrate that RL controllers can not only achieve the desired set-point temperature under varying loads while maintaining required safety margins, but also discovered a novel, more energy-efficient operational strategy.

Keywords: Brayton cycle heat pump, dynamic simulation, reinforcement learning, model-based control design

1 Introduction

Heating for industrial processes is predominantly fueled by fossil fuels, presenting a significant challenge for decarbonization efforts (IEA 2024). High-temperature heat pumps are crucial technologies for electrifying industrial process heating, and improving their control is essential for maximizing their operational efficiency and decarbonization impact.

1.1 High-temperature heat pumps

Recent advancements have significantly raised achievable supply temperatures of heat pump systems. The IEA HPT Annex 58 (Heat Pump Centre 2023) compiled heat pump demonstrators achieving temperatures of 115 °C to 280 °C. For the upper end of this range, particularly for sensible heating, gas compression heat pumps utilizing the Brayton cycle are emerging as a viable technology, with studies indicating technical feasibility up to 300 °C to 400 °C and economic potential in scenarios reaching 280 °C (Zühlsdorf et al. 2019). Oehler, Tran, and Stathopoulos (2022) note that while Brayton cycle heat pumps provide significant operational flexibility, their operation is constrained by compressor surge, thermal stresses, and natural frequencies, thus requiring a carefully designed control system.

1.2 Reinforcement learning

Reinforcement Learning (RL) is an area of machine learning focused on how agents learn to make optimal sequences of decisions through interaction with an environment. RL has proven useful in many areas, including games (Silver et al. 2018), robotic systems (Tang et al. 2025), and optimal energy dispatching (Di Cao et al. 2020). Model-free RL algorithms are particularly adaptable as they learn purely from environment interactions, but this often requires large amounts of data, highlighting the need for simulation. Modelica models have emerged as suitable simulators to train RL algorithms, as demonstrated by developments such as FMUGym (Wrede et al. 2024) and ModelicaGym (Lukianykhin and Bogodorova 2019), both of which utilize the Functional Mock-Up Interface (FMI). Although training in simulated environments offers a safe and efficient approach, these simulations inherently differ from their real-world counterparts. This discrepancy can cause policies trained in simulation to fail or underperform when deployed on the actual physical system. This challenge is widely recognized as the *reality gap* or the *Sim2Real* problem (Zhao, Queralta, and Westerlund 2020).

1.3 Other advanced control techniques

Optimica (Åkesson 2008), an extension of the Modelica language, allows users to formulate optimization problems alongside dynamic system models, which can then be processed by tools such as JModelica (Magnusson and Åkesson 2015) and the Optimica Compiler Toolkit (Modelon, Inc. 2024). These tools interface with the framework CasADi (Andersson et al. 2019), which translates the problem into a non-linear programming problem. The resulting NLP can then be solved by numerical solvers like Interior Point Optimizer (IPOPT). The described toolchain provides a mechanism for solving optimal control problems for systems modeled in Modelica. This capability is a prerequisite for Model Predictive Control (MPC).

1.4 Our contributions

This study utilizes an experimentally validated dynamic model of a Brayton cycle heat pump as an accurate training environment for RL. Three control concepts are comparatively analyzed, including a traditional approach with PI controllers, a pure RL controller and a combination of RL and PI controllers. To improve the potential for real-world transfer, the RL agents are trained using domain randomization. The results show that RL agents can learn the control tasks and discover novel and more energy-efficient operational strategies. The viability of training RL agents in a simulation environment is demonstrated by their control performance and ability to generalize across a wide range of system parameters.

2 The CoBra Heat Pump

This study investigates a closed-loop Brayton-cycle heat pump that uses air as its working fluid. The prototype under investigation, named "CoBra", was developed in Cottbus, Germany, and serves as a research platform for the design and operation of high-temperature heat pumps. Yücel et al. (2025) provide details on the system design and first commissioning tests of the plant.

2.1 System description

Figure 1 shows a flow schematic with the main components of the heat pump. The heat pump employs a two-stage compression system (A), using two radial compressors connected in series driven by an electric motor. After compression, the working fluid releases heat in the high-temperature heat exchanger (B). A three-way valve (C) controls the flow through the recuperator (G), which preheats the flow before compression using the temperature difference between the states 2 and 5. The turbine (D) expands the fluid, thereby recovering power via a generator and cooling the fluid further. A turbine bypass valve (E) operates in parallel to the turbine, allowing adjustment of the loop resistance to control the compressor operating point. After expansion, the cold fluid absorbs heat from a heat source or provides cooling in the low-temperature heat exchanger (F). Finally, the fluid passes through the recuperator (G) to be preheated before re-entering the compression system (A).

As investigated by Oehler, Gollasch, et al. (2021), the heat pump's fluid inventory (total working fluid mass) can be adjusted using a pair of valves. An inlet valve (H1) injects air from a high-pressure buffer tank to the low-pressure section to increase the fluid inventory, while a relief valve (H2) vents air from the high-pressure section to the ambient environment to decrease it. This fluid inventory control allows modulation of the heat pump's thermal output while maintaining the aerodynamic operating conditions of the turbomachinery. The demonstrated range for this control spans compressor inlet pressures (p_0) from 0.8 to 1.4 bar.

