Dear Participants of the 16th International Modelica & FMI Conference,

Our biennial conference is the primary event for our community to share the latest developments in the Modelica Association's standards. With numerous advancements since the last conference, there is much to discuss. Here are the key milestones achieved:

- **FMI** now supports over 250 simulation tools, reinforcing its position as the world's leading standard for model exchange and co-simulation.
- The first version of new layered standards, notably **FMI-LS-BUS** for network communication, has been released. This concept enables decentralized standard development.
- **SSP 2.0** has been launched, enhancing its value for industrial applications. Explore its impact through dedicated user presentations and tutorials.
- **Modelica Standard Library (MSL) v4.1** is out, offering critical, backward-compatible improvements over v4.0. MSL development will now shift to a continuous integration model.

I extend my gratitude to our members, especially the Modelica Association project leaders, for their dedication in driving this progress. This surge in activity is reflected in the conference program. With over 100 scientific papers submitted, we carefully selected those for presentation. It's exciting to see diverse domains covered, including new fields like pharmacology and marine applications. As our standards gain traction in industry, we've introduced a dedicated track for industrial user presentations, welcoming contributors from fields like wastewater treatment and aerospace.

While the Modelica Association began with a single modeling language, it now supports a suite of standards for modeling and simulation. This is evident in the record 15 tutorials offered at this conference, covering these standards and their applications. Having achieved these milestones, the Modelica Association is setting new goals in three key areas:

International Expansion
Our biennial conference schedule allows for Modelica events in America and Asia between our main conferences. The North American Modelica Users Group (NAMUG) has built a thriving community in the U.S., with the next American conference scheduled for Atlanta, Georgia, October 12-14, 2026. In Asia, where Modelica is gaining popularity, particularly in China, we are forming a local team. To strengthen this community, we proudly announce the 2026 Asian Modelica Conference from September 21 to 22 in Hangzhou, China. The Modelica board is committed to ensuring robust representation for our Asian members.

Cross-Layered Standards
Layered standards, initially developed for FMI, enable decentralized creation of sub-standards for specific applications without altering the main standard. These often involve enhanced meta-information relevant to other standards like SSP and the Modelica language. The Association will work to harmonize these efforts, fostering cross-layered standards applicable to both FMI and Modelica.

Education Initiative
Equation-based modeling requires specialized training. While many professors and consultants provide this, the Association's teaching materials need updating. We invite educators to join us in organizing these resources. Additionally, developing simpler, more robust libraries will lower the entry barrier. Many tool developers are also reducing this barrier by offering web-based services with user-friendly interfaces. The Modelica Association supports these efforts to advance global education in modeling and simulation.

Concluding Remarks
Recent advancements in artificial intelligence (AI) are disrupting information technology, including modeling and simulation. Tools like AI-driven co-pilots and neural network components are transforming how we program and interact with software. While it's hard to predict how Modelica and its standards will evolve alongside AI, their core value remains:

- Open-source libraries based on open standards are invaluable for both humans and AI.
- Widely applicable standards for model exchange and co-simulation benefit both humans and AI.
- Standardized formats for model parameterization and results are equally essential for humans and AI.

In these dynamic times, we must remain grounded in our mission: creating useful mathematical descriptions of the world and making them accessible, executable, and shareable through open standards.
I am confident that the 16th International Modelica & FMI Conference will showcase outstanding examples of this mission. I wish you all an inspiring and productive exchange!

Dirk Zimmer **and** **Ulf Christian Müller**

Keynote Speeches

Physics-Informed AI

AI is increasingly being used in the fast and accurate simulation of physical systems. In this keynote, we will discuss how knowledge of the underlying physics can be explicitly incorporated into AI systems for physical simulations. Key examples will highlight the potential gains as well as the involved challenges.

Opportunities and Challenges in Design and Operation of Integrated Energy Systems

The complexity of modern integrated energy systems demands the systematic use of systems engineering methods and tools to address key challenges across the product lifecycle. This keynote will explore three related and critical areas:

1) the demand for diverse model fidelities and analysis,
2) maintaining consistency across design layers, and
3) the importance of seamless tooling and integration.

Real-world, HVAC specific examples will highlight how these challenges are being tackled in practice and the opportunities they present. For over two decades, Carrier has relied on Modelica as a cornerstone technology for model-based product design. The journey began with the development of control systems for transportation refrigeration, where transient simulations allowed for rapid control function development and verification.

Today, while controls development remains a vital application, Carrier has expanded Modelica's use across the entire product lifecycle – from conceptual design, through testing and verification, to business sales tools, and into operation with monitoring and diagnostics. Design and operation of highly integrated energy systems such as data centers and district heating systems also calls for new methods and tools. Differentiated applications has driven diversified analysis with Modelica models. Modelica-based steady-state simulation has emerged as a back-bone in product design, sales tools, as well as in field diagnostics. Steady-state and transient optimization is also a necessary element across the product life cycle. The need for diversified analysis and computation is further amplified by application of systems engineering methods where requirements, design space exploration, and validation and verification are key elements.

Panelists

For the first time at the International Modelica Conference, we will have a Panel discussion. The topic is:
Open Standards vs. Open source, Collaboration or Conflict?

We choose panelists from a broad range of companies and organizations using Modelica for their product design and research. Our distinguished Panelists are:

Adam Moravanszky, Senior Director Simulation Technology, NVIDIA. At NVIDIA, Adam leads teams advancing open source simulation projects such as PhysX and Newton, and chairs the Physics Working Group of the Alliance for OpenUSD (AOUSD) open standard.

DOI
10.3384/ecp218

Clément Coïc, Technology Cluster Lead - Digital Mechatronics, Siemens Healthineers. Clément leads innovation projects that investigate the value and interconnection of new digital technologies for Siemens Healthineers purposes. A specific focus is carried into leveraging system simulation for better control or path planning of robotic systems, enhancing Machine Learning models with Physics, and modeling the physical behavior of PhysicalAI developments. His works heavily relies on open standards, like Modelica and FMI, and open-source modules - like Julia's SciML ecosystem, ROS or OpenCV and Yolo, to name a few.

Dirk Zimmer, Chairman of the Modelica Association. Expert for equation-based modeling and simulation at the Institute of Robotics and Mechatronics, German Aerospace Center (DLR). The open Modelica standards provide a real technical, economical as well as societal benefit. Promoting them in Dirk's role as Chairman is hence an honor. Also, DLR profits from them: in the field of robotics the multi-domain simulation and control aspects play a crucial role for further advancement.

Marius Dupuis, CEO, ASAM e.V. The CEO's role at ASAM is to manage a team that keeps things running, kicks off new endeavors, and makes sure we are seen and heard. Marius' role is right in the midst of system simulation and (open) standards. It comprises getting members on board, motivating them to initiate and conduct standardization projects, providing a roadmap and legal framework that fit the market, and keeping the association in a good shape.

Michael Wetter, Computational Senior Scientist, Lawrence Berkeley National Laboratory (LBNL). Leading the development of modular modeling, design and controls based on Modelica and FMI for building and district energy and control systems. Michael Wetter has been leading the Modelica Buildings Library which is used in industry and academia for the design of HVAC equipment, building and district energy systems, and data center cooling systems. He also spearheaded the development of digitalization of building control design-installation-commissioning, leading to the proposed ASHRAE Standard 231P, expected to be approved within the next few months, which uses a subset of Modelica to standardize control logic formulation in a vendor-independent format.

Hans-Martin Heinkel, Project Leader prostep SmartSE, and Bosch expert in MBSE and simulation-based engineering. Hans-Martin has more than 35 years of experience in systems engineering, system simulation, Hardware-in-the-Loop, and the integration of simulation into development processes. His main focus, both within Bosch and in the prostep project, is on collaboration based on simulation-supported engineering.

Organizing Committees

Program Chairs
Prof. Dr. Ulf Christian Müller, University of Applied Sciences and Arts Lucerne, Switzerland
Dr. Dirk Zimmer, German Aerospace Center, Germany

Program Board
Prof. Francesco Casella, Politecnico di Milano, Italy
Prof. Lars Mikelsons, University of Augsburg, Germany
Dipl.-Math. Christian Bertsch, Robert Bosch GmbH, Germany
Dr. Hubertus Tummescheit, Model Based Innovation LLC, USA
Dr. Rui Gao, RIGO TECH Co. Ltd., Japan
Prof. Martin Sjölund, Linköping University, Sweden

Program Committee
Dr. Dai Araki, Toshiba Digital Solutions Corporation, Japan
Prof. Bernhard Bachmann, Hochschule Bielefeld - University of Applied Sciences and Arts, Germany
Dr. John Batteh, JuliaHub, USA
Prof. Albert Benveniste, INRIA, France
Dipl.-Math. Volker Beuter, VI-grade GmbH
Dr. Torsten Blochwitz, Keysight Technologies Deutschland GmbH, Germany
Dr. Scott Bortoff, Mitsubishi Electric Research Laboratories, USA
Prof. Robert Braun, Linköping University, Sweden
Dr. Dag Brück, Dassault Systèmes AB, Sweden
Dr. Johannes Brunnemann, XRG Simulation GmbH, Germany
Dr. Benoît Caillaud, IRISA / INRIA, Rennes, France
Dr. Yan Chen, Pacific Northwest National Lab, USA
Prof. Christoph Clauss, Fraunhofer IIS EAS Dresden, Germany
Dr. Clément Coïc, Siemens Healthineers AG, Germany
Dr. Edo Drenth Volvo, Autonomous Solutions, Sweden
Dr. Hilding Elmqvist, Mogram AB, Sweden
Dr. Olaf Enge-Rosenblatt, Fraunhofer IIS EAS Dresden, Germany
Prof. Gianni Ferretti, Politecnico di Milano, Italy
Leo Gall, LTX Simulation GmbH, Germany
Dr. Rui Gao, RIGO TECH Co., Ltd, Japan
Prof. Cláudio Gomes, Aarhus University, Denmark
Prof. Anton Haumer, OTH Regensburg, Germany
Dr. Dan Henriksson, Dassault Systemes
Dr. Yutaka Hirano, Woven Planet Holdings, Inc., Japan
Dr. Andreas Junghanns, Synopsys, Germany
Dr. Daeoh Kang, IVH, South Korea
Prof. Jiri Kofranek, Charles Univesrity, Czech Republik
Dr. Christopher Laughman, Mitsubishi Electric Research Laboratories, USA
Dr. Oliver Lenord, Robert Bosch GmbH, Germany
Prof. Alessandro Maccarini, Aalborg University, Denmark
Dipl.-Ing. Pierre Mai, PMSFIT, Germany
Prof. Antonello Monti, RWTH Aachen University, Germany
Prof. Thierry Stephane Nouidui, The United African University of Tanzania, South Africa
Prof. Christoph Nytsch-Geusen, Universität der Künste Berlin, Germany
Dr. Hans Olsson, Dassault Systèmes, Germany
Prof. Martin Otter, DLR, Institute of System Dynamics and Control, Germany
Prof. Maurizio Palmieri, Dept. of Information Engineering, University of Pisa, Italy
Dr. Kaustubh Phalak, Ingersoll Rand, USA
Dr. Adrian Pop, Linköping University, Sweden
Dr. Katrin Proelss, Airbus Operations GmbH, Germany
Dipl.Ing. Clemens Schlegel, Schlegel Simulation GmbH, Germany
Dr. Klaus Schuch, AVL List GmbH
Dr. Michael Sielemann, Hensoldt, Germany
Prof. Arne Speerforck, TU Hamburg, Germany
Dr. Wilhelm Tegethoff, TLK-Thermo GmbH, Germany
Dr. Bernhard Thiele, DLR, Germany
Prof. Alfonso Urquia, Universidad Nacional de Educación a Distancia (UNED), Spain
Prof. Luigi Vanfretti, Rensselaer Polytechnic Institute, USA
Dr. Antoine Viel, Siemens DISW,
Dr. Volker Waurich, TU Dresden, Germany
Dr. Michael Wetter, Lawrence Berkeley National Laboratory, USA
Dr. Stefan Wischhusen, XRG Simulation GmbH, Germany
Prof. Liu Yanfang, Beihang University, China

Improved Unit Inference and Checking in Modelica

Hans Olsson[1]

[1]Dassault Systemes AB, Sweden, hans.olsson@3ds.com

Abstract

This paper will present a new unified algorithm for unit checking and inference, and showing the benefits for various libraries.

The Modelica Language supports declaring units for variables using the SI-standard. This allows dimensional checking to detect possible errors in equations. The units for variables make it easier to interpret, input and plot their values. When we infer the unit of a variable we get the same benefits also for variables without a declared unit. We will use unit inference and checking for the combination, even if the check is primarily a dimensional check.

Both dimensional checking and unit inference are already implemented in several Modelica tools, but not consistently. The original motivation for this paper was to understand the different approaches, and demystify the unit handling with the goal of making it more available. Based on that understanding, this paper will also present a new unified algorithm combining the different strengths, and showing the results for various libraries.

Keywords: unit, Modelica, Hindley-Milner

1 Unit background

This will explain the various considerations for the units of variables and unit equality in expressions.

1.1 Allowed units

The stated goal in Modelica is that variables should use SI-units – for the unit-attribute, the displayUnit-attribute is not considered in this paper. The SI-system (BIPM 2019) is based on seven base quantities, and every quantity is a product of them raised to various powers (called the dimension of the quantity). If all powers are zero it is called dimensionless. The seven base quantities correspond to the seven base units of the SI-system, and all units are directly expressed – without any conversion factors. This eliminates some causes of errors, provided only SI-base-units are used. However, when equations contain different prefixed SI-units (e.g., mm instead of m or g instead of kg[1]), or SI-acceptable units like bar or kWh the dimensional analysis does not suffice, and that is an important aspect that will be considered. Additionally to directly quote (BIPM 2019)

> "In practice, with certain quantities, preference is given to the use of certain special unit names to facilitate the distinction between different quantities having the same dimension. ... Even though torque has the same dimension as energy (SI unit joule), the joule is never used for expressing torque."

Plane angles (with unit radian "rad") and solid angles (with unit steradian "sr") are a supplementary units in the SI-system, and even if they are useful for human understanding they are formally dimensionless. Since radians are important we follow Mattsson and Elmqvist (2008) and the FMI-standard (see (Modelica Association 2014)) and treat them similarly as the seven base units when possible – but allow mismatches.

It has also been proposed to add new orthogonal non-physical base quantities like currency to Modelica; the approaches in this paper support them as well.

1.2 Unit Strictness

This paper builds on the proposal from Casella (2016) for unit checking. The basic idea is that literal values inside multiplicative expressions are dimensionless, while literal values on their own can have any unit. That has been found to be a pragmatic solution that allows checking and infering units in a large number of existing Modelica models without any changes. Consider

```
parameter SI.Capacitance C=2; // Ok
SI.Energy E1=C*v^2/2; // Ok
SI.Energy E2=C*v*4; // Error
SI.Voltage v;
```

On the first line `2` gets the desired unit, but on the next line two `2` are dimensionless. The `E2` line is rejected even if we could find a unit for `4` that makes it correct.

Note that for this proposal the equal sign does not fully represent equality, since replacing `C` by `2` in another equation leads to unit errors – or incorrect unit inference. In particular this is an issue if the model was originally constructed by manually substituting expressions based on equality.

The approaches described in this paper work with other rules as well. Alternatives include allowing numeric literals to have any unit everywhere except for `1/x` see (Mattsson and Elmqvist 2008), the same without the exception, or only allowing the zero literal to have any dimension see (Kennedy 1996). The future work will contain some proposals to modify the rules, both to strengthen them for some common cases, and weaken them for experimentally derived equations.

[1]Remember that the base-unit for mass is kg

1.3 Arrays

Most arrays are homogenous, i.e., all of their elements have the same unit. However, there are some arrays that are heterogenous – in particular the state of the transfer-function (each element is the derivative of the previous one) and polar coordinates as an array of two elements (magnitude and angle). Thus this paper will allow arrays to be heterogenous, but try to infer the common unit if it exists and/or infer units for specific elements (for array elements with literal subscripts – they are seen as scalars).

One can consider variants of this, one would be to enforce that all arrays are homogenous, and another would be to perform all unit inference on the scalar level. Neither extreme seems acceptable, but the first approach will be discussed more later.

Instead the solution is to view an array built as `C=[A,B]` as only having a unit if it is homogenous (the implications will be discusssed later). Similar considerations apply to subscripted elements of arrays.

The subscripts themselves are integers and should thus be dimensionless.

1.4 Unit for variables

The general idea is that a variable has a statically determined unit, or is free to have any unit. That may seem obvious, but apart from heterogenous arrays some libraries (Zimmer, Meißner, and Weber 2022) have variables getting different units depending on an evaluable parameter. Another case are constants such as `eps` – that are treated like small literal values. Trying to deduce a unit would be especially problematic for package constants, because the same constant can be used in unrelated parts of a model.

For algorithms (in particular in functions) one could imagine that one variable is re-used to store values with different units – we will consider that an error. Other common cases where one variable have multiple units are s-parameterizations, where positive and negative values have different units – that can be handled by making both cases dimensionless in the model, see (Mattsson and Elmqvist 2008). An important consideration is that variables are free to not have a unit, this allows building blocks that can be re-used with different units.

2 Approaches to unit inference and checking

There are multiple approaches to unit inference and checking in various programming languages, both related to the nature of the language and to the goals of the check.

2.1 Simple unit inference and checking

In traditional imperative programming languages it is straightforward to propagate unit forwards from variables, so that the unit of `z=x*y` gets the unit of `x` multiplied by the unit of `y`, and addition will just check that the two terms have the same unit, and give the result that unit. This has been implemented multiple times, see (Hilfinger 1998) for an early variant for ADA.

This propagation up-wards is insufficient in an equation-oriented language such as Modelica. Dymola has traditionally extended this with also propagating the unit down-wards, i.e., if we know the units of `z` and `x` in `z=x*y` we conclude the unit of `y` is the unit of `z` divided by the unit `x`. The basic framework for unit checking in Dymola is described by Mattsson and Elmqvist (2008) including down-ward propagation. The unit-checking in Dymola has after that paper built on that framework and can be configured in different ways. In this paper the rules for literals (literals have any unit, except for `1/x` where `1` is dimensionless) are replaced by the stricter rules from Casella (2016) that only allow literals to have any unit in additive contexts so that we can for `z=3*x+2` propagate the unit from `x` to `z`. Specifically the multiplicative literal 3 is dimensionless (allowing propagating the unit), but the additive literal 2 has any unit (avoiding a unit error).

A practical application of this can be seen in the CoupledClutches example for `sin1`, which simplified has:

```
  RealInput torque.tau(unit="N.m");
equation
  sin1.y = sin1.offset + sin1.amplitude*sin
      (2*pi*sin1.f*time);
  connect(sin1.y, torque.tau);
```

Here we propagate “N.m” through the connection and then down-wards to `sin1.offset` and `sin1.amplitude` (knowing that the output of `sin` is dimensionless).

This approach needs to be iterated (normally just a handful of times), and at first seems ad-hoc.

It does, however, work fairly well in practice. The benefits of the approach are:

- The results are understandable, for each inferred variable one can directly see which equation that the unit originates from. That is useful for analyzing errors for unit checking where having a clear understanding of how the various variables got their unit helps in finding the error.
- For unit inference it can preserve the exact units used; so if a variable has unit “N.m” variables that are equal to it can also get unit “N.m” instead of “kg.m2.s-2” or the even more confusing “J”. This is also important when not using SI-base-units, e.g., “mol/l”. Apart from "N.m" being required by the SI-standard for torque this also works together with non-SI displayUnits (suggesting “kcal” or “kWh” as display unit for a torque is not good).
- Simple and consistent handling of arrays variables:
  - We can treat homogenous arrays as scalars, and if we infer a unit for an array that is valid for the entire array. Conversely, if we know that array is heterogenous we can treat it as having unknown unit (see (Mattsson and Elmqvist 2008)).

DOI 10.3384/ecp21817

  - It is straightforward to limit the unit inference to going in one direction (conditional unit assignments). An example where this is useful is an equation involving array indexing. If the entire array has one unit that should also be the unit for the array element, but in order to support heterogenous arrays the inference cannot go from unit of an array element to unit of the entire array.
  - It is also straightforward to handle a `C=[A,B]` such that if we have a unit for `C` we can infer the unit for `A` and `B`, and if `A`, `B` both have a unit and it is the same, we can infer that `C` has the same unit. It is deliberate that if only `A` has a unit we do *not* assume that `B` (and `C`) must have that unit as well.
  - Array elements with literal indicies can be treated as scalars.

That it works for arrays is not limited to simple cases like adding two vectors with units, but also extends to scalar products, cross products, and matrix multiplications.

2.2 Hindley-Milner unit inference

The Hindley-Milner (or Damas–Hindley–Milner) unit inference traces it origins to the Hindley-Milner algorithm for type inference, and is presented as Damas-Milner by Kennedy (1996) (an alternative reference is his PhD thesis from the same year). It has previously been discussed for Modelica by Broman, Aronsson, and Fritzson (2008) and proposed by Lambert and Tidefelt (2024). We will go through it in detail, but it basically collects all unit-equations and in one sense solves them one by one and then substitutes the result in the other equations (and substitutions), until all of the unit equations have been handled.

The benefits of this approach are:

- Uses all of the unit information and nothing more, i.e., it is complete and consistent.
- Known convergence and practically linear.

2.2.1 Details

The first step in this approach is to collect all of the unit equations as equations.

Consider the model

```
model Elec
  Real pot1(unit="V"), pot2(unit="V");
  Real v, i;
  Real R(unit="Ohm");
equation
  v = i * R;
  v = pot2 - pot1;
end Elec;
```

The variable `pot1` is called p_1 below, and similarly for `pot2`. This gives the unit-equations including substitutions for known units (we use `u[v]` for the unit of `v` as a symbolic value, and reserve `v.unit` for the corresponding string).

$$u[p_1] \to V = kg \cdot m^2 \cdot s^{-3} \tag{1}$$
$$u[R] \to \Omega = V \cdot A^{-1} = kg \cdot m^2 \cdot s^{-3} \cdot A^{-1} \tag{2}$$
$$u[v] = u[i] \cdot u[R] \tag{3}$$
$$u[v] = u[p_1] \tag{4}$$
$$u[v] = u[p_2] \tag{5}$$

In practice it makes sense to have all unit-equations in the form $1 = \ldots$ – to ensure that they are normalized, $u[x]$ is the unit or dimensionality of the variable `x`, and substitutions are used for *solved* equations. The substitutions are seen as solved even if they may depend on other (unknown) units. Variables with unit-modifiers are also represented as substitutions.

Another example, which will be discussed later, is:

```
model SecondOrder
  input Real u;
  parameter Real w, D, k(unit="1")=1;
  Real y(unit="1"), yd;
equation
  der(yd) = w*(w*(k*u-y)-2*D*yd);
  yd = der(y);
end SecondOrder;
```

The declaration of k gives:

$$u[k] \to 1 \tag{6}$$

The declaration of y gives:

$$u[y] \to 1 \tag{7}$$

The subexpression `k*u-y` gives:

$$u[y] = u[k] \cdot u[u] \tag{8}$$

Introduce α_1`=w*(k*u-y)` giving:

$$u[\alpha_1] = u[w] \cdot u[y] \tag{9}$$

The subexpression α_1`-2*D*yd` gives

$$u[\alpha_1] = u[D] \cdot u[yd] \cdot \tag{10}$$

The equation `der(yd)=w*(`$\alpha_1 - \ldots$`)` gives:

$$u[yd] \cdot s^{-1} = u[w] \cdot u[\alpha_1] \cdot \tag{11}$$

The equation `yd=der(y)` gives:

$$u[yd] = u[y] \cdot s^{-1} \tag{12}$$

Equations 8 to 11 all derive from one Modelica equation. The variable α_1 is only introduced as part of unit-checking and may more accurately be described as only introducing $u[\alpha_1]$ corresponding to the unit of `w*(k*u-y)`, but not α_1 itself. Using such intermediate variables makes the construction of the unit-equations more straightforward even for complicated equations. Additionally they are needed in the proposed combined algorithm for some cases. They can trivially be excluded when reporting the result of the unit inference.

One could even introduce $\alpha_2 = k \cdot u - y$ replacing (8) by $u[\alpha_2] = u[y]$ and $u[\alpha_2] = u[k] \cdot u[u]$, and for (9) use $u[\alpha_1] =$

$u[w] \cdot u[\alpha_2]$. However, since $u[\alpha_2] = u[y]$, one can use $u[y]$ as above.

This example will be used to illustrate that Hindley-Milner can give additional units compared to the simple algorithm (which cannot find the units for `D` and `w`).

If performed naively a second intermediate step (normally included in the first step) solves some issues:

- Combine exponents for the same variable, which may even cause a variable to disappear from the unit equation (if it appears on both sides of the equation with equal exponents).
- To support `sqrt` and `nthRoot` the original unit-equations may contain rational exponents for the unit-variables, to simplify the analysis each unit-equation is raised to a suitable power to get integer coefficients (either for just the unit-variables or also extended to known units).

The third step is to take these unit-equations (in any order) and for each find a unit-variable with the exponent that is smallest in magnitude. As listed by Kennedy (1996) there are number of cases:

- There is no unit-variable, just check that equation is unit-correct.
- There is only one unit-variable remaining, find its unit and substitute its unit in the other unit-equations and substitutions.
- There are multiple unit-variables, and the smallest exponent is +/-1 or more generally the smallest exponent divides the exponents of all other unit-variables. In this case solve for such a unit-variable (as a product of fixed units and a product of other unit-variables).
- The remaining gcd-case where we introduce a new unit-variable by dividing the other exponent as much as possible, and forming a new unit-equation with the remainders, and then iterate on this unit-equation until we get to one of the other cases. This will convergence in a finite number of steps and can be seen as way of finding the greatest common divisor of those exponents, see Appendix B for details.

As an alternative to the last step one could allow rational numbers as exponents for variables, and use the penultimate step in all remaining cases (Lambert and Tidefelt 2024). The main disadvantage would be that it spreads the rational numbers.

The only really difficult part of this algorithm is understanding that it actually works, and implementing the gcd-case (or using rational numbers). Actually working mean that the algorithm finishes and it either produces a unit error, or the same unit inference (independent of the order of the unit-equations) and that the results are consistent. The gcd-case is the only concern for showing that the algorithm finishes, and that relies on the convergence of the Euclidean algorithm for computing the gcd of integers. Consistency also imply that if we add any of the inferred units for the variables to the unit-equations and re-run the algorithm it will produce the same result.

For the Elec-case the most efficient way would be to solve the second equation for $u[v]$ and then the first equation for $u[i]$, but we will show that we can solve them in the given order, which means that there is no need to describe an optimal order:

substituting the known units gives

$$u[v] = u[i] \cdot \Omega \tag{13}$$

$$u[v] = V \tag{14}$$

solving the first (13) for $u[v]$ gives

$$u[v] \to u[i] \cdot kg \cdot m^2 \cdot s^{-3} \cdot A^{-1} \tag{15}$$

substitution this in (14) gives

$$1 = u[i]^{-1} \frac{kg \cdot m^2 \cdot s^{-3} \cdot A^{-1}}{kg \cdot m^2 \cdot s^{-3}} = u[i]^{-1} \cdot A \tag{16}$$

solving this gives

$$u[i] \to A \tag{17}$$

substitution this in (15) gives

$$u[v] \to A \cdot kg \cdot m^2 \cdot s^{-3} \cdot A^{-1} = kg \cdot m^2 \cdot s^{-3} \tag{18}$$

and subsitution in the two remaining equations

$$u[p_1] \to u[v] = kg \cdot m^2 \cdot s^{-3} \tag{19}$$

$$u[p_2] \to u[v] = kg \cdot m^2 \cdot s^{-3} \tag{20}$$

And thus `v.unit="kg.m2.s-3"` (or `v.unit="V"`), and `i.unit="A"`. As noted above solving (14) from $u[v]$ and then (13) for $u[i]$ is an alternative giving the same result.

For SecondOrder we can start by handling the trivial cases to get:

$$u[k] \to 1 \tag{21}$$

$$u[y] \to 1 \tag{22}$$

$$u[u] \to 1 \tag{23}$$

$$u[yd] \to s^{-1} \tag{24}$$

$$u[\alpha_1] \to u[w] \tag{25}$$

and the non-trivial equations (10) and (11) gives:

$$u[w] = u[D] \cdot s^{-1} \tag{26}$$

$$s^{-2} = u[w]^2 \tag{27}$$

the non-trivial part (26) becomes

$$u[w] \to u[D] \cdot s^{-1} \tag{28}$$

substitution in (27) and simplifying gives

$$1 = u[D]^2 \tag{29}$$

solving (29) and substituting in (28) gives

$$u[D] \to 1 \tag{30}$$

$$u[w] \to s^{-1} \tag{31}$$

DOI 10.3384/ecp21817

The key part is that the substitutions combine `D` and `w` into one equation that can be solved, something that the simple algorithm cannot do. In particular the simple algorithm does not have the unit equation (27) due to how the equations are written, but would have it for the equivalent equation `der(yd)= w^2*(k*u-y)-2*w*D*yd;`

If we remove the unit for `y` we would not infer units for `yd`, `u`, and α_1, but the inferred units for `D` and `w` would be unchanged.

An equivalent approach is to solve integer equations for the units (this is a traditional approach in dimensional analysis - and also seen in this context by Karr and Loveman III (1978), for the connection see (Kennedy 1996)) -– those integer equations correspond to taking the logarithm of the unit-equations used by Hindley-Milner. It is important to note that the equations are integer equations and treated as such -– using the same approach for solving systems of equations with real coefficients is not numerically robust.

For this case the left-hand side of the integer equations are:

$$\begin{pmatrix} +1 & & & & & & \\ & +1 & & & & & \\ +1 & -1 & +1 & & & & \\ & -1 & & +1 & & & \\ & +1 & & & +1 & -1 & \\ & & & -1 & +1 & +1 & \\ & & & +1 & & -1 & 1 \end{pmatrix} \cdot \begin{pmatrix} \log(u[k]) \\ \log(u[y]) \\ \log(u[u]) \\ \log(u[yd]) \\ \log(u[w]) \\ \log(u[\alpha_1]) \\ \log(u[D]) \end{pmatrix} \tag{32}$$

They have been arranged to be in block-lower-triangular form, where the non-trivial block corresponds to solving for a combination of variables.

3 Comparison of the approaches

We will both investigate the relationship between the two approaches in theory, and then practically investigate it for the Modelica Standard Library.

3.1 Theoretical considerations

If we only consider scalars then the Hindley-Milner approach can infer more units, and thus also detect more errors.

There are two reasons for this:

- The combination of exponents for variables can infer the unit of `x` from the unit of `x*x` and to all variants of this (the simple algorithms handles `x^2` and extending it to detect `x*x` is trivial). Disappearing variables allows deducing the unit of `T` from `T*der(x)=x` (`T` has unit "s"), and also from `r*x+x` (`r` has unit "1"); without requiring a unit for `x`. Basically we for the first case get $u[T] \cdot u[x] s^{-1} = u[x]$, and divide both sides by $u[x]$ giving $u[T] = s$.

- Substitution means that if we have a damping factor `D` and a frequency `w` and the equations `der(yd)= w*(w*(k*u-y)-2*D*yd)` and `yd=der(y)` we can find the unit for both `D` and `w`.

The similarity between the two approaches is that by a suitable ordering of the unit-equations we can view the simple inference as prematurely stopping the Hindley-Milner algorithm. Basically we stop before we get to any of the problematic cases where we would *need to* substitute a unit-variable depending on another unknown unit-variable, or combine unit-exponents. This has some implications consequences:

- The simple algorithm gives a consistent sub-set; not a different result.

- By continuing with Hindley-Milner after running the simple algorithm we clearly see which additional unit inferences (and possible errors) it gives.

There are some caveats here:

- It is only the case for a suitable ordering, the Hindley-Milner can process the unit-equations in any order, and thus first find that the unit of `z` depends on the unit of `x`, and after substituting this solve another equation giving the unit for `x`.

- It is only the case if the unit-equations are created in a suitable way, specifically to handle `z=a*b+y` the simple algorithm would be stuck if we add the equations $u[z] = u[a] \cdot u[b]$ and $u[a] \cdot u[b] = u[y]$ instead of $u[z] = u[a] \cdot u[b]$ and $u[z] = u[y]$. A solution is to introduce a new unit-variable α_1 and $u[\alpha_1] = u[z]$, $u[\alpha_1] = u[a] \cdot u[b]$, $u[\alpha_1] = u[y]$, since it ensures that as soon one of the three unknowns get a unit it can be propagated to the other two (in this case we can skip the extra variable and reuse `z` or `y`, but in general all of them could be complicated expressions). Hindley-Milner can handle these cases without new variables.

- It also requires that we don't convert known units to base-units in Hindley-Milner during that part (in order to get the benefit of the original units). In theory this could be disastrous for performance, but in practice it does not seem problematic and if it is a problem it could be limited to units with a few factors.

- Combining arrays and Hindley-Milner causes problems. This will be discussed later.

Keeping the original units (i.e., not converting to base-units) in the normal Hindley-Milner would be more complicated due to the repeated substitutions, that problem practically disappears due to the suitable ordering.

For unit-errors keeping the original units allows the error message to include both the original units and the result converted to base-units; where either may be more helpful depending on the circumstances.

Additionally, this suggest that the algorithms can be unified, i.e., first running the part of Hindley-Milner corresponding to the simple algorithm – even extended to combining variables. That will automatically preserve most of the benefits of the simple algorithm (locality and understandable unit strings), and then later running the complete algorithm for the small additional gain – but restricted to scalars.

Instead of iterating all equations for the simple algorithm one could keep track of where unit-variables are used and after updating the impacted ones for each substitution check those substitutions to check whether there is at most one unknown unit in that equation. That ensures that the simple algorithm is practically linear, similarly as Hindley-Milner.

3.1.1 Array issue

Lambert and Tidefelt (2024) indicate that there are issues for arrays by limiting it to scalars, but we want to make the issues clear. The obvious issue is that conditional equalities for arrays (for subscripting and concatenation) do not naturally fit the unification based on equality.

However, they can be handled by introducing an unknown array variable (in case the array occurred inside an expression) and after substitutions check if either that array has a unit, or the other side has homogenous units and only then add it as an equality. It is not known whether this will give good results when substituting unit-variables depending on others.

There is also a worse problem that is less obvious, consider `T*der(x)=A*x;` For scalars we can see that `A.unit="1"` (regardless of the unit of `x`), and simply applying the algorithm would give the same result for a matrix `A`. However, if we have `x.unit={"m","s"}` then we should have `A.unit=["1","m/s";"s/m","1"]` (i.e., only the diagonal has unit 1). Solutions to this would be to scalarize before performing unit inference and checking, or adapting the algorithm to handle the various kinds of array equations. In practice both variants would make the implementation considerably more complicated as one needs to ensure that scalarization does not perform any simplification that would impact unit inference or checking. Neither approach has been implemented.

Note that the problem does not occur for *all* array expressions. E.g., if `A` is a scalar then the simple result is correct regardless of whether `x` is a scalar, vector, or matrix. Similarly, for `v1*x=v2*x` or `v1.*x=v2.*x` we can eliminate `x` to conclude that `v1` and `v2` have the same unit(s).

However, even if non-homogenous arrays exist in some models having an option to test enforcing homogenous array is useful — the idea would be to discover missed units, and manually add them to the model.

3.2 Practical difference

The previous section showed that it is possible to first run the simple algorithm, and then extend it to the Hindley-Milner algorithm (for scalars). During these tests we naively keep the unconditional array equations in the second step.

This means that we can isolate the impact of the advanced parts. This has been implemented and tested on the Modelica Standard Library (MSL, specifically on (Modelica Association 2025b)) and the experience was:

- The Hindley-Milner approach is actually easier to implement and also easier to get right.
- The reason is that for the simple unit inference one needs to implement unit-inference going both "up" and "down". If there are a large number of different operations that can be substantial work, and instead Hindley-Milner only needs to go "up" and collect equations in a standardized form.
- The most complicated part of implementing Hindley-Milner is the gcd-case, and that does not occur in MSL (it is unclear if it occurs for any actual models).
- No new unit-errors were reported by the algorithm compared to the simple algorithm (there are a number of known unit-issues in the library — even if they are being reduced).
- Apart from squared variables, it detected new units for variables in seven models that could not be found by the simple algorithm; three of them were useful – three of less practical use, and in one case the results were incorrect (due to how the model was constructed – it did not indicate a problem with the algorithm).

There are two kinds of squared variables, one was propagating a unit down for `V=sqrt(re*re+im*im)` for electrical models. The other occurs if we keep array equations and gives that `T` has unit "1" from `r1=transpose(T)*T*r2` (where `r1` and `r2` are positions). The latter is the only case where naively keeping array equations made any difference. In this specific case the unit is correct (and the derivation is even correct in general for this specific array expression), but given that `T` is the orthogonal transformation matrix we even know that $T^T \cdot T = I_3$, and thus that `transpose(T)*T` does not matter in that equation. This indicates that at least for MSL skipping array equations in the second part of the full algorithm has neglible impact.

The useful results were for models such as SecondOrder which has `der(yd)= w*(w*(k*u-y)-2*D*yd)`, where we can find the unit for both `D` and `w`; even if we cannot find either unit directly.

The ones of less practical use were UniformNoise from the Clocked part which has `y = u + noiseMin + (noiseMax - noiseMin)*noise;` where we see that `noise.unit="1"`. The unit for that variable is of limited use as it is a protected variable (so no impact on other variables and not intended for plotting), and `unit="1"` isn't useful for unit conversion.

DOI
10.3384/ecp21817

The one with incorrect result was the most interesting and it is the Motor model used in the R3Robot example where we have:

```
  parameter Real w=4590 "Time constant of
      motor";
  parameter Real D=0.6 "Damping constant of
       motor";
...
  Modelica.Electrical.Analog.Basic.Inductor
       La(L=(250/(2*D*w))) ...;
  Modelica.Electrical.Analog.Basic.Resistor
       Ra(R=250) ...;
  Modelica.Electrical.Analog.Basic.Resistor
       Rd2(R=100) ...;
  Modelica.Electrical.Analog.Basic.
      Capacitor C(C=0.004*D/w) ...;
```

Just applying the algorithm gives the conclusion that $u[D] \rightarrow \Omega^{-1}$ (or Siemens), and $u[w] \rightarrow s^{-1}$, which is based on assuming that literal numbers have unit "1" inside equations (but unknown unit when they appear alone). Since the unit is seemingly correct for `w` it would be tempting to consider the entire result correct. However, looking carefully shows that 0.004=1/250, and an obvious thought is that all three uses of 250 likely have unit Ohm. Testing this by replacing 0.004 by 1/250 and then replacing those three uses of 250 by a common parameter gives the result $u[D] = 1$, $u[w] = s^{-1}$; and a damping constant 0.6 (with unit "1") make perfect sense.

The SI-standard, (BIPM 2019), recommends against "s-1" due to the ambiguity of whether it is a frequency ("Hz") or angular frequency ("rad/s"), numerically they differ by a factor of 2π. However, it is not possible to resolve this ambiguity automatically and thus the non-recommended "s-1" is safest. Manual checking (and also the name `w`) shows that it is an angulary frequency, "rad/s". The extra factor "rad" may seem to be unit-incorrect, but this supplementary unit is dimensionless, and thus the capacitance and inductance are unit-correct even if they do not contain a factor "rad".

Normally the parameter with value 250 would explicitly be declared as a resistance parameter, but that could also be inferred. A pull-request has been prepared that declares `w` and `D` with proper types with units, and also add the resistance parameter; as that is a more understandable model. Just adding the resistance parameter would still require Hindley-Milner to infer the units for `w` and `D`.

3.3 Impact of unit inference and check

The new algorithm was tested on different libraries and the variables were split into different categories. Variables in common models are counted multiple times, but the special variable `time` was excluded. Only models that passed unit check were considered for the inference statistics.

Library	MSL		MSL
Version	4.0.0		3.2.3
Scalars	336899		329763
Declared	238268	(70.7%)	239798
Simple	9171	(2.7%)	9325
Advanced	44	(0.01%)	39
Arrays	73553		55222
Homogenous	57312	(77.9%)	38384
Heterogenous	191	(0.3%)	308
Simple	4869	(6.6%)	1035
Advanced	0		0
Elements	40	(0.05%)	55
Tot. Classes	6299		5954
Inference	1083		931
Errors	67		147
Adv. Errors	0		2

And some smaller libraries for comparison.

Library	ThermoFluid-	VehicleInterfaces
Version	Stream 1.1.0	2.0.1
Scalars	43163	9692
Declared	33582	4287
Simple	1268	143
Advanced	0	0
Arrays	3198	10579
Homogenous	2774	8508
Heterogenous	0	0
Simple	15	712
Advanced	0	1
Elements	0	0
Tot. Classes	2156	252
Inference	106	28
Errors	40	14
Adv. Errors	0	0

The "simple" are scalar and homogenous arrays inferred by the simple algorithm. The "advanced" refer to the additional ones found by the algorithm proposed in this paper. For MSL the "advanced" cases are the previously mentioned squared variables in electrical models, and the seven additional cases – which are counted multiple times due to model re-use. The "elements" refer to arrays where units of some elements are inferred by the simple algorithm. The "declared" and "homogenous" and "heterogenous" are variables that are declared with units.

Although counting all variables the same is oversimplified it still gives an indication of the impact. The percentages do not fully capture the advantages, e.g., the simple algorithm only inferred the unit for 6.6% of the arrays in MSL 4.0.0, but that represents 30% of the arrays that lacked a declared unit.

The number of arrays where elements have different units (both declared as "heterogenous" and deduced as "elements") underestimates their already small number. The reason is that algorithm is not designed to find them, and e.g., state-space vectors are not detected as having elements with different units.

The "tot. class" include a large number of documentation classes, interface classes (where no inference is pos-

sible), and other classes without units and thus the classes with unit inference is more interesting. The "errors" are the number of classes containing errors, where a single error may be reported for multiple classes. As the unit-proposal is yet to be approved, the "errors" do not necessarily indicate quality problems.

MSL 3.2.1 had two models with advanced errors, they were both due to the gain `k` having unit "1" in the PI-block, which is used in the Controller in the NoiseExamples. That has later been removed in general, and did not indicate any error in the tested model. Note that the number of classes, including the classes with inferred units have increased in the later MSL version – while the number of errors has decreased.

4 Combined algorithm

The array issues imply that a combined algorithm would be to run Hindley-Milner corresponding to the simple algorithm (including arrays — both simple array equations and one-sided; and without combining unit-exponents and substituting unknown units), then combine exponents and run the full Hindley-Milner on the remaining unit equations only involving *scalar* variables. We would generally propose this as it is simple to explain and gives reasonable results.

However, a more detailed analysis shows that also simple equations involving arrays can be kept in the second phase, as long as one only combines exponents for scalars and only uses substitutions with scalars in the right-hand-side. (The reason is that if an array has a unit depending only on the unit of scalar variables multiplied by a fixed unit then it must be a homogenous array.) One could even extend this from only scalars to scalars *and homogenous arrays*, where operations such as `sum(v)`, `max(v)`, or `v*u` (where `u` is homogenous) imply that `v` is homogenous.

As the practical tests only found one case with any benefit from naively keeping array equations the difference between these variants will be minor.

One can construct cases where the difference between these algorithm matters, e.g.,

```
  Real x;
  Real v[3];
  Real w[3](each unit="m");
equation
  v*v=1; // Normalize
  v*x=w;
  ...
```

Considering equations involving arrays is needed to find the unit for `v` and `x`. Without any special logic for `v*v`, we can solve the second equation for $u[v] \to m/u[x]$, and substitute that in the first equation to give $u[x] \to m$ and thus $u[v] \to 1$.

5 Future Work

The most important future work for the Modelica Language is to get an agreement on the unit rules. For tools the important part is implementing these rules.

For libraries (not only MSL) the first part is to remove any unit errors and in some cases incorrect units. A particular consideration is to use rational exponents consistently, both in units-string (added by Modelica Association (2025a)) and in models. For models this implies one should use `sqrt(x)` instead of `x^0.5` and `nthRoot(V, 3)` instead of `V^(1/3)` (also introduced by Modelica Association (2025a)). Automatically handling some common rational exponents (with diagnostics) is possible and helpful for users, but using `sqrt` and `nthRoot` more clearly shows the intent.

Unit handling in equations involving arrays could be investigated further. An obvious improvement would be to prove that some operations require homogenous input (such as `sum` and `cross`) and view their inputs as homogenous *everywhere*.

Combining this approach with the analysis on subcomponents for partial result as by Broman, Aronsson, and Fritzson (2008) would be interesting. Having the possibility to store the inferred units in the model seems like a natural possibility for the future, but it seems redundant and if too automated it may include dubious units like “s-1” instead of either “rad/s” or “Hz”.

5.1 Proposed Extensions

Adding a generic type for the dimensionless case to `Modelica.Units.SI` would make it easy to clarify the many cases where a variable is known to be dimensionless (there are already a number of types for *specific* dimensionless quantities).

Having the possibility to disable unit-checking for a specific equation, or all equations in a model has been found useful. That basically means that no unit-equations are added for the corresponding equations. Testing of the Buildings 10.0.0 library, (Wetter et al. 2014), similarly revealed a need to disable the the new rules for literals on the package level.

For converting between different prefixed SI-units, or non-SI-unit it would be beneficial to have a function `UnitConvert(a, fromUnit, toUnit, factor)` that just returns `a*factor`, that should be the unit-conversion factor from one unit to another. (Also proposed by Lambert and Tidefelt (2024)) Having a special name it clarifies the intent of convertering between the units, and including the units and the factor it is trivial to implement for tools that don’t implement units – while still allowing tools to verify that the factor is correct. The *intent* is important as one cannot assume any parameter with such a unit is a conversion – e.g., an up-hill road could have slope of 100 mm per m.

6 Conclusions

This paper shows how to unify the simple unit-algorithm from Mattsson and Elmqvist (2008) traditionally implemented in Dymola with Hindley-Milner unit-inference. It shows that this will give the benefits of both – preserving understandable units and locality for the large num-

DOI 10.3384/ecp21817

ber of simple cases – including arrays, while also getting units for all the remaining scalar cases. The understandable units make it easy to input and interpret values for variables without a declared units, including switching to compatible units for display. Any errors will also (with rare exceptions) be localized to specific equations, where the units for all involved variables are easy to trace. Even if the number of additional variables with inferred units is small, it is still worth in terms of providing a stronger theoretical basis – especially considering the effort.

Based on experience in Dymola it is even simpler to implement than the complete simple unit-inference. The algorithm has been test-implemented in Dymola 2025x Refresh 1, and will also part of 3D Experience Platform 2026x.

It also shows that only implementing a conventional Hindley-Milner approach would require more care, both to get good unit strings and either not work for arrays or require scalarization for arrays (without any clear benefit).

Acknowledgements

This work has been supported by VINNOVA (grant number 2023-00969, OpenScaling). The authors would also like to thank the Modelica Language group for pushing improvements for units.

A All used unit rules

- Addition, $u[z] = u[x], u[y] = u[x]$ for `z = x + y`, `z = x - y`, `z = x .+ y`, `z = x .- y`, `z = min(x, y)`, `z = max(x, y)`, `z=rem(x, y)`[2], `z = mod(x, y)`[2], and `z = homotopy(x, y)`[2].
- Multiplication[3], $u[z] = u[x] \cdot u[y]$ for `z = x * y`, `z = x .* y`, and `z = cross(x, y)`.
- Division[3], $u[z] = u[x]/u[y]$ for `z = x / y`, and `z = x ./ y`.
- Trigonometic function, $u[z] = 1, u[x] = \text{rad}$ for `z = sin(x)`, `z = cos(x)`, and `z = tan(x)`.
- Inverse trigonometic function, $u[z] = \text{rad}, u[x] = 1$ for `z = asin(x)`, `z = acos(x)`, and `z = atan(x)`.
- Differentation, $u[z] = u[x]/\text{s}$ for `z=der(x)`.
- Dimensionless function, $u[z] = 1$, $u[x] = 1$ for `z = log(x)`, `z = log10(x)`, `z = exp(x)`, `z = sinh(x)`, `z = cosh(x)`, and `z = tanh(x)`.
- Propagate first argument, $u[z] = u[x]$ for `z = -x`, `z = skew(x)`, `z = fill(x, ...)`, `z=hold(x)`, `z = noEvent(x)`, `z = noClock(x)`, `z = min(x)`, `z = max(x)`, `z = abs(x)`, `z = sample(x, ...)` (clocked version), `z = superSample(x, ...)`, `z = subSample(x, ...)`, `z=backSample(x, ...)`, `z = shiftSample(x, ...)`, `z = previous(x)`, `z = scalar(x)`, `z = vector(x)`, `z = matrix(x)`, `z = promote(x)`, `z = transpose(x)`, `z = diagonal(x)`, `z = delay(x, ...)`, `z = pre(x)`, `z = actualStream(x)`[2], and `z = inStream(x)`[2].