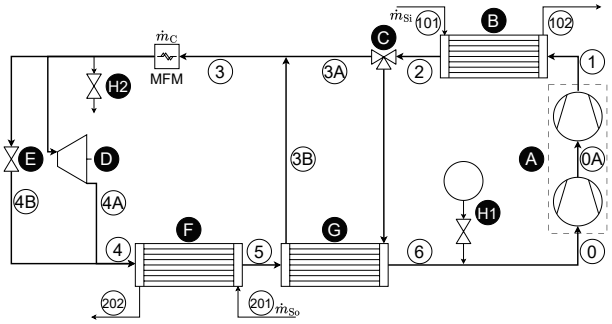

Figure 1. Flow schematic of the CoBra heat pump. (A) Two-stage compression system, (B) high-temperature heat exchanger, (C) three-way valve, (D) turbine, (E) turbine bypass valve, (F) low-temperature heat exchanger, (G) recuperator, (H1) buffer tank and air inlet valve, (H2) relief valve, MFM: Coriolis mass flow meter. Adapted from Tran and Stathopoulos (2025).

2.2 Dynamic model

A dynamic thermo-fluid model of CoBra heat pump was implemented in Modelica using the Dymola environment, as presented in previous work (Tran and Stathopoulos 2025), combining and extending models from the Modelica Standard Library (MSL), Buildings library (Wetter et al. 2014) and ThermoPower library (Casella and Leva 2006) to model the relevant thermodynamic processes and system dynamics. The model diagram is shown in Figure 2.

The libraries were selected due to their shared use of interfaces from the MSL, defined in `Modelica.Fluid` and `Modelica.Media` for fluid flow and properties, `Modelica.Thermal` for heat transfer, and `Modelica.Mechanics` for rotational mechanics. The specific contributions of each library to the overall model are as follows:

ThermoPower: The turbomachinery models (compressor and turbine) were implemented using models adapted from the ThermoPower library. These models assume steady-state behaviour without inherent mass or thermal dynamics, an assumption justified by the fast response time of the turbomachinery relative to other system components. Their behavior is defined by performance maps that relate pressure ratio, corrected mass flow, corrected shaft speed, and isentropic efficiency. The turbomachinery models also feature an `Modelica.Mechanics` flange, which enables a connection to the rotational components.

Buildings: The Buildings library was used to model the plant's piping, valves and fans. The volume and thermal inertia of the extensive piping network were represented using `MixingVolume` with dynamic energy and mass balances. Frictional losses in each pipe segment were modeled by two `PressureDrop` models in series, one with a quadratic ($\Delta p \sim \dot{m}^2$) and another with a linear ($\Delta p \sim \dot{m}$) pressure loss correlation. The three-way and turbine bypass valves are represented by the provided valve

DOI 10.3384/ecp2181017

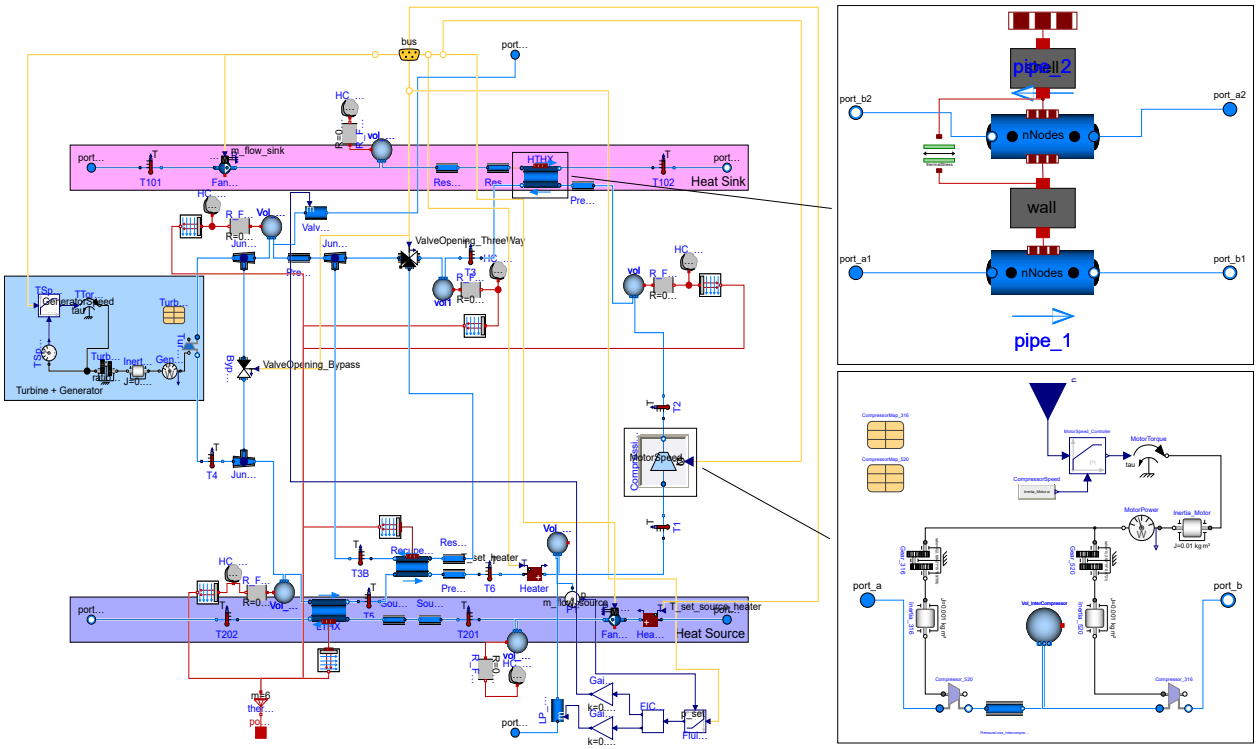

Figure 2. Diagram of the heat pump model in Dymola. Left: Overall heat pump. Top-right: Heat exchanger. Bottom-right: Compression system.

models with valve characteristics and sizings taken from manufacturer data. The fans providing air flow to the heat source and sink were represented by the library's flow-controlled mover models.

MSL: Beyond providing the interfaces, the MSL was employed to model mechanical components and heat exchangers. The rotational components, including the motor, generator, shafts and belt drives, were modeled using components from `Modelica.Mechanics`. The heat exchanger models were adapted from the `BasicHX` model and use a spatial discretization approach. In this method, the fluid flow paths and the solid metal structures (tubes and shell) are divided into multiple segments. For the purpose of this study, the baseline `BasicHX` model was extended to model several features of the real component: the heat capacity of the heat exchanger's outer shell, an additional heat port to model heat exchange with the ambient environment, and a model that calculates thermal stresses based on the temperature distribution along the tube and shell length.

2.3 Experimental validation

The methodology for calibrating the model against experimental data was presented in previous work (Tran and Stathopoulos 2025). Adjusting the compressor performance maps was a main focus, employing a transformation method aimed at minimizing prediction error while preserving the map's original shape, ensuring smoothness, and allowing for plausible extrapolation into unmeasured regions. Other model parameters, mainly heat transfer, heat loss and pressure loss coefficients, were tuned using numerical optimization to minimize deviations between simulation results and measurements.

For this study, a recalibration of the model was performed. This was necessary because new measurement data became available, recorded from a test setup that includes fully recuperated heat pump operation, a condition not covered in the previous work. An example test run from the new dataset is shown in Figure 3. In this test, following an initial ramp-up to nominal motor speed, a PI controller was applied to maintain the supply temperature (T_{102}) at 200 °C by adjusting compressor speed. Subsequently, the compressor inlet pressure (p_0) was varied stepwise (1.1 bar down to 0.8 bar in hourly intervals) using fluid inventory control. The test aimed to find the optimal operating point for the target supply temperature, indicated by the highest measured COP. The highest steady-state COP was measured at a pressure of 0.8 bar, which is the lower bound of investigated pressures. This suggests that the optimum might be at even lower pressures.

The predictions from the recalibrated model are compared to the measurement data shown in Figure 3. The resulting root mean squared errors (RMSE) and mean-normalized root mean squared errors (NRMSE) for the primary process variables are presented in Table 1. For the measured temperatures, pressures, and mass flow rate, the NRMSE values are in the range of 0.05 % to 1.95 %.

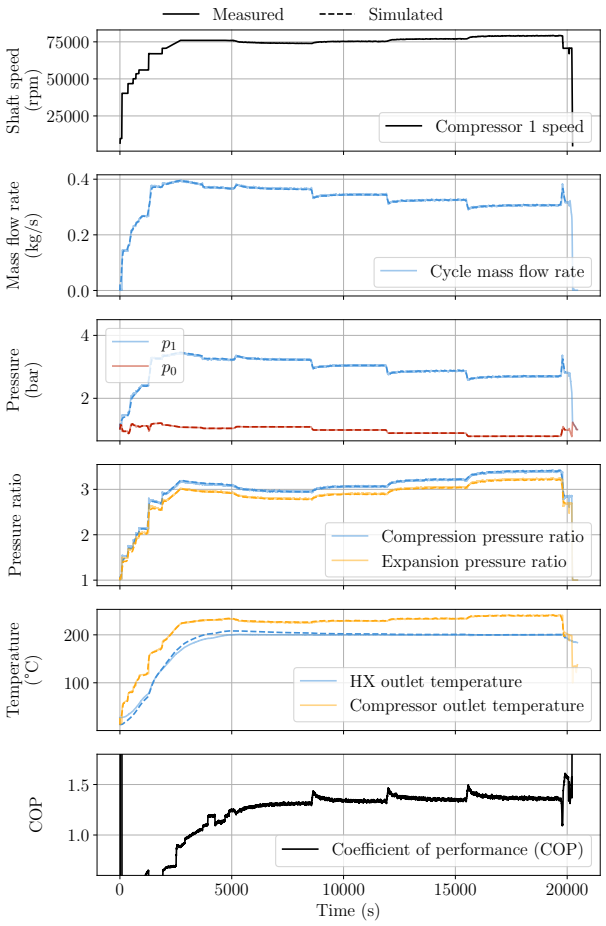

Figure 3. Comparison of measured (solid) and simulated (dashed) time series. The plot shows the alignment of experimental data and simulation results over time.

3 Heat Pump Control

The heat pump's target supply temperature (T_{102}), the return temperature from the process (T_{101}) and the heat sink mass flow rate ($\dot{m}_{\mathrm{Si}}$) are typically defined by process requirements. Consequently, a heat pump's control system is designed to track the set-point supply temperature while maintaining safe operating conditions. The CoBra heat pump features three main control variables that affect the supply temperature:

1. The *motor speed* (n_M) is the main manipulated variable for controlling the heat pump's supply temperature because it directly governs the compressor pressure ratio, mass flow rate and temperature lift.