[2] Implemented after testing

[3] With special treatment of literals

- Smooth, $u[z] = u[y]$, for `z = smooth(p, y)`.
- Reinit, $u[x] = u[y]$ for `reinit(x, y)`.
- Root, $u[z]^n = u[x]$ for `z = nthRoot(x, n)` (if we can evaluate n) and with $n = 2$ for `z = sqrt(x)`.
- Relations $u[x] = u[y]$ for `z = x > y`, `z = x >= y`, `z = x < y`, `z = x <= y`, `z = x == y`, and `z = x != y`.
- Time-units, $u[z] =$ s, for `z=time`, and `z=interval()`
- Truncated division $u[z] = 1$, $u[x] = u[y]$ for `z = div(x, y)`[2].
- Rounding $u[z] = 1$, $u[x] = 1$ for `z = floor(x)`[2], `z = ceil(x)`[2], and `z = integer(x)`[2].
- Arctan2 $u[z] =$ rad, $u[x] = u[y]$ for `z=atan2(x, y)`[2].
- Semilinear $u[z] = u[m] \cdot u[x]$, $u[x] = u[y]$ for `z = semiLinear(m , x, y)`[2].
- Integer power, $u[z] = u[x]^n$ for `z=x^n` if integer expression n (and ignored unless we can evaluate n).
- Non-integer power, $u[z] = 1$, $u[x] = 1$, $u[y] = 1$ for `z=x^y` if y is not an integer expression.
- Sample, $u[x] =$ s, $u[y] =$ s for `sample(x, y)`[2] (non-clocked version).
- Condition, $u[z] = u[x]$, $u[y] = u[x]$ for `z=`**`if`**` c `**`then`**` x `**`else`**` y` if `c` is not an evaluated expression.
- Only propagate arrays if either side has homogenous unit, $u[z] = u[x_1] = \ldots = u[x_n]$ for `z = {`x_1`, ..., `x_n`}`, `z = [`x_1`, ..., `x_n`]`, `z=[`x_1`; ...; `x_n`]`, and `z = cat(p, `x_1`, ..., `x_n`)` (ignoring `p`).
- Array subscripting `z = x[i]` if `i` is literal then treat $u[x_i]$ as scalar, otherwise only propagate from homogenous $u[x]$ to $u[z]$,
- Special case for literals and `zeros(...)` (the latter to handle **`equation`** `a.f + b.f = zeros(3);`).
- Connect-statements are handled by checking the equations generated from the connection-sets, the details will only impact diagnostics for incorrect models.

B Gcd-case

For completeness we will present the gcd-case for the algorithm, even if we haven't seen any practical models requiring this.

```
model GcdCase
  Real x;
  parameter Real y=1;
  Real area(unit="m2");
  parameter Real T(unit="s");
equation
  der(area)=x^4*y^6;
  T*area=x^4*y^(-6);
end GcdCase;
```

After some substitutions we get the unit-equations:

$$1 = u[x]^4 \cdot u[y]^6 \cdot \frac{s}{m^2} \tag{33}$$

$$1 = u[x]^4 \cdot u[y]^{-6} \cdot \frac{1}{s \cdot m^2} \tag{34}$$

for the first equation we introduce a new variable

$$u[z] \to u[x] \cdot u[y] \tag{35}$$

giving (36)

$$1 = u[z]^4 \cdot u[y]^2 \cdot \frac{s}{m^2} \tag{37}$$

$$1 = u[z]^4 \cdot u[y]^{-10} \cdot \frac{1}{s \cdot m^2} \tag{38}$$

importantly we solve the *same* equation again for y

$$u[y] \to (m^2 \cdot s)^{1/2} \cdot u[z]^{-2} \tag{39}$$

$$1 = u[z]^{24} \cdot \frac{s^4}{m^{12}} \tag{40}$$

giving

$$u[z] \to \frac{s^{1/6}}{m^{1/2}} \tag{41}$$

$$u[y] \to s^{-1/6} \tag{42}$$

$$u[x] \to m^{1/2} \tag{43}$$

The example is as contrived as it looks, but it shows that the case can be handled. The introduced variable has exponents corresponding to truncated integer division for all of the other exponents, which corresponds to one step in the normal algorithm for greatest common divisor. It stops when the new smallest exponent divides all others, and that exponent is the greatest common divisor (in this case 2).

Implicit Unit Conversion in Modelica

Henrik Tidefelt[1] Quentin Lambert[1]

[1]Wolfram MathCore, Sweden, {henrikt,qlambert}@wolfram.com

Abstract

There are many situations in which a Modelica model needs to handle quantities which are not expressed in the often preferred unscaled SI units. Applying correct unit conversions is extremely important in such situations, and the risk of human error needs to be mitigated using unit-aware technology. Considering the power of unit checking mechanisms in several Modelica tools today, one can be surprised that unit conversion in Modelica still needs to be performed using error-prone user-written formulas and functions. It is demonstrated how automatic and implicit unit conversion can be introduced in Modelica, and that this can be done safely. The benefits of this approach are illustrated in a variety of examples and applications.

Keywords: unit checking, unit conversion, Modelica

1 Introduction

1.1 Why model with units?

Units of measurement, in this work simply referred to as *units*, play an important role in the modeling domains where Modelica is used for several reasons. An often cited reason is that attention to units of measurement would have avoided some spectacular engineering failures in the past due to mixing up numbers in metric units with numbers in non-metric units. Another reason is that use of units of measurement allows *dimensional analysis* of programs, allowing certain errors in expressions and equations to be detected during model translation. Units of measurement also enrich the presentation of computed results, and give hints regarding the kind of quantity that computed numbers represent. A key convenience of working with unit aware tooling is also the possibility of separating the units used in numeric computation and storage of results, from the units used to conveniently enter parameter values and display results.

1.2 The use of unit conversion in Modelica

If all units in the world of Modelica models were equivalent to unscaled SI base units, there would be no reason to have support for unit conversion. However, many Modelica models exist in a context where also other units are used, and in such tool chains there needs to be proper support for keeping track of and converting between units in order to avoid the sometimes subtle but catastrophic consequences of interpreting numeric values with an incorrect understanding of the associated units. In a complex environment where a Modelica model is interfaced with surrounding systems, it is hard to imagine a better place for performing the necessary unit conversions than inside of the Modelica model – it would be unreasonable to expect that all of the surrounding systems should be capable of adapting their interfaces to a choice of units governed by the Modelica model.

1.3 Unit conversion in Modelica today

There are two common approaches to performing unit conversions in Modelica models today, namely unit conversion factors (possibly embedded in gain blocks) and unit conversion functions. The Modelica Standard Library contains a selection of unit conversion functions as well as examples of using gain blocks with conversion factors.

The approach of using a dedicated function for every supported unit conversion does not scale well to the general task of performing conversion between any pair of conversion compatible units.

With the conversion factor approach, conversions are often created as needed instead of being provided as a collection of predefined conversions. This makes the method of using `displayUnit = "1"` a viable technique for manually setting the correct value of the conversion ratio – the correct value is 1 when expressed in the unit `"1"`, reflecting that there is no scaling in terms of value of quantity:

```
  Real x(unit = "m");
  Real y(unit = "yd");
  final constant Real m_per_yd(
    unit = "m/yd", displayUnit = "1")
    = 0.9144;
equation
  x = m_per_yd * y;
```

However, when a conversion factor is used in equations like above there is a high risk that the value will rarely be seen expressed in the display unit, making it a potential source of error.

On the other hand, when the conversion factor is embedded in a gain block, the gain block with a gain displayed as 1 may appear as unnecessary clutter to an untrained eye, or to someone who is not familiar with the need for explicit unit conversion in Modelica. If the `displayUnit` is removed, the gain block might appear less like unnecessary clutter due to no longer displaying a gain of 1, but at the cost of no longer making it obvious that the block is merely performing a unit conversion, not actually scaling the value of quantity.

1.4 State of the art

General purpose computer algebra systems with unit handling tend to allow implicit unit conversion. For instance, all of the following computer algebra systems support adding values of quantity expressed in different units: Wolfram Language, Maple (through the Units package), Python (through the Pint package), Julia (through the Unitful.jl package), and JavaScript (through the Math.js library). Further, none of the systems allow adding, say, a length to a numeric value. (*Wolfram Language – Quantity* 2025; *Maple – Tutorials Part 10: Units* 2025; *Pint – Tutorial* 2025; *Unitful.jl – Conversion/promotion* 2025; *Math.js – Units* 2025)

An interesting feature of Unitful.jl which is particularly relevant for the current work is the `FixedUnits` concept. It is a mechanism for locally taking control over the implicit unit conversion by disabling it.

Likewise, in systems for causal modeling, the widespread Simulink software offers implicit unit conversion between connected blocks. There is also a block for explicit unit conversion, but no block for getting automatic unit conversion at a particular place in a model.(*Simulink – Converting Units* 2025)

On the more formal side, Kennedy (1997) argues that one reason for annotating programs with units of measurement rather than physical dimensions is that it enables compilers to automatically inject unit conversions.

When it comes to Modelica, unit handling is less developed, explained partly by the added complexity that comes with not having prescribed causality of computations, but probably partly also due to the difficulties caused by not having a syntax for attaching units to numeric literals. Early developments include Mattsson and Elmqvist (2008) and Aronsson and Broman (2009), but to date the only thing which has been formalized in the Modelica language is the string syntax for expressing units. That said, the use of *display units* is well established, allowing values of a variable to be displayed or entered in a different unit than the unit used for the underlying numeric representation. This means that existing Modelica tools already have capabilities for unit conversion, but these capabilities are not leveraged by the Modelica language.

Several Modelica tools implement unit checking with unit inference, and even though implementation details differ, there are no major controversies regarding whether a model is using units consistently or not. It is an ongoing work to standardize unit checking in Modelica, so that a model considered consistent by one tool will also be considered consistent by other tools. To our knowledge, no Modelica tool is currently supporting a non-standard extension for allowing automatic or implicit unit conversions.

1.5 Limitations

This work does not elaborate the handling of units with offsets – typically temperature units – for which there is a difference in the interpretation of a unit depending on whether a value of quantity is relative or absolute. The limitation is a matter of presentation; the unit handling framework in which the current work has been implemented also supports the distinction between relative and absolute values of quantity, but a discussion of its design in this regard would overshadow the cetral topic of this work.

The unit symbols required to be recognized according to the Modelica specification are not even sufficient to support the Modelica Standard Library – for instance, the unit of the `Pressure_bar` type is the "non-standard" (that is, not supported by the Modelica specification) `"bar"`. In order to more closely relate to real world applications with need for unit conversion, examples in this work also make use of non-standard units such as `"lb"`. All of these and many more are supported out of the box by the computer algebra systems mentioned in subsection 1.4, and the authors believe that Modelica one way or another will need to develop in the same direction. In the meantime, there are several ways in which a Modelica tool could provide support for non-standard units. For example, the unit handling framwork used here supports all units appearing in the Modelica Standard Library and a conservative selection of additional well established units out of the box, and also supports per-library customization through vendor-specific Modelica annotations. It is a limitation of this work that the question of how to ensure a consistent selection of non-standard units across tools is not addressed, but the proposed ideas for unit conversion would remain relevant also with only current Modelica's standard units since the standard supports the use of unit prefixes (as in `"mm"`) as well as several unit symbols for time and volume. For example, `"L/min"` is a standard Modelica unit which might require conversion to, say, `"m3/s"`.

2 Notation and preliminaries

2.1 Notation

Concrete units will be written in the style of their Modelica string representation. For example, `"m"` represents the meter, and `"1"` represents the unit of a dimensionless number.

A *numeric value* refers to a real number without unit. For instance, 1.5 is a numeric value. Numeric value is not the same as dimensionless number, as the latter has a unit of `"1"`.

The combination of a numeric value and a unit is denoted a *value of quantity*. (In other contexts, this may also be referred to as a *value* or a *quantity*, but both these terms already have conflicting established meanings in the Modelica context.)

Objects with unit (values of quantity, variables, expressions, etc) belong to a *quantity space*, which is either an *affine space* or *vector space*. Values of quantity in affine space are often said to be *absolute*, while values in vector space are sometimes said to be *relative*.

DOI
10.3384/ecp21827

A numeric literal is said to have empty unit.

2.2 Simple non-standard operators for unit handling

In order to not distract from the central topic of this work in the following sections, a few simple non-standard operators for unit handling will be taken for granted.

2.2.1 Construction of value of quantity

The non-standard expression `withUnit(`x`, `u`)` constructs a value of quantity with numeric value x and unit u. The expression x shall have empty unit.

Example:

```
Real x = withUnit(1.0, "m");
```

When `withUnit` is used with literal operands, the expression is referred to as a *unitful literal*.

There are several appealing alternatives for using special syntax instead of calling the operator by its name as above. In this work, a unitful literal may be constructed by providing the unit in the form of a quoted identifier following the numeric literal:

```
Real x = 1.0'm';
```

2.2.2 Fixed unit conversion

The expression `inUnit(`v`, `u`)` is used to express the value of quantity v in the unit u. The expression v shall not have empty unit. The unit u shall be given by a constant expression and be conversion-compatible to the unit of v. The `inUnit` is an affine function of its first operand, and a tool can inline calls early to reduce the need for symbolic processing rules.

Example:

```
Real x(unit = "m") = 1.0;
Real y(unit = "yd") = inUnit(x, "yd");
```

This operation only uses the same sort of information that Modelica tools need to possess in order to support display unit conversions, with the difference that the information is needed during model translation rather than when editing values or plotting results.

2.2.3 Extraction of numeric value

The expression `withoutUnit(`v`, `u`)` obtains the numeric value of the value of quantity v expressed in the unit u. The expression v shall not have empty unit. The unit u shall be given by a constant expression and be conversion-compatible to the unit of v. The returned numeric value has empty unit.

For example, this can be used to make a unit-safe function for an empirical relation which only holds for a particular choice of units, while the function interface is free to use a more common choice of units:

```
function empirical
  input Real u(unit = "kg");
  output Real y(unit = "kg") =
    inUnit(y_lb, "kg");
protected
  Real u_lb = withoutUnit(u, "lb");
  Real y_lb =
    someEmpiricalRelationInPounds(u_lb);
end empirical;
```

3 Unit checking machinery

This section gives a very brief overview of the constraint-based approach to unit checking which is the foundation for the extended semantics proposed in this work. It is based on ideas found in Hindley-Milner type systems.(Hindley 1969; Milner 1978) The description in this section describes the machinery without support for implicit unit conversion, currently in use in Wolfram System Modeler for checking unit consistency in agreement with common (still not standardized) understanding of how units should be used in current Modelica. A more detailed description of the machinery is outside the scope of this work, but is available in the form of a pull request within the Modelica Change Proposal MCP-0027 *Unit checking* (currently in the state *In Development*).(Lambert and Tidefelt 2024) Although currently not standardized, the unit semantics resulting from the machinery presented in this section will be denoted the *current semantics*. In subsection 6.2, it will then be shown how the machinery can be extended to support automatic and implicit unit conversion.

In addition to the unit of an expression, the machinery also keeps track of the quantity space. Similar to unit checking, there are rules for quantity space checking, and the rules may be used for inference of quantity space. While details of the quantity space handling are outside the scope of this work, it should be mentioned that it is largely independent of the handling of units. In particular, the constraint-based approach to unit checking described in this work is carried out without modification also when quantity space is considered, but it must be remembered that unit inference does not consider – and hence does not determine – unit offsets. For vector quantity space, unit offsets are irrelevant, and hence units inferred by unit checking are fully accurate. For affine vector space on the other hand, unit offsets matter, and in principle it is a responsibility of quantity space checking to determine them. Alternatively – and this is by far the most common situation and corresponding to the limitations of this work – if an inferred unit has zero offset and all conversion compatible units also have zero offset, then knowing the quantity space is neither needed to conclude that the correct offset would be zero in case of affine quantity space, nor to perform correct unit conversion. Hence, it would be needlessly strict to make unknown quantity space an error in this situation, and it can be seen that quantity space checking can be safely ignored as long as units with offset are not considered.

Unit checking is carried out by solving a set of unit *equivalence compatibility* constraints. The unknowns are a combination of unit variables associated with variables in the model, and auxiliary variables introduced during the

process of collecting the constraints. A constraint is a relation between two unit *meta-expressions*, a very simple expression language with operations for multiplication, raising to a power, and differentiation.

In order to make unit inconsistency an error according to the Modelica specification, it needs to be a tool independent property of a model. To this end, the collection of unit constraints takes place at an early stage of model translation where expressions and equations still have a close and dirrect correspondence to the original Modelica input. (Alternative approaches to unit checking applied at later stages of model translation might be easier to implement, but be difficult to define in such a way that unit consistency would become a tool independent property of a model.)

The literals of the meta-expression language, denoted *meta-literals*, consist of the *concrete* units, the empty unit, and the undefined unit. The concrete units correspond to well-formed Modelica unit strings. A constraint is trivially satisfied if either side is empty or undefined, and the inference will never determine a unit variable as empty or undefined. Hence, after completed unit inference, each unit variable will either be determined as a concrete unit or left undetermined.

The notation $\texttt{var}_\texttt{u}$ is used for the unit variable associated with the model variable `var`.

4 Shift of mindset

4.1 The unit equivalence mindset

In current Modelica there is an unstated mindset based on unit equivalence. For example, it is generally expected that this model shall pass unit checking:

```
Real x(unit = "J/s");
Real y(unit = "W") = x;
```

That is, the unit of `y` (`"W"`) does not need to be written identically to the unit of its binding equation (`"J/s"`).

Adding expressions with equivalent units comes down to just adding numeric values:

```
Real x(unit = "J/s") = 1.0;
Real y(unit = "W") = 2.0;
Real z = x + y;
```

It suffices to assume that there is no unit inconsistency in order to conclude that the numeric value of `z` is 3.0. Units only serve as complementary information to the numeric values, but have no impact on the computation of numeric values. A unit for `z` can be determined by unit inference, and it is not perceived as a problem that the exact form of the unit is not uniquely defined; knowing that the inferred unit for `z` will be equivalent to both `"J/s"` and `"W"` is enough.

When all expressions have units, and units are used consistently, mathematical field axioms are fulfilled. For example, let

```
Real x(unit = "s");
Real y(unit = "s");
Real z(unit = "s");
Real u(unit = "m");
```

Then the following properties hold:

- Commutativity: `x + y = y + x`
- Associativity: `(x + y) + z = x + (y + z)`
- Distributivity: `u * (x + y) = u * x + u * y`

When empty literals are present, there is a tradeoff between convenience and possibility of detecting unit inconsistencies. Standardization of unit checking is pointing in the direction of avoiding the "wildcard effect" of literals in multiplicative expressions:

```
// OK, 1.0 effectively has unit "s":
Real a(unit = "s") = x + 1.0;
// Error, 1.0 effectively has unit "1":
Real b(unit = "m.s") = u * 1.0;
```

Unfortunately, this means that multiplication does not distribute over addition in Modelica:

```
Real c = u * (x + 1.0);    // OK
Real d = u * x + u * 1.0; // Error
```

The semantics proposed in this work will preserve the important properties of commutativity and associativity. Likewise, distributivity will be preserved when all expressions have units.

To fix the problem with general distributivity in Modelica will require another approach with is outside the scope of this work, namely broad adoption of unitful literals, so that all remaining literals written without unit can be assigned the unit `"1"`. For example, `u * (x + 1.0's') = u * x + u * 1.0's'`.

4.2 The value of quantity mindset

As long as units are used consistently, the particular choices of units become less important, and it becomes possible to view the relations in the model in terms of related values of quantity rather than the numeric values that would vary with the choice of units. This mindset requires trust in two things:

- Correctness of annotated as well as inferred units.
- That consumers of translated models pay proper attention to units, annotated as well as inferred.

It is of particular importance that a numeric value together with a unit of measurement is understood as just one of infinitely many equivalent representations of the same underlying value of quantity.

To establish the required trust is beyond the scope of this work. However, recent developments in unit checking in common Modelica tools as well as awareness of gained quality of existing Modelica libraries thanks to unit checking support in tools, is expected to build up such trust over time.

DOI 10.3384/ecp21827

5 From error to automatic resolution

This section presents a sequence of models, giving a natural progression from how an equation which is erroneous according to current semantics, eventually can be interpreted as valid thanks to an implicit unit conversion. Details of the implicit unit conversion will be given in section 6.

5.1 Unit inconsistency is an error

A prerequisite for this work is that inconsistent use of units is an error.

```
  Real x(unit = "m") = 1.0;
  Real y(unit = "yd");
equation
  // Prerequisite that this is an error:
  x = y;
```

Thanks to being an error to start with, it will be possible to define semantics without breaking backwards compatibility.

5.2 Explicit unit conversion

The inconsistency can be resolved using `inUnit` for explicit unit conversion:

```
  Real x(unit = "m") = 1.0;
  Real y(unit = "yd");
equation
  x = inUnit(y, "m");
```

5.3 Explicit automatic unit conversion

A non-standard operator named `autoUnit` will be used to denote explicit automatic unit conversion. The operator is similar to `inUnit`, except that the target unit of the conversion is determined from the context.

Let e be an expression of the form `autoUnit(`e_1`)`, and let unit(e) denote the unit of the expression e. Similar to additive operators, a unit variable is conceptually introduced for unit(e). No unit constraints are associated with the `autoUnit` expressions, but all of the following shall hold after completed unit inference:

- unit(e) is a concrete unit.
- unit(e_1) is a concrete unit.
- unit(e_1) is convertible to unit(e).

After completed unit inference, `autoUnit(`e_1`)` is replaced with `inUnit(`e_1`,` unit(e)`)`.

Applying `autoUnit` to resolve the unit inconsistency above:

```
  x = autoUnit(y);
```

5.4 Implicit unit conversion

Finally, as an alternative to explicitly introducing `autoUnit` calls to resolve unit conflicts, it only remains to let the tool implicitly introduce `inUnit` calls where a unit inconsistency between conversion-compatible units would otherwise result. Considering that different ways of resolving a unit conflict using unit conversion may result in different interpretation of empty unit expressions as values of quantity, it must be ensured that implicit unit conversion does not cause any actual or apparent ambiguity of computed values of quantity. How to ensure this is the topic of section 6.

Now, the equation originally considered to be in error is instead interpreted as having implicit unit conversion:

```
  x = y;
```

6 Well-defined values of quantity

This section describes how the unit checking machinery can be extended to support implicit unit conversion without introducing ill or even poorly defined values of quantity. In order to serve as a viable extension of current Modelica, the design will meet the following criteria:

- No change of semantics for models free of unit errors according to current semantics.
- No actual or apparent ambiguity of computed values of quantity.
- Preserved associativity and commutativity of addition.

The first of these items is obtained by only allowing implicit unit conversion where the current semantics would have detected a unit inconsistency. Therefore, existing Modelica programs free of unit inconsistency will remain unaffected by the introduction of implicit unit conversion in the language.

The last two items are related, and will be addressed in the following.

6.1 The potential source of ambiguity

When a potential unit inconsistency is resolved using `inUnit`, it is important to be aware that different choices may lead to different interpretations of empty unit expressions. Consider the following expression, without allowing implicit unit conversion:

```
1.0'cm' + 0.5 + 1.0'm'
```

The expression has a unit inconsistency which can be resolved using unit conversion. Here, the conflict will be resolved using `inUnit`. It would also be possible to use the more convenient `autoUnit`, but this might have obscured the fact that the problem is unrelated to the automatic choice of unit.

All of the following are valid ways of resolving the unit inconsistency:

```
inUnit(1.0'cm', "m") + 0.5 + 1.0'm'
inUnit(1.0'cm' + 0.5, "m") + 1.0'm'
1.0'cm' + inUnit(0.5 + 1.0'm', "cm")
1.0'cm' + 0.5 + inUnit(1.0'm', "cm")
```

Note how the interpretation of the literal `0.5` is affected by where `inUnit` is applied. This demonstrates that the explicit use of `inUnit` (or `autoUnit`) gives control over the interpretation of empty unit expressions.

This is also where the danger of implicit unit conversion lies; if the inconsistency was automatically resolved by the tool introducing `inUnit` somewhere in the expression, the interpretation of `0.5` would seem ambiguous, especially to someone who expected addition to be commutative and associative. The authors believe that even if a unique choice of unit for `0.5` could be defined without sacrificing commutativity and associativity, the rules for implicit conversion would become too unintuitive to be of practical relevance with human users in mind. Instead, implicit unit conversion needs to be constrained so that the interpretation of empty unit expressions remains as intuitive as in current Modelica.

In subsection 6.2, the rules for implicit unit conversion will be defined so that the problematic cases above can be rejected.

6.2 Extensions to unit checking machinery

This section describes how the unit checking machinery from section 3 is extended to support implicit unit conversion. The unit semantics resulting from the extended machinery is denoted the *extended semantics*.

It is observed that in almost all situations where a unit constraint is introduced according to the current semantics, at least one side of the constraint corresponds to an expression which could be wrapped in `inUnit(...)` to resolve a unit inconsistency. The two exceptions are `unit`-attributes and `connect`-equations.

The `unit`-attribute exception is not a problem, since there are good reasons anyway to constrain the unit inference by giving these constraints priority over all other constraints in the sense that a unit variable is always solved from its `unit`-attribute constraint in case one exists. It follows that these constraints are never resolved using implicit unit conversion. Besides ensuring that `unit` -attributes are obeyed exactly for the variable they belong to, this also provides an important mechanism for delimiting the potential issues associated with allowing implicit unit conversion.

A `connect`-equation constraint is an exception since neither operand of `connect` is allowed to be an `inUnit(...)` expression, and this exception will be dealt with towards the end of this section.

The extended semantics for the non-exceptional cases is that unit constraints are now introduced in the form of *directed* equivalence compatibility of two unit meta-expressions. When x is required to be equivalence compatible to y, the direction from x to y shall indicate that x corresponds to an expression that can be unit converted if needed. When a unit constraint free of unit variables is obtained during inference, it is first checked whether it is equivalence compatible. If it is, there is no need of unit conversion and the constraint can safely be dropped. Otherwise, if it is not convertibility compatible, there is a unit inconsistency that implicit conversion cannot resolve. In the remaining case, implicit unit conversion is tentatively injected on the source side of the constraint in order to establish equivalence compatibility. After completed unit inference, the tentatively introduced conversions are analyzed to ensure that they do not introduce ambiguous values of quantity. This analysis is denoted *robustness analysis* and will be described below.

Computations where all `Real` expressions have units, and the units are used consistently, have uniquely defined values of quantity as outcome – the alternative would have been a serious flaw of the current semantics. Similarly, computations where all `Real` expressions have empty unit, are interpreted as operations on real numbers, and since no units are present, there is no risk of ambiguity due to automatic unit conversions. The risk of ambiguity arises where the two kinds of computation meet, due to the Modelica convention of treating an empty unit expression as if it had a unit which fulfills a unit constraint with a concrete unit on the other side.

In the extended semantics, units determined by the unit inference machinery are only uniquely determined up to convertibility. For example, a variable could end up getting the unit `"J"` or the unit `"kN.m"` depending on how the unit constraints are processed, but the ambiguity in the unit of a variable isn't by itself causing ambiguous values of quantity. The ambiguous values of quantity arise when an ambiguous unit is used to interpret an empty unit expression as a value of quantity.

Ambiguous units originate where a tentative unit conversion is introduced, since it is generally not uniquely defined where the conversion must be introduced. Such a unit constraint is denoted an *origin of ambiguity*. The ambiguity of the constraint gets propagated to any unit variable solved from the constraint. If a unit variable is found to be ambiguous, the ambiguity gets propagated to all unit constraints where the unit variable is present. If the variable `x` has a `unit`-attribute, then x_u does not propagate ambiguity and is said to be *robust by definition*. If the propagation of ambiguity back and forth between constraints and unit variables reaches a constraint where the empty unit is on one side of the constraint, then an ambiguous value of quantity has been detected, a situation which will be denoted a *robustness conflict*.

Thus, robustness analysis comes down to showing that there are no robustness conflicts. This problem is naturally studied on the bipartite incidence graph of unit constraints and unit variables. A constraint where one side is empty or undefined is said to be an *origin of fragility*. Existence of a robustness conflict is equivalent to existence of a path in the graph from an origin of ambiguity to an origin of fragility, after excluding the variables which are robust by definition. Such a path is denoted a *robustness conflict path*.

Note that the origins of ambiguity in a robustness analysis graph depend on the order in which the unit constraints

DOI
10.3384/ecp21827

are processed during unit inference, so other implementations are likely to produce different graphs. However, if one implementation marks a constraint as an origin of ambiguity, another implementation will also mark a constraint as origin of ambiguity within reach from the former constraint. Hence, the existence of a robustness conflict path will not depend on the order in which the constraints are processed.

Returning to the exception of `connect`-equations, the only difference in the handling compared to other equations is that the introduction of `inUnit(...)` to resolve unit conflicts is delayed until the connection set equations have been generated. For instance, the robustness analysis makes no difference between unit constraints coming from `connect`-equations and unit constraints coming from other equations; the need for implicit unit conversion in the constraint of one `connect`-equation will be an origin of ambiguity, and as all the connectors in the connection set will be connected in the robustness analysis graph, the ambiguity will reach the entire connection set. At the time of elaborating the connection set equations, it must be remembered that the established unit consistency of the `connect`-equations is only for convertibility, not equivalence. For each generated flow or potential equation a common unit for the equation is selected among the ones which are already present; this will ensure that no implicit unit conversion in the connection set equation will take place when all units are equivalent. Then all terms of the flow or potential equation are conceptually converted to the common unit using `inUnit(...)` (which will be a no-op in case the term already has a unit which is equivalent to the common unit).

6.3 Examples

Examples in this section will be illustrated using the following conventions for the display of a robustness analysis graph:

- Constraint vertices are placed to the left, and variable vertices to the right.
- An origin of ambiguity is colored in blue, and an origin of fragility is colored in orange. The remaining constraint vertices have dark gray color.
- A variable which is robust by definition is colored in light gray, while other variables have dark gray color.
- All edges incident to robust variables are colored in light gray (they cannot be part of robustness conflict paths). Edges reachable from an origin of ambiguity are drawn with an arrow in the direction of increasing distance to the origin of ambiguity. The remaining edges are drawn with dashed line and without arrow.
- In a constraint, empty is presented as ∅, and undefined as ?.

With this representation, existence of a robustness conflict path corresponds to an orange vertex with an incoming arrow. A robustness conflict path can then be reconstructed by following the directed edges in reverse direction until a blue vertex is reached. Note that the robustness analysis graphs presented below correspond to one of many possible orders of processing the unit constraints, but that while other implementations are likely to find other origins of ambiguity, the existence of a robustness conflict path does not depend on the order in which the constraints are processed.

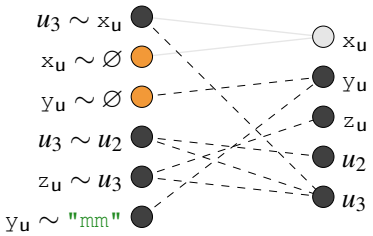

Figure 1. Robustness analysis graph without conflict path.

Consider the following simple model with explicit automatic unit conversion:

```
Real x(unit = "m") = 0.1;
Real y(min = 1.0'mm') = 10.0;
Real z = x + autoUnit(y);
```

The robustness analysis graph in Figure 1 contains origins of fragility, but no origins of ambiguity since all unit constraints are fulfilled without implicit unit conversion. Without any origins of ambiguity there cannot be any robustness conflict.

Now consider the same model again, but without `autoUnit`:

```
Real x(unit = "m") = 0.1;
Real y(min = 1.0'mm') = 10.0;
Real z = x + y;
```

The robustness analysis graph in Figure 2 contains a robustness conflict path leading to the fragile constraint for the binding of `y`.

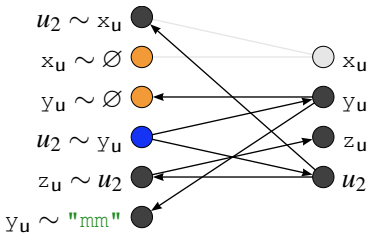

Figure 2. Robustness analysis graph with conflict path.

By adding a `unit`-attribute for `y`, the robustness conflict path is cut by the removal of the node y_u. Then, add the literal `1.0` the sum:

```
Real x(unit = "m") = 0.1;
Real y(unit = "mm") = 10.0;
Real z = x + 1.0 + y;
```

The robustness analysis graph in Figure 3 contains a robustness conflict path also this time.

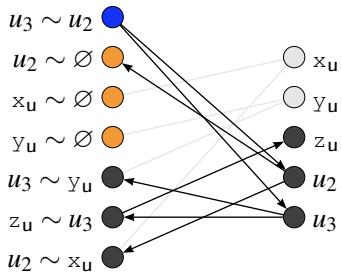

Figure 3. Robustness analysis graph with conflict path.

Now change units so that unit conversion is not needed:

```
Real x(unit = "m") = 0.1;
Real y(unit = "m") = 0.01;
Real z = x + 1.0 + y;
```

This is robustness analysis applied to existing Modelica models in a nutshell; there are plenty of origins of fragility, but no origins of ambiguity. As expected, the robustness analysis graph in Figure 4 has no robustness conflict path.

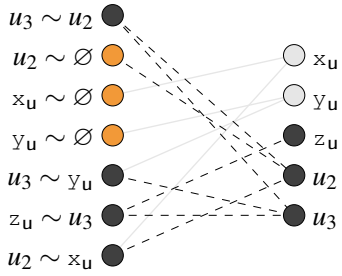

Figure 4. Robustness analysis graph without conflict path.

Robustness analysis doesn't require that all unit variables have been determined:

```
Real x = 2.0;          // Undetermined unit
Real y = 3.0;          // Undetermined unit
Real z = 1'm' + 100'cm';
Real u = x + y * z;
```

As expected, the robustness analysis graph in Figure 5 has a robustness conflict path.

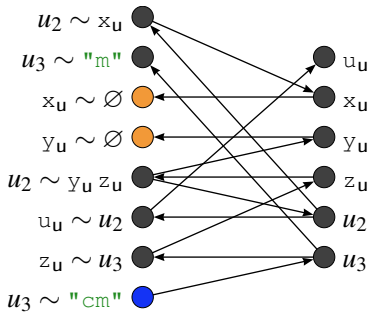

Figure 5. Robustness analysis graph with conflict path.

A consequence of the desire to avoid the "wildcard effect" of empty literals in current Modelica is that multiplication does not distribute over addition when empty literals are present:

```
Real x(unit = "m") = 2.0;
Real y(unit = "m") = 3.0;
Real u = x * (1.0 + y);    // 6.0'm2'
Real v = x * 1.0 + x * y; // Inconsistent
```

Since there is a constraint which cannot be resolved using implicit unit conversion, robustness analysis is neither needed nor applicable.

The following equation is considered consistent in units according to current Modelica, and is therefore also considered valid with the extended semantics:

```
  Real x(unit = "m");
equation
  x = 2.0;
```

Note how the literal `2.0` gets its unit from the other side of the equation. The robustness analysis graph in Figure 6 has no robustness conflict path.

Figure 6. Robustness analysis graph without conflict path.

Now try to adding the same value of quantity to both sides of the equation:

```
  Real x(unit = "m");
equation
  x + 300.0'mm' = 2.0 + 300.0'mm';
```

Looking at the right-hand side alone, the addition of 300 millimeters has changed it from 2000 millimeters to 302 millimeters, a quite unpleasant surprise. It is reassuring to see that the robustness analysis graph in Figure 7 has a robustness conflict path.

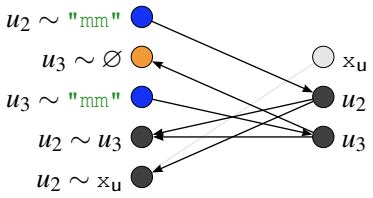

Figure 7. Robustness analysis graph with conflict path.

Consider subtracting the same literal without unit from both sides of an equation:

```
  Real x1(unit = "m");
  Real x2(unit = "m");
equation
  x1 + 1 = 1.0'mm';
  x2 = 1.0'mm' - 1;
```

The solutions to the two equations are not the same, that is, the solutions for `x1` and `x2` are poorly defined values of quantity. Again, it is reassuring to see that the robustness analysis graph in Figure 8 has two independent robustness conflict paths.

DOI 10.3384/ecp21827

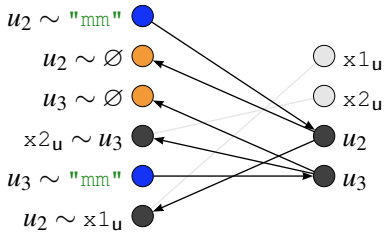

Figure 8. Robustness analysis graph with two independent conflict paths.

Ambiguity can spread through multiplicative constraints:

```
  Real x = 1'cm' + 1'm';
  Real y;
  Real z = y + 1.0;
equation
  1.0'J' = x * y;
```

The robustness analysis graph – omitted due to space constraints – contains a robustness conflict path via y_u.

Variation of the previous example:

```
  Real x = 1'cm' + 1'm';
  Real y;
equation
  1.0'J' = x * (y + 1.0);
```

The robustness analysis graph in Figure 9 has a robustness conflict path. That giving `y` a `unit`-attribute does not help is a sign of the conservativeness of the proposed semantics.

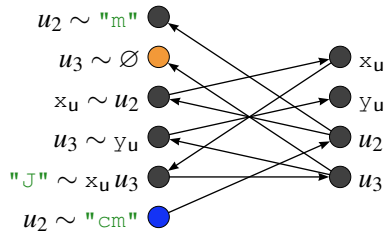

Figure 9. Robustness analysis graph with conflict path.

The trivial resolution of the conflict is to attach the intended unit to the literal:

```
  1.0'J' = x * (y + 1.0'kN');
```

When units are undefined, the possibility of implicit unit conversion must not invalidate models that are valid according to current conventions:

```
function f
  input Real u;
  output Real y = u;
end f;

Real x(unit = "m") = 2.0;
Real y(unit = "mm") = 300.0;
Real u = y + f(x);
Real v = u + 1.0;
```

Intuitively, however, `f(x)` should have had unit `"m"`, and there should be a need for unit conversion resulting in an origin of ambiguity incident to u_u, which in turn would reach the origin of fragility from `u + 1.0`. What actually happens is that `f(x)` has undefined unit, meaning that there is no origin of ambiguity in the model and that the model is accepted also according to the extended semantics.

Now take a model which is inconsistent according to current Modelica:

```
Real u = 1.0'cm' + f(2.0'm');
Real v = 1.0'cm' + u + 1.0'mm';
```

The function call's undefined unit will lead to an origin of fragility, and the need for implicit unit conversion means that there will be at least one origin of ambiguity in the robustness analysis graph. Without any robust variables in the graph, it is easy to see that a robustness conflict path exists. This is in agreement with what would happen if `f(2.0'm')` was inlined, so that there would be no undefined units in the model.

While robustness analysis of equation-based models is essential for illustrating the principles, the final example in this section is a component-based model where implicit conversion is needed in a connection set. Unlike some of the nontrivial examples above, it is representative of the simple way in which implicit conversion matters most to applications. That is, `unit`-attributes are present near the place of implicit conversion on both sides, shielding any origins of fragility in other parts of the model from being reachable from the origin of ambiguity:

```
  Sources.Constant a(k(unit = "m/h") = 1);
  Math.Gain b(u(unit = "mm/s"), k = 1);
equation
  connect(a.y, b.u);
```

7 Applications

In the following, let `Convert` be the block version of the `inUnit` operator, that is, a block for explicit conversion to a given unit. Similarly, let `Value`, `NumericValue` and `AutoConvert` be the block versions of the `withUnit`, `withoutUnit` and `autoUnit` operators.

7.1 Eliminating conversion blocks

In current Modelica, a unit conversion block can be created by careful parameterization of a gain block:

```
final Gain from_MW_to_W(
  u(unit = "MW"),
  y(unit = "W"),
  k(unit = "W/MW", displayUnit = "1") = 1e6
);
```

While the use of `displayUnit = "1"` helps entering and verifying that the value of `k` is correct for the current choice of source and target units (compare subsection 1.3), the setup is still error-prone and users who are not familiar with gain blocks used to perform unit conversion could find the use confusing.

With `inUnit` or `autoUnit`, defining a reusable unit conversion block is straight-forward, but unnecessary

when implicit unit conversion is allowed. Instead of using a unit conversion block between a source with unit `"MW"` and a sink with unit `"W"`, the source and sink may be connected directly. While this may appear strange with the unit equivalence mindset, it is the natural way of connecting the blocks with the value of quantity mindset.

Sometimes, the shift of mindset alone may be enough to eliminate a conversion block. Here, if the sink would have been an integrator for computing total amount of work based on input power, the value of quantity mindset makes it less important whether the unit of the total work is `"W.s"` or `"MW.s"`. For instance, a user might prefer to use a display unit such as `"J"` or `"kW.h"`, and then the underlying unit will not matter for the presentation.

7.2 Working with table data

When table data is expressed in different units than what is used in the rest of a model, there are several interesting options based on the proposed extended semantics. As before, the starting point is to ensure that the table component for accessing the data has connectors with correctly specified `unit`-attributes.

By putting a `Convert` block after a table output, it is possible to read table data in an explicit choice of unit. In a model made without declared units, a `NumericValue` block can be used instead of the `Convert` block to access the table data in the undeclared units assumed by the model. In a model with declared units, a `Convert` block will generally be redundant in view of implicit unit conversion, but if there is a preference of unit conversion to happen as close as possible to the table block, an `AutoConvert` block can be used to pinpoint the transition between the table's units and the units used in the rest of the model.

Similar options exist handling the need for unit conversion of table inputs.

7.3 FMI import

Although the creation of an FMU wrapper model for each imported FMU opens up the possibility of adding unit conversion blocks in the wrapper model, the recommended approach is to use FMU's units in the interface of the wrapper model. With this approach, working with FMUs is even easier than working with table data, since the FMI standard makes it a responsibility of the FMU import mechanism to set up correct units in the wrapper model interface.

7.4 Connecting with external processes

The typical way of connecting a Modelica model to an external process is to use a library providing blocks for reading and writing data over some process communication protocol. Again, the important part of the setup is to ensure that the block instances for reading and writing data have correctly configured `unit`-attributes. When supported by the communication protocol, the library should verify that the units configured for the read blocks agree with incoming data, and that the units configured for write blocks are transmitted with the written data.

7.5 Combination with unitful literals

Consider setting a length parameter to 40 feet. In current Modelica, it is not easy for a human looking at the source code to see that the parameter has a simple value in the `displayUnit`:

```
parameter Real p
  (unit="m", displayUnit="ft") = 12.192;
```

By combining constructs proposed in this work, the intent of the parameter setting can be made clear also to humans looking at the source code by writing `40'ft'` directly in the declaration equation. Further, if the preferred unit for plotting the result is not feet, the `displayUnit` can be changed independently of the unit used to set the parameter value.

It is observed that adding dedicated graphical user interface support for this way of expressing declaration equations would provide a clean solution to the problem of how many digits to present when display unit conversion is lossy due to finite precision, such as in the common case of having degrees as display unit for angles in radians.

7.6 Comparing a ratio to a threshold

Consider some variants of (attempting to) compare a ratio to a threshold:

```
Real x = 1.0'm';
Real y = 1.0'cm';
Boolean b1 = x / y > 50;
Boolean b2 = inUnit(x / y, "1") > 50;
Boolean b3 = x / y > 50'1';
```

In the first case (`b1`) one gets the quite surprising result that one meter is not more than 50 times longer than one centimeter. The second variant is the most verbose, but gives the desired result and does not rely on implicit conversion. The third variant is the most compact thanks to relying on implicit conversion.

8 Future work

It might come as a surprise that the proposed extended semantics considers the following a robustness conflict:

```
Real x1 = 1.0'm' + (1.0'mm' + 1.0);
```

That is, not even parentheses can be used to remove ambiguity. One idea for future work is therefore to make the robustness analysis aware of the parentheses.

Depending on how the methods proposed here for locally taking control over the implicit unit conversions are received, there could be reasons to explore other options as well. This would include the `FixedUnits` approach taken by Unitful.jl, but the Modelica setting also offers the possibility of specifying an annotation on the level of a class or equation for disallowing implicit unit conversion.

The relation between evaluable variability and unit conversion needs clarification. Here, more work is required

DOI
10.3384/ecp21827

to analyze the tradeoff between complexity of interleaving parameter evaluation and unit inference, and the limitations that would come with more restrictive approaches with less implementation effort.

There are currently several tool-specific mechanisms for defining additional unit symbols beyond the ones required by the Modelica specification, but a standardization effort is needed to make use of these units portable across tools. Alternatively or as a complement, the need for customization could easily be mitigated by adding many more well established units to the Modelica specification, and having well established units in the specification would also reduce risk of conflicting custom definitions or multiple symbols being introduced for the same unit.

When understanding of unit checking for units without offset in Modelica has matured, the time would be ripe for a discussion about units with offset, that is, the topic of quantity space checking. With quantity space checking, it becomes possible to detect an inconsistency when computing the difference between two absolute temperatures in degree Celsius and kelvin. When combined with implicit unit conversion, the inconsistency is automatically resolved by converting one operand to the unit of the other before carrying out the subtraction.

In the long run, it would be interesting to pursue a development in another direction, namely to support moving the Modelica ecosystem away from the legacy of allowing expressions with empty unit to be interpreted as values of quantity based on units taken from the context. This would align unit handling in Modelica with unit handling in other popular languages, and could eventually completely eliminate the need for the robustness analysis presented in this work. By only keeping the possibility of interpreting empty unit expressions as values of quantity with unit `"1"`, the threshold comparison in subsection 7.6 could finally be correctly expressed simply as `x / y > 50`.

9 Summary and conclusions

It has been demonstrated how implicit unit conversion can be safely allowed in Modelica. The crucial difference to other languages and software for unit aware computation is the Modelica legacy of allowing expressions without unit to be interpreted as values of quantity based on units taken from the context. When implicit unit conversion is allowed, this creates a risk of interpreting such expressions based on units which are not uniquely determined. A simple and conservative condition for rejecting programs in risk of ambiguously determined values of quantity has been presented. The condition will allow implicit conversion in typical situations where it is useful, as well as never reject any Modelica program which is valid according to current unit semantics. In addition to implicit unit conversion, a set of basic operators for working with units and values of quantity has been proposed. These operators add value on their own, and can also be used to locally take control over the implicit unit conversions.

The importance of understanding a model in terms of related values of quantity rather than merely seeing units attached to variables as decorative ornaments has been stressed. Without this understanding, implicit unit conversion in Modelica would make as little sense as it would in any of the other languages and softwares that allow implicit unit conversion today.

The usefulness of the proposed unit semantics has been demonstrated in several real world examples of Modelica use, and the safety of the approach has been illustrated with numerous minimal test cases.

Abstract

Modelica models exhibit excellent cross-platform compatibility (they can be compiled and simulated on any platform supporting Modelica). However, experiments have revealed that simulation results of the same Modelica model may vary across different platforms (under identical simulation algorithm configurations). The root cause of such discrepancies lies in model translation uncertainty introduced by improper modeling practices, such as insufficient initial constraints or ambiguous state variables selection. Different Modelica tools may have different translation strategies. Therefore, model disambiguation should be performed to ensure consistent simulation results. It can be addressed by three parties: through language improvements, such as the proposal of relevant annotations, by vendor tools; and by the modelers through manual intervention. This paper presents a model disambiguation technology in MWORKS.Sysplorer that enables modelers to automatically correct model text based on translation information, eliminating uncertainties and ensuring model portability across Modelica platforms.

Keywords: Model Disambiguation, Cross-platform, Modelica, MWORKS.Sysplorer

1 Introduction

Modelica's declarative and object-oriented modeling approach lowers the barrier to modeling complex systems. Specialized model library vendors, research teams, and open-source communities provide foundational model components, which users then leverage to build their own research objects. These foundational components often come with default configurations, such as default start values and state variables selection (Mattsson and Söderlind 1993). Modelers must adjust these settings according to their specific application scenarios, including designing necessary initial constraint equations to ensure their Modelica model satisfies well-defined mathematical constraints.

Although Modelica platforms can still translate and simulate models based on default configurations, such models may yield different simulation results across different platforms. These discrepancies can arise from platforms selecting different state variables or applying non-equivalent initial constraint conditions. Additionally, most modern Modelica platforms support nonlinear equation tearing techniques, but implementation differences may lead to the selection of distinct nonlinear iteration variables. When nonlinear equations have multiple solutions, variations in the chosen iteration variables and their initial estimates can further affect simulation outcomes.