2. The *three-way valve opening* (θ_{3W}) controls the amount of heat that is internally recovered by the recuperator. A value of $\theta_{3W} = 0$ represents full recuperation, whereas $\theta_{3W} = 1$ corresponds to fully non-recuperated operation.

3. Manipulation of the fluid inventory, indicated by the *compressor inlet pressure* (p_0), directly scales with the mass flow rate in the heat pump cycle, thereby providing control over its overall thermal output capacity.

Table 1. Root mean squared error (RMSE) and mean-normalized root mean squared error (NRMSE) of the main process variables.

Measurement signal		RMSE	NRMSE
Compressor outlet	T_1	1.64 K	0.33 %
HTHX outlet	T_2	3.89 K	1.19 %
Recuperator outlet (HP)	T_{3B}	0.72 K	0.25 %
Turbine inlet	T_3	0.56 K	0.19 %
Turbine outlet	T_{4A}	0.70 K	0.29 %
LTHX outlet	T_5	0.39 K	0.14 %
Recuperator outlet (LP)	T_6	1.73 K	0.56 %
HTHX inlet (sink)	T_{101}	0.15 K	0.05 %
HTHX outlet (sink)	T_{102}	4.82 K	1.06 %
LTHX inlet (source)	T_{201}	0.31 K	0.11 %
LTHX outlet (source)	T_{202}	1.23 K	0.49 %
Compressor inlet	p_0	1047 Pa	1.07 %
Compressor outlet	p_1	2337 Pa	0.79 %
Turbine inlet	p_3	2485 Pa	0.88 %
Mass flow rate	$\dot{m}$	0.0065 kg/s	1.95 %

During operation of the CoBra heat pump, two main safety constraints require monitoring. *Compressor surge* can occur when a compressor operates at low mass flow rates, potentially causing flow destabilization and detachment, which may lead to structural damage. However, the radial compressors currently installed in the heat pump feature broad performance maps, resulting in high inherent flow stability. Therefore, compressor surge is not considered a limiting operational constraint in this work. *Thermal stresses* arise in heat exchangers due to differences in thermal expansion of the tubes and the shell. Analyses of the HX model show that transient stresses are strongly correlated with the rate of heat accumulation, while steady-state stresses are correlated with the logarithmic mean temperature difference in the HX. Consequently, the rate of heat accumulation $\dot{Q}_{\mathrm{acc}}$ is used as a measurable proxy for these stresses. It is determined from the energy balance across the heat exchanger (HX) using measured mass flow rates and inlet/outlet temperatures, as defined in Equation 1:

$$\dot{Q}_{\mathrm{acc}} = (\dot{m}c_p)_{\mathrm{C}} \cdot (T_1 - T_2) - (\dot{m}c_p)_{\mathrm{Si}} \cdot (T_{102} - T_{101}) \quad (1)$$

A cascaded control strategy, shown in Figure 4, is applied to the supply temperature (T_{102}) while limiting the rate of heat accumulation ($\dot{Q}_{\mathrm{acc}}$). The outer loop controls T_{102} and sets the target accumulation rate ($\dot{Q}^{\mathrm{set}}_{\mathrm{acc}}$) for the inner loop, which adjusts the motor speed (n_M) accordingly. Limiting the outer loop's output combined with appropriate tuning of both controllers ensures that the thermal stress safety constraint is met.

The following three temperature control concepts are investigated in this work. Figure 5 shows schematics of the control concepts.

DOI
10.3384/ecp2181017

Concept 1: PI controllers This control approach utilizes proportional-integral (PI) controllers. Temperature control is achieved using the cascaded controller (`PI_T`) illustrated in Figure 4. In parallel, a separate PI controller (`PI_F`) adjusts p_0 to maintain a cycle-to-sink mass flow ratio of 1 ($\dot{m}_C/\dot{m}_{\mathrm{Si}} = 1$), as this ratio is typically near-optimal for minimizing heat transfer exergy losses. Throughout the operation, the three-way valve position is fixed at full recuperation ($\theta_{3W} = 0$), as heat recuperation is beneficial when the difference between T_2 and T_5 is sufficiently large to outweigh the additional pressure losses.

Concept 2: RL policy controller In this approach, a policy (usually a feed-forward neural network) trained through RL adjusts n_M, θ_{3W} and p_0 depending on the observed heat pump state and set-point value provided to the policy. Prior to deployment, the RL policy is trained to perform control actions that maximize an accumulated reward signal which incorporates the control task including the safety constraints.

Concept 3: PI and RL This approach combines traditional control and RL by using the cascaded controller for temperature control and a RL policy that learns to optimize the other control actions.

4 Reinforcement Learning

The objective of RL is for the agent to learn a policy π that maximizes the cumulative sum of rewards expected over time.

As described by Sutton and Barto (2018) and Achiam (2018), the standard RL setup involves an agent and an environment that interact over a series of time steps. At each step t, the agent receives an observation o_t from the environment. Based on this observation, which may be a subset of the full state s_t, the agent selects an action a_t according to its current policy π.

$$a_t = \pi(o_t) \tag{2}$$

In response to the action, the environment transitions to a new state s_{t+1} and provides the agent with a numerical reward r_t. This reward indicates the immediate value associated with taking action a_t in state s_t, as defined by a reward function R:

$$r_t = R(s_t, a_t) \tag{3}$$

Figure 5. Control concepts for controlling the supply temperature (T_{102}) using the motor speed (n_M), three-way valve opening (θ_{3W}) and compressor inlet pressure (p_0).