To ensure Modelica model portability across platforms, potential translation ambiguities must be resolved during the modeling phase. However, most modelers have limited knowledge of Modelica's translation and solving theory, making it difficult to construct ideal models. Moreover, for complex models (e.g., those with hundreds or thousands of state variables), relying on modelers to eliminate uncertainties is neither reliable nor cost-effective.

The paper is organized as follows. Section 2 uses a series of extremely simple examples to systematically dissect the sources of model translation uncertainty. Section 3 presents MWORKS.Sysplorer's model disambiguation technology and proposes standardized Translation annotation semantics for Modelica specifications. Section 4 empirically demonstrates the practical effects of model disambiguation through experimental validation.

2 Model Translation Uncertainty

Model translation uncertainty primarily stems from three aspects: lack of initial equations, selection of state variables, and nonlinear tearing. We will provide a detailed explanation using a series of extremely simple examples (though lacking engineering significance) in separate subsections, demonstrating how it leads to inconsistent simulation results.

2.1 Lack of Initial Equations

An initial system in Modelica remains valid even with missing but consistent equations (Pantelides 1988), as tools automatically supplement them. Modelica specifies that start values should be used to supplement initial values. If no start value is available, default values are applied (0 for Real and Integer types, false for Boolean types). When selecting m equations from n candidates with $0 < m < n$, uncertainty arises. Different tools have significant discretion in how they perform this completion, and the underlying mechanisms they employ are generally not the same. Vendors should report supplemental information to alert modelers.

2.2 Start Value Recommended Priority

As "Start Value Recommended Priority"(see §8.6.2 (Modelica Association 2023)) states, the start values from models closer to the top level are considered more reliable. However, some vendor tools may not follow this recommendation for various reasons. Subsequent tool upgrades adopted this specification-recommended strategy for selecting start values, resulting in incompatibility with older versions.

Listing 1. An example of model translation uncertainty caused by lack of initial equations with multiple start value

```
model Case1
  model M
    Real x(start = 1);
  equation
    der(x) = 1;
  end M;
  M m;
  Real y(start = 2) = m.x;
end Case1;
```

In Listing 1, tools adopting Modelica's recommended start value selection strategy will set the initial value of x to 2. However, older versions may initialize x with 1 instead. Considering that not all modeling tools support this feature uniformly, MWORKS.Sysplorer's will elevate start values to initial conditions by adding "fixed=true" attributes when performing model disambiguation.

2.2.1 Lack of initial equations for state variables

Listing 2. An example of model translation uncertainty caused by lack of initial equations for state variables

```
model Case2_1
  Real x;
  Real y;
equation
  x + y = 1;
  der(x) - der(y) = 0.5;
end Case2_1;
```

Noted that not all differential variables will be identified as state variables. In Listing 2, both x and y are differential variables, and they are subject to the algebraic constraint $x+y=1$. As a result, the system has only one degree of freedom, meaning only one of them can be selected as a state variable. The system does not provide additional information to determine which variable x or y is the better choice as the state variable.

Listing 3. A mathematically equivalent example to Listing 2

```
model Case2_2
  Real x;
  Real y;
equation
  y + x = 1;
  der(x) - der(y) = 0.5;
end Case2_2;
```

Changing $x+y=1$ to $y+x=1$ in Listing 2 yields Listing 3, which are mathematically equivalent, but get different result in Dymola 2024x trivial version. This is because Dymola selects y as the state variable in Listing 2, while choosing x as the state variable in Listing 3. As a result, the initial value $(x,y)=(1,0)$ in Listing 2, while $(x,y)=(0,1)$ in Listing 3. The root cause is that the original model lacks an initial condition, and the selection of state variables affects how default conditions are supplemented.

Listing 4. An alias example to Listing 2

```
model Case2_3
  Real x;
  Real u;
equation
  x + u = 1;
  der(x) - der(u) = 0.5;
end Case2_3;
```

Similarly, by renaming y to u in Listing 2, we obtain Listing 4. When simulating with MWORKS.Sysplorer, y is selected as the state variable in Listing 2, while x becomes the state variable in Listing 4. The default values of the state variables are used as the initial conditions, resulting in completely different outcomes.

To eliminate this uncertainty, modelers can: (1) Assign a start value to either x or y in Listing 2 to explicitly determine the state variables selection. However, if both are given start values, they return to an equally weighted condition, providing no additional information to prioritize one over the other. (2) Use the StateSelect attribute (see §4.8.7.1 (Modelica Association 2023)), such as StateSelect.prefer, to explicitly specify the preferred state variable. But if both variables are marked with this attribute, the ambiguity persists.

Since the fixed mechanism alone cannot reliably resolve such conflicts (particularly when multiple variables carry additional constraints), Sysplorer adopts the following strategy when performing model disambiguation: (1) Automatically applies "fixed=true" to elevate start values to initial conditions. (2) Uses "StateSelect.always" to enforce unambiguous state variables selection. Additional note: In cases of dynamic state variables selection, MWORKS.Sysplorer will only automatically process a subset of differential variables with "fixed=true" when performing model disambiguation.

2.2.2 Lack of initial equations for discrete variables

Listing 5. An example of model translation uncertainty caused by lack of initial equations for discrete variables

```
model Case3
  Integer x;
  Integer y;
equation
  when sample(0, 0.1) then
    x = pre(x) + 1;
    y = pre(y) + x;
  end when;
initial equation
  y = x + 1;
end Case3;
```

DOI
10.3384/ecp21839

In Listing 5, both x and y are discrete variables with only one initial equation provided, requiring an additional initial condition to be supplemented. The key issue lies in whether to set $x = 0$ or $y = 0$ as the supplemental condition. Although mathematically equivalent, when the initial equation $y = x + 1$ is reformulated as $x = y - 1$, both MWORKS.Sysplorer and Dymola2024x exhibit changes in their automatically supplemented conditions. This ultimately leads to inconsistent simulation results.

To eliminate this uncertainty, modelers can similarly assign start values to either x or y in Listing 5, which explicitly uses the start value as the initial condition. However, when both variables have start values specified, the system returns to an equally weighted condition where no additional information exists to determine which start value should take precedence as the initial condition. The fixed attribute mechanism alone cannot reliably resolve this conflict when both variables carry additional constraints. To address this, MWORKS.Sysplorer automatically applies "fixed=true" to elevate the start values to initial conditions.

2.3 Necessity of Start Values for Nonlinear System

The uncertainty in model solving arises from the existence of multiple solutions in nonlinear systems. Currently, the specifications do not provide clear recommendations for the selection of nonlinear iteration variables (i.e., nonlinear tearing), which may lead to inconsistencies in nonlinear tearing across different versions. Consequently, the initial iteration values may vary, resulting in different solutions or even cases where one version succeeds in finding a solution while another fails.

Listing 6. An example of necessity of start values for nonlinear system

```
model Case4_1
  Real x;
  Real y = x - 2;
equation
  (x - 0.78) * (x - 1.57) * (x - 3.14) = 0;
end Case4_1;
```

In Listing 6, the direct simulation yields a result of 0.78. However, when x's start value is set near 1.5, the simulation result becomes 1.57 and when x's start value is set near 3, the result changes to 3.14.

This demonstrates that the tool cannot autonomously determine which solution the modeler intends to obtain, and consequently performs iterations based on the provided start value. This observation underscores the critical necessity of specifying start values as initial estimates for nonlinear systems.

2.4 Nonlinear Tearing

Listing 7. An example of nonlinear iteration variables selection

```
model Case4_2
  Real x;
  Real y;
equation
  x - y = 2;
  (x - 0.78) * (x - 1.57) * (y - 1.14) = 0;
end Case4_2;
```

Listing 6 and Listing 7 are mathematically equivalent, but yield different simulation results in MWORKS.Sysplorer: x=0.78 in Listing 6 versus x=1.57 in Listing 7. This discrepancy occurs because x is explicitly determined as the nonlinear iteration variables in Listing 6 while both x and y qualify as potential nonlinear iteration variables, and MWORKS.Sysplorer defaults to selecting y In Listing 7.

Providing a start value for x forces its selection as the iteration variables. However, when both x and y have start values, the system reverts to the original ambiguous state. Nonlinear iteration variables has no *StateSelect* attributes like *state variables*. So MWORKS.Sysplorer innovatively employs annotation markup to explicitly specify which variable should serve as the nonlinear iteration variables. This annotation-based approach effectively eliminates the ambiguity, and the entire process can be automatically handled by the model disambiguation technology in MWORKS.Sysplorer.

2.5 More Words about Nonlinear Tearing

Note that, it is possible that some variables appear in both the nonlinear system and the initial nonlinear system. For instance, variable y in Listing 8 falls into this category

Listing 8. An example of nonlinear iteration variables selection

```
model Case5
  Real x;
  Real y;
  Real z;
equation
  der(x) = sin(time);
  x^2 + y^2 = z^2;
  z = x * sin(y) + y * cos(x);
initial equation
  x + y + z = 1;
end Case5;
```

2.6 More Words about State Variables Selection

Even when the initial equations have sufficient initial conditions, the selection of state variables can still introduce uncertainty. In Listing 9, if y is chosen as the state variable, then x and z form a nonlinear system. However, if x is selected as the state variable, no nonlinearity exists. This discrepancy leads to non-negligible differences in simulation results between platforms that choose x as the state variable and those that select y.

Listing 9. An example of model translation uncertainty caused by state variables selection

```
model Case6
  Real x(start = 0);
  Real y(start = 0.5);
```

```
  Real z;
equation
  der(x) + der(y) = 1;
  z = sin(x)^2 + 1;
  z = x + 2 * y + time;
initial equation
  x = 0;
end Case6;
```

In Listing 9, if the "stateSelect=StateSelect.always" attribute is added to x and y separately, and simulations are performed for each case, the results are as shown in Figure 1.

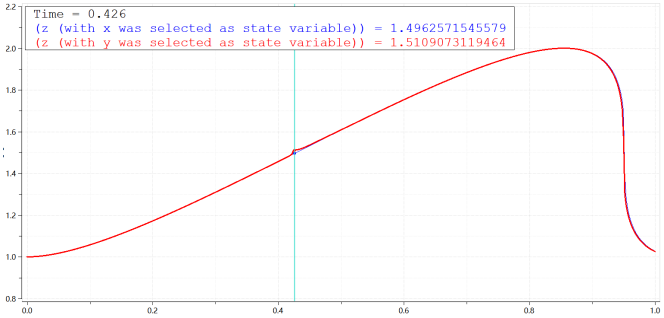

Figure 1. An example of inconsistency caused by State Variable Selection

2.7 A graphic example about State Variables Selection

We provide a simplified circuit model (which may lack physical significance) to demonstrate that even when using a drag-and-drop component assembly method, inconsistent selection of state variables can lead to divergent simulation results.

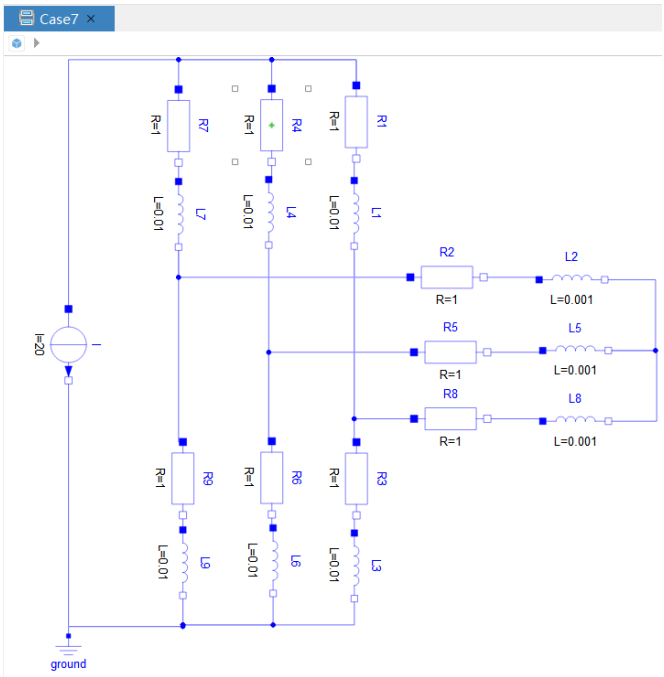

Figure 2. A graphic example about State Variables Selection

The circuit model Figure 2 contains 9 inductors with algebraic constraints, but only 4 of them can have their currents (which must be linearly independent) selected as state variables. MWORKS.Sysplorer selected L6.i, L7.i, L8.i, and L9.i as state variables, while OpenModelica chose L1.i, L4.i, L5.i, and L8.i. This difference in selection leads to inconsistent initial conditions between the two platforms, for instance, L1.i has an initial value of 20A in MWORKS.Sysplorer, but 0A in OpenModelica.

3 Model Disambiguation Technology

MWORKS.Sysplorer utilizes the results of the first simulation to perform the following actions during model disambiguation in the second translation:

1. Add the "fixed=true" attribute to variables that were supplemented with initial values in the report.

2. Add the "stateSelect=StateSelect.always" attribute to state variables listed in the report.

3. Record vendor-customized annotations for nonlinear iteration variables and initial nonlinear iteration variables, and assign them corresponding start values.

4. If the above modifications involve protected variables, vendor annotation could be used, otherwise, they would conflict with Chapter 4.1 of (Modelica Association 2023).

The following model Listing 10 represents the disambiguated version of all models mentioned in the previous section. Specifically, Case2_1_protected, Case4_2_protected, and Case5_protected correspond to modified versions of Case2_1, Case4_2, and Case5 respectively, where all model variables have been set as protected variables.

Listing 10. An example of disambiguated model

```
model DisambiguationModel
  Case1 m1(m(x(stateSelect=StateSelect.
      always,fixed=true)));
  Case2_1 m2(y(stateSelect=StateSelect.
      always,fixed=true));
  Case2_1_protected m2_p;
  Case3 m3(x(fixed=true));
  Case4_1 m4(x(start=0.78));
  Case4_2_protected m4_p;
  Case5 m5(x(stateSelect=StateSelect.always
      ),y(start=0.349110989362788),z(start
      =0.4190691332521359));
  Case5_protected m5_p;
  Case6 m6(y(stateSelect=StateSelect.always
      ),x(start=0));
  Case7 m7(L7(i(stateSelect=StateSelect.
      always,fixed=true)),L9(i(stateSelect=
      StateSelect.always,fixed=true)),L6(i(
      stateSelect=StateSelect.always,fixed=
      true)),L8(i(stateSelect=StateSelect.
      always,fixed=true)));
```

end DisambiguationModel;
```

The following are keynotes when doing model disambiguation:

1. If the original model is read-only, you can create a new model that references it, then perform disambiguation in the new model.

2. If the model fails to solve in the first place, disambiguating its state becomes rather meaningless, and the modelers need to modify the model themselves.

3. After Performing model disambiguation, modelers can still manually fine-tune the model by editing the text. Regardless of whether the original model is modifiable, it is recommended to create a new model for disambiguation to clearly track all modifications.

4. After Performing model disambiguation, providing explicit start values will accelerate the solving of the initial value system.

5. MWORKS.Sysplorer uses vendor-specific annotations to explicitly define the selection of nonlinear variables.

6. A variable may appear in both the nonlinear system and the initial nonlinear system, so MNonLinearVariables and INonLinearVariables are used to control them separately. MNonLinearVariables means nonlinear iteration variables during model simulation, while INonLinearVariables means nonlinear iteration variables during Initialization.

7. Unlike Modelon (Kari 2022), which considers both iteration variables and residual equations to resolve ambiguity caused by nonlinear tearing, we focus solely on iteration variables for the following reasons: configuring annotation is difficult when equations aren't at the simulation model's top level; different tools process iteration and residual equations maybe inconsistently; and our practical experience demonstrates that restricting iteration variables alone sufficiently eliminates model ambiguity.

8. If the modeler modifies the model after model disambiguation, causing variables in the annotations to become invalid, a warning message must be issued. There are two typical handling methods: directly ignoring the annotations or striving to satisfy the annotations. The tool may offer an option to let the modeler choose the preferred approach.

9. While other platforms don't recognize MWORKS.Sysplorer's vendor annotations, the model disambiguation provides deterministic initial values and relatively accurate compatible initial guesses for nonlinear iterations - making it highly probable to maintain result consistency across other platforms.

3.1 Annotation of Translation

Since the minimal tearing problem is NP-hard (Karp 2009) (Elmqvist and Otter 1994), most simulation platforms prioritize translation efficiency by employing greedy or heuristic algorithms to approximate minimal tearing. Even if vendors develop improved heuristic strategies, concerns over version compatibility often discourage modifications, hindering tool advancement.

Generally, better heuristics should facilitate nonlinear system solving. A typical scenario where models solvable in the original tool fail in new tools occurs because when initial modeling in the original tool, users would supplement appropriate start values as nonlinear iteration initial guesses if missing values caused solving failures, after switching to new tools with different tearing strategies, some models may lack required start values due to altered variable selection, necessitating manual re-supplementation.

Therefore, we propose that the Modelica specification incorporate Translation Annotations to govern nonlinear/-linear tearing and initial-value system tearing, thereby eliminating strategy-induced inconsistencies for modelers. For tool vendors, the implementation priority should be:

1. First satisfy the tearing requirements specified in the annotations.

2. Then prioritize variables based on start value hierarchy (top-level variables take precedence).

3. Finally pursue minimal tearing under equal conditions.

This strategy ensures tearing consistency across all compliant platforms when users provide comprehensive annotation specifications. The benefits are threefold:

1. Better interoperability between different vendors' tools.

2. Enhanced control for modelers over system solving.

3. Optimal utilization of each tool's translation and solving capabilities.

Ultimately, this advancement moves Modelica closer to the ideal of "Write once, run on any Modelica tool" - significantly improving model portability and reducing maintenance overhead. However, even with identical model

descriptions and unified nonlinear/linear tearing through translation annotations, achieving simulation results that differ only by rounding errors across platforms under identical settings remains a significant challenge. Key persistent discrepancies include:

1. Inconsistent precision tolerance interpretations across platforms
2. Divergent implementations of nonlinear/linear solvers
3. Algorithmic variations in implicit integration methods
4. Discrepancies in variable-step size adjustment strategies
5. Interpolation method variations
6. Event handling policy differences
7. Integrator restart strategy implementations

While writing this paper, we observed that both OpenModelica (Fritzson et al. 2022) and Modelon (Kari 2022) employ vendor-specific annotations for tearing, which exhibit subtle differences not only between themselves but also when compared with MWORKS.Sysplorer. This phenomenon demonstrates that such requirements are relatively common. Therefore, we hope the Modelica Association could provide an official annotation standard to eliminate inconsistencies across different implementations.

4 Experimental Results

When simulating the model "LoadTestExpRecovery" from the model library OpenIPSL-3.0.1 (Vanfretti et al. 2016), it was found that the results from MWORKS.Sysplorer and OpenModelica were completely inconsistent, for example, the variable "pwLine2.P12". After investigation, the inconsistency was traced to differences in nonlinear tearing. Since it was hard to control OpenModelica's nonlinear selection at the modeling level, we instead used custom annotation in MWORKS.Sysplorer to control nonlinear tearing, as shown in the Listing 11.

Listing 11. An example of control nonlinear tearing using Translation annotation

Data Reconciliation for Industrial Experiments

Baptiste Mazurié[1] Audrey Jardin[1] Pascal Borel[1] Frans Davelaar[1] Didier Boldo[1] Luis Corona Mesa-Moles[1]

[1]R&D, Electricité de France, France, firstname.lastname@edf.fr

Abstract

This paper presents the use of data reconciliation to improve the characterization of the operating state of experimental installations in an industrial context. It focuses on the development of a data reconciliation approach using the OpenModelica prototype to study: the detection of the defects in an experimental hydraulic test loop; and to validate measurement data of an HVAC testing facility. Data reconciliation is shown to be effective for the most pronounced defects intentionally introduced in the system. Regarding the characterization of HVAC measurements, data reconciliation identified two initially unnoticed invalid experiments.

Keywords: data validation, data reconciliation, default detection, uncertainties, measurements, Modelica, model reuse, industrial experiments

1 Introduction

Control of measurement equipment and associated acquisition chains is a key element for monitoring and diagnosis of industrial installations, in particular in the domain of electricity production, where constraints related to safety and resilience for securing the supply of energy networks require a sound and accurate knowledge of the true operating state of the system. To that aim, several experimental installations exist in premises of EDF Lab to improve the characterization of uncertainties associated with the examination of the main circuits of interests by testing new methods, using either direct measurements (via new sensor technologies) or indirect measurements (via the complementary use of knowledge models).

This article falls into this second category showing how a physical simulation model combined with statistical assessments can be used to:

- detect deviations from nominal operation and alert operators of the occurrence of possible faults
- validate measurement campaigns.

In practice, the work focuses on the use of a technique known as Data Reconciliation (DR). The aim is to obtain an estimate of the most likely state of the system by correcting the measured values on the actual installation so that the reconciled values are consistent with the equations governing the behaviour of the system.

While data reconciliation exists for several decades and its application to energy systems is ruled by a German standard (VDI 2048 2017), it is finding a renewed interest in the nuclear field for Measurement Uncertainty Recapture (MUR) and potential associated power uprates (EPRI 2020).

Dedicated tools (VALI, PROCESSPLUS, Thermal System Monitoring Enterprise, BILCO ...) exist to perform data reconciliation, but they require the physical models to be specifically developed for that purpose. They use their own proprietary language and are sometimes restricted to a specific domain (e.g. material processing industry). This makes data reconciliation costly and difficult to use. A possible answer to that problem is to apply data reconciliation on existing Modelica general purpose models, developed and validated for system operation.

This is why DR has been implemented in OpenModelica enabling the reuse of simulation models by automatically extracting the equations that should be considered for binding the measured variables together.

The principle and use on a simple example has been documented in (Bouskela et al. 2021). This paper presents first Data Reconciliation algorithm (Section 2) and then shows its applicability on two industrial experiments: one to control liquid flow rate measurements (Section 3) and a second to measure air flows (Section 4).

2 Data Reconciliation Theory

Industrial processes are usually monitored with a number of measurement equipments which can be more or less isolated on different sections of the circuit and of different technologies leading to differences in terms of representativeness, accuracy and reliability. The problem is to determine whether all these measurements, which are necessarily subject to error, are physically and statistically consistent with each other and whether they are a reliable mirror of the installation.

Data reconciliation is an optimization process that allows numerical correction of measurement values so that they satisfy the physical equations of the system (the model). If the corrections are too significant, the measurements are invalidated: in that case reconciliation alerts to a possible instrumentation defect (e.g., poor calibration or a faulty sensor), a process defect (e.g., an unmodeled leak) or a poor knowledge of sources of measurements uncertainties (e.g., lack of correlation effects). If the measure-

ments are validated, the reconciliation exploits the redundancy of information to reduce uncertainties and obtain an estimate as close as possible to the true state of the system.

2.1 Mathematical Foundations

Data reconciliation aims at improving the accuracy of measurements by reducing the effect of random errors in the data. The main difference between data reconciliation and others techniques for propagating uncertainties such as Quadratic Combination or Monte Carlo simulation (Baudin et al. 2017; EPRI 2020) is that data reconciliation uses a model to express the physical constraints on the variables of interest. The measured values of these variables are then adjusted such that the estimates satisfy the constraints: the variables are thus reconciled.

Let $\{X_0^t,\ldots,X_d^t\}$ be a vector of d physical quantities constrained by a set C of r equations or auxiliary conditions derived from physical laws. These quantities must satisfy Equation 1 to ensure consistency.

$$\begin{aligned} C &: \mathbb{R}^d \to \mathbb{R}^r \\ 0 &= C(X^t) \end{aligned} \tag{1}$$

Measurements $\hat{X}$ of X^t inevitably have uncertainties, which are commonly modeled by a random variable X with a multivariate Gaussian distribution characterized by its mean vector μ and its variance-covariance matrix Σ.

$$\pi(X) = \mathcal{N}(\mu,\Sigma) \tag{2}$$

The contradiction vector U of a given state $\{X_0,\ldots,X_d\}$ is given by:

$$U = C(X) \tag{3}$$

The objective of data reconciliation is to define a conditional probabilistic distribution of measurements, called the reconciled distribution, such that Equation 1 is satisfied by the random variable $X|C(X)=0$. This reconciled distribution is a multivariate Gaussian characterized by a mean vector μ' and a variance-covariance matrix Σ'.

$$\pi\left(X|C(X)=0\right) = \mathcal{N}(\mu',\Sigma') \tag{4}$$

(Bouskela et al. 2021) present a detailed methodology for solving this optimization problem using Lagrange multipliers as stated in (VDI 2048 2017). The optimization problem consists in minimizing the following objective function in order to determine the set of reconciled values μ':

$$J(\mu') = (\mu'-\mu).\Sigma.(\mu'-\mu)^\top \tag{5}$$

The variance-covariance matrix of reconcilied values derive from the general formula of uncertainty propagation:

$$\Sigma' = \partial_\mu \mu'.\Sigma.\partial_\mu {\mu'}^\top \tag{6}$$

Relevancy of the reconciled distribution can be assessed using local and global test : χ^2, reflecting the relevancy of the estimated reconciled distribution based on prior measurements uncertainty knowledge. The global test involves verifying the following statistical hypothesis, where r denotes the number of degrees of freedom and p represents the significance level associated with the χ^2 distribution:

$$J(\mu') \leq \chi^2_{r,p} \tag{7}$$

The improvement vector v is defined as:

$$v+\mu = \mu' \tag{8}$$

Local tests, measurement by measurement, can help to identify measurements with a too large improvement pushing the most probable reconciled value to be out of its confidence range defined by the prior measurement knowledge as presented in Equation 9.

$$|\mu'_i - \mu_i| < \Sigma^v_{ii}\lambda_p \tag{9}$$

where μ_i is the i^{th} measurement, μ'_i is the i^{th} reconciled measurement which is also the mean of the i^{th} marginal of the reconciled distribution and λ_p is the confidence interval width, usually taken as 1.96 corresponding to 95% of the possible values. Σ^v is the variance-covariance matrix of the improvement v defined as:

$$\Sigma^v = \partial_\mu v \Sigma \partial_\mu v^\top \tag{10}$$

2.2 Measurement Uncertainty: GUM

The measurement of physical quantity inevitably has an uncertainty which has to be estimated. Let X_i^t the true value of physical quantity to measure, $\hat{X}_i$ the corresponding measurement with an uncertainty ε_i

$$X_i = \hat{X}_i + \varepsilon_i \tag{11}$$

ε_i is a random variable with a null mathematical expectation which can by decomposed in elementary uncertainty sources as follows:

$$\varepsilon_i = \varepsilon_i^0 + \ldots + \varepsilon_i^n \tag{12}$$

One can follow the guide (ISO/IEC GUIDE 98-3 2008) to establish a model of the random variable ε_i by proposing a multivariate statistical distribution $\pi(\varepsilon_i)$. Typically, there are five sources of uncertainty: sensor calibration, sensor environment impact, sensor acquisition chain, measurement methodology, and repeatability uncertainties. The first four are epistemic uncertainties, which must be determined a priori, usually based on sensor provider documentation or calibration reports. The last source, if it exists, is a stochastic uncertainty that must be evaluated by empirical samples collected during measurement.

When the uncertainty sources are assumed to be Gaussian, it is necessary to specify the variance-covariance matrix of the uncertainty sources, denoted as Σ. Estimating the correlation is a challenging aspect that can significantly impact uncertainty propagation. In practice, without empirical samples, the correlation is often assumed to be either null or total.

DOI
10.3384/ecp21845

Complex measurements of quantities Y can be based on several measurements of elementary quantities that are combined with a function g.

$$Y = g(X) \tag{13}$$

Uncertainty propagation with methods such as first-order Taylor series expansion or Monte Carlo simulation aims to estimate the statistical distribution of Y. In the context of data reconciliation, estimating the multivariate distribution of Y, which is assumed to be a multivariate Gaussian distribution, is a crucial step that must be performed meticulously. This includes accurately estimating the correlation between the uncertainties of different measurements. The construction of this multivariate distribution can be achieved using OpenTURNS (Baudin et al. 2017), as illustrated in Figure 1.

2.3 Data Reconciliation in OpenModelica

The main added-value of performing DR in OpenModelica lies in the reuse of models initially developed for other purposes than data validation or diagnosis.

In particular the equational nature of the Modelica language is used to automatically extract from a complete simulation model (i.e. a square system of equations with the same numbers of equations than unknowns) a minimal subset of auxiliary equations that will bind the measured variables together (i.e. here a non-square system of equations since the redundancy of measurements is exploited for the reconciliation).

The extraction algorithm has already been fully described in (Bouskela et al. 2021) and is now available in the standard release of OpenModelica.

For the sake of clarity, Figure 1 summarizes the main steps required to perform a complete data reconciliation process in OpenModelica. For more details and illustration on the simple example of a splitter, the user is invited to read the documentation accessible online (*OpenModelica Documentation: Data Reconciliation* 2021).

On Figure 1 light blue refers to steps implemented in OpenModelica while dark blue highlights steps performed in a third-party tool dedicated to uncertainty quantification (in this case OpenTURNS (Baudin et al. 2017) but other tools can be chosen). Basically, the user :

1. states the reconciliation problem by specifying which variables should be reconciled and which equations should be voluntary not be considered as an auxiliary condition (typically the boundary conditions). This is done by decorating the Modelica model with dedicated annotations;

2. defines the set of measurements and quantifies their corresponding uncertainties (potentially with the help of a dedicated tool). The numerical information to be reconciled can be provided in the form of a csv file;

3. launches the DR functionality which will extract the auxiliary conditions and computes the reconciled data. Based on the results, a report is generated in the form of an html file with reconciled outputs and statistical tests.

4. analyses the validity of reconciled data with respect to the initial assumptions.

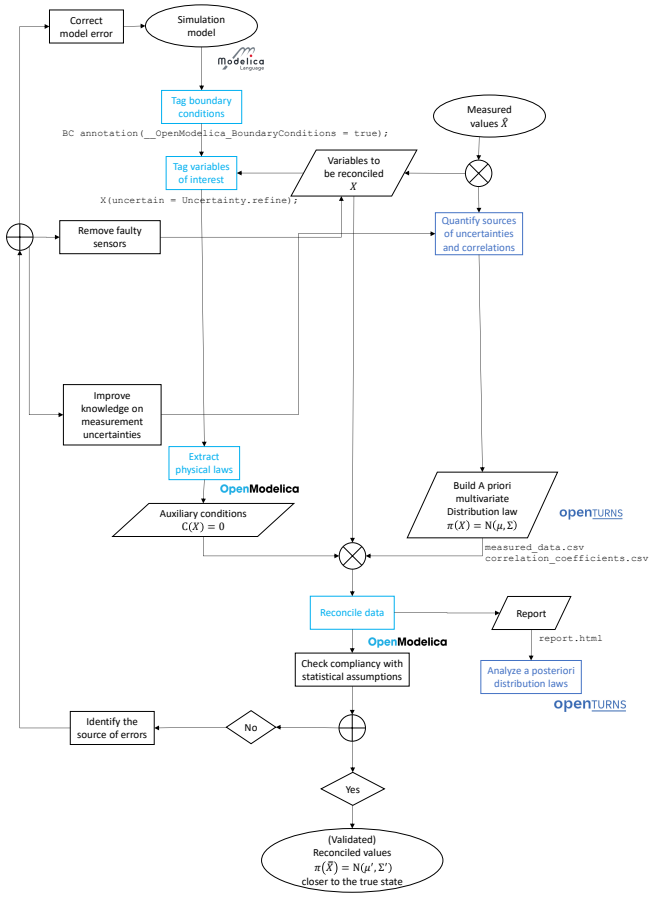

Figure 1. Data reconciliation workflow in OpenModelica

3 Flowrate Measurement with EVEREST Facility

3.1 Description of the test loop

3.1.1 Global Description

EVEREST (Thibert et al. 2019) is a closed loop facility with a liquid flow rate regulation (Table 1). The fluid is clean demineralized water. EVEREST consists of three parts: a flow metering reference section, an operation section and a modular flow metering test section (Figure 2). Table 1 shows the EVEREST design specifications.

The test bench provides a steady water stream with Reynolds numbers as low as 5.10^4 up to 2.10^6. Flow circulation is provided by a variable centrifugal pump (315

Prime features	Details
Calibration test type	Closed regulated loop
Flow meter reference	Master meters method
Test section pipe size	From DN40 up to DN350
Pipe compositions	Stainless steel
Fluid	Demineralised water
Pressure range	From 1 up to 10 bar
Fluid temperature range	From 20°C up to 40°C
Environment Temperature	From 10°C up to 35°C
Flow rate range	From 5 $m^3.h^{-1}$ up to 1200 $m^3.h^{-1}$
Flow metering uncertainty	0.2% (volume and mass flow rate)

Table 1. Overview of the design specification of EVEREST

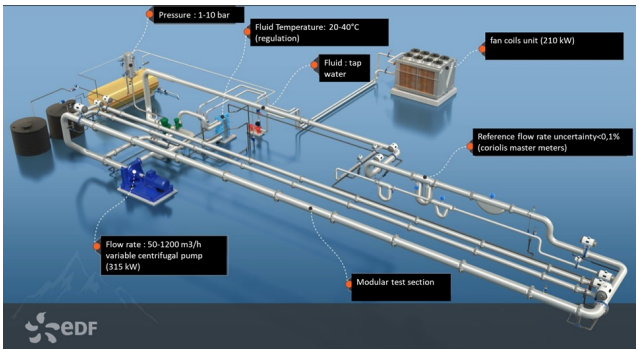

Figure 2. EVEREST test facility layout design

kW). Depending on the geometrical configuration of the test section, the flow can range from 25 $m^3.h^{-1}$ up to 1100 $m^3.h^{-1}$. Thanks to regulation systems, a steady flow rate is maintained in the reference and the test sections. The heat produced by the pump is absorbed by the pumped liquid flowing in the pipes. Due to the EVEREST loop configuration, this phenomenon consequently increases the fluid temperature. To compensate this phenomenon, the water temperature is regulated thanks to a plate heat exchanger (215 kW). The cooling system including the fan coils unit is located at the outside of the experimental hall. The fluid temperature can thus be maintained at a specific value according to the desired test conditions, generally between 20°C and 40°C. The fluid pressure is regulated at a set-point between 1 bar up to 10 bar thanks to a pressuriser.

The EVEREST loop is designed to minimise its environmental impact by managing efficiently its water consumption. Three water storage tanks are used to fill and empty the circuits between two test campaigns requiring different pipe configurations.

3.1.2 Reference Flow Rate

The reference flow rate is calculated from four different master meters based on the Coriolis technology. Two meters are used for low flow rate calibration tests, from $50m3.h^{-1}$ up to $350m3.h^{-1}$. They are installed on a DN100 stainless steel pipe. The other two devices operate under high flow rate calibration tests conditions, from $150m3.h^{-1}$ up to $1200m3.h^{-1}$. They are installed on a DN250 stainless steel pipe. This configuration aims at decreasing uncertainty over the whole loop flow rate rangeability, so each meter is used in its nominal operative flow rate.

For each reference line, one Coriolis meter is used as the reference flow rate while the other is used as a "drift detection" meter. This choice allows monitoring and detecting any reference sensor drift between two consecutive calibrations.

The EVEREST reference flow rate can be calculated either as a volume or as a mass flow rate. The EVEREST test loop has been ISO17025 accredited with a volume (resp. mass) flow rate uncertainty of 0.2% from 25 $m^3.h^{-1}$ (resp. $t.h^{-1}$) up to 1100 $m^3.h^{-1}$ (resp. $t.h^{-1}$).

3.1.3 Modular Test Section

The flow metering test section is located at the end of EVEREST (see Figure 3) and resides completely inside the building. Devices to be tested are mounted on stainless steel pipes, they can be invasive as well as non-invasive according to the sensor technology. This section constitutes an available space with a length of 25 m, a width of 5 m and with a high ceiling of 5 m.

Figure 3. EVEREST test facility test section

This test section is designed to perform calibration tests not only under ideal thermo-hydraulic conditions (fully developed and swirl-free velocity profile thanks to a long straight pipes at the upstream of the tested meter) but also calibration tests under non-ideal thermo-hydraulic conditions due to the presence of various fittings located upstream or downstream of the tested meter.

Summerizing, the test section of the loop allows the recreation of numerous process pipe geometries or to install a reduced scale mock-up of typical industrial components for metrological purposes. This flexibility is a key feature of the loop as it allows EDF R&D to investigate the impact on the accuracy of flowmeters installed in real industrial conditions.

3.2 Detection of Defects

As described in §3.1, the EVEREST test loop is a representative and reliable experimental test facility. Therefore, it is an interesting use case for Data Reconciliation

DOI 10.3384/ecp21845

in order to improve the reliability of the facility's state estimation. Indeed, the test loop being modular, deliberately machined defects can be introduced into the system to impact its behaviour. The defects are introduced upstream the mass flow rate measurement and are shown in Figure 4. They are representative of what could be found in thermal hydraulic installations, such as weld bead defects (trapezoidal or rectangular) or changes in diameter at the junction of two pipes (referred to as step defects). Those defects have more or less impact on the flow and are sorted by order of impact in Figure 4, with the one having no defect showing no impact, and the change in diameter having the greatest impact on the flow. Thus, the goal is to determine whether data reconciliation will allow the detection of these defects.

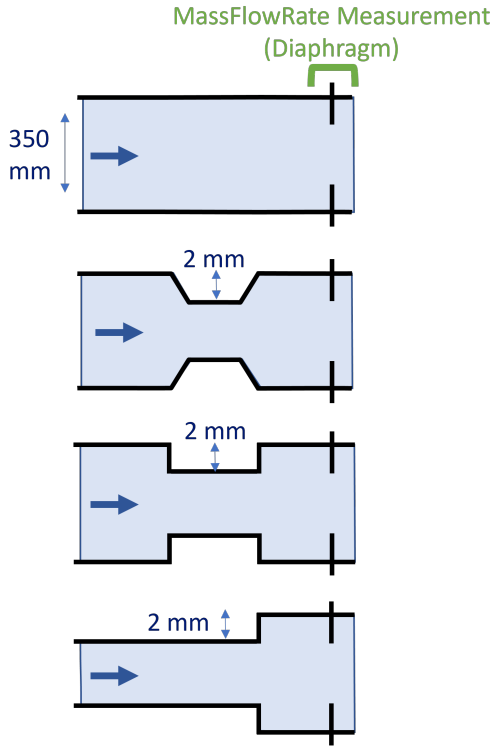

Figure 4. Diagram of the different defects introduced in the EVEREST test loop: no defect, trapezoidal weld bead defect, rectangular weld bead defect, change of diameter (also refered as step defect) sorted by order of impact from the one having the less impact (no defect added), to the one having the more impact on the flow (step defect).

A data reconciliation approach using the OpenModelica prototype is thus developed to study the detection of these defects thanks to an experimental test campaign on the loop. This workflow is inspired from (EPRI 2020). First a Modelica model of the facility is developed using manufacturer's data of the different equipment and calibrated by inversion of `n` parameters based on `n` historical measurements from the facility. Initial tests of data reconciliation are run to make sure that the data reconciliation problem is well-posed. Those first steps ensure a good numerical representativity of the installation and that the data reconciliation problem is well-posed. Once the initial phase completed, test campaigns are conducted, both with and without defects, to allow comparison with a control test. The data reconciliation algorithm is run and challenges the prior uncertainties with the posterior results. If the results are significantly different (in the sense of a χ^2 test as described in §2.1), it can be concluded that an inconsistency has been detected: either the model is incorrect or the measurements are false.

A readily available ThermoSysPro (El Hefni and Bouskela 2019) model of EVEREST test loop shown Figure 5 was adopted and calibrated. Test campaigns are then

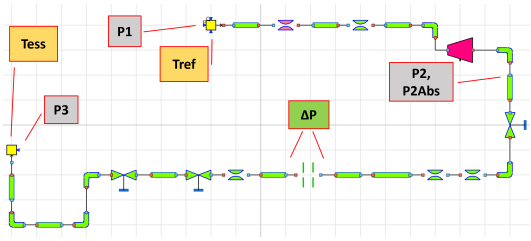

Figure 5. ThermoSysPro model of the EVEREST test loop with the different measurements used (Pressure, Temperature and MassFlowRate).

conducted, starting with a characterisation test, followed by one defect at a time. For each test campaign (each defect), different thermal hydraulic conditions are tested (variation of mass flow rates) both with and without the defect. A test campaign for one defect thus consists of 105 measurement sets (with and without the defect). Effectiveness of defect detection with data reconciliation can be evaluated in many ways. For instance, the global and local tests for data reconciliation can be used in order to identify if a test is detected as faulty by comparing it to a threshold λ as described by Equation 9. If so, the confusion matrix for such a case can be written as shown in Table 2. For industrial use case defect detection, it is desirable to have as few *False Positive (FP)* as possible.

Confusion matrix	**Test with a defect**	**Test with no defect**
Detected with a defect	True Positive (TP)	False Positive (FP) *False alarm*
Detected with no defect	False Negative (FN) *No detection*	True Negative (TN)

Table 2. Confusion matrix for defect detection

With numerous measurements to evaluate the effectiveness of defect detection using data reconciliation, new indicators can be computed. Sensitivity and Specificity are defined. Sensitivity (or true positive rate) is the probability of detecting a defect for a test containing a defect (Equation 14). Specificity (or true negative rate) is the

probability of not detecting any defect for a test that does not contain any (Equation 15). In a perfect scenario, Sensitivity and Specificity should be equal to 1 as all defects would be detected and no false alarms would appear.

$$Sensitivity = \frac{TP}{TP+FN} \tag{14}$$

$$Specificity = \frac{TN}{TN+FP} \tag{15}$$

For each test campaign, the data reconciliation algorithm is applied to each measurement set. As the result of the Sensitivity and Specificity for each set depends on the threshold λ, it is plotted with respect to λ. Starting with the defect having the greatest impact on the flow, Figure 6 shows the Sensitivity and Specificity against the threshold for the step defect. It can be seen that with the default value of $\lambda = 1.96$, this defect can be detected perfectly as Sensitivity and Specificity are equal to 1.

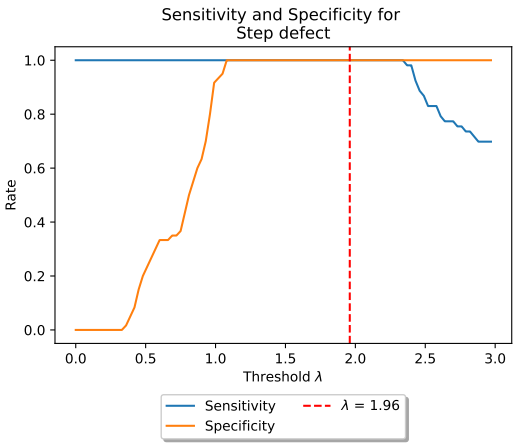

Figure 6. Sensitivity and Specificity against threshold λ for the Step defect. The defect can be detected perfectly with $\lambda_{default} = 1.96$ as Sensitivity and Specificity are equal to 1.

However, the default value of λ does not always lead to a perfect diagnosis. Indeed as shown on Figure 7, the rectangular weld bead defect can be detected perfectly, but not with $\lambda_{default} = 1.96$. Indeed with this default value, the Sensitivity is equal to 0.35. λ should be in the interval $[1.05; 1.35]$ so that the diagnosis is perfect. This difference has an impact on the diagnosis as more *False Negatives* would have been found.

Finally, for the trapezoidal weld bead defect, which has the smallest impact on the flow, it is seen on Figure 8 that the defect can not be perfectly detected as no range of threshold λ gives a Sensitivity and Specificity equal to 1. However the threshold could be reduced so that the Specificity is still high, but that some *True Positives* have been found.

Thus, data reconciliation can detect defects that were intentionally introduced in the system. On the most pronounced defects as the step defect, the impact is such that global and local tests fail with the default threshold value

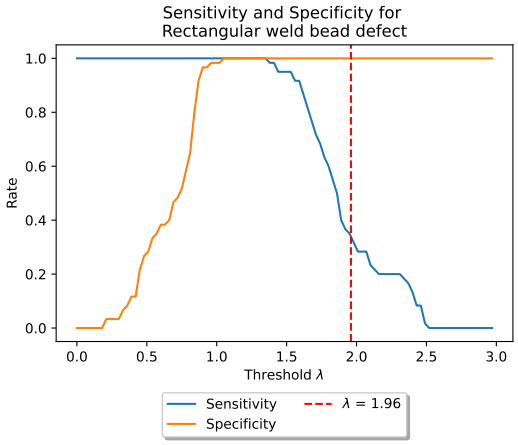

Figure 7. Sensitivity and Specificity against threshold λ for the Rectangular Weld Bead defect. The defect can be detected perfectly, but not with $\lambda_{default} = 1.96$, but with $\lambda \in [1.05; 1.35]$.

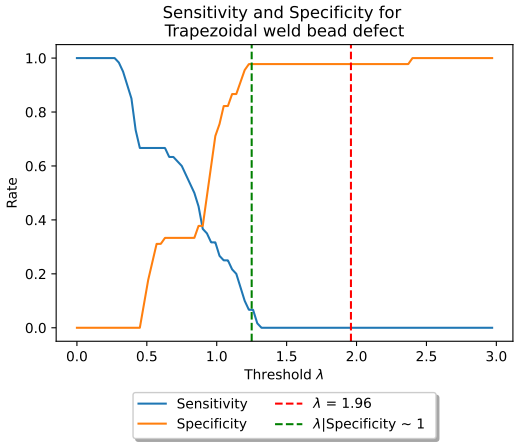

Figure 8. Sensitivity and Specificity against threshold λ for the Trapezoidal Weld Bead defect. The defect can not be detected perfectly.

of $\lambda_{default} = 1.96$. However with less serious defects, $\lambda_{default}$ is not always appropriate. The optimal threshold $\lambda_{optimal}$, depends on the defect that is studied and should be fixed to a value minimising the number of false alarms.

4 ZEPHYR Facility for Testing HVAC Cooling Coil with Latent Exchanges

4.1 In search for good measurement data

The modular test facility ZEPHYR provides air at a precise flow and temperature. On hot days, the air is cooled by a heat exchanger and under humid conditions, condensation can occur. To predict the performance of this heat exchanger at very high temperature and humidity, a validated simulation model is needed. While several theoretical models are available, all of them need "good" input data to calibrate their parameters. Therefore, an experimental test campaign on the cooling coil of the main Air Handling Unit of ZEPHYR and illustrated on Figure 9,

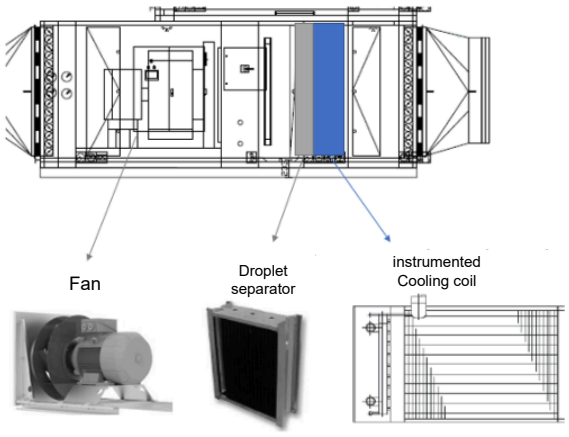

Figure 9. Instrumented cooling coil of Air Handling Unit of ZEPHYR laboratory

was developped to create a set of validated measurement data.

4.2 Experimental campaign

Sensors were installed on the (cool) water side and the (hot) air side of the heat exchanger. On the water side, input and output temperatures as well as the flow are measured. Air measurements at the inlet include temperature and humidity, and at the outlet, temperature and flow. For latent heat, the quantity of condensate is measured. Additionally, the uncertainty of each calibrated sensor has been determined, primarily from data sheets and measured data points. The uncertainty distribution of each sensor can be considered Gaussian. The outlet temperature at one point can be considered representative, because the uniformity of the outlet air temperature was confirmed using an optical fiber installation with approximately 60 measurement points evenly distributed across the entire cross-section.

Over fifteen steady-state experiments were conducted over two days, with varying flows and inlet temperatures (coolant and air). One of these experimental data points is shown in Table 3.

Label	Description	Value	σ	Units
Q_w	Coolant flow	7.91	0.09	kg/s
ΔT_w	Coolant temperature difference	1.62	0.03	°C
Q_a	Air flow	5.82	0.09	kg/s
T_{ai}	Inlet air temperature	29.0	0.30	°C
T_{ao}	Outlet air temperature	20.0	0.47	°C
RH_{ai}	Inlet air relative humidity	42.9	1.5	%
Qc	Condensate flow	1.62	0.03	kg/h

Table 3. Example of sensor data : values and uncertainty (k=1)

It can be observed that the uncertainty on the air side is higher than on the coolant side. One reason for this is that the inlet air was taken from outside the building, causing the temperature and humidity to change gradually throughout the day.

While the amount of condensate at the exit can be measured precisely, the phenomena related to condensation on the plates inside the heat exchanger are complex. Discrepancies, such as the transport time and the thickness of the condensate layer, may lead to invalid experimental data. The idea was to apply data reconciliation to eliminate these invalid experiments and simultaneously improve the accuracy of the measurement set. Since this set contained some level of redundancy, data reconciliation based on basic conservation laws was possible.

4.3 Driving equations

The purpose of this paragraph is to model the thermal exchanges inside an HVAC exchanger that cools humid air coming from outside, as illustrated in Figure 10. The air temperature inside the exchanger can drop below the dew point, caused by the relatively cold surface temperature of the coils, and produce condensation. The main energy balance equations are :

$$\begin{cases} P_w = Q_w(h_{wi} - h_{wo}) \\ P_a = Q_{ai}h_{ai} - Q_c h_c - Q_{ao}h_{ao} \\ 0 = P_w + P_a \\ Q_{ai} = Q_{ao} + Q_c \end{cases} \tag{16}$$

where h denotes the fluid enthalpy, Q the massflowrate and P the thermal power exchanged between the two fluids within the exchanger. The subscript $_a$ denotes air, $_w$ denotes water, $_c$ denotes condensate, $_i$ denotes inlet, and $_o$ denotes outlet. Psychrometric charts of humid air are

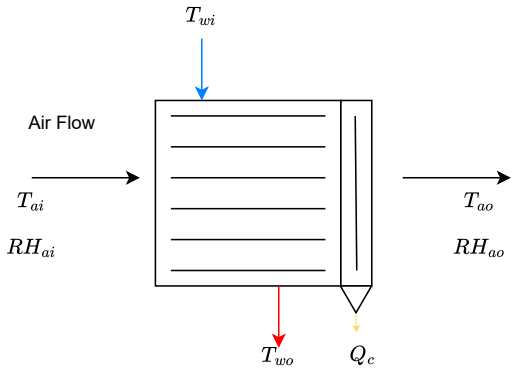

Figure 10. Scheme of the studied HVAC cooling coil with latent exchanges

typically used to visualize the thermodynamic processes occurring within the HVAC cooling coil, as shown in Figure 11.

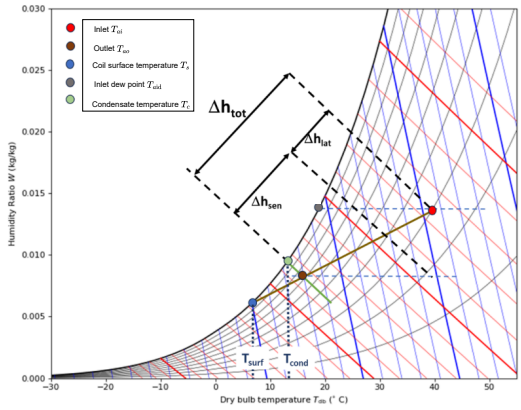

Figure 11. Typical thermodynamic process within an HVAC cooling coil

4.4 Data Reconciliation

Using the conservation equations Equation 16 and the experimental measurements listed in Table 3, it becomes evident that one measurement is redundant and can be deduced from the others. The enthalpy of the humid air and water, assuming the total pressure is equal to atmospheric pressure, is computed using T and RH for air, and T for water, utilizing the media package of the `Modelica Standard Library` as declared below:

Listing 1. HVAC Modelica media

```
replaceable package MediumAir = Modelica.
    Media.Air.MoistAir;
replaceable package MediumWater = Modelica.
    Media.Water.StandardWater;
```

Condensate rate is computed from the other measurements, solving a non linear system to respect mass and energy balances involving condensate rate. Measurements are declared as presented in Listing 2

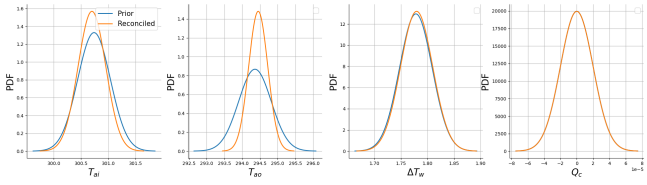
Listing 2. Declare measurment for data reconciliation

```
/*Measurement*/
Modelica.SIunits.MassFlowRate Qa_mes(
    uncertain=Uncertainty.refine, start=1)
    "Air flowrate [kg/s]";
Modelica.SIunits.MassFlowRate Qe_mes(
    uncertain=Uncertainty.refine) "water
    flowrate [kg/s]";
Modelica.SIunits.Temperature Tai_mes(
    uncertain=Uncertainty.refine) "air
    inlet temperature [K]";
Modelica.SIunits.Temperature Tao_mes(
    uncertain=Uncertainty.refine) "air
    outlet temperature [K]";
Modelica.SIunits.Temperature Twi_mes(
    uncertain=Uncertainty.refine) "water
    inlet temperature [K]";
Modelica.SIunits.TemperatureDifference
    DeltaTw_mes(uncertain=Uncertainty.
    refine) "water temperature rise [K]";
Real RH_ai_mes(uncertain=Uncertainty.refine
    ) "air inlet relative humidity [-]";
Modelica.SIunits.MassFlowRate Q_c(uncertain
    =Uncertainty.refine) "condensate rate [
    kg/s]";
```

In this case, the number of obtained auxiliary conditions r is equal to one. The results of the data reconciliation for two typical experiments are presented on Figure 12 produced by interfacing `OpenModelica` data reconciliation with an OpenTURNS (Baudin et al. 2017) `https://openturns.github.io/` module as illustrated in Listing 3.

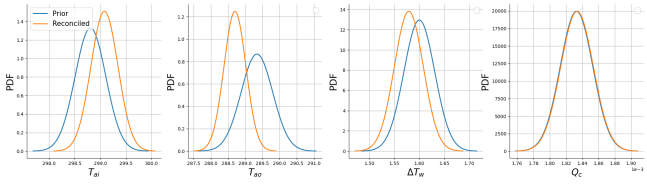
Listing 3. Perform data reconciliation with OpenTURNS and OpenModelica

```
covarianceMatrix = priorDistribution
    .getCovariance()
priorMeasurements =
    priorDistribution.getMean()
dataR = otDataR.DataReconciliationOM
    (modelName, VarNames,
    priorMeasurements,
    covarianceMatrix, casePath,
    simuMatPath)
dataR.reconcileData()
reconciledDistribution = dataR.
    getPosteriorDistribution()
```



For the first experiment, the data is considered consistent, the result of the local being positive, which is qualitatively in agreement with the prior and posterior Gaussian distribution of the measurements. For the second experiment depicted on Figure 12, the prior and posterior distribution are clearly inconsistent. One can notice that the results of the data reconciliation process indicate that the air temperature measurement may be potentially incorrect, while the condensate rate measurement shows little variation between the prior and posterior distributions. This result is strongly driven by the specified prior distribution. The condensate rate measurement, relying on the mass of the condensate collected over a period, is specified as a measurement with a very low prior uncertainty while some uncertainty sources can have been misidentified due to the complex condensation phenomena occurring within the exchanger. It underlines that output of data reconciliation process has to be carefully analysed to identify correctly defectuous sensors in case of measurements set declared as non consistent.

Measurement with uncertainty before and after reconciliation are illustrated in Figure 13 and Figure 14. It can be observed that experiment number 8 leads to inconsistent measurement after data reconciliation, as the cooling coil outlet state is above the saturation curve. Therefore, this experiment has been discarded.



5 Conclusions and future work

The implementation of data reconciliation with OpenModelica has been successfully tested on two industrial experimental installations. For the EVEREST test loop

DOI
10.3384/ecp21845

(a) Positive local test and improve measurements

(b) False local test for some measurements

Figure 12. Example of reconciled data leading to: improve outlet air temperature measurement (a) - inconsistent measurements (b).

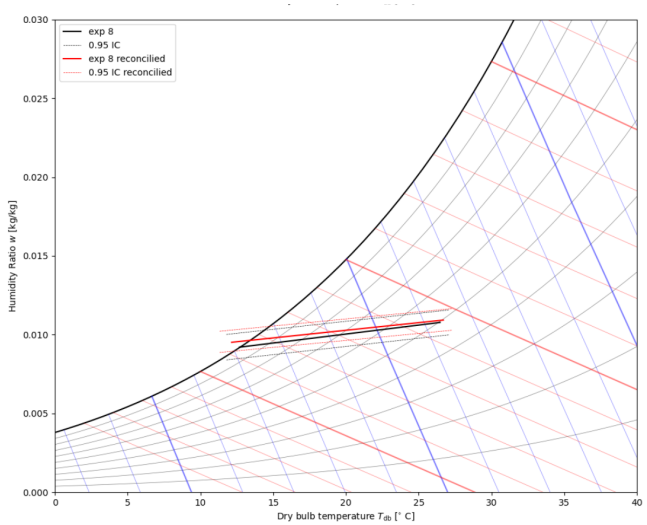


Figure 13. Measurements with uncertainty before and after data reconciliation for experiment number 8

aiming at controlling measurements of liquid flow rates, some defects were intentionally introduced and data reconciliation detected efficiently the most pronounced defects. The detection threshold λ should however be carefully chosen as it has a great impact on the detection results: for less serious defects such as the trapezoidal weld bead defect, the detection is not perfect and *False alarms/No detection signals* will be returned. Further work could be to integrate data reconciliation as a monitoring tool to study sensor drift of the facility in addition to other defect detection methods like comparing a measurement set to a validated reference characterisation test campaign to observe the relative difference through time.

Data reconciliation on the HVAC application for measuring air flows not only improved the accuracy and uncertainty of the measurements but it also identified two initially unnoticed invalid experiments. This high confidence reconciled data set, contains thus "good" measurements that can be used as inputs for parameter calibration of simulation models.

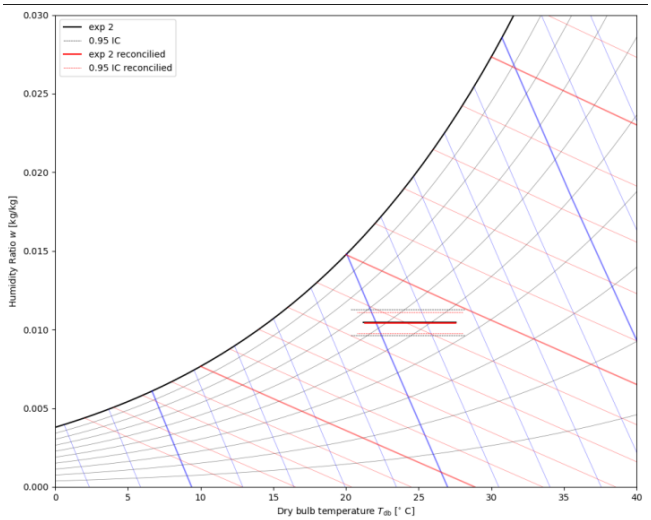

Figure 14. Measurements with uncertainty before and after data reconciliation for experiment number 2

Data reconciliation tools exist and have already proven their worth in the industrial sector. However, they are limited to a restricted modelling domain and often use a dedicated, proprietary modelling environment. In practice, this restricts the scope of reconciliation: apart from use cases where reconciliation is used as a real-time monitoring tool to gain operating margins, few use cases can afford this costly environment. Other applications can nevertheless be imagined: support for experimental installations as presented in this article, support for the design of systems to assist in the positioning and selection of sensors and provision of rigorous proofs to justify the control of uncertainties of sensitive quantities, etc. The integration of data reconciliation into OpenModelica opens up new possibilities: users no longer need to create a dedicated reconciliation model in a dedicated environment; they can derive it from pre-existing models, such as those used for classical simulation studies. The Modelica language is used there as a sole and standardized format for modelling the physical phenomena of the system hence bridging the gap between design tools and operation tools.

From the software standpoint, although the current implementation of data reconciliation in OpenModelica is still in the prototype stage, the article demonstrates its ability to handle industrially realistic models. The prototype documentation will be updated based on the application cases described here, particularly with regard to the methodology to be followed when using third-party tools to calculate uncertainties for pre- and post-processing of data reconciliation. Further improvements to the prototype are also expected to enable a better scaling for larger or more complex models. This will include improvements to the user interface for providing inputs to be reconciled - especially for linking model variables to uncertainty data- and for optimising the visualisation of reconciled outputs.

It will also include adjustments of the extraction algorithm to handle models embedding algebraic parts which cannot be easily inlined and symbolically processed (e.g. if-then-else clauses, function with external codes...).

Acknowledgements

The authors would like to thank Arunkumar Palanisamy, Lennart Ochel and Adrian Pop for their implementation of data reconciliation in OpenModelica. This functionality has been initially supported by DGE (France) and Vinnova (Sweden) in the scope of the ITEA3 OPENCPS project and then improved within the Open Source Modelica Consortium thanks to EDF funding.

[2]First Faculty of Medicine, Charles University, Czech Republic

marek@matfyz.cz

Abstract

Free open-source Modelica library called Chemical 2.0 (https://github.com/MarekMatejak/Chemical) provides expressions between chemical substances and processes. These robust and unified definitions allow users to choose whether define processes or substances in their dynamic (electro-)chemical models. Propagation of substance definition and chemical solution through connected components simplify configuration. Chemical pathways can start even with unknown substances. Chemical kinetics was rewritten.

The possibilities and performance of chemical pathways modeling are increased using a new type of connectors based on inertial electro-chemical potential. Chemical processes can be directly connected without need to add unsignificant states. Parameterization of chemical reactions is also streamlined, e.g. using forward rate and dissociation coefficient.

Keywords: Chemical 2.0, inertial electro-chemical potential, Modelica library, physical chemistry, thermodynamics equilibria, electrochemical potential, electrochemical cell, internal energy, semipermeable membrane, chemical kinetics, chemical pathways

1 Introduction

Motivation to improve Chemical library from version 1.4 (Mateják et al. 2015) to version 2.0 comes from following Modelica libraries:

A) Media.IdealGases from Modelica Standard Library (Casella et al. 2006): Chemical substances and chemical processes can be described by the selected extensive physical quantities.
B) ThermofluidStream (Zimmer 2020): Inertial connectors can be generalized for chemical domain.

As selection of physical quantities for each substance and process definition we chose a similar approach used in Modelica.Media.IdealGases, which comes from (McBride, Zehe, and Sanford 2002). Having this definition as a record of constant coefficients, there is a possibility to calculate molar heat capacity, free molar formation energies, free molar entropy and many other thermodynamic properties in dependence on given substance activity and state of chemical solution (temperature, pressure, electric potential, etc.). Moreover, unlike the previous version, there is no need to have separate calculations for different states of matters (phases), because phase is also included in extensive physical quantities of the definition records. Therefore, every chemical equilibrium of each process can be expressed only using the definitions of included substances and processes (Peter Atkins, De Paula, and James Keeler 2018). And because we chose extensive quantities, they can be easily added or subtracted as in common chemical processes notations (e.g. mass of substrates = mass of products; charge of substrates = charge of products; enthalpy of substrates + enthalpy of reaction = enthalpy of products, entropy of substrates + entropy of reaction = entropy of products, etc.).

The connectors from ThermofluidStream library are revolutionary (Zimmer, Bender, and Pollok 2018). This library still allows user to define very complex thermodynamic behavior of predefined media in the same level of detail as in Modelica.Fluid and Modelica.Media does (Zimmer, Meißner, and Weber 2022). However, ThermofluidStream library permits connections between processes without unnecessary accumulations of media, simultaneously eliminating a number of non-linear systems in the model (Meißner and Zimmer 2022). By eliminating numerous middle-state components accumulating and mixing medium the model becomes more readable. And during the simulation run there is no longer need to solve implicit equations for many non-linear systems. All this results in significant improvement of the performance and readability, with minimal compromise in the model details (Zimmer, Meißner, and Weber 2021).

Using the inertial approach of ThermofluidStream in chemical domain promises the analogical improvements for Chemical 2.0. As a result, the processes can be connected directly together to define complex chemical

pathways such as in biochemistry or physiology. Additionally, allowing to define better chemical kinetics (Sauro 2009), complex processes and more detailed calculations of any part of the model.

The inertial approach is connected with following basic composition rules:

- Electro-chemical pathways shall start and end at a boundary component. Enabled substance ports must be connected.
- Connecting more than two substance ports together should use splitters and junctions from package Topology. Splitting directly using the connector is only recommended for the use of sensors.
- Each cyclic flow must be broken by at least one Substance component.

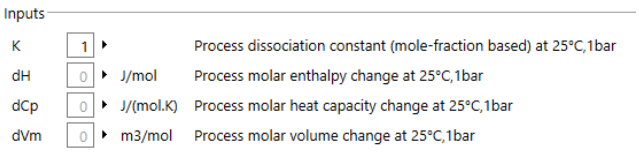
2 Definition

The previous version of Chemical library has various definitions of substances. In version 2.0, all these structures for all type of substances and even for all type of chemical processes are unified into one type of operator record called Chemical.Interfaces.Definition. This record can define each substance and process used in the previous version. In addition, the user can set their values independently on internal representation using suitable constructors or the function processData. This function creates process definition based on dissociation constant (molar-based) and consumed heat of the process (free molar enthalpy change) (**Figure 1**). Using relation between this process definition and its substances definitions, the user can easily evaluate new definition of the new chemical substance or new chemical process using expressions with '*', '+' and '-' operators.

For example, a definition of aqueous O2 can be set from gaseous O2 and water dissolution process with tabulated Henry's coefficient (0.0013, 1500K). For another example, a definition of H2O formation reaction from H2 and O2. Each new definition can be set as an algebraic equation between reaction, products and substrates (**Listing 1**).

Listing 1. Example of definitions

```
import Chemical.Interfaces.Definition;
import Chemical.Substances.Gas;
import Chemical.Substances.Liquid;
import Chemical.Interfaces.processData;
constant Real R = Modelica.Constants.R;



constant Definition O2_aq =
  Gas.O2 + processData(
              K = 0.0013,
             dH = -1500*R);

constant Definition H2O_formation =
  Gas.H2O - (Gas.H2 + 0.5*Gas.O2);

constant Definition Hemoglobin =
  Liquid.Unknown;
```

Each chemical pathway can start with Unknown substance. And next substance can be defined relatively by process definition. The default definition of Unknown substance is molar mass 1kg/mol and molar heat capacity 1 J/(mol.K), with zero free formation Gibbs energy and zero free formation enthalpy. These values are used if the user does not specify the substance. Because free formation energies are always defined in a relative manner, unknown substances can be used, such as any base substance with unknown formation process. If they play a role in the solution properties, at least definition data in relation with the changing solution properties should be set. E.g. molar mass and molar volume must be set if they play a role in solution composition; molar heat capacity must be set if it plays a role in heat accumulation in the chemical solution during simulation.

Figure 1. Inputs of processData function

3 Chemical solution

There are two options for how to define a chemical solution. The first involves the Chemical.Solution component and connecting all substances through its solution connector. This was the only option in the previous version, which was retained in this version. If a chemical solution is defined this manner, then all its properties are dynamically calculated during the simulation.

Listing 2. Example of fixed solution state

```
import Chemical.Interfaces.SolutionState;
import Chemical.Interfaces.Phase;

constant SolutionState SATP =
  SolutionState(phase = Phase.Gas,
                T = 298.15);

SolutionState heatingSolution =
  SolutionState(phase = Phase.Gas,
                T = 273.15+time);
```

However, there is not always a need to change the solution properties. If solution properties, such as temperature, pressure, total mass, total volume, total amount of particles, and electric potential, are assumed as constant during simulation, then the solution state (**Listing 2**) can

DOI
10.3384/ecp21855

be set as a parameter. If the user did not set a solution property, then its default value (**Figure *2***) will be used.

Figure 2. Default chemical solution properties

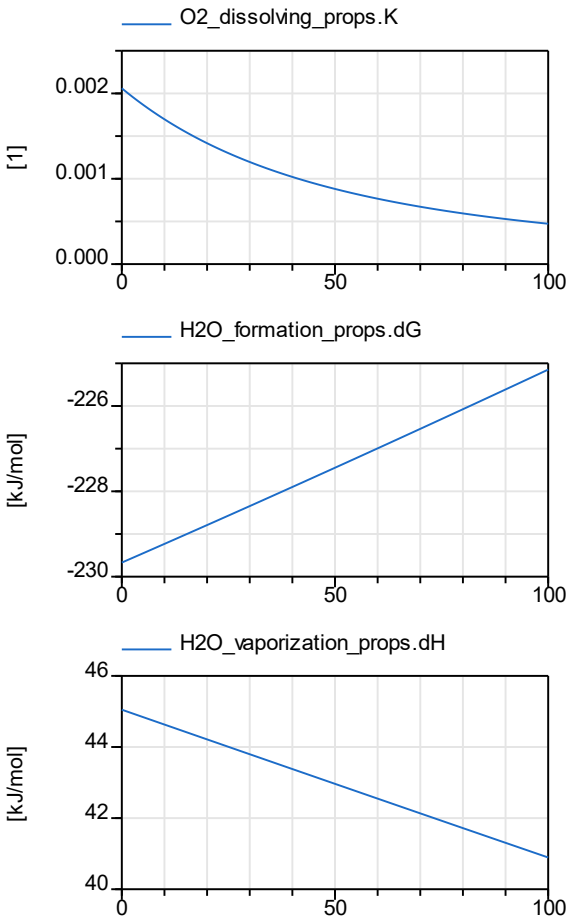
T	20	°C	Temperature of the solution
p	1.01325	bar	Pressure of the solution
m	1	kg	Mass of the solution
V	1	l	Volume of the solution
n	1	mol	Amount of the solution
v	0	V	Electric potential in the solution
G	0	J	Free Gibbs energy of the solution
Q	0	C	Electric charge of the solution
I	0	1	Mole fraction based ionic strength of the solution

4 Properties of chemical processes

Each process has different properties (e.g. dissociation coefficient, free Gibbs energy or free enthalpy) in dependence on its definition and on the current state of chemical solution (e.g. temperature, pressure, etc.). The user needs to connect the substance definition and solution to model Chemical.Interfaces.ProcessProperties to evaluate these properties.

Listing 3. Example of process properties

```
import Interfaces.ProcessProperties;



ProcessProperties O2_dissolving_props
(definition = processData(0.0013,-1500*R),
 solutionState = heatingSolution);

ProcessProperties H2O_formation_props
(definition = H2O_formation,
 solutionState = heatingSolution);

ProcessProperties H2O_vaporization_props
(definition = Gas.H2O - Liquid.H2O,
 solutionState = heatingSolution);
```

After the simulation of code (**Listing 1-3**) for 100 seconds, the temperature of the solution changed from 0°C to 100°C, and we can see the recalculated properties that resulted from temperature change such as dissociation constants (Henry's coefficient), free Gibbs energy change of reaction or consumed heat by process (free enthalpy change) – e.g. **Figure *3***.

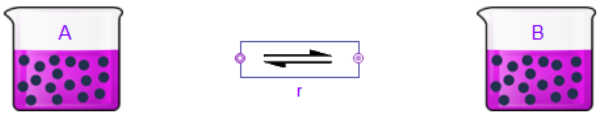


Figure 3. Results of simulation (**Listing 1-3**) per temperature [°C]

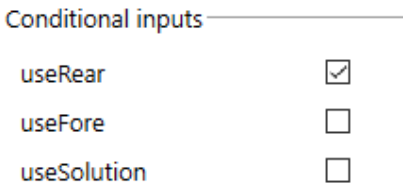
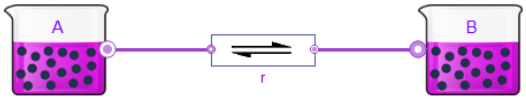
5 Chemical process



To create a model of a chemical reaction using Chemical 2.0, drag and drop component Substance from package Chemical.Boundaries as substance ***A*** and substance ***B***. In the same way, put into the model Reaction as process ***r*** from package Chemical.Processes (**Figure 4**).

Figure 4. Components of simple chemical reaction



The default setting for the substances does not provide any connector, so it is necessary to setup which connectors will be used. This is done in parameter dialog by selecting the ***useFore*** checkbox for substance ***A*** and ***useRear*** for substance B (**Figure 5**).

Figure 5. Configuration of substance connectors

Having all necessary connectors, it is possible to connect substances with chemical reaction ***r*** **(Figure 6)**.

Figure 6. Connections

This model could be simulated, but everything remains constant because the dissociation coefficient is equal to one and both substances are the same (defined as Liquid.Unknown). However, if we change the dissociation coefficient ***K*** to 2 (as shown in **Listing 4**) then we can see dynamic behavior in the default chemical solution. And after 5s of simulation time, the reaction reaches almost the equilibrium where the amount of product ***B*** is two times higher than the amount of substrate ***A***. We can change reaction speed by setting forward reaction rate coefficient ***r.k_forward*** lower than its default value. Backward reaction rate is not possible to set as a reaction parameter because it is defined as ***k_forward/K***. This reaction can have as many substrates (***nS***) and as many products (***nP***) as needed, and its index is defined by the order of drawn connections. Note, that default chemical solution in this example is set to **Figure 2** and remains constant during simulation.

Listing 4. Generated code for a reaction example

```
model SimpleReaction
 extends Modelica.Icons.Example;

 import Chemical.Boundaries.Substance;
 import Chemical.Processes.Reaction;
 import Chemical.Interfaces.processData;

 Substance A( useFore = true );
 Substance B( useRear = true );

 Reaction r( nP = 1, nS = 1,
    process = processData(2) );

equation
  connect( A.fore , r.substrates[1] );
  connect( r.products[1] , B.rear );
end SimpleReaction;
```

If the user prefers products definition before definition of process, then it is possible to set process option ***firstProductFrom*** into ***"Substance"*** selection. This enables the parameter ***firstProduct*** (the first product definition) in the same dialog as the process setting. With knowledge of all products and all substrate definitions the process definition can be evaluated, so the process definition parameter is disabled during this selection. Please note, that each product is by default defined by process, so it is not necessary to define it again in following process or boundary component.

Figure 7. Process defined by substances

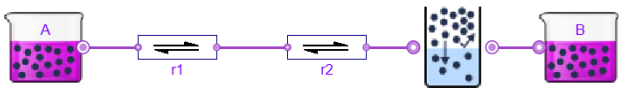
In addition, stoichiometric coefficients can be set as parameter ***s*** for substrates and parameter ***p*** for products as in previous version. The new extension for processes allows to change chemical kinetics as redefinition of relation between electro-chemical gradient and process molar rate called ***uLoss***. By default, ***uLoss*** is set to traditional chemical kinetics based on forward rate coefficient, but the user can define their own type of chemical kinetics constrained by proposed interface for potential loss functions.

Listing 4. Example of reaction defined by product with uncommon chemical kinetics

```
import Chemical.Utilities.Types.
         FirstProductChoice;
import Chemical.Processes.Internal.Kinetics;

Chemical.Processes.Reaction H2_burning (
    firstProductFrom =
        FirstProductChoice.Substance,
    firstProduct = Gas.H2O,
    nS=2, s = {2,1},
    nP=1, p = {2},

    redeclare function uLoss =
         Kinetics.fastPotentialLoss,



)
```

DOI
10.3384/ecp21855

6 Data propagation

The version 2.0 of the Chemical library is based on a special type of substance ports. These connectors propagate the state of substance without inertial part in flow direction and generate equality of inertial electro-chemical potential, instead of direct equality of the total electro-chemical potential. The equilibria and even the dynamic simulation reach almost the same values if inertia is fast enough. As proven by (Zimmer 2020) this type of connector has physical background and better performance because it eliminates non-linear systems of equations where solvers typically spend the most of time. Moreover, this design allows users to connect more processes together without any accumulation of substance (or just a few Substance components). As a result, it is possible to define long chemical pathways as are usual in physiology.

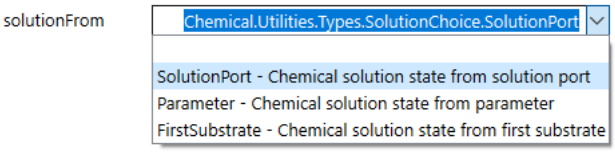
Figure 8, Example of possible pathway connection

To have a chemical pathway such as in **Figure *8*** there is a need to have each substance definition between each chemical process. This is done automatically using a propagation pattern from forward connectors (called fore) into rearwards connectors (called rear). Please note that substances definition propagation is not dependent on flow direction. Each substance definition remains constant during simulation, so the direction of definitions propagation does not take any role during simulation and vice versa. In **Figure *8*** only the substance ***A*** can be defined by user. The definition of a product of reaction ***r1*** is evaluated from the definition of this reaction and its substrates. So generally, each process can define the first product from its other products, substrates, and process definition. Even the substance ***B*** does not have to be explicitly defined, because its definition can come from PhaseTransition process.

In the same way, the fixed state of the chemical solution can be propagated. If the state of chemical solution is constant, it remains the same for each substance in the solution during each step of the simulation. In the model shown in **Figure *8*** it means that chemical solution is specified only in substance ***A*** and propagated trough connections to each other components as the same constant values.

To model the situation when processes cross different solutions, there is an option to break the solution propagation. In some processes, such as Diffusion, Membrane or PhaseTransition, the solution states are not propagated by default because they change the chemical solution between substrates and products. As a result, the new solution must be defined for the process and its product to propagate into next processes. Please note, that "next" here is not defined by molar flow but by fore-rear connections.

Listing 5. Example of process changing chemical solution



```
import Chemical.Processes.PhaseTransition;
import Chemical.Interfaces.SolutionState;
import Chemical.Interfaces.Phase;
import Chemical.Substances.Gas;

PhaseTransition PhaseTransition(
     solutionParam =
        SolutionState( phase = Phase.Gas ),
     Product = Gas.CO2 );
```

Diffusion and Membrane process have the same substance on both sides. PhaseTransition changes the substance. This allows to use it even for solvation (gas dissolution in liquids and gas volatility from liquids) or for phase transition (vaporization, condensation, sublimation, deposition, melting and freezing). Note that the definition of each chemical compound is dependent on phase. For example, gaseous water was defined differently from liquid water. Phase transition of a substance is a chemical process, which even consumes/releases heat (has non-zero free enthalpy change).

Please note, that if a chemical substance significantly changes the chemical solution properties, then it must be connected to Solution component using ***SolutionPort*** instead of fixed parametrized solution propagation. This situation is selected by choice ***solutionFrom*** (**Figure *9***).

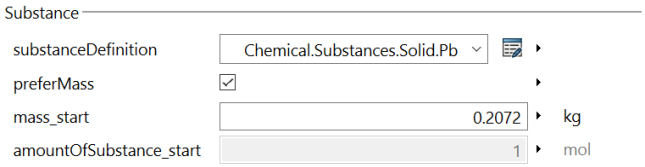


Figure 9. If substance change the solution

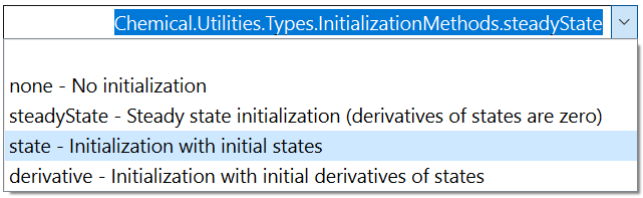
7 Initialization



Substance component is initialized by initial mass or amount of base substance molecules. Recalculation from number of base molecules and mass is obtained through molar mass, which is part of the substance definition. Switching between mass-based and molar-based accumulations is based on ***preferMass*** checkbox (**Figure *10***). If mass is preferred, ***amountOfSubstance_start*** is disabled and ***mass_start*** is enabled as an initial value of substance.

Figure 10. Substance amount initialization

A principle of the inertial connectors affects the initialization of the model processes. Having acceleration of molar flows on each connection, each flow has a state. Therefore, the simplest process initialization is to set values of molar flows (**Figure *11***). From these values the gradients of electro-chemical potentials on process components are calculated as a relations of substance states between boundaries.

Figure 11. Molar flow initialization

Alternatively, it is possible to set the initial process state to steady state. This will take inertial electrochemical potential change ***r*** to zero. If each process has this type of initialization, then the solver is looking for the non-accelerated state of whole system, where derivation of each flow is zero.

8 Discussion

ThermofluidStream is a proof of concept that even a complex models could improve usability, performance, details and interfaces. We hope that the update of Chemical library from version 1.4 to version 2.0 marks also this kind of a progression.

Despite the complexity of this code containing many physical equations and parameters, the user interface is simplified significantly. It is permitting users to start with basic models without any significant alterations to the default component settings. And it works, because common (electro-)chemical assumptions are hidden as these default values. Starting with a very simple model and extending significant details during each modeling step leads to optimal model development with minimal effort. This development strategy can be reversed if something does not work – model can be simplified and results should be also well interpretable.

Theory behind Chemical library at the level of physical chemistry is summarized in documentation found at: Chemical\Resources\Documentation\Chemical.pdf.

Abstract

Mechanistic modeling of drug behavior and response is essential for rational drug development and personalized therapy, yet constructing, maintaining, reusing and customizing complex pharmacokinetic–pharmacodynamic and physiologically based pharmacokinetic models can be error-prone when implemented solely via equations or code. We introduce Pharmacolibrary, a free Modelica library offering standardized acausal components for pharmacokinetics, pharmacodynamics, toxicokinetics/toxicodynamics and pharmacogenomics from compartmental and physiologically based templates to effect models and genotype–phenotype records—to simplify model reuse, customization, and interoperability. Its utility is showcased with gentamicin, midazolam, and fentanyl case studies, including pharmacogenomics-driven clearance adjustments and pharmacodynamics simulations.
Keywords: Modelica, Pharmacology, Pharmacokinetics, Pharmacodynamics, Pharmacogenomics, Modeling

1 Introduction

Pharmacology investigates how drugs modulate biological functions—spanning their origin, mechanisms of action, therapeutic benefits, and adverse effects—while toxicology focuses on chemical-induced harm. Core subfields include pharmacokinetics (PK; absorption, distribution, metabolism and elimination processes of a drug in organism) and pharmacodynamics (PD; effect, concentration–response relationships), with analogous toxicokinetics/toxicodynamics (TK/TD) in the toxicity domain. Pharmacogenomics (PGx) quantifies how genetic variation shapes PK and PD. Physiologically based pharmacokinetics (PBPK) augments classical PK with anatomical and physiological detail to predict drug distribution(Rosenbaum 2016). Quantitative systems pharmacology (QSP) further integrates PK/PD with systems-biology to capture drug interactions within complex molecular networks(Azer et al. 2021).

A variety of commercial and academic tools support these methods: Certara's SimCyp(Jamei et al. 2009) and Bayer's PK-Sim/MoBi for PBPK and Open-system pharmacology community(Lippert et al. 2019); MediWare's MWPharm++ for pharmacogenetically informed therapeutic drug monitoring(Schön et al. 2022); MATLAB SimBiology® and its gPKPDSim extension for PK/PD workflows(Hosseini et al. 2018); and Modelica-based libraries (Biochem, Physiolibrary, Chemical) for pathway, physiological, and physicochemical modeling. However, these platforms either specialize in a single aspect or blend modeling with simulation in proprietary environments.

Some of the existing Modelica libraries can be currently used to mimic e.g pharmacokinetics like the Biochem library for biochemical pathways(Nilsson and Fritzson 2005), Physiolibrary for human physiology models(Mateják et al. 2014) or Chemical for using electrochemical potential and physical chemistry principles to model chemical reaction and behavior of various substances(Matejak et al. 2015). However, these libraries focus on different aspects of biology, physiology and physical chemistry.

Here, we introduce *Pharmacolibrary*, a reusable Modelica library unifying PK, PD, PBPK, TK/TD, and PGx constructs with standardized pharmacological terminology, units, and acausal connectors. By decoupling model definition from simulation, our library leverages Modelica's auto-generation of correct equations from diagrams, supports FMU export for integration into Python/Julia/-MATLAB/WebApp workflows, and interoperates with existing Modelica libraries to enable advanced QSP applications. In the following sections, we describe the library's components and demonstrate exemplar models that reproduce experimentally observed drug behaviors.

2 Pharmacolibrary

As a foundational concept for pharmacology modeling, we first define the following connectors, which hold and exchange drug mass and concentration via various types between components.

The ConcentrationPort connector (table 1) contains MassFlowRate as a flow variable and MassConcentration as a non-flow variable that is usually used to model chemical domain. The ConcentrationPort is intended to be used in compartment based pharmacokinetics model where the volumetric flow is not taken into account or is neglected and ideal mixing can be assumed among connected components.

The FlowPort connector (table 2) contains Volume-

	**ConcentrationPort** is acausal connector that contains mass flow rate quantity q_m and concentration c defined as follows:
	
	`flow MassFlowRate qm;`
	`MassConcentration c;`
	
	When a component is connected using such a connector, standard Modelica tool will ensure that flow variable q_m is not accumulated in connected connectors by ensuring that $\sum_{i=0}^{n} q_{m_i} = 0$ and also that all non-flow variables - in this case concentration c are equilibrated i.e. $c_1 = c_2 = ... = c_n$ (n is number of connected components via a connector).

Table 1. Graphical connectors for drug-mass and concentration exchange.

FlowRate as a flow variable and MassConcentration as a stream variable and Pressure as a non-flow variable. The combination of VolumeFlowRate and Pressure is usually used to model pressure-volume hydraulic domain, we additionally add a concentration. The FlowPort is intended to be used in physiology based pharmacokinetics model (PBPK) where the substance (e.g., drug) transport is resolved through branching and merging conduits, automatically enforcing mass-balanced mixing at junctions according to the instantaneous flow rates.

	**FlowPort** is acausal connector that contains flow quantity q_v, stream quantity c and non-flow quantity p defined as follows:
	
	`flow VolumeFlowRate qv;`
	`stream MassConcentration c;`
	`Pressure p;`
	
	Using such definition, when a component is connected using a connector, standard Modelica tool will ensure that flow variable q_v is not accumulated in connected connectors by ensuring that $\sum_{i=0}^{n} q_{v_i} = 0$ and additionally all variables in stream connector (in this case concentration c) are ensured to be correctly and physically consistently mixed based on the flow quantity. All non-flow (potential) quantities (in this case pressure p) are equalized among connected components.

Table 2. Graphical connectors for drug-mass and concentration exchange in case of volumetric flow and mixing is taken into account.

By employing these two connector types, we can distinguish between pure compartment based models (where active flow and compartmental distribution can be simplified to diffusion kinetic) and PBPK models (where drug particles are exchanged via active distribution, i.e. volume flow rate and compartment are matched with anatomical and/or physiological tissues or systems).

2.1 Pharmacokinetics - compartment models

Pharmacokinetics studies how drug is absorbed, distributed, metabolized, and excreted (the “ADME” processes). The compartmental pharmacokinetic (PK) model abstracts the organism as one, two, or several interconnected compartments through which the drug distributes, with exchange between compartments generally described by first-order kinetics.(Fleishaker and Smith 1987) A compartment need not map to a specific anatomical tissue or organ; its defining parameter—the apparent volume of distribution V_d—is usually obtained by numerically fitting the time-course of blood-concentration data after drug administration.

By measuring drug concentrations in blood, tissues, or other biological fluids, pharmacokinetics compartmental analysis seeks to characterize the parameters of the components involved in ADME processes. For absorption the known parameters are dose mass, dose duration, administration route and unknown is bioavailability F. For distribution the volume distribution V_d of compartments. For Metabolism and Excretion the kinetic rates and clearance rates.

For modeling mainly the ’Distribution’ part of ADME processes in pharmacokinetics, we define the reusable compartment components as in table 3. For modeling the rest of the ADME processes, we define additional components as in table 4.

	**NoPerfusedTissueCompartment** expresses basic theoretical volumetric distribution of a drug in a hypothetical compartment, that does not necessarily be equivalent to an anatomical tissue or organ. With the following equations: $$\frac{dM}{dt} = q_m$$ $$C = \frac{M}{V_d}$$ Where derivation of M is mass flow rate q_m and concentration C is mass of drug in compartment M divided by compartment’s volume of distribution V_d.
	**SystemicTissueCompartment** express volumetric distribution of a drug via arterial or venous bloodstream through 2 flowports and 1 concentration port using these main equations: $$\frac{dM}{dt} = \sum q_{vxi} \times \text{actualStream}(c_{xi}) + q_m$$ $$c_a = c_b = \frac{M}{V_d}$$ where M is drug total mass in compartment, parameter V_d is volume of distribution, $q_v a$ and $q_v b$ are distribution of volume flow rates in ports a and b and q_m is mass flow rate that may happen directly in the blood tissue. c_a and c_b are actual concentrations on connected ports a and b respectively.
	**TissueCompartment** expresses not only distribution of a drug through bloodstream, but additional a simple constant tissue-blood concentration ratio k_{TB} as $$c = \frac{c_t}{k_{TB}}$$

Table 3. Compartment components.

DOI
10.3384/ecp21861

	**TransferFirstOrderNonSym** express basic first order non-symetric transfer between compartments defined by intercompartmental clearance parameters Cl_a and Cl_b.
	**SingleDose** expresses a source that contributes to concentration change by administering a certain amount of drug during administering duration into the 1 concentration port. $$q_m = \frac{\text{adminMass}}{\text{duration}}$$
	**FlowGround** The component FlowGround express the ground of concentration within the stream from the flowport connector. Note, that this component does not affect the model behavior, as no volume normally flows in or out, yet is required for mathematical completeness. An error is raised when any flow leaks or is added inadvertently.
	**ClearanceDrivenElimination** expresses simplified elimination that is driven by the clearance parameter by the following equation: $$q_m = CL \times c$$ $$\frac{dM_{exc}}{dt} = q_m$$ Where M_{exc} is excreted drug mass, CL is clearance parameter usually in liters per minute, c is drug concentration and q_m is massflowrate of the drug that is eliminated.
	**FixedFlow** express enumerated flow that is forced to be through this component. It can be used e.g. to mimic cardiac output or partial flow within a specific organ or tissue. It's parameter is prescribed flow Q which is then given to the connected ports a and b as: $$q_{va} = -q_{vb} = Q$$

Table 4. Additional components

2.2 1-compartment models

The single-compartment pharmacokinetic (PK) model is a theoretical model where whole organism is represented as a single, well-mixed compartment. In this model, the drug is absorbed according to its bioavailability, distributed uniformly throughout the apparent volume of distribution, and eliminated at a constant rate. Such a PK model can be described by the following integral equation of concentration c over time t where initial concentration c_0 and clearance rate of elimination Cl:

$$c = c_0 \times e^{-Cl \cdot t} \tag{1}$$

or in derivative form

$$\frac{dc}{dt} = -Cl \times c \tag{2}$$

When a mass of a drug is taken into account M, a theoretical parameter "volume distribution" V_d is in equation:

$$c = \frac{M}{Vd} \tag{3}$$

So the PK model can be described as

$$\frac{dM}{dt} = -Cl \times c \tag{4}$$

In Modelica language, the equations (3) and (4) can be implemented directly as seen in model implementation fig.1 (A). However the component NonPerfusedTissueComponent (implementing equation (3)) is connected with ClearanceDriveElimination which implements and correctly connect equation (4) so the diagram mode Fig.1 (B) is equivalent to the text mode of implementation.

(B)

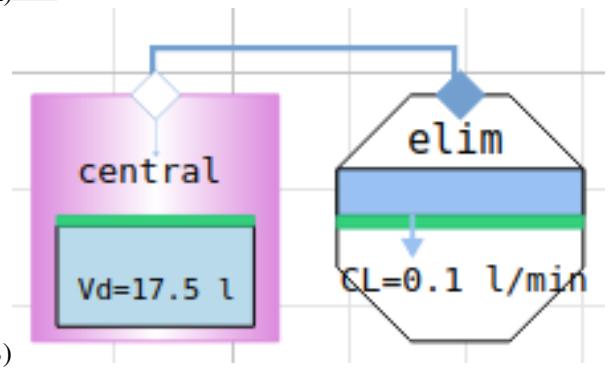

Figure 1. Equivalent representations of the single-compartment model. (A) Text mode, in which the governing equations (3) and (4)—are written out explicitly. Text mode is ideal for simple models or for defining individual components. (B) Diagram mode, which links predefined component icons into a acausal component diagram. Diagram mode is preferred when domain-specific components are already well defined and can be reused and composed in different settigns. Example parameters of PK of gentamicin with an initial dose of 400 mg, a clearance of 0.1 L/min, and a volume of distribution of 17.5 L. In text mode, the parameter values are declared in basic SI units. In diagram mode, tools such as OpenModelica(Fritzson et al. 2020) allow user to chose the prefered unit and automatically recalculate and display all units in SI within the component icons, dialogs and plots.

This model requires setting the initial drug mass at time zero. To incorporate single-dose absorption, a SingleDose component can be connected as shown in the modified diagram in Fig 2.

Single-compartment models describe the PK of a drug whose distribution via the cardiovascular arterial tree system can be neglected—typically because they are absorbed and distributed rapidly and do not significantly bind to tissues.

For example, gentamicin is an antibiotic administered intravenously, usually once daily, to treat serious bacterial infections. Sample parameter values of gentamicine's PK model are given in Figure 1 and its caption. A primary concern in drug administration is efficacy; for gentamicin, the minimum inhibitory concentration (MIC) represents the lowest concentration that prevents bacterial growth. Another concern is toxicity: gentamicin can cause nephrotoxicity (kidney toxicity) and ototoxicity (ear toxicity). The toxicity for gentamicine should not reach a $C_{tox,peak}$ value for short term toxic effect and minimal concentration before second dose should be bellow $C_{tox,valley}$ or sometimes dedicated as $C_{tox,trough}$. The dosing goal for clinical pharmacologist can be described as simplified rule to maintain drug concentrations above the MIC for a sufficient portion of the dosing interval while keeping peak level and trough level below toxic thresholds. For gentamicin the MIC and toxicity thresholds are in Fig.2(C).

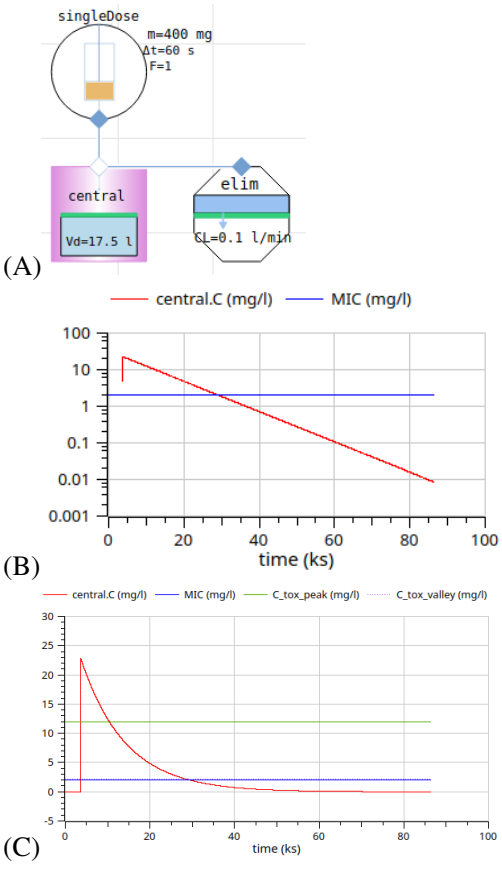

Figure 2. (A) Single-compartment model with a SingleDose component, a central compartment, and an elimination component. (B) Simulated concentration plotted on a logarithmic scale, illustrating the model's constant log-linear decline. (C) Example simulation configured for gentamicin pharmacokinetics—initial dose 400 mg, volume of distribution 17.5 L, clearance 0.1 L/min—showing the central compartment concentration (red), the minimum inhibitory concentration (MIC)(Hodiamont et al. 2022), and observed peak and valley (trough) toxicity levels (green) and (dotted blue).

2.3 2-compartment models

If the experimental concentration–time curve is biphasic, a two-compartment model usually fits better: the central compartment represents blood and well-perfused tissues, while the peripheral compartment represents tissues that transiently store the drug. Figure 3(A) shows this arrangement—administration and elimination occur from the central compartment, and drug moves between compartments by first-order transfer.

Midazolam—a fast-acting benzodiazepine used for sedation, anxiolysis, and anesthesia induction—exemplifies a drug whose intravenous pharmacokinetics are well described by a two-compartment model. Sample PK parameters are in Figure 3 caption. The plasma concentration required for anesthesia induction must remain above a defined minimal effective threshold C_{min}.

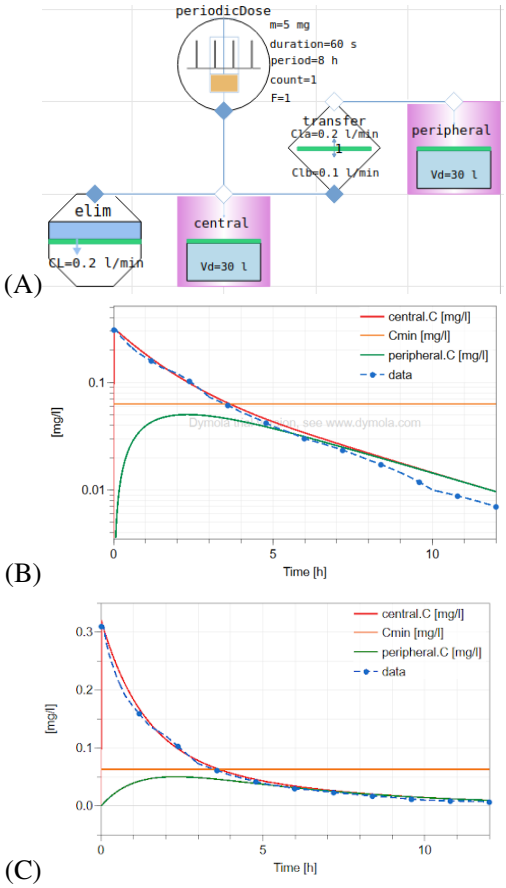

Figure 3. (A) Diagram view of a two-compartment pharmacokinetic model, showing drug administration and elimination in the central compartment with bi-directional transfer to the peripheral compartment. (B) Simulation on a logarithmic scale, illustrating the non-constant log-linear decline of concentrations in both compartments. validated against data (blue dots) from Heizmann et al. (1983)(Heizmann, Eckert, and Ziegler 1983). (C) Simulation of midazolam concentration in the central (red) and peripheral (green) compartments, alongside the minimal effective concentration (blue). A 9.6 mg IV dose is administered; both compartments have an apparent volume of distribution $V_d = 30l$, inter-compartmental transfer rate constants $k_{12} = 0.2h^{-1}$ and $k_{21} = 0.1h^{-1}$ and a systemic clearance $Cl = 0.2l.min^{-1}$

DOI
10.3384/ecp21861

2.4 Multicompartmental models

When a drug distributes into multiple tissue types, its post-administration concentration decline exhibits more complex behavior, making multi-compartment models more appropriate than single- or two-compartment models.

Fentanyl is a potent synthetic opioid used to manage severe pain and as an anesthetic adjunct during surgery. After intravenous administration, it rapidly distributes into highly perfused organs—such as the brain, heart, lungs, and kidneys—while also partitioning more slowly into poorly perfused tissues like fat and muscle. Over time, both tissue groups release fentanyl back into the plasma. The pharmacokinetics of fentanyl can be captured by the three-compartment model shown in Figure 4, in which the "peripheral" and "peripheral2" compartments represent highly and poorly perfused tissues, respectively.

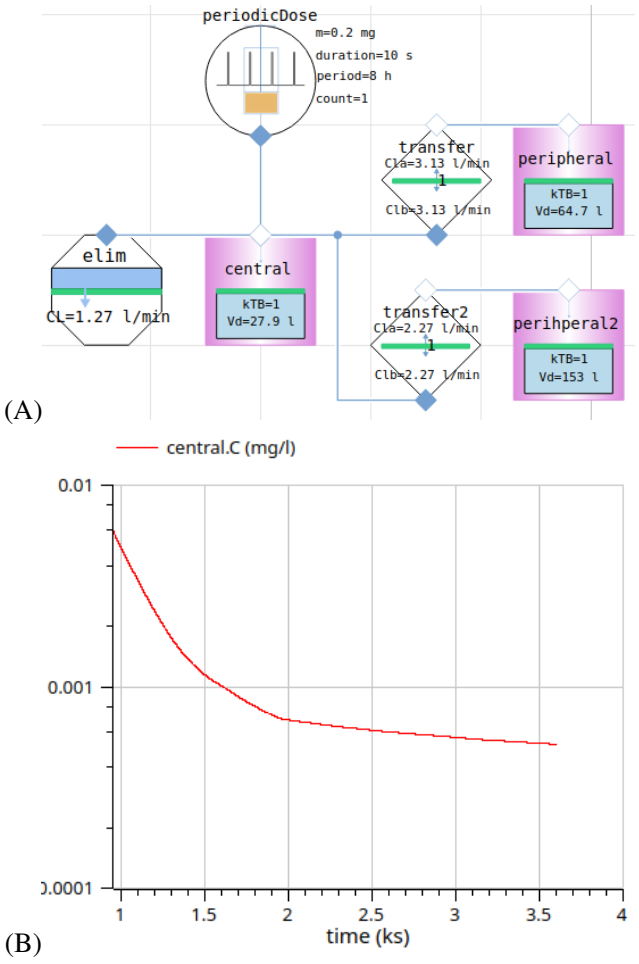

Figure 4. (A) Three-compartment PK model diagram. (B) Log-scale simulation of fentanyl plasma concentration 10–60 min after a 0.2 mg bolus. Parameters: V_d=27.9L (central), 64.7L (peripheral$_1$), 153L (peripheral$_2$); Cl=1.27, 3.13, 2.27L min^{-1}, respectively(Kaneda and Han 2009). The curve inflects as both peripheral pools return drug to the central compartment.

2.5 Physiology based pharmacokinetics models - component models

Compartmental PK models fit empirical compartments to concentration–time data but lack anatomical meaning. Physiologically based PK (PBPK) models instead assign compartments to real organs, enabling organ-level and inter-individual simulations when parameters are available.

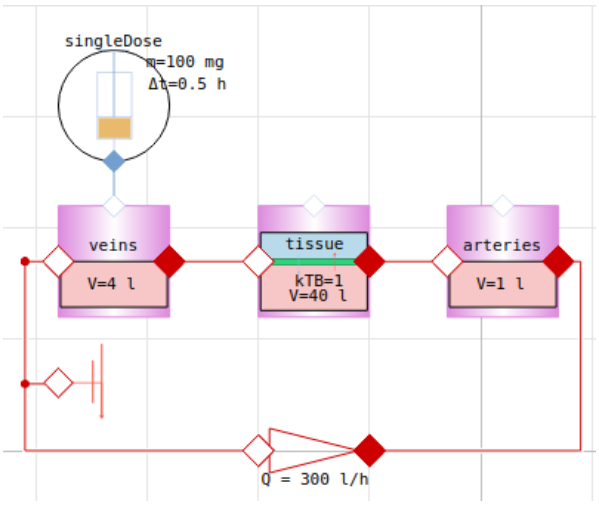

Figure 5. Model diagram of three-component PBPK model. Linked red FlowPorts enforce mass flow rate and resolve stream variables by flow direction. ConcentrationPorts join SingleDose→Veins (IV 100 mg in 0.5 h). A dedicated block sets unidirectional flow at a cardiac output of 5 L min^{-1} (300 L h^{-1})

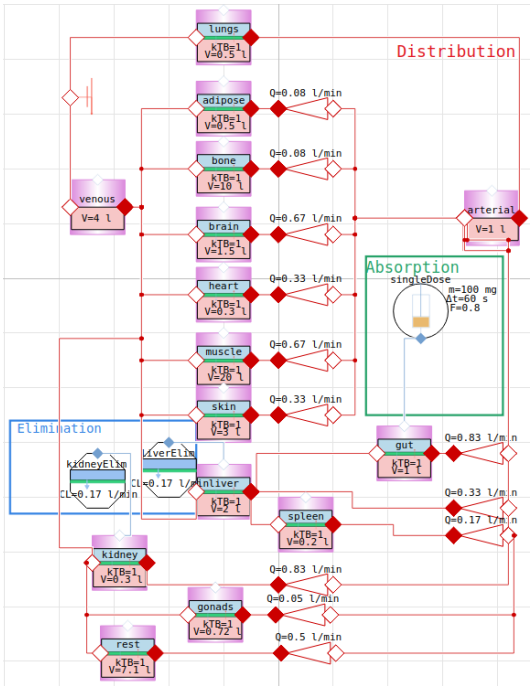

Figure 6. Whole-body PBPK model, utilizing main tissues with normal blood flow distribution. This is suitable for extension by a particular drug.

Figure 7. Excerpt from the flattened model—the text form automatically generated from the PBPK diagram by a standard Modelica tool. At line 332 the flows from all connected tissues sum to zero, and at line 359 the derivative of venous drug mass equals the flow-weighted mix of incoming concentrations, as dictated by the stream-connector logic. In a purely equation-based implementation these relations would have to be coded manually.

The basic three-component PBPK model, which accounts for cardiac output and drug distribution through the arterial and venous systems to target tissues, is illustrated in Figure 5.

Complex PBPK model follows cardiovascular distribution across multiple tissues (Figure 6). Linked red FlowPorts connect venous and arterial pools to fourteen organ/tissue compartments, automatically enforcing mass balance and setting stream variables by flow direction. A SingleDose block drives gut absorption (oral 100 mg, F = 0.8), while hepatic and renal clearance components (Cl=0.17 L min^{-1} each) handle elimination. A dedicated component sets cardiac output at 5 L min^{-1} (300 L h^{-1}). Figure 8 shows simulated tissue concentrations. An equivalent text model must state every equation and link, as illustrated by the flattened equation-based model generated by the Modelica tool in Figure 7.

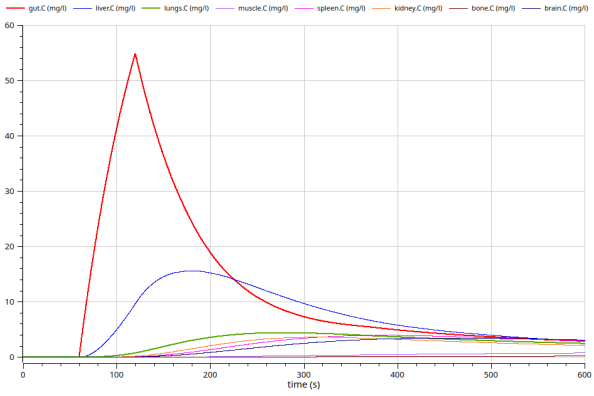

Figure 8. Simulation of the first 10 minutes of a generic drug using physiology-based pharmacokinetic model from Fig.6. Simulation reveals that majority of the drug administered orally goes first through liver and then it is subsequently distributed to other tissues.

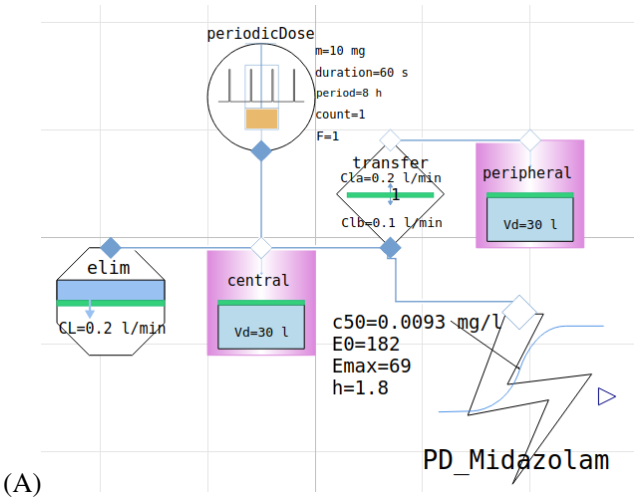
2.6 Pharmacodynamic models



Pharmacodynamics (PD) is the bridge that converts "how much drug is present" into "how much effect is produced." In its direct or static form, the instantaneous drug concentration at the site of action is passed through an algebraic dose-response relationship. We present several such direct-effect components (Table 5): a linear effect component for low-dose proportionality, a hyperbolic E_{max} effect component for simple saturation, and a sigmoid-E_{max} effect component whose Hill exponent tunes the steepness of the transition. These components assume the effect is reversible: when the concentration falls, the response follows it back to baseline with no memory.

	**LinearEffect** depicted as equation $$E = E_0 + S \times C$$ Where E is effect, E_0 is baseline effect without drug influence, S is slope (effect per concentration), C is drug concentration.
	**EmaxEffect** Depicted by the equation $$E = E_0 + \frac{E_{max} \times C}{C_{50} + C}$$ where E is the final effect, E_0 is the baseline effect in the absence of drug, C is the drug concentration, C_{50} is the concentration producing 50% of the maximal effect E_{max}, and E_{max} is the maximal effect.
	**SigmoidEmaxEffect** Depicted by the equation $$E = E_0 + \frac{E_{max} \times C^h}{C_{50} + C^h}$$ where E is the final effect, E_0 is the baseline effect in the absence of drug, C is the drug concentration, C_{50} is the concentration producing 50% of the maximal effect E_{max}, E_{max} is the maximal effect, and h is the Hill exponent.

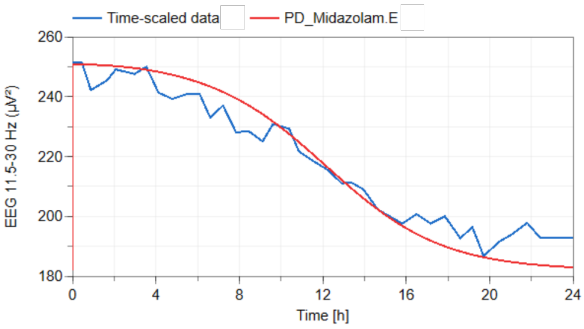


Table 5. Graphical connectors for drug-mass and concentration exchange.

Some drugs act irreversibly—e.g., covalent enzyme inhibition, receptor down-regulation, or DNA alkylation—so their effect depends on cumulative target inactivation rather than current concentration; these indirect, irreversible mechanisms are not yet covered in the current library.

Midazolam—whose intravenous disposition is captured by the two-compartment PK model in Figure 3—rapidly partitions into the highly perfused central nervous system, where it depresses electroencephalographic (EEG) activity, producing sedation, anxiolysis, and anaesthetic hypnosis. Cleton et al.(Cleton, Voskuyl, and Danhof 1998) showed that the concentration–effect relationship for the EEG β-ratio follows a sigmoid E_{max} curve. In the library, the midazolam PK–PD model couples the two-compartment PK model to a sigmoid-E_{max} PD component (Figure 9).

2.7 Pharmacogenomic models

Pharmacogenomic (PGx) modeling seeks to quantify how inherited genetic variation modulates both drug pharmacokinetics and pharmacodynamics. We propose the following components to integrate genotype–phenotype–specific parameters—such as transporter activity, metabolic capacity, and receptor sensitivity—directly into established PK/PD frameworks. We define six commonly used metabolizer status classes:

```
type MetabolizerStatus =
    enumeration(
      Unknown      "No mapping implemented / uncertain",
      Poor         "Little or no functional activity",
      Intermediate "Reduced activity",
      Normal       "Reference activity",
      Rapid        "Increased activity",
      Ultra        "Greatly increased activity");
```

Next, we define two generic record types Genotype and Phenotype to encapsulate an individual's genotype (allelic composition), corresponding phenotype, and simplified functional modifications of PK/PD effects:

```
partial record Genotype
  parameter String allele[2] = {"*1","*1"};
  replaceable parameter PGx.Phenotype ph
      constrainedby PGx.Phenotype
      annotation( ...);
end Genotype;
```

```
record Phenotype
  parameter String[:] poor = fill("", 0);
  parameter String[:] intermediate = fill("", 0);
  parameter String[:] rapid = fill("", 0);
  parameter String[:] ultra = fill("", 0);
  parameter Real[6] CLscale = {1.0,0.7,0.85,1.0,1.2,1.3};
  parameter Real[6] Fscale  = {1,1,1,1,1,1};
end Phenotype;
```

Additional helper functions are defined as follows:

`phStatus(ph, allele1, allele2)` Maps a pair of star-alleles (`allele1`, `allele2`) and a `PhenotypeTemplate` instance (`ph`) to a `MetabolizerStatus`, using the allele lists specified in `ph`.

`phScaleCL(ph, allele1, allele2)` Returns the clearance-scaling factor corresponding to the combined genotype (`allele1`/`allele2`) and phenotype instance `ph`.

Based on these record templates, a modeler can define sample genotypes and phenotypes that may affect, for example, the renal clearance of a drug. For instance, the SLC22A2 gene encodes organic cation transporter 2 (OCT2), a key renal transporter responsible for the uptake and clearance of many endogenous substances and drugs from the blood into renal tubular cells, thereby influencing their urinary excretion (Koepsell 2013).

Sample implementation of SLC22A2 genotype holds default normal alleles denoted as $*1*1$ which can be changed later in runtime as a common parameter in a model:

```
record SLC22A2Genotype
  extends PGx.Genotype(
   allele = {"*1","*1"},
   redeclare parameter Phenotypes.OCT2_Phenotype ph );
end SLC22A2Genotype;
```

Phenotype OCT2 defines an intermediate metabolizer with at least one allele denoted as 808T and according altered clearance by factor 0.85:

```
record OCT2_Phenotype
  extends PGx.Phenotype(
    intermediate = {"808T"},
    CLscale = {1.0, 0.7, 0.85, 1.0, 1.2, 1.3},
    Fscale = {1, 1, 1, 1, 1, 1}
  );
end OCT2_Phenotype;
```

In order to integrate genotype–phenotype influences into the gentamicin PK model, we must adjust the clearance parameter—either by directly invoking the function phScaleCL() or by delegating the adjustment to a specialized ClearanceModifier model. An example of the gentamicin PK model, implemented in equations and augmented with PGx influence via ClearanceModifier, is shown in the following listing:

```
model PKPG_1C_GentamicineEquation
extends Modelica.Icons.Example;
  Pharmacolibrary.Types.Mass M(start = 0.000400);
  Pharmacolibrary.Types.MassConcentration C(displayUnit = "mg/l");
  parameter Pharmacolibrary.Types.Volume Vd = 0.0175;
  parameter Pharmacolibrary.Types.VolumeFlowRate Cl_nom = 0.1/(1000*60);
  parameter Boolean usePGx = true "true = apply genotype scaling";
  Pharmacolibrary.Pharmacogenomics.Modifiers.ClearanceModifier clMod(
    base = Cl_nom,
    redeclare type Gtype = Pharmacolibrary.Pharmacogenomics.Genotypes.SLC22A2Genotype,
    redeclare parameter Pharmacolibrary.Pharmacogenomics.Genotypes.SLC22A2Genotype g(
      allele = {"*1", "*1"}/* <- change one entry to "808T" for Intermediate */)
    );
  Types.VolumeFlowRate Cl_eff "effective clearance";
equation
  Cl_eff = if usePGx then clMod.modified else Cl_nom;
  C = M/Vd;
  der(M) = -Cl_eff*C;
  annotation( ...);
end PKPG_1C_GentamicineEquation;
```

PGx simulation of such PK model with normal allele and with variant 808T with altered clearance is seen in the following Figure 10:

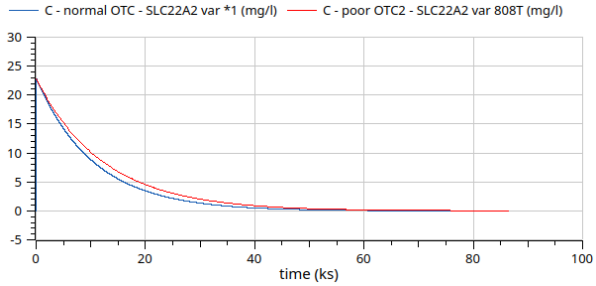

Figure 10. comparison of PGx simulation of PK model of gentamicine with normal SLC22A2 alleles compared to allele '808T' with altered clearance.

To support PGx modeling using diagram view, we define the components in Table 6.

With these components, we can extend PK models with additional PGx influence by applying clearance modifications appropriately and cascading the influence of multiple genes—e.g., CYP2C19 and SLC22A2—as illustrated in the model diagram in Figure 11.

	**ClearanceModifier** q_{vin} is baseline volume flowrate value, u is modification factor from an outside component, e.g. from genotype-phenotype component, q_{vout} is modified output volume flowrate value by equation: $$q_{vout} = u \times q_{vin}$$
	PhenotypeGenotype component joins genotype with it's phenotype and outputs the scale factor that can be used to modify other quantities $$\text{scale} = \text{phScaleCL}(p_h, a_1, a_2)$$ Where p_h is phenotype, a_1 is first allele and a_2 second allele.

Table 6. Components for diagram view to support pharmacogenomic modeling.

DOI 10.3384/ecp21861

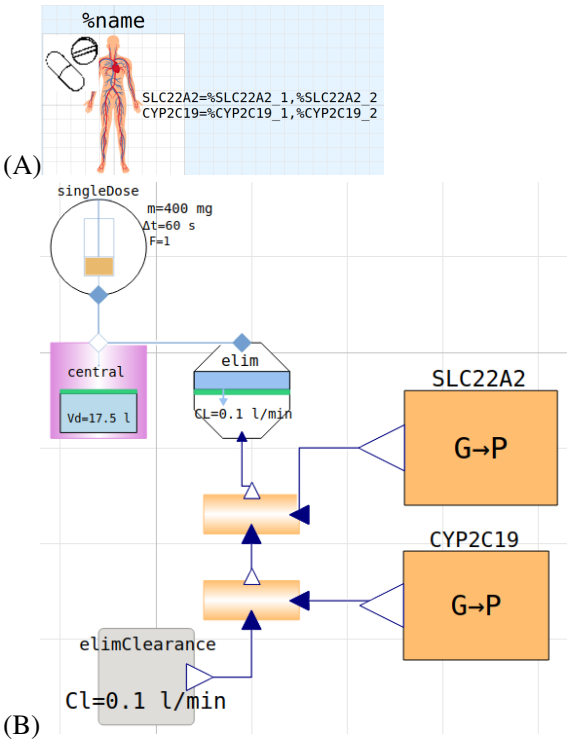

Figure 11. PKPGx model icon (A) and diagram (B) of 1-compartment PK of gentamicine where elimination clearance rate is influenced by PGx of CYP2C19 genotype and SLC22A2 genotype.

Theoretical influence of all combination of the variants of gene mutation of SLC22A2 and CYP2C19 on periodical administration of gentamicine is visible in model and simulation of 4 variants in Figure 12.

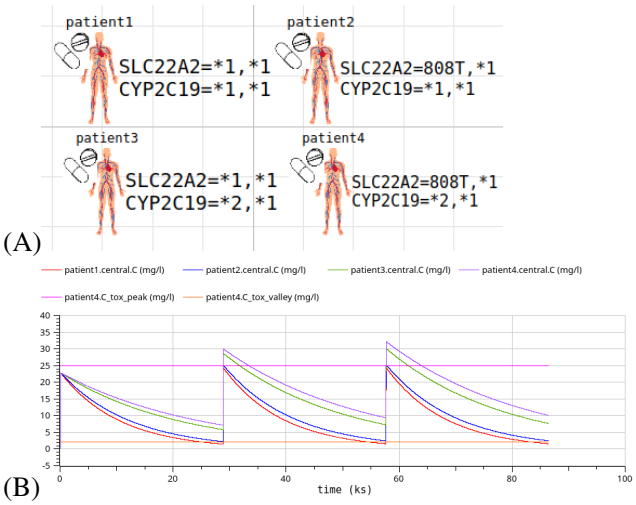

Figure 12. PGx of 4 variants of patients with various gene mutation of SLC22A2 and CYP2C19. Model diagram (A) showing the instance of PKPGx model with specific SLC22A2 alleles and CYP2C19 alleles (patient1 has normal alleles, patient2 with mutation 808T, patient3 with mutation *2 and patient4 with both mutations 8080T and *2). Simulation (B) of PK of gentamicine on all these patients during 3 days, gentamicin is administered every day. Toxicity peak and trough (valey) levels are shown too.

Note that while standard dosing in a normal patient keeps drug concentrations below toxic peak and trough thresholds, rare variants in the cited genes slow elimination; in patient3 and patient4 this raises levels above the toxicity limit, markedly increasing the risk of side effects.

The models in Figures 11 and 12 are illustrative only; the real impact of pharmacogene mutations on drug pharmacokinetics and pharmacodynamics is likely more complex and lies beyond the scope of this paper.

2.8 Integration to simulation workflows

Models exported as FMUs can be instantiated and customized via runtime parameters without requiring recompilation. The following figure illustrates a demo workflow that integrates FMU export into a Python environment using the FMPy library, retrieves experimental data from an external PK database, overlays the data on the simulation chart, and supports interactive parameter updates.

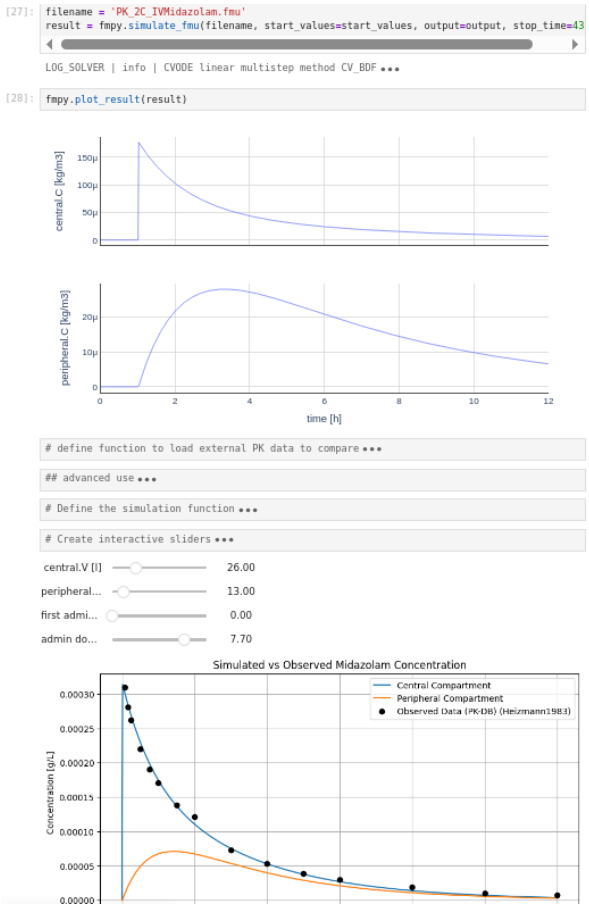

Figure 13. 2-compartment PK model of Midazolam exported to FMU and instantiated in Python using fmpy library. Jupyter notebook is used to visualize interactively model simulation and data of specific drug concentration time series retrieved from PK-DB (Grzegorzewski et al. 2020).

2.9 Integration to other Modelica libraries

Pharmacolibrary can be integrated with other Modelica libraries. The acausal connectors are unique for Phar-

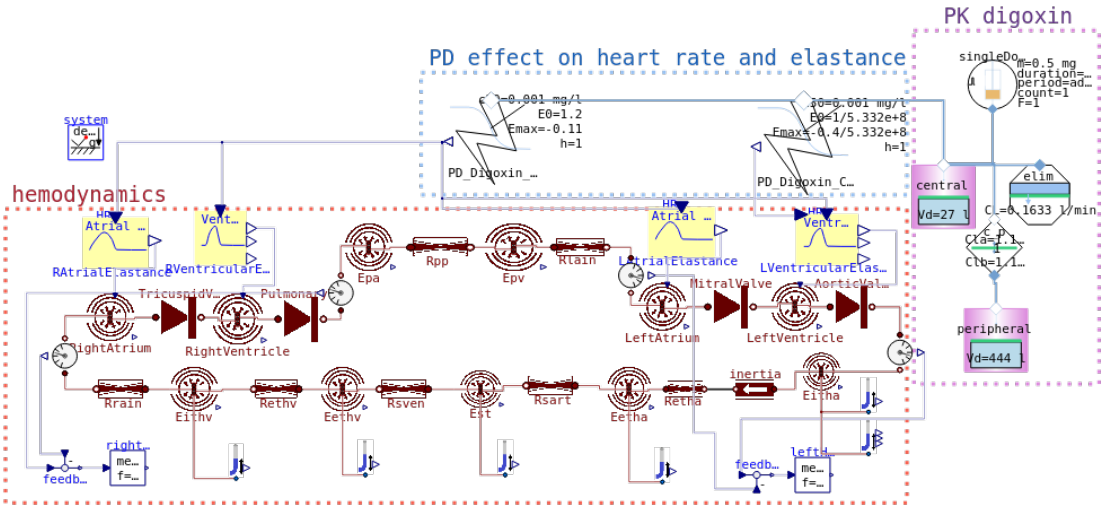

Figure 14. Example integration of PKPD model with Physiolibrary 3.0 (Mateják 2023) 1. hemodynamics of cardiocascular system as published by (Van Meurs 2011), 2. example of 2-compartment PK model of digoxin and PD model of influence of variable elastance during cardiac cycle as published by (Hornestam et al. 2003). PD effect on elastance/compliance just illustrative.

macolibrary, however causal connectors that holds only one variable can be directly connected to any appropriate component. Following the common convention in Modelica libraries, connector nominal values use SI units: compliance is expressed in $m^3\,Pa^{-1}$ (converted from $mL\,mmHg^{-1}$), and heart rate in s^{-1} (Hz) rather than beats min^{-1}. Digoxin is a drug used to treat e.g. acute atrial fibrilation as it has combined effect on inotropy (ventricular elastance) and heart rate. Example of PK PD integration of digoxin to model of hemodynamics is visible in Fig.14 with PD effect parameters in basic SI units and illustrative simulation is at Fig. 15.

3 Discussion

Implementing multicompartmental pharmacokinetic/pharmacodynamic models can be cumbersome and error-prone when using generic programming language, or modeling language and methods using equation-based or block-diagram approaches. While simple one- and two-compartment models (Fig. 1 A, B) can be implemented either in diagram mode or in equivalent equation text mode, more complex architectures quickly become unwieldy in text mode (e.g., Fig. 6, and 7). In contrast, Modelica tools automatically generate consistent textual representations from acausal diagram views—translating connected variables and component definitions into correct equations. Combination of acausal and stream connectors (connectors exchanging flow, non-flow and stream variables) ensure that non-flow (equality) and flow variables equilibrate appropriately, while stream connectors enforce mass balance by mixing based on flow direction. This component-oriented approach preserves the precision of underlying equations while retaining an intuitive, schema-like structure plausible for non-programmers.

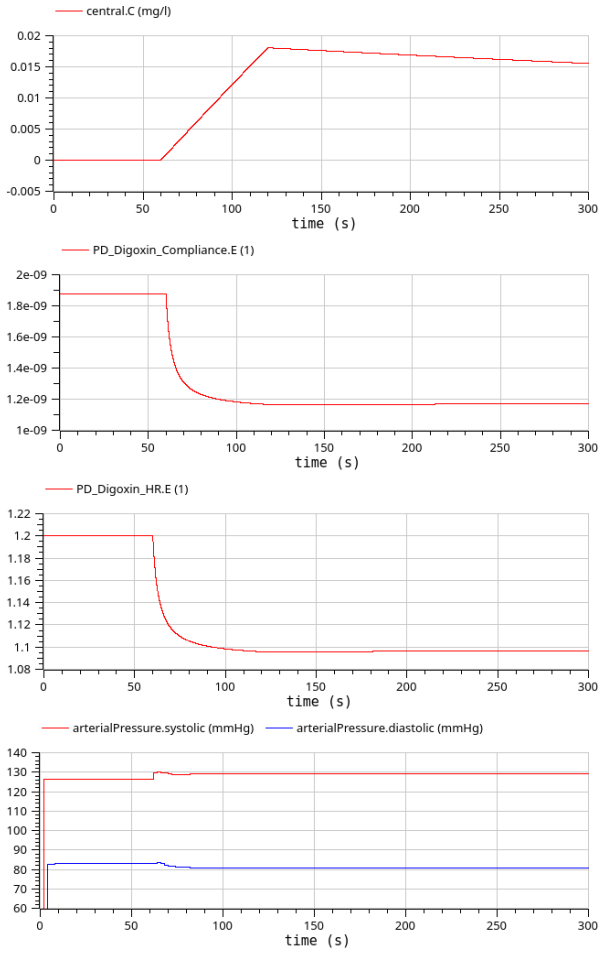

Figure 15. Simulation of PK, PD effect on compliance and heart rate and systolic/diastolic pressure in 5 minutes before, during and after administration of intravenously applied digoxin. Digoxin is administered after 60 seconds. Note that while systolic pressure slightly increases the diastolic pressure slightly decreases when the drug is administered.

DOI 10.3384/ecp21861

Pharmacology modeling must also accommodate extensive genetic and physiological variability. Embedding all genotype- and phenotype-specific variants directly in static diagrams can become impractical as well as to model PK of all drugs using drug-specific models. To address this, our library's core components are designed for post-compilation parameterization: users can adjust pharmacokinetic, pharmacodynamic and genotype-phenotype influences (e.g., via ClearanceModifier or phScaleCL()) at runtime without recompiling it.

Pharmacogenomics is rapidly maturing: e.g. the Dutch Pharmacogenetics Working Group and the Clinical Pharmacogenetics Implementation Consortium now recommend genotype-based dose adjustments for many drugs. Embedding these recommendations into physiologically based models enables truly personalized simulations that account for both genetic polymorphisms and physiological differences. Current Pharmacolibrary allows only basic components for PGx modeling which may be a foundation for systematic approach in this context interconecting phenotypes and it's effect on different tissues during drug lifecycle in organism.

Pharmacolibrary contains also basic PK models of all approved drugs that was generated by a workflow extracting knowledge from the literature—or infers it from structurally similar compounds—using recent advances in AI and large language models (LLMs). These PK models are stored in the "Drugs" package and categorized by Anatomical Therapeutic Chemical (ATC) codes[1]. Each model contains essential drug information and references generic one-, two-, or three-compartment PK model with specific instance parameter. Such generated models needs manual verification and refinement, however, may be useful as starting point for drug modeling. If a human modeler later derives additional parameters or adds another route, that supplementary model is saved alongside the generated one.

Drug effects often exhibit time lags or hysteresis between tissue concentrations and observable responses. Standard Modelica libraries support modeling such delays (e.g., via transport or delay blocks). Additionally, pharmacodynamic outcomes can be modulated by the body's regulatory feedback. By connecting PKPD models to broader physiological frameworks (for example, Modelica's Physiolibrary or Chemicals library), one can simulate homeostatic mechanisms and regulatory dynamics alongside drug action as it is illustrated in one example in Fig.14 and Fig.15.

As models can be exported to FMUs following the FMI standard and integrated into diverse simulation workflows (Python, Julia, MATLAB, or bespoke environments) the interoperability can be made with various other systems biology libraries, frameworks and workflows. One such example is illustrated integrating model in Jupyter notebook with Python code and data from PK-DB in Fig.13.

Because Pharmacolibrary is still in its infancy, a thorough comparison with commercial or open-source alternatives would be premature. Even so, within the broader Modelica ecosystem, the library already fills a crucial niche for modeling biological systems with an emphasis on chemical compounds and drugs.

3.1 Library limitations

To keep models transparent and user-friendly, we adopted pharmacology-centric units and terminology—such as volume flow rate (SI base unit m^3/s, displayed as l/min) via FlowPort connectors, even though under variant temperatures or pressures (e.g., during gas exchange or hypothermia) mass flow rate (kg/s) would be more accurate. A similar point applies to the use of concentration as a quantity: at membranes, it is actually the chemical potentials—not the concentrations—that equilibrate. However, modeling this explicitly would introduce unnecessary complexity, whereas our goal is to keep the model intuitive, and user-friendly.

4 Conclusion

In this work, we have introduced *Pharmacolibrary*, a flexible Modelica-based library for mechanistic pharmacological modeling that spans pharmacokinetics, pharmacodynamics, toxicokinetics/toxicodynamics, physiology based PK/PD and pharmacogenomics. By providing standardized acausal connectors, reusable compartment and effect components, and genotype–phenotype records, our library simplifies model construction, ensures mass and concentration balance. The models are Exportable as FMUs in accordance with the FMI standard, Pharmacolibrary models can be embedded into diverse computational workflows (e.g., Python, Julia, R,...), enabling interactive parameterization, data-driven validation, and high-throughput simulations.

The library is open-source maintained at GITHUB [2] and listed in ZENODO (Kulhánek and Ježek 2025)

Implementations of gentamicin, midazolam, fentanyl, and digoxin—including genotype/phenotype-adjusted clearance—demonstrate that Pharmacolibrary can replicate experimental data and underpin personalised dosing. Moreover, the library contains simplified generated PK models of all drugs classified by anatomical therapeutical chemical (ATC) codes. As of 06/2025 there were 5496 unique records at ATC level 5, corresponding to 4363 distinct chemical substances.

By separating model definition from the solver and building on the Modelica ecosystem (Physiolibrary, Chemicals, Biochem), it promotes reproducibility, interoperability, and extensibility. Ongoing work will add transporter and enzyme-kinetic blocks, compile and improve a catalogue of simplified drug models, incorporate

physiological feedback, and validate clinical case studies to further advance quantitative systems pharmacology.

Combining static and dynamic optimization approaches for path planning, with collision avoidance

Dr. Clément Coïc[1] Marco Masannek[1,2]

Abstract

In response to staff shortages in hospitals, healthcare providers aim at increasingly automating their systems. Defining automated system paths – with collisions avoidance – is a critical step towards automation. In this paper, three different approaches for path planning are investigated: a static, a dynamic and a hybrid approach. The hybrid approach, that sequentially combines part of the static and dynamic approaches, results in improved accuracy against the static approach and improved performance against the dynamic approach.
Keywords: Path planning, C-space, Dynamic Optimization, Hybrid approach

Figure 1. Project AURORA: Target operation room environment (left) and real robot (right)

1 Introduction

The staff shortage in the healthcare industry is a bottleneck when it comes to patient touchpoints. Healthcare system automation can partially solve this issue. Should automated systems reduce the workload of qualified healthcare professionals, these would be available for interventions - where they can add value, save life, care for the patients or plan procedures, to name but a few. There are different tasks currently performed by qualified by healthcare professionals that could be taken over by automation. First, existing systems could perform in a more automated manner. For the sake of simplicity, this paper focuses on robotic systems evolving freely on the hospital floor - though the entire discussion could be extended to any type of system, e.g. ceiling systems. A typical example could be to provide qualified voice command to, for example, a CIARTIC Move (Siemens Healthineers AG 2025) - such as "Take a 3D scan of the patient right foot." - and the Ciartic Move would autonomously evolve in the room until the foot is at the isocenter of the scan, would ask for permission to scan and proceed. In a second step, new robotic systems could be developed to perform actions that are not part of today's offering. For example, the research project Autonomous Robotic Operation Room Assistance (AURORA) (MITI Research Group 2024) aims to assist in operations by performing tasks required by circulators, which focus on actions in the periphery of the operating table, e.g. equipment preparation (see Figure 1).

In both above examples, one key capability the system shall have is determining the path it shall take to safely evolve in its environment. Additionally, the system shall sense its moving environment and adapt the path based on the potential new or moving obstacles along its path. This paper focuses on solving that path planning problem with fixed obstacles. This can be justified by the fact that the authors already mitigated part of the risk associated with moving obstacles by presenting a novel approach relying on a semantic understanding of the environment, and path adaptation can be done with reinitiating the path planning under the new constraints. The remaining of the paper will present three different approaches for solving the path planning problem. In Section 2, a static approach is discussed. This method relies on discretizing the environment and determining the C-space of the robotic system to define the feasible paths. Section 3 tackles the problem from the perspective of the dynamic motion of the robotic system: what is the optimum path under the constraints of the robotic system kinematic. Section 4 discusses a hybrid approach consisting of sequentially applying part of the static and dynamic approaches. Finally, the paper is concluded and perspective to the work are presented.

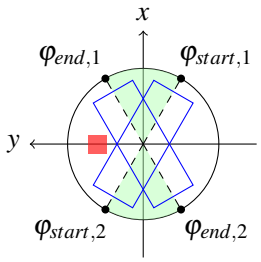
2 Static Path Planning

In most mobile robotic applications, the problem of finding a collision-free path is approached by first creating a map of the environment using sensors and Simultaneous Localization and Mapping (SLAM) algorithms (Placed et al. 2022). In a second step, the map is then converted into a discretized occupancy grid map, also commonly referred to as cost map, which assigns specific cost values for each

cell depending on the proximity of obstacles. By utilizing these cost values as a basis for node evaluation during graph search algorithms such as A* or RRT, current robotic systems achieve computation times of often less than 100ms even for longer paths.

However, this approach has two major limitations affecting the quality of generated paths, which are the missing consideration of vehicle dynamics and the often-inaccurate representation of valid configurations for non-circular robots, e.g. for rectangular shapes. To overcome the latter, we introduce a method for fast and memory-efficient computation of the collision-free configuration space (C-space) for any shape robots.

2.1 C-Space for non-circular robots



To determine valid poses within a given environment, most approaches start by creating a Euclidian Signed Distance Field (ESDF) which describes the distance to the nearest obstacle for each x-y-cell in the cost map. For circular robots, these values can already be utilized to perform complete collision evaluation by comparing the distance with their own radius. Cells below this threshold are usually marked as colliding, while distances above the threshold mark free and therefore traversable space. Since the orientation (heading) of a circular robot has no effect on its radius and therefore minimal distance threshold, the classification holds true for all headings φ.

However, rectangular or any shape robots need to consider their actual occupied space for each discrete heading φ_h at a given position $p(x,y)$ to reason about whether or not the robot would collide at a specific pose $P(x,y,\varphi)$. The angular resolution r_φ that is required to ensure valid collision checks in the discretized grid can be determined using the cell resolution r_c and the circumscribing radius of the footprint d_{cr} (furthest point of the shape) and often lies in a range from 1° to 10°. Since this creates a necessity for a three-dimensional grid (third dimension being the heading), generated c-spaces can grow very large for big environments with high resolution requirements.

To overcome this challenge, (Lau, Sprunk, and Burgard 2013) introduced the concept of valid angle intervals (see Figure 2), which describe a set $\mathbf{v_I}$ of collision-free intervals of heading for an arbitrary shaped robot. This method allows for efficient computation of collision checks for any pose $P(x,y,\varphi)$ by simply evaluating if the angle φ intersects with any interval of $\mathbf{v_I}$. Cells with a single interval spanning the full angular range can additionally be marked as completely free to save further memory.

2.2 Example C-Space for a hospital floor

Figure 3 shows an exemplary hospital floor map with hallways, patient rooms, treatment rooms and bathrooms. In order to plan paths for a rectangular robot (e.g. a patient bed or the CIARTIC Move) between any two positions, the complete floor needs to be processed. Brute force calculations of the C-space would result in over 180 million cells when given a map of 1280x720 pixels and a required

$$\mathbf{v_I}(\mathbf{x}|\mathbf{y}) = \begin{bmatrix} (60°, 120°) \\ (240°, 300°) \end{bmatrix}$$

Figure 2. Example angle intervals for a rectangular robot (blue) for a close obstacle (red square)

angular resolution of 1.8° (equals 200 angles per rotation). Utilizing the method described in section 2.1, we are able to reduce the size of the c-space map by over 80% to roughly 35 million cells.

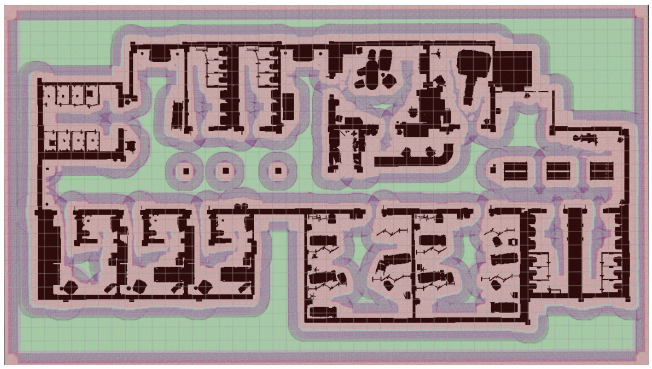


Figure 3. C-Space for a hospital floor and rectangular robot. Black cells mark physical obstacles such as walls, beds or other objects. Green cells are completely free, red cells cause collisions. Purple cells mark cells with valid angle intervals.

2.3 Collision graph from angle intervals

In order to plan a path through the occupancy grid including its angle intervals, a customized graph structure needs to be created that accounts for the presence of multiple angle intervals on the same position $p(x,y)$. We therefore create an adapted neighborhood discovery step during expansion in our graph search (utilizing A*) which discovers all valid intervals of a neighboring cell. Connections are established only when intervals overlap to ensure that a continuous path can be created in the end. Since completely free cells have overlaps with all intervals, connections between them can always be established (see Figure 4).

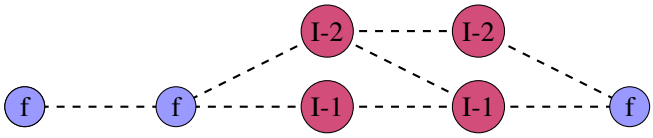

Figure 4. Example edges between free and and orientation interval nodes

DOI
10.3384/ecp21873

2.4 Limitations of grid-based planning

Figure 5 shows a typical path planning problem in hospitals, where a patient bed must dock to a magnetic resonance imaging system in a narrow room.

While our static path planning is able to produce collision-free paths for non-circular robots even through the narrow sections (see Figure 5), the generated trajectories are not smooth and also imply following using an omni-directional movement model (e.g. shopping cart).

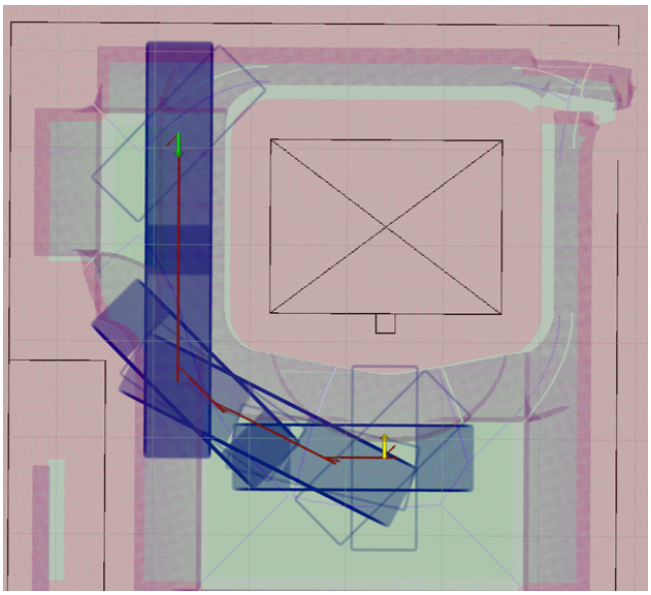

Figure 5. Planned path using our custom collision graph. The arrows mark the start (green) and goal (yellow) pose for the robot; the blue phantoms depict the footprint along the path.

3 Dynamic Optimization

The static approach to path planning proved to be very efficient in finding a solution. However, it does not guarantee that a robotic system, with constrains on its kinematic motion, could actually achieve the found path. This might not be an issue for some robotic systems - holonomic, such as the CIARTIC Move, which drive system allows for any type of motion on the 2D plan (i.e. rotation on the spot, translation in all directions (even lateral) and combination of both motions). However, many other types of drive systems are non-holonomic - i.e. they have constrained kinematics that should be accounted for when planning for their path.

Dynamic optimization (Åkesson 2008) is leveraged here to solved for the optimum path of a behavioral model of the robotic system, under its environment constraints. Four steps have been followed to implement this solution. First, a simplified behavioral model of the robotic system is developed. Then, a simplified model of the environment is introduced together with the collision assessment with the robot. In a third step, the dynamic optimization function is implemented. Finally, the resulting path is run in a forward simulation of a more detailed behavioral model. These four steps are detailed below, after a quick discussion on the need for these two fidelities of behavioral models.

3.1 Behavioral Model Purposes

Models are developed with a purpose in mind. Here, our aim is to easily assess the behavior of different drivetrain set ups for our robotic systems and their impact on the trajectory they can achieve. We collected the two different set of requirements associated with this purpose.

1. Path planning: the behavioral model shall represent the system dynamics, while being as simple as possible, to allow for a fast optimization. As directional derivatives are leveraged by the dynamic optimization solver, it is of high importance that the behavioral model is C2-continuous, i.e. continuous, derivable and the derivative is continuous too.

2. Behavioral path following: the behavioral model shall allow for modeling the different drivetrain in more details to assess how they perform when following a specified path.

In order to meet both requirements, the choice was made to have two separate models - one for each purpose. The behavioral model dedicated to path planning is a point-heading motion model, with potential constraints on the trajectories it can follow. The behavioral model dedicated to studying the path following response is a multi-body model with detailed kinematics of the drivetrain.

3.2 Point-heading Optimization Model

A point-heading motion model, as the names indicates, consists in modeling the system as a point with a heading, and some constraints on its motion. In addition, the robot envelope around the point is also known so that we can easily check for collision of the real system - and not only the point. At this stage, two different cases are made possible:

1. The robotic system is holonomic, i.e. it can evolve freely in all directions and motion types (like the CIARTIC Move).

2. The robotic system is non-holonomic, i.e. it can only continuously change the path curvature with respect to its reference frame.

The former case does not constrain the path with respect to the robot heading. For example, a path forming a 90° angle with the heading corresponds to a sideway translation. The latter means that the rate of change (derivative) of the path heading cannot be higher than the point steering capability. In other words, the path and point headings shall align. These two cases can easily be modeled by adding a constraint on the path to heading angle that should be 0 in case of non-holonomic robots.

Listing 1. Point-heading Optimization Model

```
model PointHeading
 // Cartesian coordinates
 Modelica.Units.SI.Position x "Global x
     position";
 Modelica.Units.SI.Position y "Global y
     position";
 Modelica.Units.SI.Angle phi(start=phistart,
     fixed=true) "Global heading";
 // Change to local coordinates
 //...
 parameter Boolean isHolonomic = true "false
     , if heading should be fixed =0";
 // Defining robot body
 // ...
equation
 // motion ...
end PointHeading;
```

The resulting Modelica model shown in Listing 1 is very simple and includes some additional variables for changing the reference frame from global to local and for defining the body of the robotic system around the point. It remains C2-continuous and suitable for a fast dynamic optimization application.

3.3 Simplified Environment Model

The environment where the robot evolves is a bounded rectangle. Internally, it is composed of the floor set-up - including walls, defining the rooms and corridors - and all types of objects and persons that could be on the way - e.g. an MRI or CT machine, a bed with patient, or even a plant. From the perspective of the robot, these are all seen as obstacles. Therefore, there is no need to differentiate them in this approach, and it was decided rather to allow for modeling a couple of shapes - specifically rectangles and circles - as footprint on the floor. As discussed in section 2, circles are efficient as there is no need to model their orientation - the Euclidian distance is the same for any angle. Rectangles require their orientation to be modeled. For this purpose, specific classes have been developed - Circle, Rectangle -, that contain their dimensions and take the position of the object in motion to check for collision. As many obstacles as desired can be introduced in the environment and a combination of them can represent more complex shapes. For example, a square room with an open-door access can be represented with 4 rectangle obstacles. (Alternatively, should a scenario happen exclusively within a rectangular room, it is possible and more efficient to define the bounds of the room as constraints to the robot coordinates in the optimization problem.)

3.4 Optimization Problem

Now the point-heading model and its environment are defined, the next step is to look at the path the robot shall follow. Note again that the path and the trajectories of the robot model (x, y, phi) are not necessarily the same: specifically, for non-holonomic robots, the heading of the robot and of the path may not be aligned. Therefore, a heading variable for the path itself, phi_p, is introduced. Additionally, we define a velocity along the path, v_p, its projections on the x and y axes, v_x and v_y, and its time integral gives us the length of the path d_p.

The cost function of our optimization model is a combination of the path length and the rate of change in path curvature. The goal is to minimize the distance while avoiding abrupt changes in curvature. Obviously, this cost function can easily be adapted based on the needs and would lead to different optimum paths.

The inputs to optimize are the heading derivatives of the path and of the bed. Note that because the velocity is a set, these headings fully define the trajectories. (Alternatively, the velocity could be considered an input.) However, the headings derivatives are selected here as these are needed for the cost function (no abrupt changes in heading) and because the headings are easily obtained by further integrations.

To fully define the optimization problem, the following constraints are added:

- The robot remains within the bounds of the environment.
- Potential alignment of headings for non-holonomic robots (see end of subsection 3.1).
- Checking that the distance to obstacle remains positive.
- Ensuring that the initial and final target positions are met.

The optimization problem is written in the Optimica language, allowing us to extend the existing Modelica behavioral and environment models, similarly to (Coïc, Budinger, and Delbecq 2022).

Listing 2. Pseudo Point-heading Optimization Model

 y(finalTime) = y_end;
 phi(finalTime) = phi_end;
end PointHeading;
```

Figure 6 is an example of a rectangular holonomic robot (in grey) entering a challenging room. The blue rectangles represent walls with small tolerances. The room dimensions are above the minimum recommendations, yet the door is placed with an angle, which limits the robot in its movements. This simulation proved that the non-holonomic robot was not able to find a path in this challenging environment (only by few centimeters), yet the holonomic could manage.