4.1 Training setup

The RL training methodology in this work, depicted in Figure 6, employs established tools and standards for interfacing the heat pump model and the RL algorithm. The model is exported as a Co-Simulation Functional Mock-up Unit (FMU). A custom, Gymnasium-compliant (Towers et al. 2024) `Environment` interfaces with the FMU, providing motor speed, three-way valve opening, and compressor inlet pressure as control inputs.

The `Environment` uses the FMPy library to interface with the FMU. Following the modular design proposed by Tassa et al. (2018), problem-specific logic is delegated to a `Task` module, which calculates the reward based on the state and objective and adjusts simulation parameters and boundary conditions. This abstraction allows tasks to be interchanged - for instance, to switch between randomized and deterministic scenarios. Each episode begins from a "cold start" state, meaning all initial pressures and temperatures within the heat pump are set to ambient conditions.

Training is performed on episodes with a fixed length of 700 steps using a step size of 30 s, resulting in 21 000 s of simulated time per episode. This work utilizes the Stable-Baselines3 library (Raffin et al. 2021) which provides implementations of RL algorithms and offers parallelization and monitoring tools.

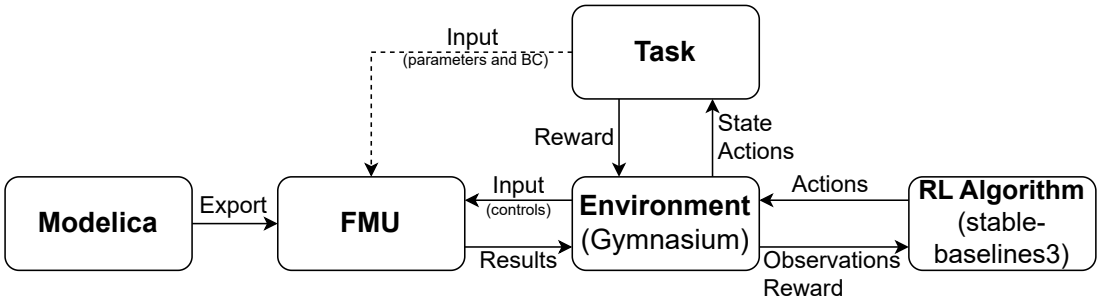

Figure 6. Task-supplied reinforcement learning using FMUs.

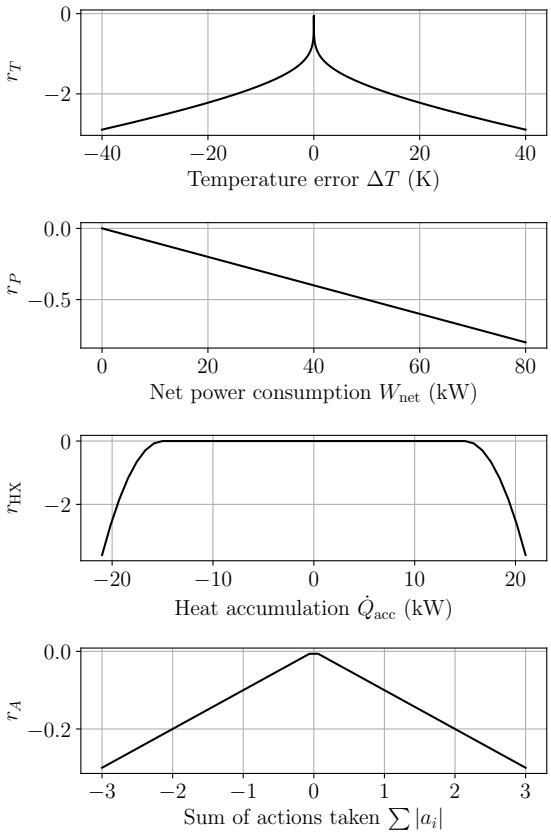

Figure 7. Components of the reward function.

4.2 Action and observation spaces

The action and observation spaces used for training are summarized in Table 2. As introduced in section 3, the action space consists of θ_{3W} and p_0 for both control concepts, with n_M additionally included for concept 2. Instead of outputting absolute values, the controller determines the desired *change* for each control input (delta action). The environment then adds this delta to the current value. This approach inherently constrains the slew rates of the actuators, while the simulation model enforces separate limits on the final values to keep them within their allowable operational range. For this study, the lower bound for compressor inlet pressure (p_0) was lowered from 0.8 bar to 0.55 bar. This adjustment was made because experimental results suggest the optimal p_0 value might be below the original 0.8 bar limit. The observation space includes the actual actuator signals, the rate of heat accumulation, pressure ratio, and various temperature and flow signals from the plant. All signals from the observation space are measured in the physical plant.

Table 2. Action and observation spaces.

Action space	
Change of motor speed	Δn_M
Change of three-way valve opening	$\Delta\theta_{3W}$
Change of compressor inlet pressure	Δp_0
Observation space	
Temperature control error	ΔT
Rate of heat accumulation	$\dot{Q}_{\text{acc}}$
Motor speed	n_M
Three-way valve opening	θ_{3W}
Compressor inlet pressure	p_0
Cycle mass flow rate	$\dot{m}_C$
Sink mass flow rate	$\dot{m}_{\text{Si}}$
Sink inlet temperature	T_{101}
Sink outlet temperature	T_{102}
Compressor outlet temperature	T_1
HTHX outlet temperature	T_2
Compressor pressure ratio	Π_C
Coefficient of performance	COP

4.3 Reward function

A major challenge in RL is the reward function design: maximizing the reward must yield the desired control behavior, yet the function should also guide the agent's learning. The reward function in Equation 4 used in this work is a sum of four reward components. Each component is defined as a penalty term (a negative reward) representing a training goal, and the agent maximizes the total

DOI
10.3384/ecp2181017

reward by learning to minimize these penalties.

$$R = r_T + r_P + r_{\text{HX}} + r_A \tag{4}$$

$$r_T = b_T \cdot \left(|\Delta T|^{0.2} + 0.02 \cdot |\Delta T|\right) \tag{5}$$

$$r_P = b_P \cdot W_{\text{net}} \tag{6}$$

$$r_{\text{HX}} = \begin{cases} b_{\text{HX}} \cdot \left(|\dot{Q}_{\text{acc}}| - \dot{Q}_{\text{acc}}^{\text{lim}}\right)^2 & \text{if } |\dot{Q}_{\text{acc}}| > \dot{Q}_{\text{acc}}^{\text{lim}} \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

$$r_A = b_a \sum_i |a_i| \tag{8}$$

For the temperature tracking goal r_T, the penalty is calculated based on the control error ΔT. It includes terms proportional to $|\Delta T|^{0.2}$ and $|\Delta T|$. This structure leads to the behaviour shown in Figure 7. The linear term ($|\Delta T|$) provides a consistent gradient signal while the power term ($|\Delta T|^{0.2}$) creates a steep reward gradient near the setpoint. This discourages the agent from trading off precise temperature tracking for the conflicting goal of energy minimization.

The r_P component directly penalizes net power consumption W_{net}, thereby incentivizing energy-efficient operation.

r_{HX} penalizes the rate of heat accumulation ($\dot{Q}_{\text{acc}}$) if it exceeds a soft limit, $\dot{Q}_{\text{acc}}^{\text{lim}}$. The penalty increases quadratically with the level of exceedance. This design makes minor and brief overshoots more acceptable than large and sustained violations.

r_A penalizes the magnitude of the control actions taken, discouraging excessive actuation and promoting smoother control.

The overall behavior is shaped by the weighting coefficients (b_T, b_P, b_{HX}, b_a) within the reward components. These coefficients are carefully selected to prioritize certain objectives. For example, maintaining the target temperature (r_T) and ensuring heat exchanger safety (r_{HX}) were weighted more heavily than optimizing for energy efficiency (r_P) or minimizing control action (r_A). In this work, good learning results were found for coefficient values of $b_T = -1$, $b_P = -1 \times 10^{-5}$, $b_{\text{HX}} = -1 \times 10^{-7}$ and $b_a = -0.1$.

4.4 Domain randomization

Domain randomization is a method proposed by Tobin et al. (2017), addressing the Sim2Real challenge when deploying the agent on the real system. The idea of domain randomization is to expose the RL algorithm to variance (e.g. system dynamics, set-points, boundary conditions) during training in order to train a model that generalizes and works across all variants. In this work, randomization is implemented in two ways:

Parameter variation: At the beginning of each training episode, the model parameters (including heat transfer characteristics, turbomachinery map scalers, and actuator rise times) are sampled from uniform distributions to introduce variability. The bounds for this sampling are set symmetrically around each parameter's nominal value, defining a range that is likely to contain the true physical value. The width of this range is selected according to the estimated uncertainty for each parameter. For example, well-calibrated parameters like turbomachinery map scalers are varied over a narrow range ($\pm 2\,\%$), while more uncertain parameters such as heat transfer scalers and actuator delays are given a wider range (up to $\pm 40\,\%$).

Set-point variation: Within each episode, the temperature set-point $T_{102,\text{set}}$ is varied. It follows diverse signal types including steps, ramps, constant values, harmonics, and random walks within the heat pump's temperature operating range.

4.5 Training with Soft Actor-Critic

Training was conducted using Soft Actor-Critic (SAC) developed by Haarnoja et al. (2018). SAC is an off-policy actor-critic algorithm in which a policy network, the *actor*, is optimized using feedback from a value function network, the *critic*. It is based on the maximum entropy RL framework, where the policy is trained to maximize and balance entropy (exploration) and expected returns (exploitation) by automatically adjusting the entropy coefficient. This algorithm was selected due to its sample efficiency and demonstrated suitability for continuous control tasks.

Hyperparameters for training were determined by hyperparameter optimization using RL Baselines3 Zoo (Raffin 2020). In addition to the tuning results, a linear learning rate schedule was added, starting higher for rapid initial progress and decreasing over time to allow for finer policy adjustments. The hyperparameters used to produce the presented results are summarized in Table 3.

Table 3. Hyperparameters used for training.