The path planning was implemented as web application within Modelon Impact - as in (Coïc, Andreasson, et al. 2020) - to easily generate scenarios. The resulting paths are stored as csv artifact that can easily be imported into the workspace. This results very handy as the next step is to validate that our point-heading model simplification is not too simplistic. This is verified by simulating a higher fidelity (multibody) path following robotic system.

3.5 Multibody Drive Model

For the purpose of accurately modeling the kinematics of the robotic system, it is enough to model its drive system,

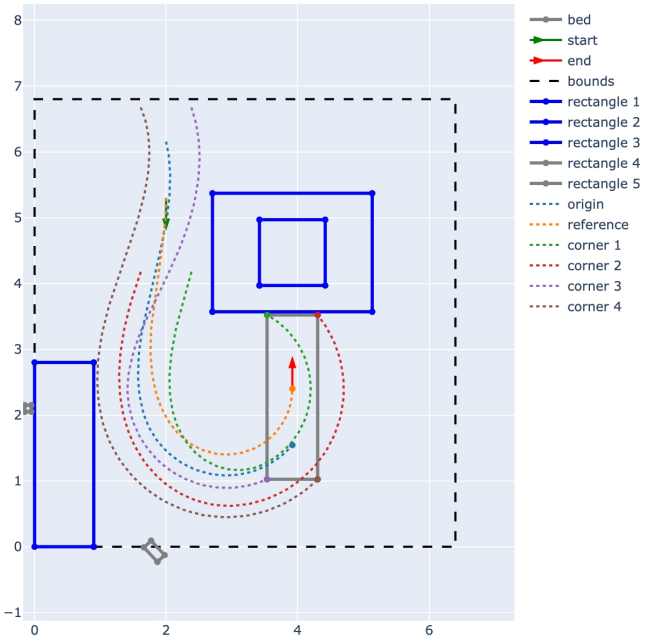

Figure 6. Optimum path planning example

and the rest as point-mass located in the center of gravity - as shown in Figure 7. Each wheel module - see Figure 8 - is a submodel that allows for representing different types of wheels: steered, driven, free, with a caster trail, etc. The tyre model is based on (Pacejka 2012). To each wheel is connected a controller that computes their commands in steering and driving - should these be activated. This makes a very flexible model that allows for investigating a variety of different robotic drive system.

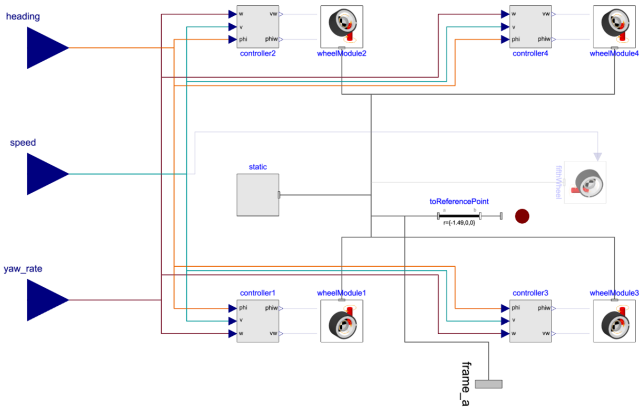

Figure 7. Multibody Model of the Robotic System Drive

As an example of holonomic robot, the four lateral wheels can be active with two caster wheels and two wheels that are both steered and driven. A robot with a fifth wheel in the middle that is locked in steering and driven while one of the other four wheels would be steered only would lead to a non-holonomic configuration - as the robot could only turn in forward motion and around the fifth wheel point of contact.

Resimulating the optimum path from Figure 6 - of the

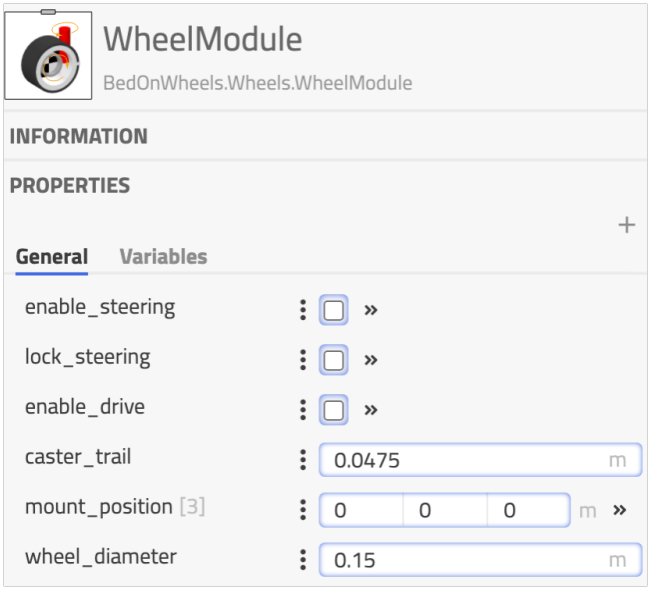

Figure 8. Fully configurable wheel module

reference point, in orange - with a holonomic drive robot, it is observed that the followed path is nearly identical to the optimum one (see Figure 9). And the small divergence could potentially be due to the path following controller. For this case, it is possible to conclude that the point-heading model is a reasonable simplification for the optimization problem.

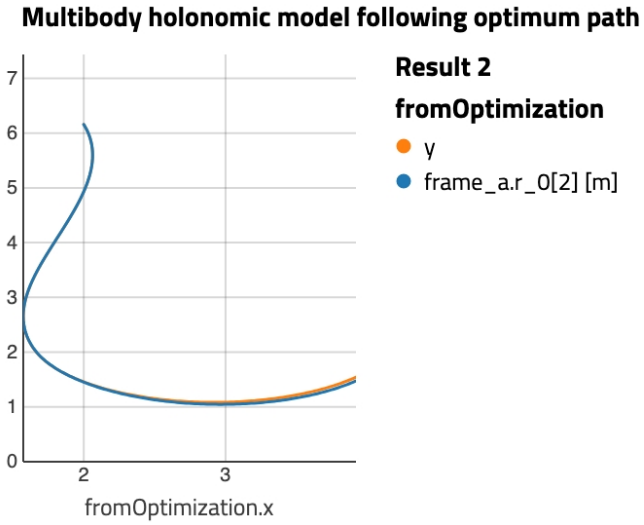

Figure 9. Multibody drive model following optimum path

4 Hybrid Approach

The dynamic optimization solution, combined with multibody path following verification, yields good results. Nevertheless, the static approach proved to be much faster - thanks to the pre-computation of the C-Space. Naturally, the next step in this research is thus to combine both approaches, to get an improved speed with respect to the dynamic optimization solution while conserving its accuracy.

The benefit of defining the environment in a full fledge programming language are multiple. Especially, the environment can be much more complex and programmatically scripted from existing hospital plans. And the C-Space can be easily precomputed with the desired discretization. However, such a discretization would introduce discontinuities, which are not optimization-friendly.

Here, the decision was taken to include the C-Space as part of the cost function (see Figure 10), instead of having it as constraints (as previously in the dynamic optimization implementation). The C-Space is imported into the Optimica model as a table with the three coordinates as inputs - (x, y, phi) - and output an associated cost. The cost is extremely high if the input result in a collision, moderately high if the collision is near and zero if the desired margin is ensured. This cost decrease is made continuous and the table is configured to have a smooth interpolation - making the C-Space optimization friendly.

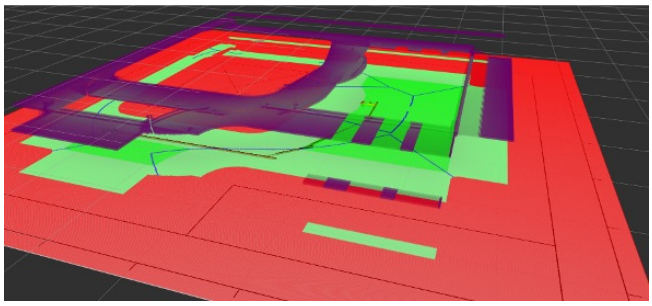

Figure 10. C-Space as a cost "heat map"

This solution also allows for an easy enhancement of the C-Space - e.g. leverage semantic knowledge of the environment to keep a larger distance from people than from fixed objects.

Figure 11 shows two results of the same scenario, with different C-Space costs. The yellow path ensures the desired margin on the persons and finds an optimum that reduces the total length of the path. The green path includes additional costs for the persons and thus leads to a longer path as optimum, with increase safety for the personal. (It is worth noting that a different cost has been applied to the chair - represented in blue -, and thus the green path is nearer to the chair than to the personal.)

As expected, dynamic optimization converges much faster with a good initial trajectory (Delbecq et al. 2021). In this case, it is trivial to provide the one found by running the static approach - which might not satisfy all motion constraints and yet ensure collision-avoidance.

While the initial development of this approach was not trivial, the results are very satisfying in terms both of speed and accuracy. The automation of the environment import, via the C-Space cost table, allows for easy scenario generation and thus increases the representativeness of this solution.

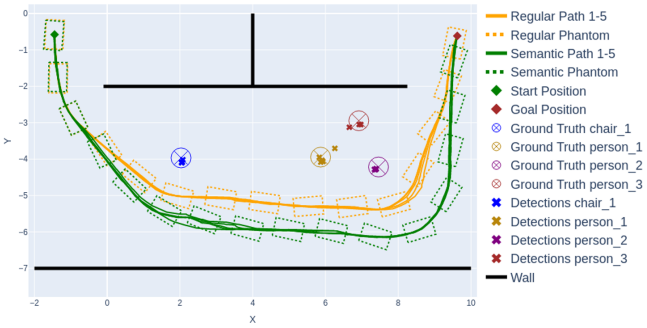

Figure 11. Semantic path planning / social path planning

5 Conclusion and Perspectives

Developing a fast and accurate path planning with collision avoidance is mandatory for automation of robotic systems. This paper presented three different approaches.

1. The static approach proved to be very fast, over a full map of a hospital floor, and yet did not ensure that path found could necessarily be achieved by a non-holonomic robot.

2. The dynamic optimization solution showed achievable trajectories, for simplified scenarios, while requiring much higher convergence times.

3. The hybrid approach showed the best trade-off between accuracy, speed, and flexibility.

As of now, only the static approach has been validated on a real robotic system. Implementing the hybrid solution - relying on dynamic optimization - on the embedded hardware is a next step to this work. This might not be trivial, and a first proof of concept might rely on IoT communication protocols (such as MQTT or OPC UA) to communicate with Modelon Impact cloud software.

Acknowledgements

The first version of the dynamic optimization and multibody models, as well as the associated web application, presented in Section 3 were developed in the scope of a paid project with Modelon AB. The authors would like to thank especially Peter Sundström for his great contributions to this project.

Prototypical Control for the Digital Twin of Aircraft Environmental Control System

Corentin Lepais[1] Dirk Zimmer[1]

[1]German Aerospace Center, Germany, {corentin.lepais,dirk.zimmer}@dlr.de

Abstract

A digital twin of the overall aircraft Environmental Control System is being developed as part of TheMa4HERA, a large European research initiative. It shall support verification and validation activities by virtually demonstrating the behavior of the complete system in various conditions. To this end, a prototypical control scheme needs to be developed so that a dynamic simulation through complete flight missions is enabled. The prototypical control scheme is tuned using a simplified version of the Digital Twin which focuses on robustness and fast computation time, while making it robust enough to be stable when used with the high-fidelity Digital Twin. An already stable and working controller for simulating the detailed Digital Twin, provides a significant gain of time, allowing for immediate preliminary results on both steady-state and transient system behaviors. This paper describes the base model of the Digital Twin and the methodology used to design the prototypical control architecture.

Keywords: Digital Twin, Modelica, Environmental Control System, Prototypical Control

1 Introduction

Inside an aircraft, the Environmental Control System (ECS) controls temperature, pressure, humidity and fresh air supply of the pressurized areas of the fuselage (Sielemann et al. 2007). Conventionally, this system uses bleed air from the engine as a source of fresh air. Therefore, the engines act as compressors for the cabin, and excess energy can be used in an air cycle machine to cool the air before distributing it to the fuselage. Consequently, ECS increases engine fuel consumption and hence, greenhouse gas emissions. To reduce these emissions, a number of research projects are looking at hybrid, hydrogen-powered or sustainable-fuel aircraft. These new aircraft concepts thus require innovative ECS architectures to replace the traditional bleed air-driven systems.

As part of the European Clean Aviation project TheMa4HERA, the German Aerospace Center (DLR) is developing a Modelica-based Digital Twin of the ECS for a hybrid electrical regional aircraft. Modelica is an object-oriented modeling language (P. Fritzson 2014) and has already been successfully used in the creation of digital twins (Delussu et al. 2022) (Peter Fritzson 2021) (Magargle et al. 2017). The aim of this model is to serve as a virtual test bench for evaluating different ECS architectures throughout a complete gate-to-gate mission and under different environmental conditions (standard, hot or cold day, high or low ambient humidity) and to support the verification and validation process by demonstrating the behavior of the complete ECS architecture in a representative virtual environment. To guarantee the validity of the results, high-fidelity models from each component of the Digital Twin are built by the different partners inside the project and validated with dedicated hardware tests. Then, they are integrated as Functional Mock-up Unit (FMU) in the simulation framework built by DLR using the Thermofluid Stream Library (TFS) (Zimmer 2020), to form the complete Digital Twin. Inside this framework, components are defined as replaceable to be able to easily switch between the robust but simple versions and the high-fidelity ones once they are available. The integration of FMU follows a new method based on a control-like approach described in (Gebhart and Lepais 2025). In this method, FMU outputs, such as a mass flow rate, are treated as setpoint signals used to control the actuator models, such as a compressor, from the TFS library. With this approach, one can integrate FMUs inside a Modelica library framework without decreasing the robustness of the overall model, especially at initialisation. Finally, the Digital Twin is simulated for complete gate-to-gate mission under different environmental conditions. This combination of hardware tests and virtual simulations allows to test and compare different ECS architectures and to evaluate their performance at aircraft level.

In order to carry out these simulations in a realistic way, a prototypical control must be designed to guarantee the respect of various mission setpoints, such as temperature and pressure inside the cabin. This prototypical control must be as robust as possible in order to accommodate various simulation conditions and ECS models of varying fidelity levels. The robustness is particularly crucial since the controller design is carried out without high-fidelity models, relying solely on a simplified version of the Digital Twin that prioritizes computational robustness and fast simulation times. Both robust and high-fidelity models share the same interface, enabling the design of a common control architecture but exhibit different dynamic behaviors, such as response time or damping. The goal of this prototypical control is not to optimize performances with the detailed models while tuning it with the simpler

ones, but to ensure it can be directly applied with the high-fidelity models in order to test their integration inside the overall Digital Twin and get preliminary results on both steady-state and transient behaviors.

The Digital Twin framework with robust models, detailed in section 2, includes all necessary components for running a complete mission, such as an atmospheric environment model for outer temperature, pressure and humidity, a mission profile block to define mission-related inputs, such as aircraft altitude, speed and controller setpoints. It also defines the interfaces of the different components and how they exchange information in the Digital Twin. In this regard, the Modelica language proves to be highly valuable because it enables the creation of a common interface for a given class of models which makes the exchange of one model by another version very simple and easy. The prototypical control scheme is designed around this common interface definition to ensure compatibility with both the base and high-fidelity versions of the Digital Twin, as shown in section 3. Finally, section 4 presents the simulation results of the base Digital Twin and provides a comparative analysis of two ECS pack architectures, both simulated using the same prototypical control to demonstrate its robustness.

2 Digital Twin

This section outlines the architecture of the Environmental Control System, providing an overview of the entire system. It describes also the objectives of the control architecture, detailing the associated requirements and the various actuators available inside the system.

2.1 Presentation of the model

The open-source Modelica library DLR Thermofluid Stream (TFS) is used as the main modelling library to develop the Digital Twin. This library enables fast and robust modeling of complex thermofluid architectures (Zimmer 2020; Zimmer, Meißner, and Weber 2022), and therefore aligns with the intended goal for the base version of the Digital Twin. The development is done using Dymola 2022x, since it is focus on Modelica development and supports the import and export of Model Exchange and Co-simulation FMUs 2.0. The overall model describes the Environmental Control System of a future regional hybrid electric aircraft, including two ECS packs, a model of the pressurized areas of the fuselage, one outflow valve (OFV) and the ambient environment. An overview of its architecture is available in this paper (Gebhart and Lepais 2025) and the top-level view in Modelica is shown in Figure 1.

ECS packs are used to supply fresh air to the crew and passengers, to control the temperature of the cabin and cockpit and to cool down the avionic bay. The reference architecture consists of an electric cabin compressor connected to the air cycle machine (ACM) and is shown in Figure 2. It is adapted from (Bender 2018) which describes a 3-wheel bootstrap cycle that uses bleed air from the engines as a source of fresh air for the cabin. Since the goal is to model a bleedless aircraft, the pack has been electrified and the bleed air is replaced by fresh air from the outside compressed using an electric cabin compressor. The other modification concerns the ram air fan which is not connected to the turbine anymore, as it is the case in the 3-wheel bootstrap cycle architecture, but to an electric motor in order to be able to fully control the ram air mass flow inside the ram air channel, especially on ground. After being compressed by the electric compressor, fresh air is cooled down against the ram air flow before entering the conventional ACM itself. At this point, part of the air flow is separated and bypassed through the Temperature Control Valve (TCV). The remaining part is compressed a second time, cooled down against the ram air channel and expanded inside the turbine to a sufficient pressure level. Before being expanded, air passes through a water extractor to remove the excess humidity. This dehumidification process, called high-pressure dehumidification, is very important on ground to prevent an excess of humidity inside the cabin and ice at the outlet of the turbine. Finally, air from the turbine is mixed with the separated air from the TCV to reach the correct temperature before leaving the ECS pack. As in today's commercial aircraft, the model includes two ECS packs for the sake of redundancy, contained in the block *environmentalControlSystem* in Figure 1. Compressors, turbine and heat exchangers models are directly taken from the TFS library. Their sizing parameters (e.g. reference mass flow rate, heat exchange coefficient) have been defined according to the project requirements and by manual testing to ensure sufficient cooling in the all conditions. Therefore, these components do not represent existing ones.

The fuselage is a generic model of air circulation between the different pressurized areas (cabin, cockpit, avionic bay and cargo bay) and through systems strongly related to air circulation (mixer, recirculation fans, outflow valve). Its implementation in Modelica is shown in Figure 3. Thermal loads, such as passengers' heat, lights and electric devices as well as heat exchanges inside each area are also part of the model, but there is no leakage to the outside. Certain thermal loads such as battery, fuel cell, or power electronics (converters, ...) are not taken into account because they have their own cooling system. Fresh air from both ECS packs enters the fuselage on the left, is mixed with recirculated air inside the mixer and afterwards distributed to the cabin and the cockpit. Air from the cabin goes directly to the cargo bay while air from the cockpit passes through the avionic bay before entering in the cargo bay. At this stage, air is warmer and more humid than fresh air. A fraction of this air leaves the fuselage by the right to be expelled through the outflow valve to maintain the correct pressure inside the pressurized areas while the rest is fed back to the mixer by the recirculation fans. Inside the cabin and the cockpit, passengers and crew members are modeled by combination of a sink and a source, representing respectively the inhalation of cabin air and the exhalation of saturated, warmer air. With this

DOI 10.3384/ecp21881

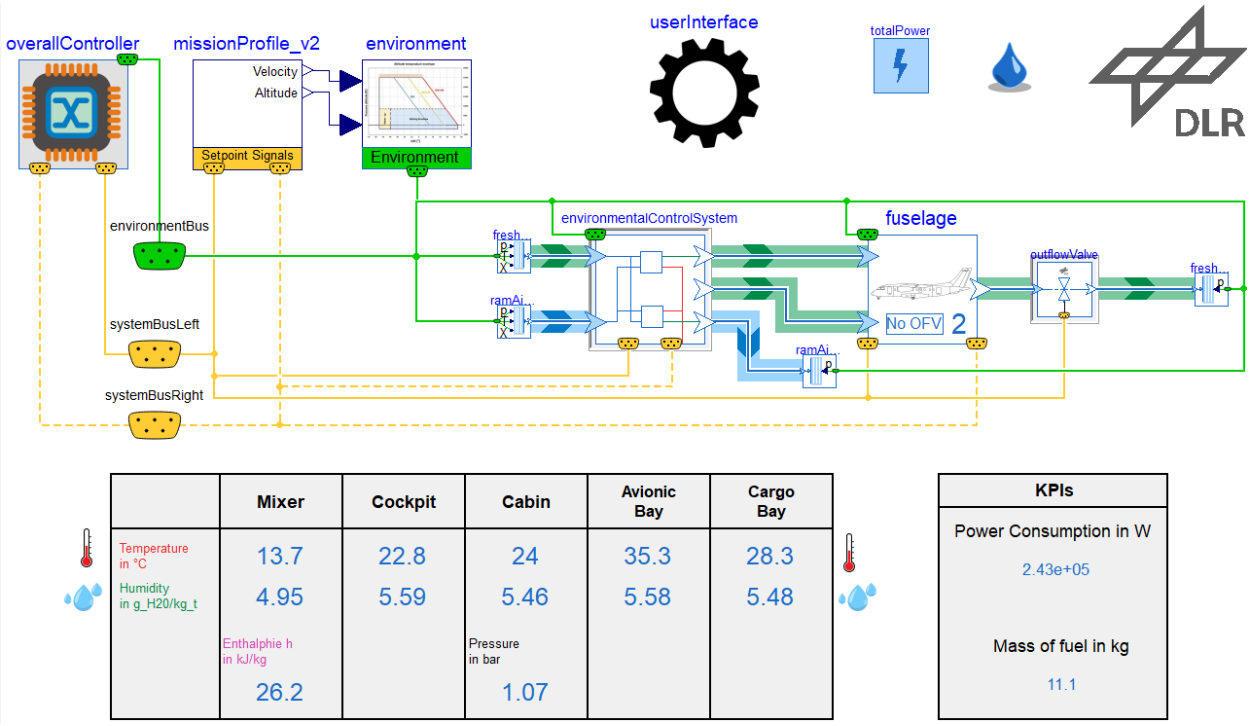

Figure 1. Digital Twin of the Environmental Control System

approach, the additional humidity brought by the passengers when breathing can be taken into account. Additionally, a heat flow source accounts for the body's heat. Each passenger is assumed to breathe at a constant volume flow rate.

The last part of the Digital Twin is the mission and environment model. It computes the temperature, pressure and mass fraction of water outside the aircraft for a given altitude profile and ground conditions, according to the International Standard Atmosphere (ISA). It also models the amount of solar radiations, as a linear function between defined ground and cruise levels. Solar radiations are used to compute the heat transfer through the windows and the fuselage of the aircraft.

This Digital Twin can be simulated for two different mission cases:

- Normal case: gate-to-gate mission with both ECS packs working
- Failure case: gate-to-gate mission with only one ECS pack working.

As described in (Gebhart and Lepais 2025), 3 typical ground conditions can be simulated:

- Standard day (STD): temperature of 15°C (288K) – 100% relative humidity
- Hot day (HD): temperature of 40°C (313K) – 50% relative humidity
- Cold day (CD): temperature of -25°C (248K) – 100% relative humidity

The "Hot day" case is the most challenging case for the design of the ECS pack and the control architecture because the highest amount of cooling power is needed.

This model is an ideal model in many different aspects. All variables can be measured and all sensors are ideal. Hence, there is neither noise nor any transport delay from the sensors or in the actuators command signals.

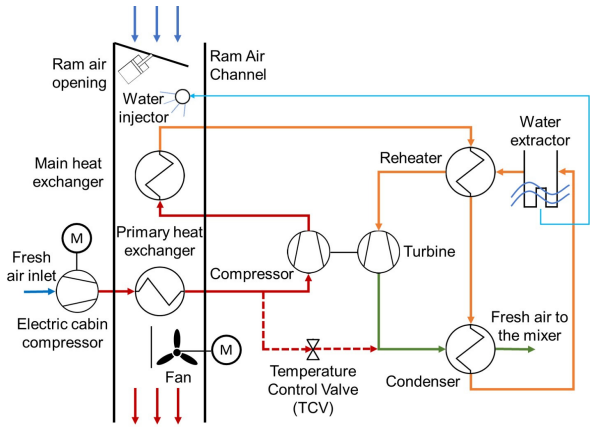

Figure 2. ECS pack architecture

2.2 Control requirements

The control requirements are various. Concerning the environmental conditions inside the cabin, the following requirements are defined:

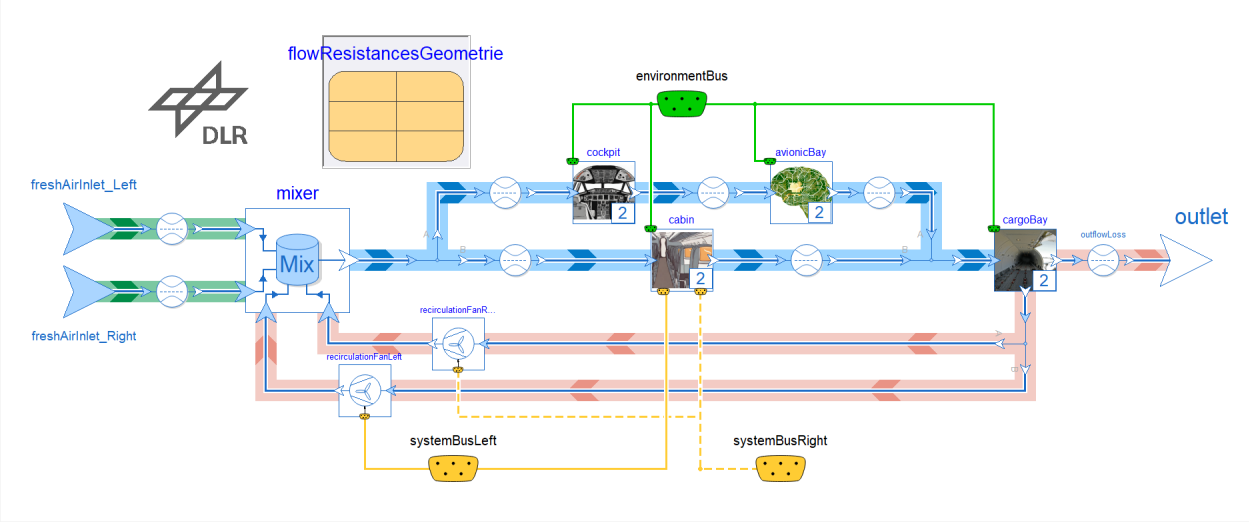

Figure 3. Fuselage architecture

- Temperature inside the cabin: in the certification specification and acceptable means of compliance 25 (CS-25), EASA defines all the constraints concerning cabin heating and ventilation for a cabin temperature equals to 24°C (297K) (European Union Aviation Safety Agency 2022).

- Pressure inside the cabin: a pressurization curve defines the cabin altitude depending on the aircraft altitude. The cabin altitude is converted into cabin pressure using the ISA model. The resulting cabin pressure curve is shown in Section 4.

- Cabin volume flow: the volume flow of air entering the cabin must be kept constant at a certain level to ensure a correct ventilation of the cabin. In today's aircraft, the mixing ratio between fresh air and recirculated is around 50% (Bagshaw and Illig 2019), which gives a volume flow of 0.75m³/s

In the current state of the model, only the cabin environment is controlled that is why there are no requirements concerning the other pressurized areas.

There are two more constraints for the ECS packs:

- Fresh air mass flow: EASA CS-25 defines a minimum amount of fresh air per person to be provided by both ECS packs in normal operation: 0.25 kg/min/person (0.55 lb/min/person)(European Union Aviation Safety Agency 2022). The aircraft transports 80 passengers, 2 crew members and 2 pilots. An additional 20% mass flow of fresh air is also considered to meet additional cooling requirements. It leads to a total fresh air mass flow in normal operation of 0.42kg/s, i.e. 0.21kg/s per ECS pack. In case of failure of one ECS pack, the minimum fresh air flow is decreased to 0.182 kg/min/person (0.40 lb/min/person). In this case, no additional fresh air is considered, leading to a total fresh air mass flow in case of failure of 0.255 kg/s.

- Compressor temperature: this requirement is only used to control the ECS packs. It defines the maximum possible temperature at the outlet of the compressor mechanically connected to the turbine. This temperature will also influence the cabin temperature. Thus, the setpoint value could be the output of a controller that takes as input the cabin temperature error and the flight profile. But this would make the prototypical control scheme more complex, which is not the aim of this first implementation. Therefore, a constant value is considered for the compressor temperature setpoint. The chosen value is 180°C (453K), as done in (Bender 2018), to prevent using too heavy and expensive compressors.

A last constraint is the humidity level inside the cabin. ECS packs are also used to dehumidify the air and avoid too high humidity levels inside the cabin. Usually, the goal is to keep the relative humidity inside the cabin around 20% (Bagshaw and Illig 2019). On cruise it is not a problem since the absolute humidity outside is very low due to the low temperature, but it can be very different on ground for a hot day, for example. The current architecture of the ECS pack contains a water extractor before the turbine, which removes the excess of water inside the air above saturation. Therefore, the inlet temperature of the water extractor is very important since it will directly influence the amount of water extracted by this component. Unfortunately, the humidity level inside the cabin cannot be directly controlled with the current architecture. Thus, the humidity level is verified afterwards to make sure it stays around this value. If it is not the case, the size of the heat exchangers has to be modified.

A summary of all the values for each requirement is given in Table 1.

DOI
10.3384/ecp21881

Table 1. Target setpoints for the control architecture

Requirements	*Normal Case*	*Failure Case*
Cabin temperature	24°C	24°C
Cabin pressure	See Figure 6	See Figure 6
Cabin volume flow	0.75m³/s	0.75m³/s
Fresh air mass flow	0.42kg/s	0.25kg/s
Maximum Compressor outlet temperatures (x2)	180°C	180°C

2.3 Actuators and controlled variables

All target variables (temperatures, mass flow, volume flow, pressure) can be measured so they will be directly used in the control scheme. There are 11 actuators available in the model. Each ECS pack has 4 actuators inside, as shown in Figure 2: cabin air compressor, Temperature Control Valve (TCV), ram air channel (ram air opening and electrical fan). The ram air channel is considered as one big actuator, even if the flow inside is controlled by both the inlet valve and the electrical fan. The fan comes in addition to the valve to increase the ram air flow if needed once the ram air channel is fully open. It is often the case on ground when the aircraft speed is not sufficient enough to generate a ram air flow. Additionally, there are 2 recirculation fans in the fuselage model, as shown in Figure 3, and one outflow valve. In total, there are 11 actuators and each of these actuators will be connected to a Single Input Single Output (SISO) controller.

Input signals have been normalized between 0 and 1. For valve actuators (TCV, outflow valve and ram air channel opening), the opening command is limited by default between 0, valve fully closed, and 1, valve fully opened. The generic TFS valve model integrates leakage when the valve is fully closed, meaning that there is still a small air flow across the valve. For turbo-actuators (compressor, fan), the rotational speed is taken as input. The reference speed ω_{ref} used in the computation of the pressure ratio is set to 1, therefore normalizing the input speed command between 0 and 1.

3 Control Architecture

This section describes the prototypical control architecture and gives some details about the methodology used to tune the different controllers.

3.1 Control Allocation

To design the control loop, all variables are considered independently. For each variable, a limited PI-Controller with anti-windup is designed. Anti-windup is used in order to guarantee a robust controller when dealing with saturation (Bohn and Atherton 1995). These controllers take the error signal between the setpoint and the current value of the controlled variable and compute the input signal for the actuator. Since only SISO controllers are considered, the control loop for each controlled variables defined in Table 1 can be represented by the generic control loop in Figure 4. The control allocation, i.e. which actuator is used to control which variable, is described in Table 2. The use of the TCV to control the cabin temperature and of the ram air opening to control the compressor outlet temperature are derived from (Bender 2018).

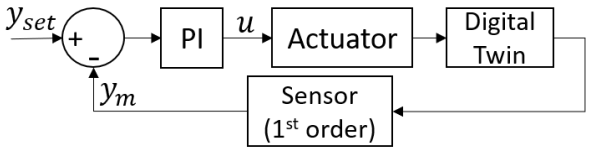

Figure 4. Generic control loop for one variable

For the cabin temperature, there are 2 control loops, one for each TCV. It only happens that both loops are identical since there is only one cabin and therefore one setpoint and one sensor signal. It is the same for the cabin volume flow with the recirculation fans.

3.2 Tuning of the different controllers

3.2.1 Limited PI-Controller with anti-windup for the fresh air mass flow

This controller computes a speed command between 0 and 1 for the electric cabin compressor inside the ECS pack, which is used to regulate the mass flow of fresh air. It has been tuned using a simple test model. In this test model, the fresh air mass flow setpoint follows a step between 0.1kg/s (first value to initialise and start the simulation) and 0.21 kg/s (setpoint of the complete model in normal operation). All other actuators inside the ECS pack (TCV, ram air fan, ram air opening) have constant inputs. To tune the controller, only a P-Controller was considered at the beginning. The gain was changed until the response approached the setpoint. But a steady-state error was still present and the controller output reached the limits. Then, the integrator was added and tuned in order to reach the setpoint value with only a small overshoot and without oscillations afterwards. Finally, the proportional gain was decreased to keep the controller output between the boundaries and avoid saturation, but without decreasing too much the response time. Anti-windup uses the default values of the Modelica limPID model.

3.2.2 Limited PI-Controller with anti-windup for the cabin volume flow

This controller computes a speed command for the recirculation fan between 0 and 1. The tuning of this controller follows the same process as described above. A simple test model including the recirculation fan and the controller, connected to a volume inside a loop, has been used for the tuning. The controller is used to control the speed of the recirculation fan in order to set a given volume flow in the loop. The setpoint for the volume flow is a step between 0.25m³/s and 0.75m³/s. The method de-

Table 2. Target setpoints for the control architecture

Variable	y_{set}	y_m	*Actuator*	u
Cabin temperature	T^{set}_{cabin}	T_{cabin}	TCV (x2)	Valves opening
Cabin pressure	p^{set}_{cabin}	p_{cabin}	Outflow valve	Valve opening
Cabin volume flow	$\dot{V}^{set}_{cabin}$	$\dot{V}_{cabin}$	Recirculation fans (x2)	Fan speed
ECS pack left fresh air mass flow	$\dot{m}^{set}_{left}$	$\dot{m}_{left}$	Cabin compressor left	Compressor speed
ECS pack right fresh air mass flow	$\dot{m}^{set}_{right}$	$\dot{m}_{right}$	Cabin compressor right	Compressor Speed
Maximum compressor outlet temperature left	T^{set}_{comp}	$T_{comp,left}$	Ram air channel left	Valve opening, Fan speed
Maximum compressor outlet temperature right	T^{set}_{comp}	$T_{comp,right}$	Ram air channel right	Valve opening, Fan speed

scribed above is also applied to tune the controller, with the goal to have a response time as small as possible without oscillations or significant overshoot.

3.2.3 Limited PI-Controller with anti-windup for the cabin pressure

Concerning the cabin pressure, the controller to be tuned computes the input signal of the outflow valve (0 valve fully closed - 1 valve fully opened). The test model used for the tuning is very simple and consists of a volume with a constant inlet mass flow. The outflow valve is placed at the outlet of the volume before the sink and is used to regulate the pressure inside the volume. The setpoint for the pressure is not a step but a trapezoid profile reproducing approximately the cabin pressure profile during a mission. The method used to tune the controller stays the same. The controller was tuned to be as fast as possible without creating too much overshoot in order to limit as much as possible drastic pressure changes in a short amount of time.

3.2.4 Limited PI-Controllers with anti-windup for the cabin temperature & compressor temperature

The control loop for the maximum compressor outlet temperature is distinct from the other loops. In this case, the ram air channel is treated as a single actuator, controlled by a SISO PI-Controller. However, two command signals are required: one for the valve opening and another for the fan. The fan operates in tandem with the valve to increase the mass flow when necessary. Since the control signals for both actuators are normalized between 0 and 1, the PI-Controller computes the sum of these two command signals, resulting in a combined signal ranging from 0 to 2. If this sum exceeds 1, the valve opening is set to 1, and the fan speed is adjusted to the remaining value. If the sum is less than or equal to 1, only the valve is opened, and the fan speed remains at 0. This command allocation strategy is made possible by the normalized actuator command signals, enabling the use of a SISO controller to manage two actuators simultaneously.

The method used to tune the two controllers differs from the one mentioned before. For the previous controllers, it was possible to use simple test models to tune them because the cabin pressure, the cabin volume flow and the mass flow of fresh air provided by one ECS pack behaves independently. To control the pressure, the outflow valve controller regulates only the amount of air expelled to the outside and does not need to know the exact mass flow of fresh air supplied by the ECS packs or the exact volume flow inside the cabin. In the test model used for the tuning, it was therefore enough to define a constant mass flow at the inlet of the volume. However, it doesn't work for the cabin and compressor temperatures. The cabin temperature is regulated by changing the pack outlet temperature, but this outlet temperature is strongly linked to the outlet mass flow of the pack, to the recirculation flow and also to the mass flow inside the ram air channel. The choice of a constant temperature setpoint for the compressor outlet temperature was also a way to split these two controlled variables.

Therefore, the complete Digital Twin model has been used for the tuning and, more precisely, a linear version of the model. Linearization has been carried out using the linear analysis tool from Modelica. The TCVs and the ram air openings were set to constant input values and the simulation was run on hot day on ground, since it is the most challenging case, until reaching steady-state (correct pressure and volume flow inside the cabin, correct outlet mass flow from both ECS packs and all other variables constant or at least stabilized). Then, the model was linearized around this steady-state point. Inputs were the TCV command signal and the ram air opening and outputs were the cabin and compressors outlet temperatures. This linear model was then imported in Simulink and both controllers were tuned using Simulink PID Tuner App. During this tuning, robustness was an important aspect so the gain and phase margins have been maximised. The response time of the cabin temperature was chosen to be as fast as possible. To finish, the coefficients of the Simulink PID were translated into the Modelica limPID to finally obtain the

DOI

last two controllers.

4 Results

This section starts by showing some simulation results obtained when simulating the base version of the Digital Twin throughout a complete gate-to-gate mission using the prototypical control architecture. In a second time, the ECS pack model is replaced by a new version to mimic the exchange of the simple model by the high-fidelity one. The new model is again simulated on a complete mission, demonstrating the stability of the controllers with a different model and showing the kind of comparison that can be performed with the Digital Twin.

4.1 Simulation of the base version of the Digital Twin

The Digital Twin is simulated by considering a unique gate-to-gate mission and the 3 environmental conditions defined in section 2 (standard, hot and cold day). The mission is defined by an altitude profile and a speed profile, shown in (Gebhart and Lepais 2025). Initially, the aircraft is stationary on ground, at sea level (0m), to simulate the passenger boarding phase. After the taxi phase and take-off, the aircraft climbs at 7620m and progressively reaches its cruise speed (154 m/s). The cruise phase has a duration of 24 minutes. After the descent, the aircraft lands at sea level (0m) and taxis to the boarding gate. Once at the boarding gate, the mission is finished that is why there is no stationary phase at the end.

The results display all the controlled variables outlined in Table 1, with the exception of the compressor outlet temperature for the right ECS pack. Since both packs and their associated controllers are identical, their results are identical as well. Therefore, only the compressor outlet temperature for the left ECS pack is presented in Figure 9. The prototypical control architecture is successful on standard and hot days. Indeed, Figure 5 to Figure 9 show that all controlled variables reach their target setpoint. Concerning the compressor outlet temperature shown in Figure 9, the goal of the control loop is mainly to prevent reaching a too high temperature, so a lower steady-state temperature is not really a problem.

On the other hand, on cold day the temperature inside the cabin is too low, as shown in Figure 5. The problem doesn't come from the controllers but from the ECS pack architecture itself. Indeed, in Figure 9, the compressor temperature on cold day is also very low compared to standard and hot days. However, this temperature is one of the hottest one inside the ECS pack. Therefore, it can be inferred that the ECS pack simply cannot heat the air sufficiently to achieve a correct temperature inside the cabin and another device is needed in this case, for example an electric heater. This behavior is directly linked to the decision of designing a bleedless ECS pack. In conventional bleed packs, the bleed air comes directly from the engine at high temperature and therefore always needs to be cooled, even on cold days.

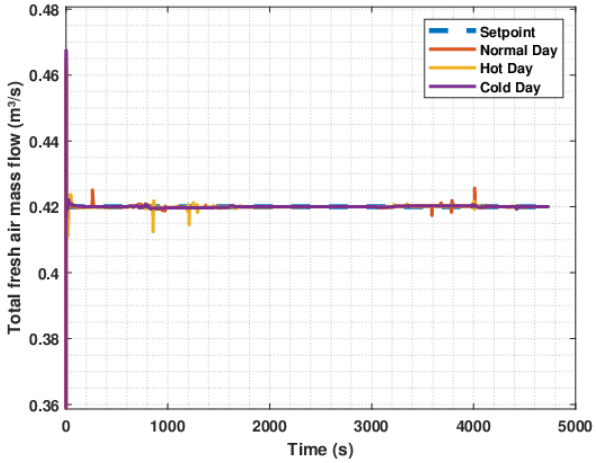

Figure 8. Total mass flow of fresh air provided by the ECS for a gate-to-gate mission with 3 different environmental conditions

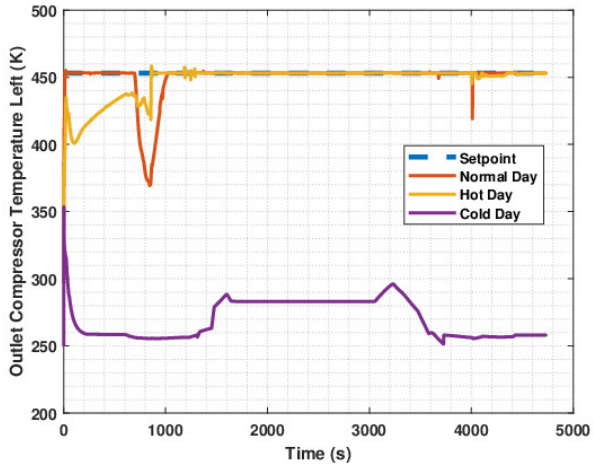

Figure 9. Left compressor outlet temperature for a gate-to-gate mission with 3 different environmental conditions

4.2 Comparison with a second ECS pack architecture

Now that the prototypical controller has been validated, the current ECS pack architecture is replaced by a modified version of a 4-wheel bootstrap cycle, described in (Sielemann et al. 2007) and (Bender 2018), to mimic what would happen when replacing the base ECS pack by a high-fidelity FMU. The conventional 4-wheel bootstrap cycle is based on the 3-wheel bootstrap cycle and adds a second turbine at the outlet of the pack, after the condenser. One of the goals of this architecture is to avoid the problem of icing at the outlet of the first turbine. The ram air fan is still driven by an electric motor. Bypassed air from the TCV is now injected at the outlet of the second turbine.

The results of the simulation with this new architecture are shown in Figure 10, Figure 11 and Figure 12. Since only the ECS packs have been changed, the focus is given on the new cabin temperature and compressor temperature. Results are only shown for standard and hot days since the new pack does not include neither any heating component.

Figure 10 shows the temperature difference inside the cabin between the new and the reference architectures ($\Delta T_{cab} = T_{cab}^{new} - T_{cab}^{ref}$). The difference is small on hot day (maximum 0.2K), but is bigger on standard day (maximum 0.8K) with oscillations during the climbing phase (at time = 1000s). When comparing with Figure 5, there are also oscillations at time = 1000s on standard day. So the controller generates stronger oscillations with the new architecture, but it is still able to ensure the correct temperature inside the cabin. Table 3 also shows a larger overshoot interval for the cabin temperature with the second ECS pack architecture but the difference is relatively small, around 0.5%. For both ECS packs architecture, the cabin temperature is maintained inside a bandwidth of 3% around the setpoint for the whole mission. Since the robustness is the main criteria, the cabin temperature controller still fulfills its goal.

Table 3. Comparison of the performances of the cabin temperature controller for initial and second ECS pack architectures

	Overshoot (%) $[min; max]$	*Mean Square Error Cabin Temperature*
Initial ECS pack	$[-2.06; 2.84]$	0.0777
Second ECS pack	$[-2.43; 3.06]$	0.1218

Figure 11 shows the temperature difference of the compressor outlet between the new and the reference architectures ($\Delta T_{comp} = T_{comp}^{new} - T_{comp}^{ref}$). On standard day, the biggest temperature difference also happens at time = 1000s and is negative. It means that the compressor outlet temperature of the new architecture is smaller than the compressor outlet temperature of the reference architecture. Since the setpoint for the compressor temperature defines a maximum value and not a target value, this smaller temperature is not an issue. However, at time = 4000s, the compressor outlet temperature of the new architecture is higher (around 20K) than the one of the reference architecture. But in Figure 9, the compressor temperature is lower than the temperature setpoint at time = 4000s on standard day. So, this positive difference does not mean that the compressor temperature is 20K above the temperature setpoint. On hot day, the compressor outlet temperature of the new architecture is always lower or equal to the reference architecture.

As for the other controlled variables (cabin pressure, cabin inlet volume flow, fresh air mass flow) they all reach their target setpoint. Performances may vary (more oscillation for example) but the steady-state behavior is the desired one.