Parameter	*Value*
Learning rate	5×10^{-5} to 5×10^{-6}
Parallel environments	8
Training frequency	1 per step
Gradient steps	8
Batch size	512
Replay buffer size	1×10^6
Discount rate	0.99
Entropy coefficient	Auto
Actor network	2 layers, each 128 neurons
Critic network	2 layers, each 256 neurons

To accelerate training, the training process was parallelized across 8 environments using the `SubProcEnv` implementation of Stable-Baselines3. To assess the effect of random initialization, all training was conducted independently on multiple agents, each for 4 million environment steps. A single training run required approximately 36 hours on a scientific computing workstation, and agents were saved periodically using the library's callback mechanism.

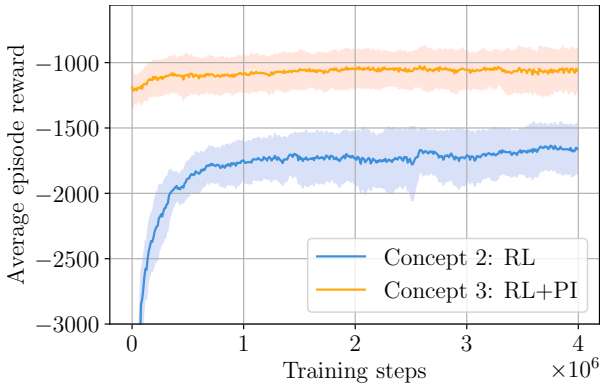

Figure 8. Average episode reward during training. Solid line: Average reward across all agents. Shaded area: Standard deviation of reward.

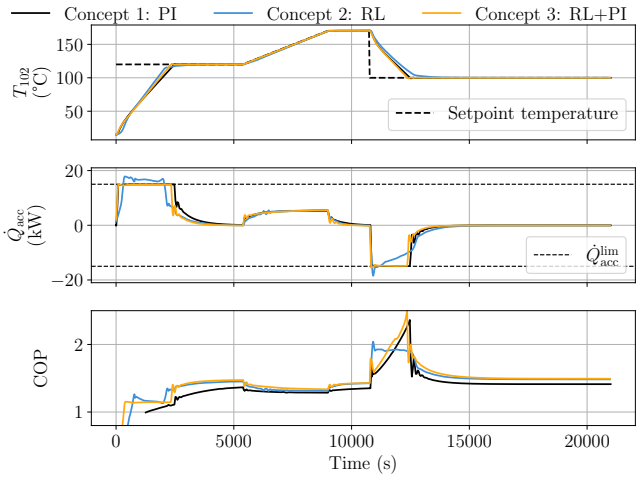
5 Results

This section evaluates the proposed control concepts, beginning with an analysis of the RL agents' training progress. All three concepts are then evaluated on a nominal baseline model, where the RL+PI agent demonstrates a novel and efficient control strategy developed during training. Finally, the RL agents' robustness and generalization capabilities are tested against a range of randomized model variations.

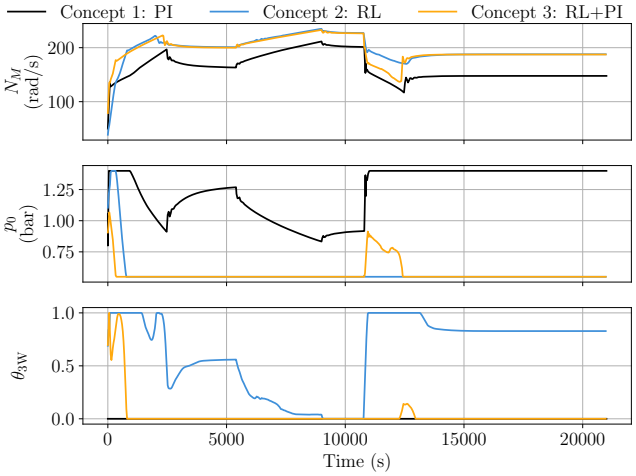
5.1 Training progress

Figure 8 shows the training performance, plotting the mean episode reward (solid line) and standard deviation (shaded area) across all runs.



The learning curves reveal different training dynamics. Concept 2 shows a standard learning progression, with rewards rising steeply as the agent learns the control tasks from scratch. In contrast, concept 3 begins with a high initial reward that improves only marginally. This is because its embedded PI controller already handles the primary temperature control objective. The RL agent's role is thus limited to optimizing secondary, lower-weighted reward terms for efficiency and control actions.

The fluctuations observed in both curves likely stem from the inherent stochasticity of the training process, amplified by domain randomization.



5.2 Control performance on baseline model

To directly compare the control performance of the three concepts, the best-performing agent for each was evaluated in a deterministic, non-randomized environment. The agents were tasked with tracking a temperature set-point trajectory not seen during training, as shown in Figure 9a. This trajectory includes a step increase to 120 °C, a linear ramp to 170 °C, a hold at that temperature, and a final step decrease to 100 °C.

Figure 9 shows the control and process variables for all control concepts. While concepts 1 and 3 rely on embedded PI controllers for temperature tracking and heat accumulation, concept 2's RL policy learned to perform

(a) Process variables

(b) Control variables

Figure 9. Comparison of the three control concepts for temperature tracking with a varying set-point signal on the baseline model, showing (a) process variables and (b) control variables.