Since the prototypical control is working successfully for both ECS architectures, the Digital Twin can now be

DOI
10.3384/ecp21881

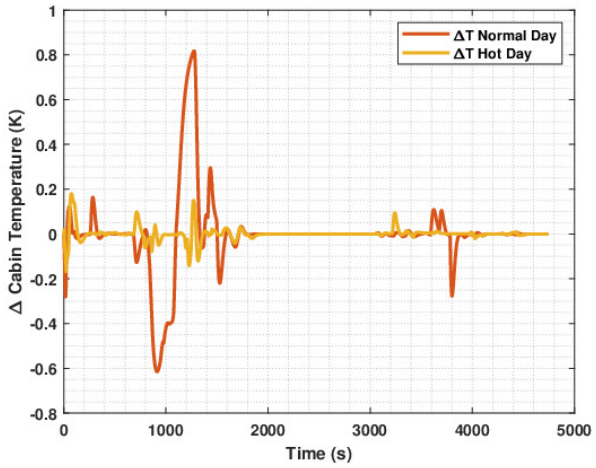

Figure 10. Cabin temperature difference between the new architecture and the reference one

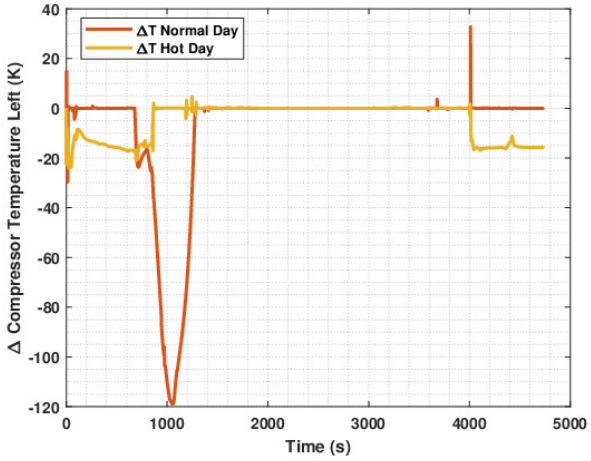

Figure 11. Left compressor outlet temperature difference between the new architecture and the reference one

used to compare them at aircraft level. For example, it can be interesting to compare the total power consumption of both architectures during the flight. Figure 12 shows the difference between the power consumption of the new architecture and the reference one ($\Delta P = P^{new} - P^{ref}$), on standard and hot days. In both cases, the difference is negative. So the new architecture has a lower power consumption for the same prototypical control. By looking more closely at the results, this difference mainly comes from the electric cabin compressors which consume less power, meaning a lower flow resistance to overcome to reach the fresh air mass flow setpoint. Besides, the TCVs are less used in the second architecture. Since, the expansion is done in two steps and air is heated up between the two steps, the temperature at the outlet of the second turbine is higher than the temperature at the outlet of the turbine in the reference architecture. A higher temperature means less hot air needed from the TCV to reach the required pack outlet temperature. A lower mass flow across the TCVs could be the reason of the lower flow resistance and so the lower power consumption from the electric cabin

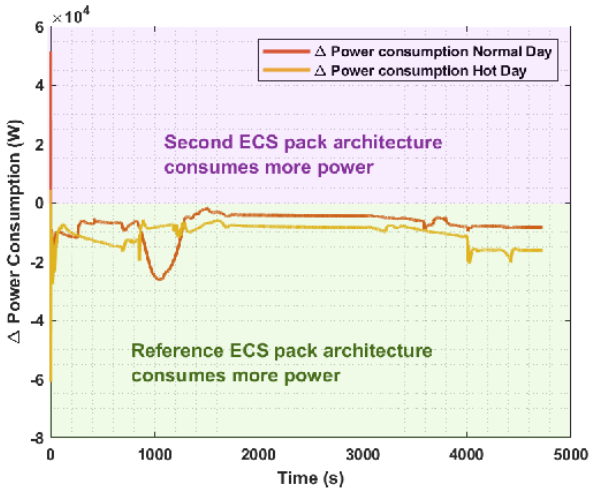

Figure 12. Power consumption difference between the new architecture and the reference one for both standard and hot day

compressors. From a power consumption point of view, the new ECS architecture seems more efficient but power consumption is not the only relevant parameter to design an aircraft. For example, this new ECS will certainly be heavier due to the second turbine. Therefore, the impact of this increased mass on the aircraft should also be taken into account. This short comparison gives an overview of how different architecture can be evaluated at aircraft level using the Digital Twin.

5 CONCLUSIONS

This paper presented the development of a prototypical control for the Digital Twin model of an aircraft environmental control system.

The approach is based on SISO limited PI-Controllers with anti-windup to robustly deal with the saturation of the different actuators, and normalized actuator command signals to ease the transfer of the control authority from one actuator to the other. The normalization is also a good solution to avoid including inside the control architecture the saturation characteristics of specific actuators, which then would require to change the tuning of the controllers each time a characteristic changes. It shows that is possible to obtain a global prototypical control that works for a complete gate-to-gate mission, for different environmental conditions and different ECS pack architectures. Improvements are still needed, especially on cold day, but the problem originates from the ECS pack architecture itself and not from the control architecture.

A comparison with an alternative ECS pack architecture was also conducted. All setpoints were reached without altering the prototypical control, although the transient behavior differed, with more and bigger oscillations observed in the cabin temperature. Nevertheless, the robustness of the controller was successfully tested, although further tests will be needed to confirm the results, especially with FMU models. The new architecture had a

lower power consumption compared to the reference one while applying the same prototypical control, highlighting the type of study that can be carried out with the Digital Twin. This demonstrates the possibility to develop a prototypical control using simple models while ensuring it is robust enough for models with different dynamic behaviors, and therefore saving time on tuning again the controllers when changing the models. The next step would be to test the prototypical control with an actual FMU of a high-fidelity ECS pack model to assess the impact of a more detailed dynamic behavior and of sampling time, particularly if a co-simulation FMU is being used. Furthermore, it would also be interesting to observe the effect of sensor and actuator signal delays, sampling times and noise on the stability of the controller. These factors often reduce the robustness, making it potentially unstable when used on the high-fidelity models.

Once the robustness is confirmed, it could also be interesting to test different controller architectures in order to optimize given parameters such as the energy consumption at aircraft level. It would be interesting to see if it is possible to design a control architecture which would minimize a top-level aircraft indicator, independently of the model used for tuning. For future hybrid electrical aircraft, a lowest possible energy consumption of the Environmental Control System would be very interesting because it could lead to smaller batteries and so significantly reduce the weight of the aircraft. This type of study would also require to validate the Digital Twin results with field data to assess the accuracy of the simulations.

[2]Hitachi Rail GTS Deutschland, Germany

Abstract

This papers reports on activities in the European project MOTIONAL that aims at the development of a digital twin environment which facilitates the modularity, interoperability and composability of complex digital twin assemblies of railway systems. The approach that refers to the Functional Mock-up Interface is justified by a discussion of the comparable activities in industry and in the automotive field compared to particularities in the railway system. The work was initiated by the selection and analysis of nine use cases. An introductory digital twin example illustrates the current implementation status and related aspects, while an outlook presents the integration into the Federated Rail Data Space as the business case and as a vision of the activity.
Keywords: FMI, railways, digital twin

1 Background and Motivation

Europe's Rail Joint Undertaking (EU Rail) established by (Council of European Union, 2021) is the European public-private partnership for rail research and innovation. As described in (Europe's Rail Joint Undertaking, 2022), it aims at

- digitising and greening the railway sector,
- improving its efficiency, amenity, user-friendliness and maintainability,
- supporting the development of a globally competitive European railway industry and
- achieving the Single European Railway Area.

To this end, EU Rail organizes a series of projects[1]. MOTIONAL, the first in this series, inter alia addresses the topic of digitalisation of the railway sector and reach for concepts, models, technologies and methods associated to data, services and digital infrastructur.

The expected output shall be exploited by all EU Rail projects in accessing and exchanging data and in building and executing digital twins. The considered use cases range from virtual certification, automatic train operation to diagnostics and railway asset management originating from other EU Rail projects such as R2DATO[1] or IAM4RAIL[1].

With this background, the digital twin related work in MOTIONAL is specifically focussed on organizing a framework which facilities the **modularity**, **interoperability** and **composability of complex digital twin assemblies**.

After this section on the project background, a short literature review on digital twins and system simulations in railway engineering will be given. This is followed by a step-by-step derivation of the approach taken, which is then illustrated using an introductory digital twin model of specific signalling devices. A more elaborate digital twin model, which is associated to the system architecture in the right hand side of Fig. 1, is being presented separately in an acompanying paper entitled *Collaborative Digital Twin Development for Railway Braking and Traction Applications* at this conference.

2 Related Work

EU Rail mainly emphasizes the expected benefits such as improved safety, availability and lower operational costs in (Europe's Rail Joint Undertaking, 2022), but only roughly specifies the concept as **„ .. a Digital Twin is a virtual representation able to imitate the behaviour of a physical system during the spans of its lifecycle .."**.

It is to the credit of (Sjarov et al., 2020) that they have narrowed down and contextualised the ambiguous, often misunderstood or misused term *digital twin* with the help of their very readable literature research. They conclude their overview on digital twin definitions by what they call "**the smallest common denominator, comprising a real and a virtual world being connected by streams of data and information**." (Singh et al., 2021) as well gives a good overview on characteristics and advantages of digital twins. (Van Der Valk et al., 2022) supplement their paper survey by a qualitative interview study with 15 industry experts. The interested reader may be referred to the long list of references of the three last-mentioned papers in order to find more specific digital twin literature,

The exploitation of the Functional Mock-up Interface (FMI) (Modelica Asssociation Project FMI, 2024) is a

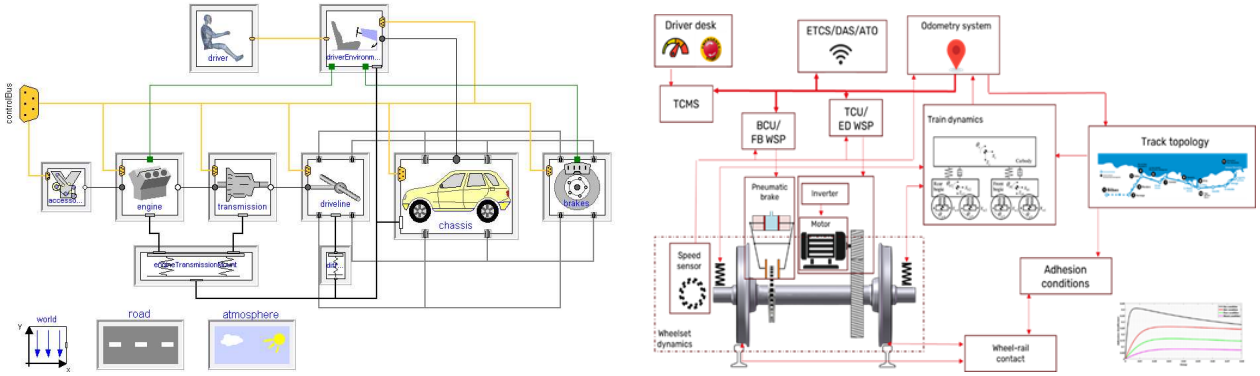

Figure 1. The system architecture of the Vehicle Interfaces Library (Dempsey et al., 2006) on the left compared to an initial architecture proposal in MOTIONAL on the right hand side (courtesy of CAF S.A.).

widespread strategy in order to build up digital twins by assembling individual component models. In fact, this free standard that defines a low-level interface to exchange dynamic models is well suited to organize the simulation of modular multi-domain systems pretty often required in digital twin applications, see e.g. (Wiens et al., 2021).

Although (Golightly et al., 2022) noted a low representation of scientific papers on FMI usage in railways, (Kugu et al., 2023) even used the System Structure and Parametrization standard (Modelica Asssociation Project SSP, 2024), which is layered upon FMI, to present two digital twin use cases from the railway domain. (Kugu et al., 2024) include the set-up and maintenance of digital twins into the Continuous Integration pipeline in order to control their changes and updates process.

The Modelica Railway Dynamics Library (Heckmann et al., 2019) provides the capability to consider vehicle dynamics issues such as traction, comfort and safety in multi-domain engineering tasks on different levels of detail. The library offers a convenient export of portable FMUs that may include railway vehicle particularities such as track joints or wheel-rail contacts. (Heckmann and Streit, 2012) explored the introduction of external infrastructure data given in the open XML-based format (RailML®, 2025) simulating the energy flow in electrical railway networks on which a fleet of railway vehicles is running.

3 Derivation of the Approach

3.1 Comparison to Automotive Activities

For the sake of exemplification of the objectives **modularity**, **interoperability** and **composability**, consider the modeling of a railway vehicle running along the track. This system maybe modularized in subsystems which e.g. represent the track infrastructure, the vehicle dynamics, the traction system, the brakes and so on. In the same manner as the real vehicle system is composed out of integrated subsystem hardware provided by supplying companies, the digital twin of the system is considered to be an assembly of subsystem models as well prepared by the same suppliers. Presumed that the interfaces of each subsystem modul, i.e. its input and output signals, are uniquely specified, the subsystem model of supplier A may be exchanged by the subsystem model of supplier B.

This concept corresponds to a coordinated activity in the automotive field which led to the initial release of the free Modelica Vehicle Interfaces Library (VIL) (Dempsey et al., 2006) in 2006. In fact, Fig. 1 demonstrates the comparability of the former automotive activity with the task considered in this paper by a face to face comparison of exemplary vehicle system architectures. As already indicated by the name, the focus of the VIL was the definition of standard interfaces, which allows for an easy exchange of submodels on brakes, engine, driveline and so on. The component models provided by the VIL only reflect their physical behavior on a very high, simplified level and are assumed to be detailed when actually used in practise. This is an important aspect which is intended to be considered in the context of the modeling of railway digital twins as well.

3.2 Particular Challenges

However, there are number of challenges which appear when the VIL approach is supposed to be transfered into the field of railway digital twins:

- It is a general observation that the modeling of railway vehicles is more complex than for automotive vehicles. It involves more mechanical degrees of freedom, since a train usually consists of more than one car and two-level suspensions are implemented to guarantee both separately, running stability and passenger comfort. In addition, a geometrical track description that is two-times continuously differentiable is required and the very stiff, geometrically and physically non-linear wheel-rail contact is a modeling and simulation challenge on its own, see (Heckmann et al., 2019).

- FMI is a free standard supported by more than 200 different commercial or open modeling tools.

DOI
10.3384/ecp21891

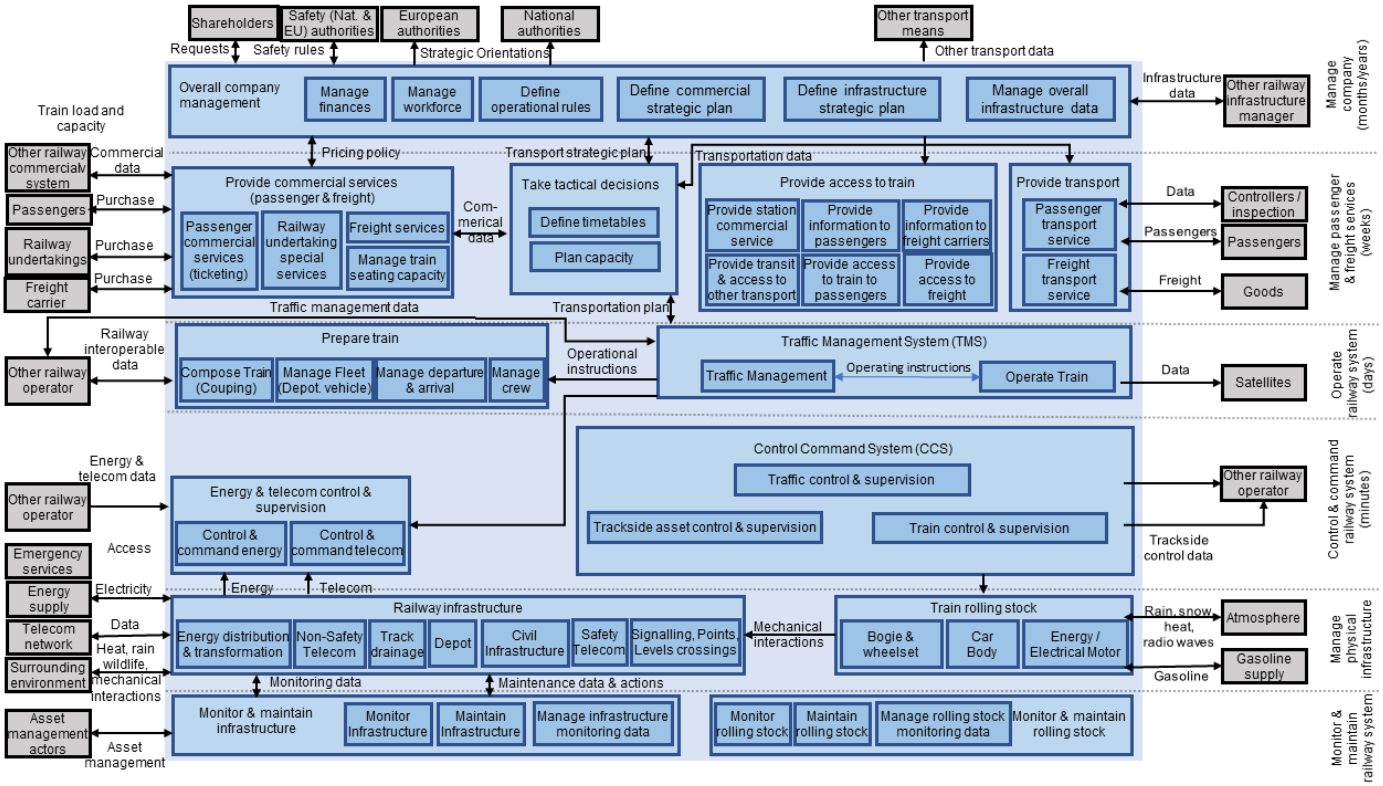

Figure 2. The high level railway system architecture as summarized by (LINX4RAIL, 2022).

Already existing models don't need to be re-implemented for digital twin modeling but simply can be exported as so-called Functional Mock-up Units (FMUs). Since FMI as well considers the export of binaries, the intellectual property on the modeling content also can be protected. The associated stakeholder is more motivated to contribute its submodels and to support the **interoperability** and **composablity** of the digital twin. However as a disadvantage, FMI does not follow object oriented modeling concepts such as inheritance, which e.g. allows for the convenient extension of Modelica connectors or model interfaces of the automotive VIL. So the flexibility to implement different levels of modeling details reflected by associated interfaces is restricted.

- Fig. 2 presents an overview of the general railway system which has been generated in a predecessor project of MOTIONAL (LINX4RAIL, 2022). It is obvious that the railway vehicle architecture exemplified in Fig. 1 only covers a small area of the whole system. Functions such as traffic management, signaling, supervision, energy supply and so on are interrelated to the motion of the vehicle and increase the complexity. Therefore, it is assumed that not one and only but several interrelated modeling architectures are required to depict the whole railway system. This is why, use cases have been selected first in order to develop this architecture landscape step by step.

- There is another conceptual aspect of **modularisation** that appears in the light of Fig. 2: subsystem or component models should be distinguished from each other in such a way that each subsystem model can be provided by a single stakeholder, such as the infrastructure manager, the railway operator or the vehicle and equipment suppliers, etc. This way, the subsystem model reflects the expertise of the associated stakeholder, which in turn determines the content and conditions of the submodel provision.

- The digital twin concept is a very general one. Fig. 3, not at all meant to be exhaustive, illustrates aspects in which digital twins may differ in practise: they may address different phases of the product life cycle, cover specific components only or represent a complex model assembly, consider CAD geometry or take transient behavior into account, just reflect a stationary property or predict dynamic evolutions and so on. This high degree of individuality is a challenge for the endeavour to create a framework for complex digital twins in the railway field.

3.3 Interim Status

The objective of the digital twin activities in MOTIONAL is the development of a digital twin environment which facilities the modularity, interoperability and composability of complex digital twin assemblies originating from the railway system in Fig. 2. The work was initiated in 2023

Figure 3. Aspects in which digital twins may differ in practise according to (Stark et al., 2019)

by collecting and analyzing use cases, shortly summarized by the following list:

- Braking and traction of railway vehicles: Vehicle models such as in Fig. 1 and data from braking experiments are compared to verify and validate the brake system design.
- ERTMS[2] digital twin: On-board units of the train protection system are certified in hardware-in-the-loop laboratories.
- Pre-assessment of automatic train operation scenarios: The ERTMS digital twin environment above is extended for the sake of examination of future automatic train operations.
- Maintenance digital twin based on graph database: Data of past maintenance actions are analyzed in order to optimize maintenance scheduling and execution.
- Failure mode of point machines: The actuators of switches, so-called point machines are monitored for the purpose of optimizing their maintenance.
- Fault detection and diagnosis in the rail infrastructure: Multi-sensor data are fused and analysed in order to explore the AI-usage in infrastructure monitoring.
- Driver cabin HVAC[3] digital twin: HVAC sensor data and environmental conditions are analyzed to schedule maintenance.
- Station Asset Management Digital Twin: BIM[4] data of stations and IoT sensor data are fused.
- Bridge Asset Management Digital Twin: BIM and sensor data of bridges are used to monitor construction.

In parallel, a review of published activities in industry and in the automotive field together with EU Rail internal discussions provided additional ideas, arguments and aspects, which are reported in this section.

The ongoing implementation of the above use cases is stored in a GitLab repository hosted by the EU Rail and accessible by all EU Rail participants. In the long term, making the use case models accessible beyond the EU Rail network is desirable, but this still needs to be agreed by all contributors.

It turned out that the provision of and access to infrastructure data, including track topologies and geometries, signalling equipment, etc., is a prominent interrelation on which many use cases rely. This is therefore addressed in the introductory digital twin example presented in the following section.

As the above discussion and the cautious paper title suggest, the findings explained in this paper are merely the first stage of a longer journey. This point is reflected in the project description by demanding two validated digital twin uses case of Technology Readiness Level 5 (European Commission et al., 2017) for the project outcome until 2026, only. Further stages of this journey are covered in the Outlook section.

4 Introductory Digital Twin Example

4.1 ETCS Eurobalises

In Europe, many different and incompatible train protection systems are currently used by individual European Union (EU) member states. In order to improve interoperability, country-specific protection systems are to be replaced by the European Train Control System (ETCS). An essential part of ETCS are the so-called Eurobalises installed on the track, see Fig. 4 and (Winter, 2009).

An Eurobalise is a standardized electronic beacon system used to communicate vital information to trains. It may be understood as a smart rail road sign that "talks" directly to trains as they pass over it. These small, robust devices are mounted between the railway tracks and contain electronic circuits that transmit data to onboard train systems when a train's antenna passes above them. By default, the ID number and the geographic coordinates of the Balises are transmitted. Furthermore, they can tell a train important things like the maximum safe speed for the upcoming section of track, whether signals ahead are green or red, the distance to the next station, or warnings about track conditions.

[2]ERTMS: European Rail Traffic Management System
[3]HVAC: Heating, Ventilation, Air Conditioning
[4]BIM: Building Information Modeling

DOI 10.3384/ecp21891

Figure 4. ETCS Eurobalise installed on the track see https://en.wikipedia.org/wiki/European_Train_Control_System, CC BY-SA 4.0

This system is crucial for modern train safety and automation, allowing trains to automatically adjust their speed or apply brakes if necessary, while also enabling features like precise positioning and automated train control across different European countries that previously had incompatible railway signaling systems. In the following, this introductory example tackles the monitoring of the Balise installations during daily operation.

4.2 Use Case Description

The use case is intended to compare two different information, one from the real world object, one from the virtual object:

- The real train runs along a given track, receives messages from the Eurobalises which are passed over and logs these messages or even transmits them as a real time data stream.
- The virtual train runs along the same track as the real train and passes over Balises, however uses the track design information in simulation in order to record virtual messages as they are to be expected by design.
- An algorithm compares these two records and issues an alert if a mismatch is observed. This mismatch indicates a malfunction to the railway infrastructure manager, who then is in charge of introducing appropriate measures.

Note, the messages nominated as real world messages above, are still results of a simulation, only. This limitation is due to the current status of the project. It will be brought closer and closer to the later application of the true digital twin as the Technology Readiness Level increases in the course of the project.

4.3 Modeling of the railway infrastructure

When working with digital twins that represent parts of the railway system, the appropriate modeling of the infrastructure is an essential component. However, the modeling requirements differ considerably depending on the specific use case. An incomplete collection of these is listed below:

- For vehicle dynamics simulations, detailed knowledge of both track layout and irregularities is mandatory
- Breaking and traction scenarios require data such as the current track gradient, speed limits and friction conditions between wheel and rail
- Railway dispatchers are dependent on an enhanced description of the railway network. This includes signalling facilities such as Eurobalises already mentioned in Section 4.1

The applications just presented make it clear that many different requirements are imposed on the description of railway infrastructure. Therefore, it is difficult provide one model which covers all scenarios simultaneously. Even if it were possible, the model would be overloaded with extensive data making it unnecessarily complex.

Therefore, it is proposed to provide a basic track model, as already exists in the Railway Dynamics Library (Heckmann et al., 2019). It only provides a rudimentary description of the track layout. The 3D-curve of the track contained in this model consists of B-Splines which are defined by supporting points imported from a track file.

If further demands are put on the description of the infrastructure, a more comprehensive model can be derived from the basic track model through inheritance. An example of this approach is shown in List. 1. The code snippet outlines the *TrackBalises*-model. Note that the corresponding graphical representation is shown in Fig. 5. It extends the features of the basic track model by outputting the ID number of the last crossed Balise based on the current vehicle position.