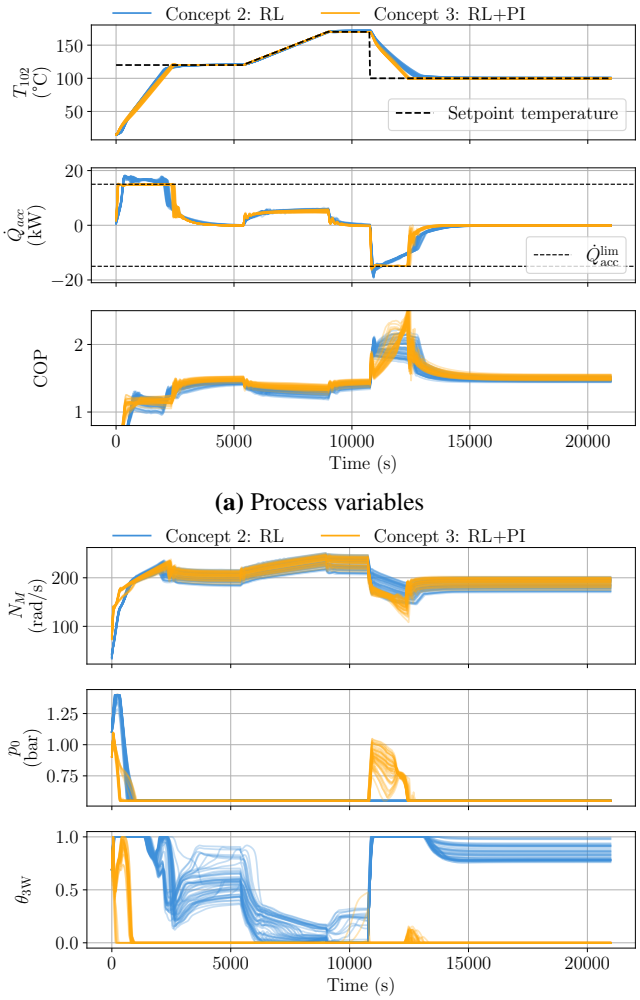
these tasks, showing relatively accurate temperature control. Regarding the thermal stress constraint, concept 3 strictly maintains the soft limit for heat accumulation ($\dot{Q}_{acc}^{lim}$), whereas concept 2 exceeds this limit by a slight but acceptable margin.

Notably, concept 3 achieves the highest efficiency, maintaining a higher COP for nearly the entire duration of the maneuver. This performance is the result of a novel policy discovered by the RL agent. Similar to the baseline in concept 1, this policy keeps the three-way valve opening (θ_{3W}) fixed at 0 (fully recuperated operation). However, it manipulates the compressor inlet pressure (p_0), minimizing it during steady-state operation and increasing it during transients. This pressure manipulation strategy is noteworthy for two reasons:

1. *Steady-state operation:* The decision to lower p_0 is initially counterintuitive. A lower inlet pressure is creates imbalanced mass flow ratios in the heat exchanger, which increases entropy generation of heat

DOI
10.3384/ecp2181017

transfer. However, the observed improvement in COP indicates that the efficiency gains from reduced overall pressure losses successfully outweigh the increased exergy losses from heat transfer.



2. *Transient operation:* The strategy of increasing p_0 when ΔT is high (e.g. after a set-point change) is a particularly surprising discovery. Further analysis reveals that this action allows the system to converge to the new temperature set-point faster without exceeding the soft limit on heat accumulation.

Although further performance gains are anticipated with longer training and hyperparameter optimization, these findings confirm that RL can be successfully integrated with traditional PI controllers to discover novel and more efficient control policies.

5.3 Control performance on model variations

To assess the robustness of the learned policies against uncertainties of the system properties and dynamics, the best-performing agent from each RL control concept was evaluated on 50 model variations. These variations were sampled from the parameter range used for domain randomization.

The results from all 100 evaluation runs (50 for each RL concept) are illustrated in Figure 10. The figure shows that both RL concepts maintain temperature tracking and thermal stress limitation across the entire set of variations. Furthermore, the general control strategies employed by the agents remain consistent with those observed under nominal conditions, as described in subsection 5.2. This suggests that the RL agents are capable of generalizing to varied system properties and can maintain control performance in the presence of model uncertainty.

6 Conclusion

This study investigated RL for controlling a high-temperature Brayton cycle heat pump, using an experimentally validated model. Different control concepts were compared: traditional PI controllers (Concept 1), a pure RL policy (Concept 2), and a hybrid PI+RL approach (Concept 3). Training was performed with the Soft Actor-Critic algorithm, and domain randomization was employed to improve controller robustness against parameter uncertainties.

The results indicate that while the pure RL agent learned the fundamental control tasks, the hybrid PI+RL approach (Concept 3) achieved higher operational efficiency. This improved performance was attributed to the discovery of a novel strategy for manipulating the compressor inlet pressure (p_0). The learned policy minimizes p_0 during steady-state operation to maximize efficiency, while temporarily increasing it during transients. This transient pressure increase, applied when the set-point temperature was changed, was a particularly noteworthy finding. It enables the system to converge to new set-points faster without exceeding thermal stress constraints. The controllers also demonstrated robust operation across a range of model parameters.

While the simulation results are positive, they do not serve as a guarantee of successful real-world deployment. The transfer and validation of the controller on the physical system are therefore planned for future work.

In summary, the findings suggest that RL, particularly when paired with traditional PI(D) controllers, is a viable method for controlling Brayton heat pumps and has the potential to increase their efficiency.