  connect(s, lookupTable.u);
end TrackBalises;
```

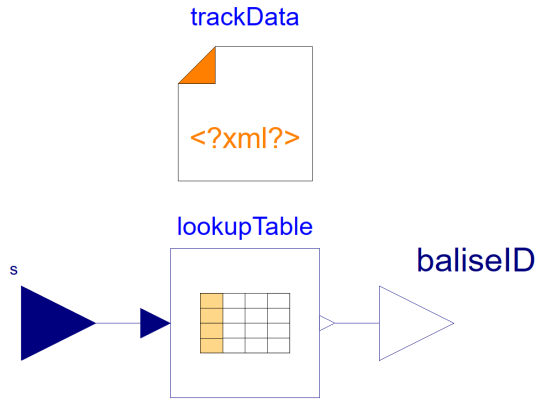

Figure 5. Graphical representation of the *TrackBalises*-model

4.4 Track description

In Section 4.3 a basic track model was introduced that provides a fundamental infrastructure description via supporting points imported from a file. In this paper we focus on a XML-based track description. In practice, however, there are many country-specific formats. It is therefore planned to support a more general approach for future work using ontologies, see (Camarazo et al., 2025).

In the XML-based data format the railway network is described as a graph in which nodes are connected by links. In the following, links are to be considered as track sections. A generic representation of a railway network is presented in Fig. 6.

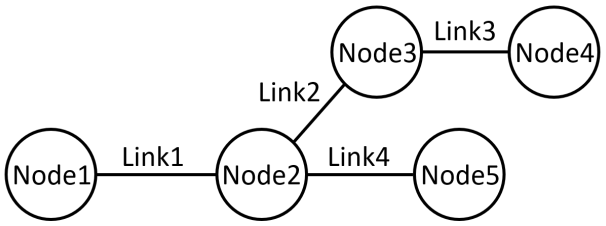

Figure 6. Graph of a generic railway network, which consists of nodes and links

The corresponding textual description of the railway network is shown in List. 2. It contains a 'Link'-element representing a track section, which is identified by the tag 'GlobalId'. Its start and end points are defined by 'FromNodeId' and 'ToNodeId', respectively, which are in turn identifiers of the corresponding 'Node'-elements. Other data included are section length and geographic coordinates of the supporting points which are used for interpolation as already mentioned in Section 4.3.

In addition to the pure track description, the track file contains data on Eurobalises installed on the track. Note that they are referred to in the file with the generalised term 'InformationPoint'. In our case, only data about the ID of the Balise and the distance travelled from the start point of the track section to the Balise are relevant.

The import of supporting points describing the track layout as well as corresponding Balise data is carried out using the ExternData library (Beutlich and Winkler, 2021). The imported data is stored in different arrays for further processing.

Listing 2. Textual description of a generic railway network

4.5 Simulation environment and FMU export

The use case outlined in Section 4.2 shall be supported by the usage of digital twins. The system presented in Fig. 7 is used for this purpose. Note that the simulation environment was created with Simulink (The MathWorks Inc., 2024), however, the individual components are based on the Modelica language and are exported as FMUs for further usage. This was done to emphasise the interoperability of the models used.

The system consists of the following components:

- The signals that come from a *real train* are summarised in one component. While running along a

DOI 10.3384/ecp21891

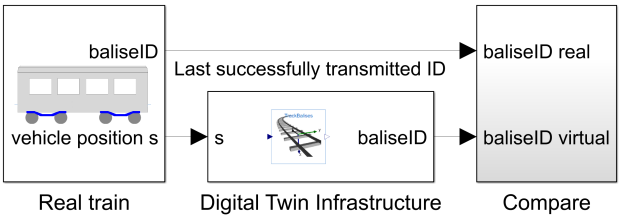

Figure 7. Illustration of the Digital Twin environment for the present use case

given track, the last successfully Balise ID number transmitted to onboard train systems is output. Furthermore, the current train position *s* is issued to the simulation environment. As already mentioned in Section 4.2, the messages nominated as real world messages, are still results of a simulation, only.

- The *TrackBalises*-model introduced in Section 4.3 takes on the role of the *digital twin of the infrastructure*. It takes the real train position signal as input and, based on imported track data as described in Section 4.4, outputs the ID number of the last crossed Balise. After exporting this model as FMU, a string parameter provides the path to a file from which track data is imported. Furthermore, since the XML-file format describes a whole railway network and not just one track, another string parameter has to be provided which represents the identifier of a specific track section. Besides XML-based description, it is currently possible to read track data in *.trm file format as used in Simpack (Dassault Systèmes, 2024).
- The task of the third component is to *compare* the signal from the real train with that of the digital twin. A graphical representation of the preliminary underlying model is presented in Fig. 8. The ID numbers of all Balises are integers. As soon as the difference between the two signals is greater than or equal to 1, it is assumed that the ID numbers do not match.

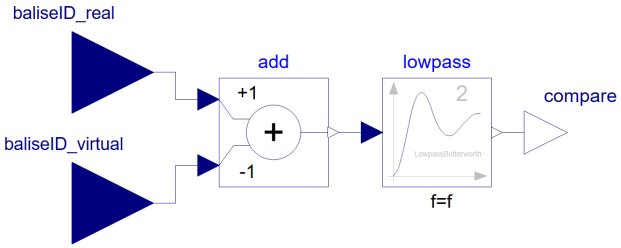

Figure 8. Graphical illustration of the *Compare*-model

The Balise ID numbers as signal outputs of both real train and digital twin come from different sources, but should be identical. As soon as a deviation occurs, this might indicate that a Balise did not transmit any data.

Note that the signals being processed in the *Compare*-model require low pass filtering. This is necessary in order to filter out high-frequency signals that might occur if the train onboard systems and FMUs shown in Fig. 7 use different sampling rates. Furthermore, it is worth to mention that the *Compare*-model presented in Fig. 8 should be considered as initial proposal. Other possible error sources such as inaccurate positioning data or time delays are not taken into account yet.

4.6 Results

An exemplary output generated in the context of the Eurobalise use case is presented in Fig. 9. The current position of the real train is shown in the top plot. The subplots in the centre show the ID number of the last crossed Balise issued by the train onboard system and the digital twin, respectively. Both signals are kept constant until the next Balise is crossed. The bottom plot shows the output of the *Compare*-model. It is clearly visible that there is a mismatch of the recorded Balise ID numbers at track position 5500 m. This indicates that a Balise did not transmit data to the train correctly and therefore should be revised.

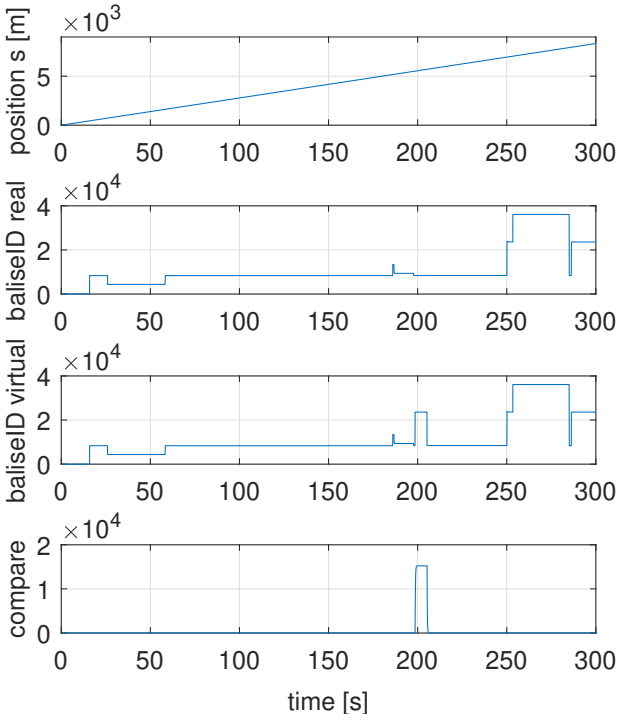

Figure 9. Exemplary history data that shows which Balise was last crossed

To make the comparison presented in Fig. 9 possible, the vehicle position along a specific track section of the digital twin and the actual train must coincide. For this purpose, the first successful transmission between Eurobalise and vehicle can be used for initialization.

The current work is dedicated to the elaboration of the use cases described in Sec. 3.3. Assuming that work can be continued in the next EU Rail funding period, a further improvement in the Technology Readiness Level and the number of validated use cases will certainly be sought.

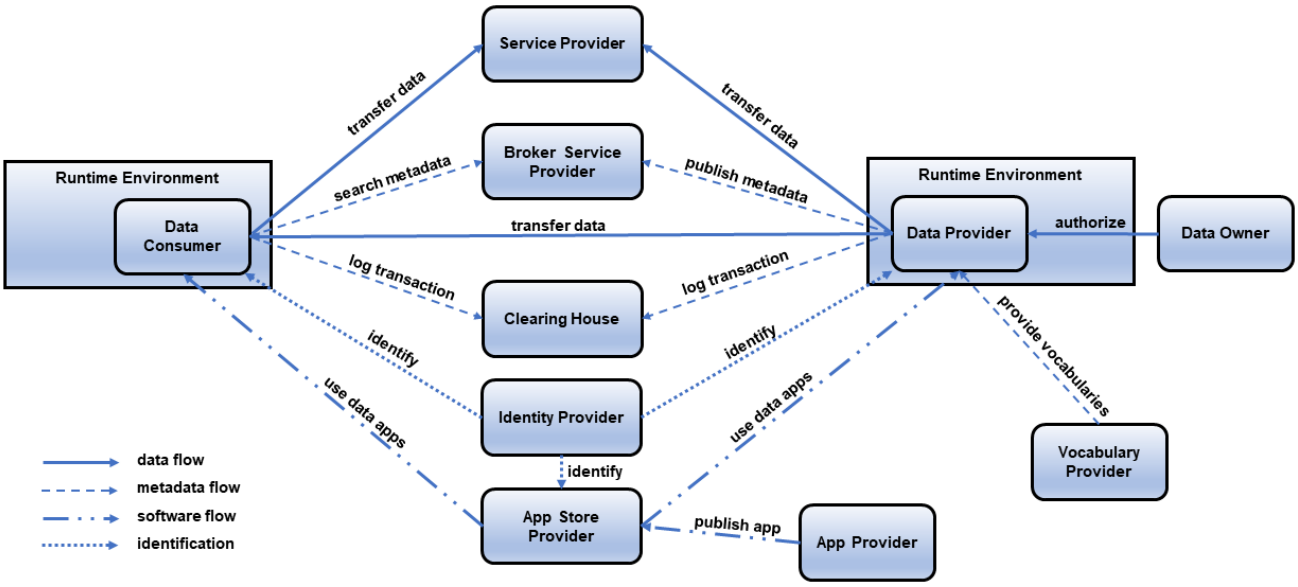

Figure 10. Reference Architecture of the IDS, cp. (Bader et al., 2020)

5 Outlook

As mentioned in Sec. 1, digital data, services and infrastructure are high level objectives of EU Rail. This is why, a parallel activity in MOTIONAL deals with the creation of a Federated Data Space for Rail. Data Spaces based on the Gaia-X[5] principles such as interoperability of data and services, sovereignty over data, security and trust use a concept of data integration without a central data repository. Data remains at its original source and is only exchanged peer-to-peer, if the transfer is explicitly requested and authorised. A data space, formed by the totality of its participants, is a distributed, federated structure with many data providers, consumers and services. The following enumerates, literally quoted from (Kraemer et al., 2023), the expected benefits related to Gaia-X business models:

- Efficiency: data is only exchanged when and to the extent necessary.
- Security: Data is protected from unwanted access.
- Control: Participants can determine exactly what access others have to their data.
- Transparency: Participants are given the necessary knowledge to decide for or against an exchange.
- Quality: Data and services are insured to be of the specified quality.
- Scalability: Required resources can be accessed as needed, quickly and comprehensively.
- Regulatory compliance: The Gaia-X ecosystem is in line with the values and laws of the European Union.

The concept has its main origin in the work of the International Data Space initiative (IDS)[6] (Bader et al., 2020). Fig. 10 presents the reference architecture of the IDS, which also considers the exchange of software tools and algorithms, addressed as applications or apps in Fig. 10.

In our context, the role of a digital twin developer corresponds to the role of an *App Provider* in terms of the IDS. Future digital twin activities in EU Rail will deal with the realization of this concept, which may be interpreted as a future business case for digital twins.

Collaborative Digital Twin Development for Railway Braking and Traction Applications

Gerhard Hippmann[1] Blas Blanco Mula[2]

[1]Institute of Vehicle Concepts, German Aerospace Center (DLR), Germany, gerhard.hippmann@dlr.de
[2]CAF & CAF I+D, Spain, blas.blanco@caf.net

Abstract

The paper presents the collaborative development of a digital twin for railway braking and traction applications as part of the ERJU MOTIONAL project. The project's goal is to enhance the efficiency, user-friendliness, and maintainability of European railways through the application of digital twin concepts across nine distinct use cases. Contributing components are shared in a common library as Functional Mock-up Units (FMUs), enabling the creation of digital twins for various applications.

Specifically, this study focuses on the braking and traction use case for virtual validation purposes. The paper details the vehicle dynamics model, control units, and their interfaces, presenting simulation results under diverse adhesion conditions. Additionally, it highlights the potential benefits of digital twins in optimizing railway operations and monitoring system integrity, ultimately enhancing the reliability and efficiency of railway transportation.

Keywords: FMI, vehicle dynamics, railways, digital twin

1 Introduction

Europe's Rail Joint Undertaking (ERJU) (Europe's Rail Joint Undertaking 2022) aims to improve the European railway sector in a public-private partnership. The work presented in this paper is part of the ERJU MOTIONAL project which addresses digitisation of railways for enhanced efficiency, amenity, user-friendliness and maintainability. For this the concept of digital twins (DTs) is applied in nine different use cases. The basic idea is that the project partners contribute components as Functional Mockup Units (FMUs) (Modelica Asssociation Project FMI 2024) to a library which can be combined to DTs for various applications. General aspects of the DT development in EU rail such as use case portfolio, maturity or technology readiness level of the development towards true digital twins with real life objects, availability and dissemination of the models beyond the project and cybersecurity are presented in (Heckmann, Posseckert, and Adusumalli 2025).

This paper describes the current status of the braking and traction (B&T) use case for virtual validation purposes. The proper operation of railway vehicles during traction and braking under different environmental and topographical conditions is the result of the synchronised work of multiple subsystems with a high level of interconnection. Figure 1 shows a scheme of the different components involved in the B&T operation. Developing DTs for B&T is challenging since the actual architecture and number of components change among projects. On top of that, it is common that several providers are involved in the development of the components. These features cause a challenge for the correct integration and commissioning of the B&T system, involving, to a greater or lesser extent depending on the complexity of the project, track testing to finalise its adjustment and ensure correct operation.

In this context, the B&T use case is intended to provide methodologies for the seamless integration of models from different suppliers into a common DT. This would redound to a reduction of errors that need to be corrected during the integration and commissioning phase, with the resulting impact on the profitability of the project as a whole and compliance with delivery deadlines.

The remaining sections of this paper are structured as follows: In section 2 the multi-body model of the vehicle is presented. Section 3 describes the control units and their interfaces. The simulation and results verification of the combined system is presented in section 4. And section 5 relates the work to the digital twin concept. Finally, section 6 concludes the paper and gives an outlook to future plans.

2 Vehicle Dynamics Model

This section describes the models that comprehend most of the mechanical components involved in the B&T DT. As described in Figure 1, the vehicle dynamics model would concern the wheelset and train dynamics, the wheel-rail contact forces, the adhesion level and the track topology.

For the B&T use case, a two car multiple unit for passenger transport is regarded. The vehicle configuration resembles that of a light-rail vehicle-type, which is in the mid-way between tram and metro vehicle-types and whose maximum speed is commonly below 100 km/h. The car bodies are carried by three bogies, i.e. two motor bogies at the ends and a trailing Jacobs bogie at the centre of the vehicle. As usual for this kind of railway vehicles, two stage suspension systems are used to achieve optimal running dynamics and passenger comfort: Rather hard primary suspensions between wheelsets and

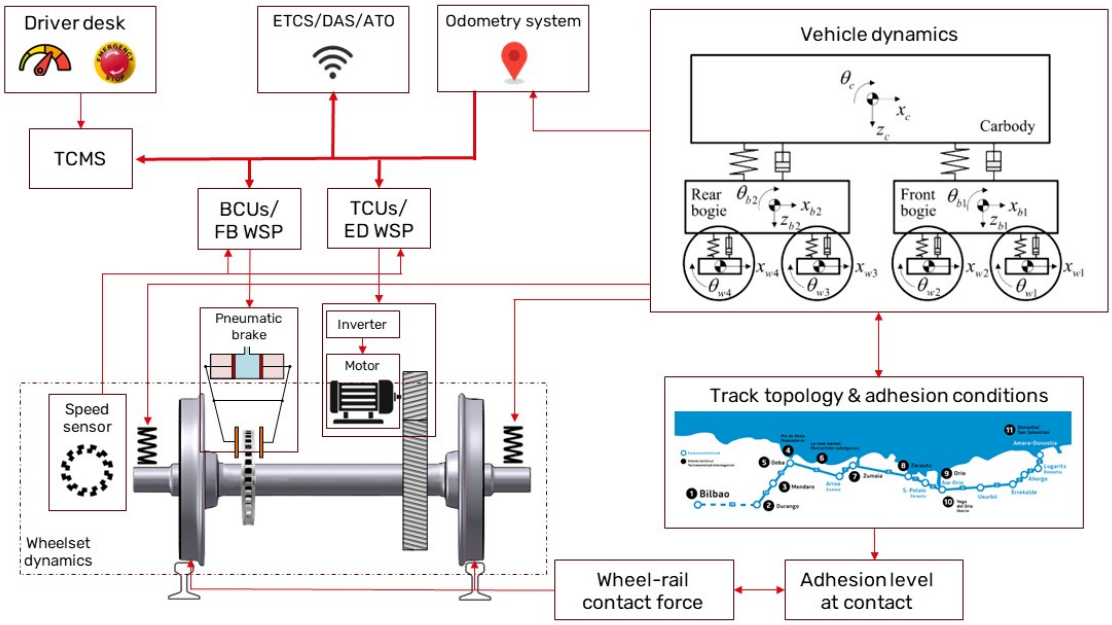

Figure 1. Scheme of the braking and traction system

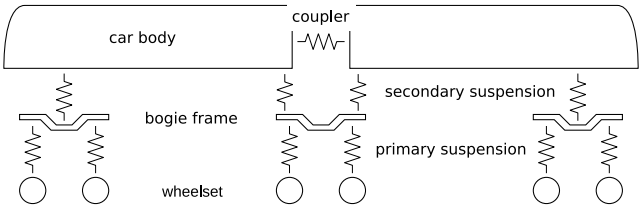

Figure 2. Multi-body structure of the multiple unit vehicle dynamics model.

bogie frames and softer secondary suspensions between bogie frames and car bodies. Completed by a coupler, this structure results in a multi-body system composed of eleven rigid bodies and eleven spring-damper force elements (Figure 2).

Modelica/Dymola using the DLR Railway Dynamics Library (RDL) (Heckmann, M. Ehret, et al. 2019) were chosen for modeling the vehicle dynamics model. In this way it was possible to take advantage of powerful FMU export and sufficient railway dynamics functionality and efficiency. Moreover this setup allowed us to implement the following modifications for the B&T use case.

For analysing B&T phenomena in the scope of this work, lateral, roll and yaw motion of the vehicle are not relevant. As a consequence, these degrees of freedom have been eliminated in the joints of all bodies of the system, resulting in half the number of mechanical dynamic states and accordingly improved computation efficiency. In principle, it would even be possible to consider only half of the vehicle, so that the computation effort of wheel-rail contacts is also halved. However, this has not been implemented so far.

Moreover, an extension of the RDL has been implemented to enable consideration of variable friction coefficients between wheel and rail during simulation. For this a scalar friction scaling factor f_μ has been introduced, which allows to modify the effective friction coefficient of the tangential force law. A common application is to define a lookup table function $f_\mu(s)$ dependent on the longitudinal track position s of the wheel.

The RDL implements different methods for the wheel-rail tangential force determination (Heckmann, Keck, et al. 2014). Since in B&T scenarios high creepage conditions can occur, Polach's method (Polach 2000) is utilised here. It allows to consider variable (e.g. dry/wet) wheel-rail conditions by modification of several parameters A, B, k_A, k_S and μ_0 (Polach 2005). However, so far we just apply the friction scaling factor to the maximum friction coefficient $\mu_0 := f_\mu \cdot \mu_0$ because this approximation is easy to handle and also applicable for other tangential force laws.

Figure 3 shows the block diagram of the vehicle dynamics model. Most of the components are instances of original or modified RDL classes. A linear spring-damper force element with preload has been implemented for sus-

DOI 10.3384/ecp218101

pensions and coupler. Velocity-dependent aerodynamic forces have been added to the RDL car body class. In addition a new brake and propulsion class has been created. It represents a frictional brake and an electric motor acting between bogie frames and wheelsets.

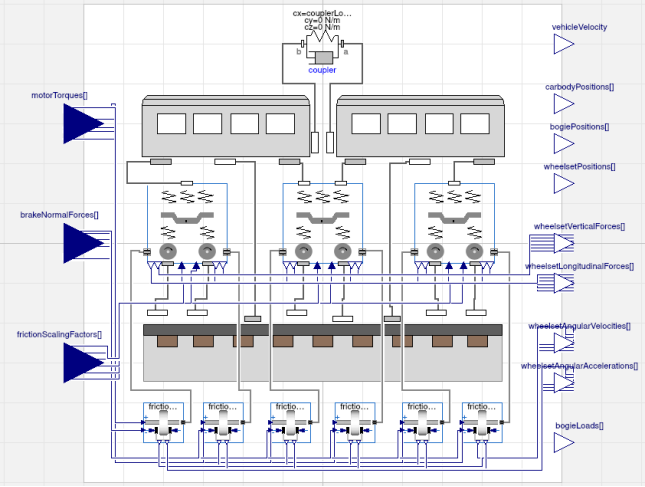

Figure 3. Block diagram of the multiple unit vehicle dynamics model.

At project start it was planned to implement the track as a separate model resp. FMU. However, this concept has been abandoned to avoid confusing and redundant modelling, because defining the track by model exchange would require eight identical track FMUs for all the track joints of car bodies and wheelsets. This is not necessary within Modelica, where the same track is defined as `outer` component of the track joints so that it can be evaluated like a global function. Nevertheless, the architecture of the RDL track implementation has been refactored to enable FMU export for other use cases (Heckmann, Posseckert, and Adusumalli 2025).

All initial conditions, tuneable parameters, inputs and outputs of the model are defined on top level for convenient FMU export. The initial conditions represent the track position and speed of the vehicle at simulation start. There are five scenario parameters, i.e. track data file, car occupancies and friction coefficients of wheel-rail and brake pad-disc, as well as 26 design parameters (mass properties, stiffness and damping values and wind resistance coefficients). Three vectorial input signals are implemented for motor torques, brake pad normal forces and friction scaling factors of the six wheelsets. And finally there are nine output signals, i.e. vehicle speed, track positions of the car bodies, bogies and wheelsets, angular velocities and accelerations of the wheelsets, secondary suspension loads of the bogies and vertical and longitudinal wheel-rail forces of the wheelsets. In the whole these variables form an interface specified for B&T control applications.

A simple test scenario has been used for debugging and testing the model. The vehicle starts at a speed of 10 m/s. From 5 to 10 s of simulation time, a trapezoidal motor

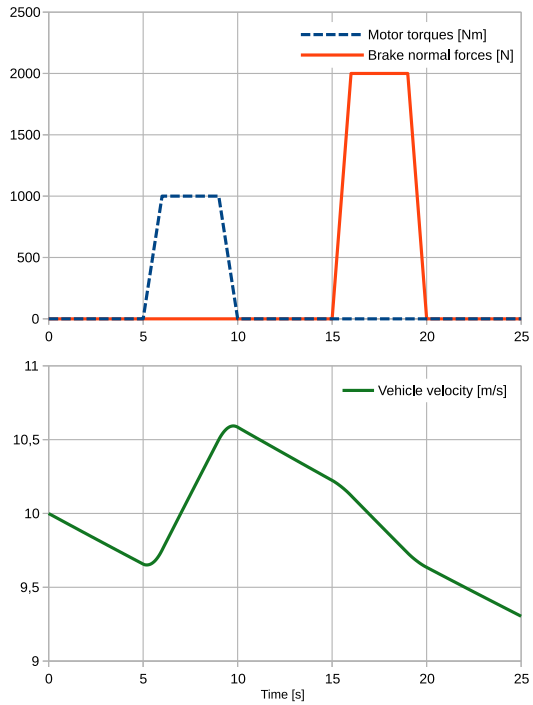

Figure 4. Motor torques, brake pad normal forces and resulting vehicle speed of the test scenario.

torque of 1000 Nm is inputted to the wheelsets. Analogously, a brake normal force of 2000 N is applied from 15 to 20 s. In Figure 4 the inputs and the resulting longitudinal velocity of the vehicle are plotted. During phases without driving torques, the speed decreases slowly due to air resistance forces. When the motor torques are active, the vehicle accelerates, and during braking deceleration increases.

3 Control Model

The control module mainly concerns the description of the logic involved in the B&T operation. Three main functionalities are due to the control module:

- Setting the effort command and operation mode by interpreting the manipulator signals.
- During braking, sharing out the efforts in the most suitable way among the electrodynamic (ED) and friction brake (FB) actuators. This functionality is known as 'blending'.
- To prevent that effort demand exceeds the available adhesion, which involves that maximum admissible longitudinal contact force is about $\mu_0 N$, where N is the normal contact force. This functionality is known as WSP, which stands for wheel-slide/slip protection depending on whether the vehicle is braking or gaining traction, respectively.

As regard to Figure 1, the components concerned by the control module are Traction and Brake Control Units

(TCUs and BCUs, respectively) and Train Control Management System (TCMS). The ETCS (European Train Control System), DAS (Driver Advisory System), ATO (Automatic Train Operation) and the odometry system are not considered in this DT, since they are not core elements of the B&T operation, however, their implementation based on an FMU approach is feasible. The driver desk is highly simplified.

The control architecture is shown in Figure 5. It consists of two TCUs placed at the motor bogies, and three BCUs, one per bogie. The TCMS recieves the driver command and sets the data bus of the vehicle from which the TCUs and BCUs receive the command, read the state of other components and publish their own data. Data communications are compacted in buses signals, which allows to define as many variables as necessary with different data types and sizes without changing the model structure.

In the following subsections, the minimal units describing TCMS, TCUs and BCUs are detailed and their output buses defined. These units are coded in Simulink and subsequently exported as standalone FMUs. The models highly simplify both functionality and included number of variables. However, the overall concept and approach remains valid and further development can effortlessly include more sophisticated or even the actual onboard code.

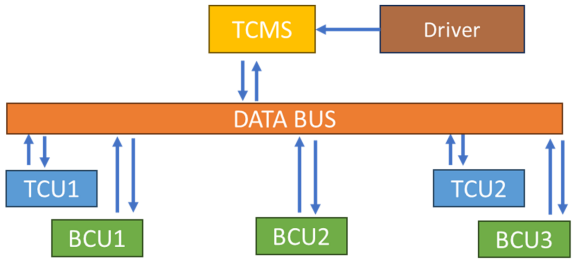

Figure 5. Control architecture of the vehicle

3.1 TCU

TCUs (Traction Control Units) are responsible for controlling the ED actuators (motor) for both ED braking or traction. Moreover, they implement the ED WSP logic. Each TCU publishes a data bus containing four variables included in Table 1.

The TCUs receive the traction or braking demand from the TCMS and calculate how much ED effort they can perform taking into account two main limitations: the effort vs. speed curve of the motor and the available adhesion due to the contact conditions and the normal loads on contact. The resulting effort is the so-called EffANoWSP, which is the effort before WSP control.

Subsequently, they measure the angular velocity of the wheels and, by comparing it with the vehicle speed, estimate whether wheel sliding/slipping is occurring due to degraded adhesion conditions and, in that case, they correct effort. The effort to be applied after WSP correction is denoted as EffA.

Variable name	Unit	Description
EffANoWsp	[N]	Bogie effort before WSP
EffA	[N]	Bogie effort after WSP
b_WSP	[Boolean]	WSP control is acting
b_ED_Ok	[Boolean]	ED is operative

Table 1. TCU data bus variables

3.2 BCU

BCUs (Brake Control Units) are responsible for controlling the FB actuators. Moreover, they implement the pneumatic (or hydraulic, depending on the FB pressure system) WSP logic.

BCUs may act only during braking. The blending strategy seeks to prioritize the ED effort to maximize energy recovery and BCUs may have a small contribution to the total braking effort when adhesion conditions are good in normal braking modes. However, under degraded adhesion conditions, emergency brake mode, or in the presence of failing TCUs, the BCUs will play an important role in the braking operation.

BCUs in trailing bogies are expected to act anytime adhesion conditions are poor due to the TCMS activating low-adhesion mode. However, the blending strategy normally minimizes the actuation of BCUs in motor bogies.

The BCUs read the braking effort demanded by the TCMS and the effort performed by the TCUs and, accordingly, they calculate the braking effort deficit. By measuring the normal load on each bogie they estimate the available adhesion and share the effort among BCUs. In the studied vehicle, only the BCU in the trailing bogie will normally act unless some of the TCUs are failing.

Finally, BCUs also read the wheelset angular velocities and by comparing them with the vehicle speed they decide whether WSP correction is to be applied for avoiding the wheel blockage, which would result in wheel flats. The variables published by the BCU in the BCU data bus are included in Table 2.

Variable name	Unit	Description
WEIGHT	[kg]	Weight on the bogie
FB_REQ	[N]	Requested FB effort
FB_APP_WSP	[N]	FB effort after WSP
FB_AVAIL	[N]	Available FB effort
b_WSP	[Boolean]	WSP is acting
b_FB_Ok	[Boolean]	FB is operative

Table 2. BCU data bus variables

DOI
10.3384/ecp218101

Variable name	Unit	Size	Description
TRC_BRK_DEM	[Integer]	(1×1)	Traction/Braking demand
NB_ED_AVAILABLE	[Integer]	(1×1)	Number of TCUs available
NB_FR_AVAILABLE	[Integer]	(1×1)	Number of BCUs available
TRAIN_WEIGHT	[kg]	(1×1)	Weight of the train
TRAIN_WEIGHT_ROT	[kg]	(1×1)	Weight of the train including rotational mass
SPEED	[m/s]	(1×1)	Vehicle speed
v_EffA	[N]	(1× TCUs)	Applied effort per TCU
v_EDOk	[Boolean]	(1× TCUs)	TCUs availability
v_EffANoWSP	[N]	(1× TCUs)	Applied effort per TCU before WSP
v_ED_WSP	[Boolean]	(1× TCUs)	WSP limiting ED effort per TCU
v_FBR	[N]	(1× BCUs)	Requested FB effort per BCU
v_FBA	[N]	(1× BCUs)	Applied FB effort per BCU
v_BOGIE_WEIGHT	[kg]	(1× BCUs)	Vertical load per BCU
v_FBAVAIL	[N]	(1× BCUs)	FB available effort per BCU
v_FBOk	[Boolean]	(1× BCUs)	BCUs availability

Table 3. Vehicle data bus variables

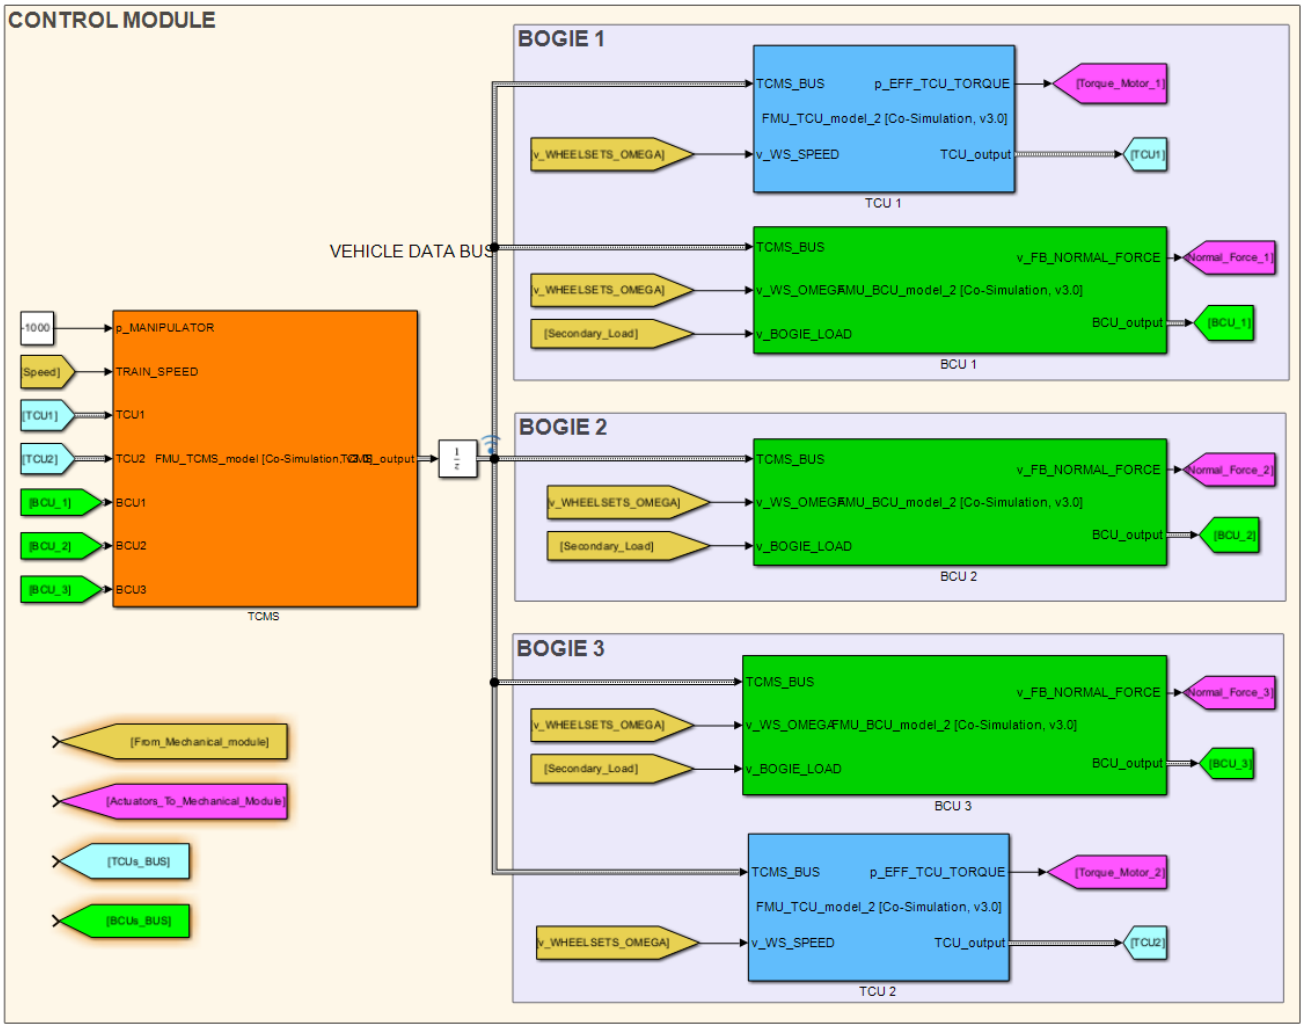

Figure 6. Control module based on FMUs

3.3 TCMS

TCMS (Train Control Management System) is the backbone of the train regarding its logic and electronics. To what concern B&T operation, it is responsible for managing the signals of different components into the vehicle data bus and performing functionalities such as speed es-

timation, setting effort commands, or defining operation mode, among others.

The TCMS receives the output from each TCU and BCU (as indicated in Tables 1 and 2) and updates the vehicle data bus, which is a unified data source from which any component reads all the necessary information to perform its operation. The vehicle data bus contains the variables listed in Table 3.

3.4 FMU-Based Control Model

The control model entirely based on FMUs is shown in Figure 6, which replicates the architecture of that shown in Figure 5. There are only three types of FMU: TCMS, TCU, and BCU types. The difference among TCUs and BCUs resides in the input parameters that identify their location in the vehicle. All TCUs and BCUs include a parameter to define the bogie that they belong to (p_BOGIE_INDEX). Moreover, the BCUs include another parameter to indicate that they belong to a motor bogie and the related TCU when it is defined as a non-zero value (p_TCU_INDEX). By using the latter, the BCUs can track the state of the TCUs and take the correct input data to perform blending from the vehicle data bus.

Figure 6 also includes a legend to indicate the type of signals. Yellow labeled tags are signals coming from the vehicle dynamics model: the speed, the wheelsets' angular velocities, and the load on the secondary suspension. By using the parameter p_BOGIE_INDEX, the TCUs and BCUs can select the correct values of the wheelsets' angular velocities and the load on the secondary suspension. The vehicle data bus is read by all the TCUs and BCUs from where they obtain the necessary information to set effort values (labeled in clear pink), which are subsequently sent to the vehicle dynamics model. Each TCU and BCU output a data bus that is sent to the TCMS that merges all the data to update the vehicle data bus accordingly. As mentioned before, the signals denoted as TCU_X, BCU_X and TCMS_BUS, are programmed as bus signals, that enable a flexible definition of variables. This makes possible to redefine interfaces avoiding changes in the control module.

4 Simulation and Verification

Vehicle dynamics and control models described in Sections 2 and 3, respectively, are coupled together. Figure 7 shows how the FMU of the vehicle dynamics model is coupled with the control module shown in Figure 6. The correct simulation of the model is checked by assessing its behaviour for different adhesion conditions, dry ($\mu_0 = 0.30$), wet ($\mu_0 = 0.10$), and contaminated surface ($\mu_0 = 0.05$) (Gallardo-Hernandez and Lewis 2008). Adhesion values, μ_0, are defined in the vehicle dynamics model as detailed in Section 2.

Figures 8 and 9 show the kinematic and effort results of the simulations, respectively. The simulation is a service braking operation from 80 km/h, which is about its maximum design speed to 0 km/h. In dry conditions, the braking distance is about 220 m. For wet conditions, the braking distance increases up to 260 m, which is 18% higher than for dry conditions. In this case, the vehicle is not able to sustain the maximum deceleration given by the dry

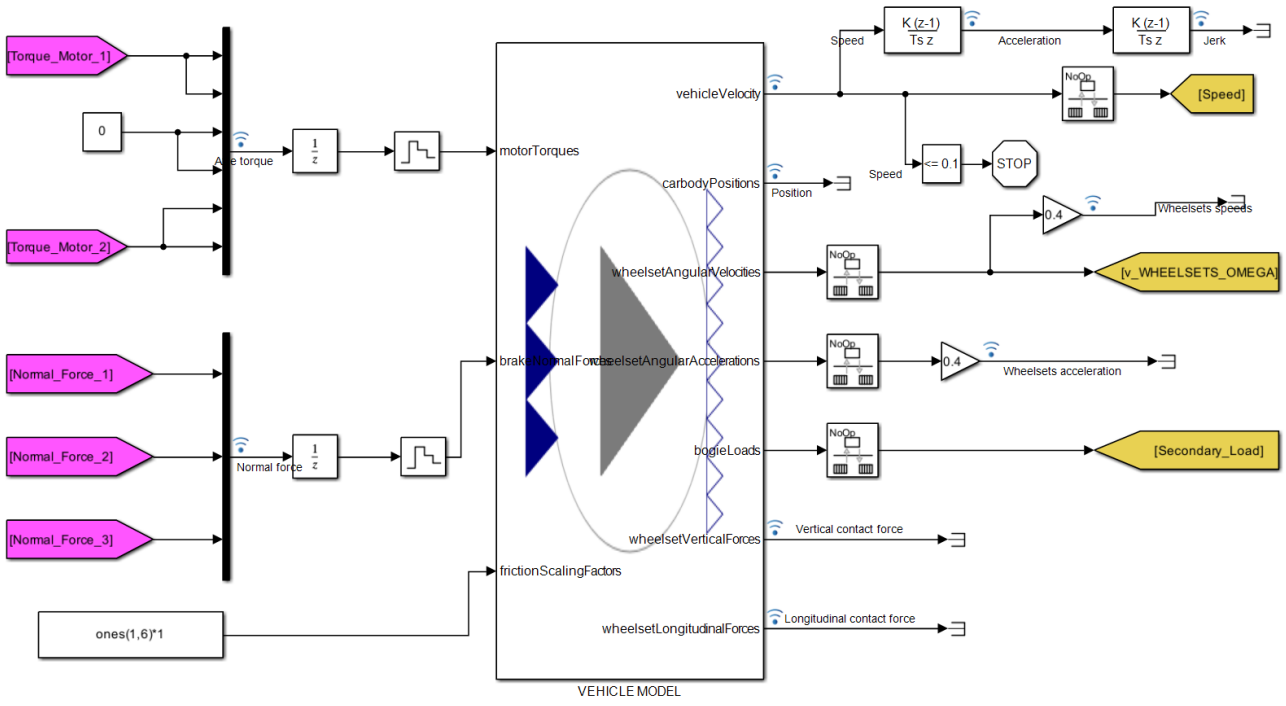

Figure 7. Vehicle module implemented along with the control module interfaces

DOI 10.3384/ecp218101

scenario, and it is reduced as a consequence of the WSP control. For very poor adhesion conditions, the braking distance increases up to 600 m. This value is significantly high and may not be acceptable in a real vehicle. Therefore, the definition of more aggressive braking modes as well as the modelling of rail cleaning phenomenon may be necessary to achieve acceptable braking distances in this scenario.

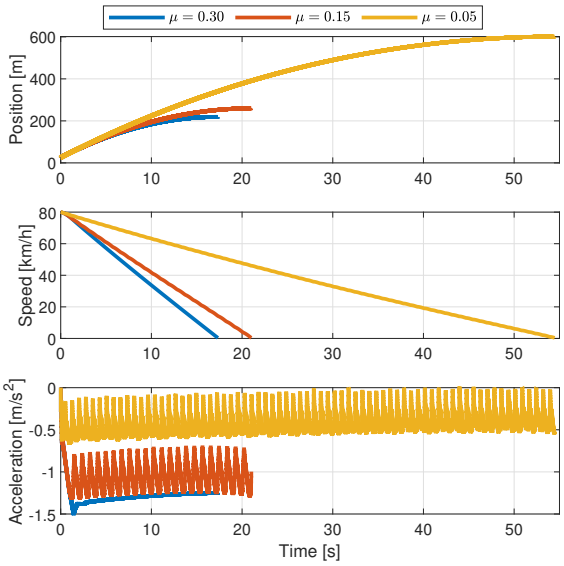

Figure 8. Vehicle kinematic results for different adhesion coefficients

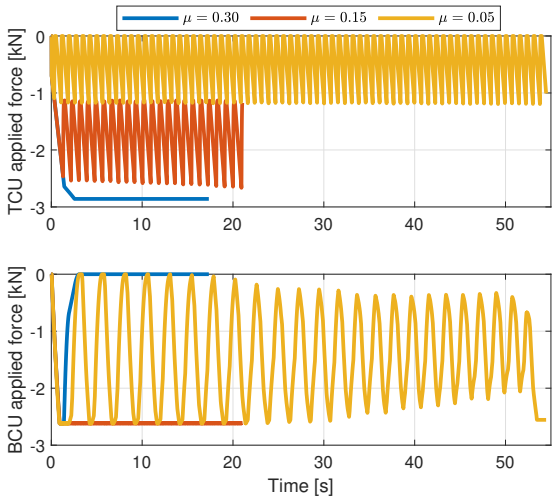

Figure 9. TCU and BCU applied efforts for the first and second bogie, respectively, at different adhesion conditions.

Regarding effort results shown in Figure 9, in the dry case, TCUs are able to provide all the braking deceleration except at the braking start. In the first seconds, the jerk-limitation prevents TCUs from increasing too quickly the effort and the BCU at the trailing bogie compensates for the braking effort deficit. Once the TCUs reach the requested effort, the BCU releases friction effort. For wet conditions, the TCUs start to limit the applied effort via WSP, while the BCU in the trailing bogie applies a constant effort to compensate for the braking deficit in the TCUs. For very poor adhesion conditions nor TCUs or BCUs are able to sustain the effort and both ED and pneumatic WSP start to limit the application of braking efforts. The ED effort is able to release and apply effort much faster than the pneumatic one.

The application of cyclic efforts due to the WSP is directly impacting on the wheelset speeds. Figure 10 shows the vehicle speed along with the linear speed of the wheelset, calculated as the angular velocity times the wheel radius, for the very poor adhesion conditions. As a consequence of the cyclic application of effort due to the WSP control under low adhesion conditions, the wheelset speed oscillates. When the effort is maximum the wheelset speed is minimum, while for close to zero efforts the wheelset speed approaches that of the vehicle. This shows how the WSP control is preventing the wheel from getting blocked, that would result in severe wheel damage.

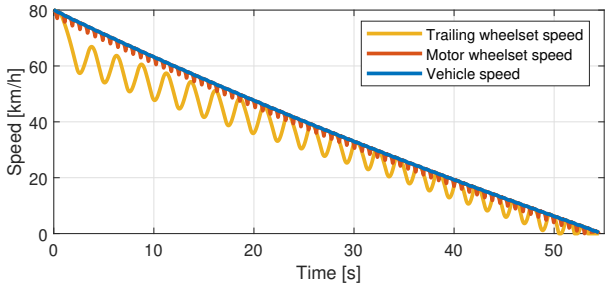

Figure 10. Wheelset speeds and vehicle speed comparison for the braking simulation with $\mu = 0.05$.

5 Digital Twin Context

Further to classical simulation applications as presented in section 4, the DT concept allows for comparison of the real world system with its digital model. Such evaluation can be used to enable improved operation as well as to monitor the current system integrity.

5.1 Improved Operation

In railway signaling, modern communications-based train protection systems like the European Train Control System (ETCS) (Wikipedia 2025) enable to run railway vehicles in *moving block* operation, where the minimum allowed distance between trains can be determined in real time. In this context, a B&T DT allows to estimate the current friction coefficient between wheels and rails (Schwarz 2021), which has significant influence on the possible braking distance (Marc Ehret 2024), and thus allows to determine optimal moving block lengths required between trains. In this way the utilisation of railway infrastructure can be increased, resulting in improved line capacity or safety.

5.2 Monitoring

Another possibility for taking advantage of a B&T DT is rolling stock monitoring. A contemporary approach is to compare sensor measurements of the real world vehicle with expected signals of the DT model using artificial intelligence methods. In this way it is possible to optimise maintenance intervals and to avoid damage and failure of railway vehicles. Hence, economic efficiency and reliability of railway transport can be improved.

6 Conclusions and Outlook

In this paper, collaborative DT development for railway braking and traction applications is presented. The developed DT clearly distinguishes two main domains, on the one hand, the vehicle dynamics involved in the braking and traction operation, and on the other hand, the elements performing the operation control. It is demonstrated that the basic concept of partners developing system modules with different tools as FMUs for DT applications can be applied successfully. Of course, this requires elaborate, iterative specification of interfaces and tuneable parameters.

Regarding the control domain, a modular structure of the control part recreating its real architecture is developed using FMUs basic units of the TCUs, BCUs, and TCMS. Communications among these components are represented via data buses that enable a versatile and compact definition of transferred data. These features are necessary to perform virtual validation and certification via substituting one or several basic units of the control module with the real unit under test.

The vehicle dynamics model successfully couples with the control module and provides it with any necessary physical signals to perform the control operation. Furthermore, this model has been proven to simulate low-adhesion conditions correctly. As a result, the B&T DT shows stable behaviour in degraded conditions such as low-adhesion scenarios. The control module activates WSP logic for both the ED and FB efforts, thus preventing wheel blockage during braking. This proves the feasibility of performing advanced virtual verification and validation of systems under extreme scenarios whose conditions are difficult to replicate via on-track tests.

In future work, the presented B&T DT is to be validated using real measurements that will give an insight of the accuracy level of the presented approach. Moreover, some other modules can be added as FMUs to increase the DT representativity, e.g., modules representing the track and ECTS/DAS/ATO.

Abstract

The convergence failure of iterative Newton solvers during the initialization of Modelica models is a serious show-stopper, particularly for inexperienced users. This paper presents the implementation in the OpenModelica tool of methods presented by two of the authors in a previous paper, to help diagnosing and resolving these convergence failure by providing ranked lists of potentially critical start attributes that might need to be fixed in order to successfully achieve convergence. The method also provides library developers with useful information about critical nonlinear equations, that could be replaced by equivalent, less nonlinear ones, or approximated by homotopy for more robust initialization.

Keywords: Initialization failure, Newton's method, Debugging

1 Introduction

The Modelica language (Mattsson, Elmqvist, and Otter 1998; Modelica Association 2023) has firmly established itself as a standard for system-level simulation of cyber-physical systems. The combination of declarative, equation-based modelling style and of modular, object-oriented composition of structured system models allows for flexible, convenient, and self-documented modelling of complex systems. Engineers can easily assemble system models using a drag-and-drop methaphor from libraries of reusable components, whereas domain experts can conveniently develop new component models by describing their behaviour through a-causal differential-algebraic equations. The solution of the overall system equation is entirely off-loaded from the modeller to the simulation tools, which use sophisticated symbolic and numerical methods to generate efficient and numerically robust code to solve the system equations and produce simulation results.

The price to pay for this flexibility and ease of use in building system models is that resulting system models often require the solution of implicit equations, both during initialization and during simulation. In some cases, implicit equations can be automatically solved in closed form using symbolic algorithms; however, in many cases, particularly for systems of non-trivial size, numerical methods must be employed.

The numerical solution of *linear* implicit equations poses no particular challenges, as long as the model is well-posed, so that the system is non-singular; automatic scaling techniques, see, e.g., (Casella and Braun 2017) can be used to improve the condition number of the A matrix of systems that are nearly singular because of bad scaling. Conversely, the numerical solution of *nonlinear* systems of equations requires the use of iterative methods, usually some kind of quasi-Newton algorithm, which can be problematic.

Iterative quasi-Newton methods require a suitable initial guess of the solution to get started; provided that the system Jacobian is non-singular in the sought-after solution, they provide fast convergence to the solution if the initial guess is close enough to it. Good quasi-Newton algorithms implement additional strategies such as damped steps, enforcing min-max limits on variables, etc., to enlarge the set of initial guesses that lead to successful convergence and to cope with poorly chosen initial guess values. Unfortunately, it is a sad fact of life that these algorithm sometimes fail to converge.

If convergence failures happen during *simulation*, where the values obtained at the previous time step (or some suitable extrapolation thereof) are used as initial guess, an effective strategy to cope with the failure is simply to retry with a shorter time step; as long as the variables of the problem are changing continuously, it is possible to get an initial guess which is arbitrarily close to the solution by picking a short enough time step, thus ensuring convergence.

The most critical scenario from a practical standpoint is the convergence failure during *initialization*, where `start` attributes are used as initial guess, because there is no easy backup strategy available in that case. If the initialization problem fails to converge to a meaningful solution, the model at hand is pretty useless.

The problem of convergence failure during initializa-

tion is compounded by the fact that the feedback provided to the modeller by Modelica tools is very low-level, compared to the nice, high-level, modular modeling style of the Modelica language. What one typically gets is an ugly log message from the solver, showing the selected initial guess values and some error message such as "The nonlinear solver failed to converge during initialization, please provide better start attributes". The question is: how is the poor end user supposed to figure them out?

A naïve strategy in this case is to inspect the list of start values that led to the failure, comparing them to one's best estimate of what their value at the solution should be; values which are obviously very far from the estimated solution can be improved one by one. However, this is a very frustrating and time-consuming strategy, particularly in the case of problems with dozens or hundreds of unknowns. For reasons that will become clear in Section 2, in some cases very large errors in the initial guess are not a problem for convergence, whereas comparatively small errors could be critical in other cases, so one may end up wasting a large amount of time fixing `start` attributes which are not critical at all. If the problem at hand has 100 unknowns, is it really necessary to fix all the 100 start attributes, or maybe fixing only a few ones will suffice to attain convergence? Answering to this question is the main goal of the methods discussed in this paper.

More specifically, based on results previously published by Casella and Bachmann (2021), this paper discusses how a Modelica tool can rank the initial guess values of failing nonlinear systems of equations, highlighting the ones which are more likely to be responsible for the convergence failure, thus helping the end user to succeed in solving the initialization problem and getting the simulation to run. It also shows how critical nonlinear equations can be identified, so that they can be, e.g., approximated by means of homotopy by the model developer. The proposed methods were implemented in the OpenModelica tool (Fritzson et al. 2020) and successfully tested against the test cases discussed in that paper.

The paper is structured as follows: Section 2 reviews the methods proposed by Casella and Bachmann (2021), introducing the notation and the main results; Section 3 discusses the implementation in the OpenModelica tool, while Section 4 shows some of the results obtained on some of the test cases discussed in (Casella and Bachmann 2021). Section 5 concludes the paper with final remarks and suggestions for future work.

2 Method

This section introduces the notation for the problem at hand and recalls the main results of (Casella and Bachmann 2021) which are relevant for the discussion.

2.1 Notation

Consider the problem

$$f(x) = 0, \tag{1}$$

where $x \in \mathbb{R}^m$ and $f : \mathbb{R}^m \to \mathbb{R}^m$ is a vector function which is continuously differentiable in an open neighbourhood $\mathfrak{D}$ of the solution $\bar{x}$, $f(\bar{x}) = 0$. In the context of this paper, problem (1) corresponds to a strong component of the initialization problem of a Modelica model, where x is a subset of the set of unknowns of such problem, namely state variables, their derivatives, algebraic variables, and unknown parameters with `fixed = false` attribute. In case homotopy-based initialization is used (Sielemann et al. 2011), the considered problem is the one at $\lambda = 0$, for which the intial guess is taken from the `start` attributes.

Denote the Jacobian matrix of function $f(x)$ with respect to x as $f_x(x)$. Assume the vector of the unknowns x is suitably ordered, so that it can be split into two subvectors $w \in \mathbb{R}^q$ and $z \in \mathbb{R}^{m-q}$

$$x = \begin{bmatrix} w \\ z \end{bmatrix}, \tag{2}$$

w being the smallest possible sub-set of x such that

$$f_x(x) = J(w), \tag{3}$$

i.e., the Jacobian matrix of $f(x)$ depends only on w and not on z. Thus, w are defined as the *nonlinear variables* of the problem, while z are defined as the *linear variables* of the problem.

Assume the equations in (1) are ordered so that $f(x)$ can be split into two vector functions $n(x)$ and $l(x)$, $n : \mathbb{R}^m \to \mathbb{R}^p$, $l : \mathbb{R}^m \to \mathbb{R}^{m-p}$

$$f(x) = \begin{bmatrix} n(x) \\ l(x) \end{bmatrix}, \tag{4}$$

where $n(x)$ contains the non-linear equation residuals and $l(x)$ contains the linear equation residuals. System (1) is thus split into *nonlinear equations* $n(x) = 0$ and *linear equations* $l(x) = 0$. The system (1) can then be rewritten as

$$f\left(\begin{bmatrix} w \\ z \end{bmatrix}\right) = g(w) + f_z z. \tag{5}$$

where $g(w)$ contains all the nonlinear terms of the system equations, while $f_z z$ denotes the linear part of the system equations.

The solution $\bar{x}$ can be computed iteratively by Newton-Raphson's method, which requires to solve the following linear equation at each iteration j

$$f_x(x_{j-1})(x_j - x_{j-1}) = -f(x_{j-1}), \qquad j = 1, 2, \cdots \tag{6}$$

starting from a given initial guess x_0, which is obtained from the `start` attributes of the unknowns x.

One very important remark is due when tearing is used to solve the implicit nonlinear system. In this case, the set of unknowns x is the set of *tearing* (or iteration) variables, whereas the set of equations (1) refers to the set of *residual* equations. In this case, determining which are the nonlinear variables and equations of the torn system requires to

DOI
10.3384/ecp218109

consider the dependencies between each tearing variable and each residual equation introduced by the torn equations, which may themselves be linear or nonlinear. For example, the system

$$\sin(a) + b = 1 \tag{7}$$
$$a + b + \cos(c) = 2 \tag{8}$$
$$a + b + c = 0 \tag{9}$$

can be solved by selecting a and c as tearing variables:

$$b := 1 - \sin(a) \tag{10}$$
$$a + b + \cos(c) - 2 = 0 \tag{11}$$
$$a + b + c = 0; \tag{12}$$

where the unknown vector of the torn system is $x = [a \quad c]'$. Although the last of the two residual equation looks linear at first glance, it actually depends non-linearly on a through the nonlinear torn equation. Therefore, both unknowns and both residual equations of the torn system are actually non-linear in this case.

2.2 Theoretical Background

This section recalls the main theoretical results of Casella and Bachmann (2021), putting them in the specific context of a Modelica tool solving a strong component of the initialization problem.

Theorem 1. ***(Superlinear convergence close to the solution)****. If the Jacobian $f_x(\bar{x})$ is non-singular in the solution $\bar{x}$ and Lipschitz-continuous in a neighbourhood of $\bar{x}$, for all x_0 sufficiently close to x, the sequence $\{x_j\}$ of the solutions of* (6) *converges not less than quadratically to $\bar{x}$.*

Theorem 2. ***(Convergence in the linear case)****. If Equation* (1) *is linear and f_x is non-singular, then Netwon's algorithm converges in one step, irrespective of the chosen initial guess x_0.*

Theorem 3. ***(Convergence in the mixed linear-nonlinear case)****. If Newton's algorithm is initialized with a first guess*

$$x_0 = \begin{bmatrix} w_0 \\ z_0 \end{bmatrix}, \tag{13}$$

the values of the approximated solution x_j at each step $j > 0$ only depend on the guess values of the nonlinear variables w_0, regardless of the choice of guess values of the linear variables z_0.

Theorem 4. ***(Linear residuals after the first iteration)****. The residuals of the linear equations in system* (1) *after the first iteration of Newton's algorithm are zero, i.e. $l(x_1) = 0$, regardless of the initial guess values x_0.*

Theorems 1 and 2 are well-known, whereas Theorems 3 and 4 were first stated by Casella and Bachmann (2021) and have two very important implications for the problem at hand:

1. only *nonlinear* equations $n(x) = 0$ and only initial guesses of *nonlinear* variables w_0 matter for convergence;

2. there is no reason to bother about `start` attributes of *linear* variables

For the subsequent discussion, it is necessary to answer the following question: how can we determine if the initial guess x_0 is close enough to the solution $\bar{x}$, so we can expect that convergence will be achieved? One naïve answer could be to consider this criterion:

$$\left\| f(x_1) \right\| \ll \left\| f(x_0) \right\|, \tag{14}$$

i.e., if the residual after the first iteration is much smaller than the residual computed with the initial guess, then it's likely that the residual after the next iteration will be even smaller and convergence will be achieved soon.

In fact, due to the consequences of Theorems 3 and 4, this is not a sound criterion: Theorem 3 suggests to trivially set $z_0 = 0$, which may lead to large values of the linear residuals $l(x_0)$, while Theorem 4 states that after one iteration, $l(x_1) = 0$ no matter what. Hence, the norm of the overall residual vector may dramatically decrease after one iteration, just because large linear residuals becoming zero in one shot; this is by no means an indication that the nonlinear variables are close to convergence.

This observation leads to the need of defining a better criterion for being close to convergence.

Definition 1. *With reference to Newton's iteration* (6)*, define the nonlinear residual at iteration point x_{k-1} as*

$$r(x_{k-1}) = f(x_{k-1}) + f_z(z_k - z_{k-1}). \tag{15}$$

This definition basically removes all the linear components that will vanish after one iteration from the residual at step $k-1$. Another possible interpretation, with reference to the decomposition shown in (5), is that it computes the residual of the nonlinear part of the system equations only, which is the only one that is relevant for possible convergence issues.

We can then replace the right hand side of the naïve criterion (14) with the nonlinear residual, thus leading to this heuristic criterion for being close to convergence:

$$\left\| f(x_1) \right\| \ll \left\| r(x_0) \right\|. \tag{16}$$

This criterion is heuristic in the sense that it is possible to build on purpose counter-examples in which this condition holds, but yet Newton's method does not converge to a solution. However, in most practical cases, if the residual $f(x_1)$ after the first iteration is much smaller than the nonlinear residual computed with the initial guess $r(x_0)$, then the residual $f(x_2)$ after the second iteration will be even smaller, and the method will converge to a solution in a few iterations.

The next step is to come up with the formulation of some indicators that can be used to express relationship (16) in an equivalent way. This requires to introduce the following definitions.

Definition 2. *Consider Newton's iteration* (6)*. Assume that the function $f(x)$ is three times continuously differentiable in an open neighbourhood $\mathfrak{D}$ containing the initial guess x_0 and the result of the first iteration x_1. Denote the i-th component of function $f(x)$ as $f^i(x)$, its Jacobian matrix with respect to x as $f^i_x(x)$, and its Hessian matrix as $f^i_{xx}(x)$. One can write the following Taylor expansion*

$$f^i(x_1) = f^i(x_0) + f^i_x(x_0)(x_1 - x_0) + \\ + \frac{1}{2}(x_1 - x_0)' f^i_{xx}(x_0)(x_1 - x_0) + h^i(x_1, x_0) \quad (17)$$

which implicitly defines the higher-order residual functions $h^i(\cdot,\cdot)$.

Definition 3. *Define the coefficients $\alpha_i > 0$, $i = 1, \cdots, m$, such that*

$$|h^i(x_1, x_0)| = \alpha_i \left\| r(x_0) \right\|_\infty, \quad (18)$$

i.e.,

$$\alpha_i = \frac{\left| f^i(x_1) - \frac{1}{2}(w_1 - w_0)' f^i_{ww}(w_0)(w_1 - w_0) \right|}{\left\| r(x_0) \right\|_\infty} \quad (19)$$

and let

$$\alpha = max(\alpha_i). \quad (20)$$

Remark 1. *It may happen that when computing $f(x_1)$ some of the residuals cannot be computed because x_1 is out of their range of definition, e.g. because of logarithms or square roots getting a negative argument. In this case, it is necessary to perform a* damped *Newton iteration:*

$$f_x(x_{j-1})(x^*_j - x_{j-1}) = -\lambda f(x_{j-1}), \qquad j = 1, 2, \cdots \quad (21)$$

By taking a small enough positive value of λ, it is possible to get x_1 arbitrarily close to x_0, thus avoiding validity range issues. The Taylor expansion can be used to define $h^i(x^*_1, x_0)$ leading to the following modified definition of α_i

$$|h^i(x^*_1, x_0)| = \alpha_i \lambda^3 \left\| r(x_0) \right\|_\infty, \quad (22)$$

motivated by the fact that $h^i(x^*_1, x_0)$ is a third-order term in the Taylor expansion, so it is expected to shrink as λ^3, thus making the definition asymptotically invariant as $\lambda \to 0$. Hence, α_i can be computed as

$$\alpha_i = \frac{\left| f^i(x^*_1) - (1-\lambda) f(x_0) - \frac{1}{2}(w^*_1 - w_0)' f^i_{ww}(w_0)(w^*_1 - w_0) \right|}{\lambda^3 \left\| r(w_0) \right\|_\infty} \quad (23)$$

Definition 4. *Define the* curvature factor Γ_{ijk} *of the i-th nonlinear equation with respect to variables w_j, w_k after the first iteration as*

$$\Gamma_{ijk} = \left| \frac{1}{2} \frac{\partial^2 g^i(w_0)}{\partial w_j \partial w_k} \frac{(w_{1,k} - w_{0,k})(w_{1,j} - w_{0,j})}{\left\| r(x_0) \right\|_\infty} \right| \quad (24)$$
$$i = 1, \ldots, p,$$
$$j = 1, \ldots, q,$$
$$k = 1, \ldots, q.$$

Equipped with these definitions, we can now state the following Theorem:

Theorem 5. *Given a constant $\beta > 0$,*

$$\sum_{jk} \Gamma_{ijk} \leq \beta \qquad \forall i = 1, \cdots, p. \quad (25)$$

implies that

$$\left\| f(x_1) \right\|_\infty \leq (\alpha + \beta) \left\| r(x_0) \right\|_\infty \quad (26)$$

The main consequence of Theorem 5 is that if $\alpha_i \ll 1$ and $\Gamma_{ijk} \ll 1 \; \forall i, j, k$, then $\alpha \ll 1$ and it will be possible to pick a value of $\beta \ll 1$ that satisifes (25); hence, $\alpha + \beta \ll 1$ and therefore, thanks to (26), the heuristic convergence condition (16) will be satisfied. In short, if all the α_j and Γ_{ijk} coefficients are small, Newton's method is very likely to converge in a few steps. This condition is sufficient but by no means necessary to achieve convergence, in particular if more robust quasi-Newton methods are used to actually solve (1). However, one can put forth the following heuristic argument:

> *If the (quasi-)Newton solver fails to converge, and if some of the α_i and Γ_{ijk} coefficients are much larger than one, they are likely to be pointing out the initial guesses and nonlinear equations that are responsible for the convergence failure.*

Specifically, large α_i values will indicate that the i-th equation is involved, whereas large values of Γ_{ijk} will indicate that the i-th equation and the initial guesses of w_j and w_k are involved.

Note, from definition (24), that the Γ_{ijk} indicators exploit second-order information provided by the system Hessian, by weighting the magnitude of the change of the solution estimate $(w_{1,j} - w_{0,j})$ after the first Newton step with the curvature of the residual function.

This is a crucial point: the fact that the initial guess value of some variables are very far from the solution, so that $(x_{1,k} - x_{0,k})$ is very large, is *per se* not a relevant indicator of potential convergence issues; in fact, as Theorems 3 and 4 clearly imply, it is not relevant at all for linear variables z. It becomes more and more relevant as the residual depends on the variable in a strongly nonlinear way, as measured by the value of the second derivative.

DOI 10.3384/ecp218109

Regarding the α_i indicators, it is clear from their definition in (17)-(18) that they instead account for the combined effect of terms of order higher than two on the convergence to the solution. Unfortunately, these indicators only point to the involved nonlinear equations, but they cannot discriminate which of the initial guess(es) of nonlinear variables $w_{0,k}$ showing up in those equations are to blame for the convergence issues.

Additional indications about initial guess values potentially being responsible for convergence failure can be obtained by exploiting the following Theorem:

Theorem 6. *The sensitivity of the solution x_1 after the first NR iteration, with respect to changes in the initial guess x_0, can be computed as:*

$$\frac{\partial x_1}{\partial x_0} = \Sigma, \tag{27}$$

where

$$H_i = (w_1 - w_0)' f^i_{ww}(w_0) \tag{28}$$

$$H = \begin{bmatrix} H_1 \\ H_2 \\ \cdots \\ H_p \end{bmatrix} \tag{29}$$

$$\Sigma = -\left[f_x(w_0)\right]^{-1} \begin{bmatrix} H_{p\times q} & 0_{p\times(m-q)} \\ 0_{(m-p)\times q} & 0_{(m-p)\times(m-q)} \end{bmatrix}. \tag{30}$$

When computing the sensitivity Σ at the solution $x_0 = \bar{x}$, since $w_1 = w_0 = \bar{w}$, it follows that $H = 0$, so that $\Sigma = 0$. This means that if an initial guess equal to the solution plus an infinitesimally small perturbation $x_0 = \bar{x} + \delta x$ is chosen, the solution x_1 after the first NR iteration is not affected at all. This is consistent with the fact that $f(x)$ can be approximated as a linear function in a small neighbourhood of the solution $\bar{x}$, so that Theorem 2 guarantees that the first NR iteration converges to the solution $\bar{x}$ in just one iteration, irrespective of the initial guess.

If the initial guess x_0 is close enough to the solution $\bar{x}$ that the function $f(x)$ is still approximately linear in a neighbourhood containing x_0 and $\bar{x}$, then the same behaviour is preserved, i.e., the result after the first iteration will be insensitive to small changes of the initial guess, so $\Sigma \approx 0$.

As x_0 is chosen farther away from the solution $\bar{x}$, nonlinear effects kick in, accounted for by matrix Σ, which can be then considered an indicator of how far the initial guess is from the sweet spot of NR convergence. In particular, $\left|\sigma_{jj}\right| \ll 1$ means that the effect on $w_{1,j}$ of applying a certain perturbation to $w_{0,j}$ will be much less than the perturbation itself, meaning that the nonlinear effects are moderate, whereas if $\left|\sigma_{jj}\right| \gg 1$ the effect of such perturbation will be amplified after the first iteration, which is not consistent with the behaviour close to convergence. Hence, it is possible to put forth an argument similar to the one concerning α_i and Γ_{ijk} indicators:

> *If the Newton solver fails to converge, and if $\left|\sigma_{jj}\right| > 1$ for some j, then the initial guesses $w_{0,j}$ are likely to be responsible for the convergence failure.*

Similarly to the Γ_{ijk} indicators, the σ_{jj} indicators rely on second-order information provided by the system Hessian to assess the effect of the nonlinearity of the system of equations on the convergence of Newton's method. Contrary to Γ_{ijk}, σ_{jj} indicators only provide information about potentially problematic initial guesses $w_{0,j}$, while not providing any information about the involved nonlinear equations.

An interesting property of σ_{jj} coefficients, when computed from sets of equations containing quantities with physical units, is that they are dimensionless, so they are invariant with respect to the choice of units of the problem, and in general to the scaling of the system of equations. This makes them readily computable from the Modelica equations in SI units, even if the equations and variables are badly scaled from a numerical point of view.

The α_i and Γ_{ijk} indicators are also invariant with respect to the choice of the units of the unknowns x; however, they are *not* invariant with respect to the choice of the units of the *residual equations* $f^i(x)$. In fact, the definitions of both indicators rely on the infinity norm of the residual $\left\|r(x_0)\right\|_\infty = \max_i \left|r^i(x_0)\right|$, which is conceptually ill-defined if the residuals $r^i(x_0)$ have non-homogenous units: what is the maximum between 70 kg/s and 10^8 W in a system of equation with a steam flow rate equation and a power balance equation?

Hence, a proper implementation of the computation of α_i and Γ_{ijk} requires to employ *normalized* function residuals, which can be computed as explained in (Casella and Braun 2017). Once the residuals are nomalized, the α_i and Γ_{ijk} indicators will be invariant to the choice of units of the problem and to its scaling in general.

2.3 Diagnosing Newton Solver Failures

In case the quasi-Newton method of choice fails to solve one of the nonlinear strong components of the initialization problem (in the case $\lambda = 0$ if homotopy is used), it is possible to compute the α_i, Γ_{ijk} and σ_{jj} indicators as explained in the previous subsection. They can then be ranked in descending order and displayed.

The initial guesses $w_{0,j}$ and $w_{0,k}$ corresponding to the largest values of Γ_{ijk} and $\left|\sigma_{jj}\right|$, as well as the unknowns showing up in the equations with the larger values of α_i, are the most likely to be responsible for the solver failures, so their start attribute should be checked and possibly fixed first. If it is recognized that they have a different start value than what was expected, e.g. 300 K for a flame temperature instead of 1800 K, this can be easily pin-pointed and corrected. Otherwise, they could be tentatively increased or decreased based on the sign of $(w_{1,j} - w_{0,k})$.

This method will be particularly helpful in the case of large systems with many unknowns and only a few critical

start attributes, that will be spotted immediately at the top of the list of ranked indicators.

This method can also help library developers to pinpoint equations that are heavily involved in the failure because of their strong nonlinearity, as indicated by large α_i and Γ_{ijk} values. Such equations could be replaced with other equivalent ones that are less nonlinear, e.g. $a = b * c$ instead of $a/b = c$, or replaced by less nonlinear approximated equations by means of homotopy.

3 Implementation

The method illustrated in the previous Section was implemented in the OpenModelica runtime, where it can be activated by setting the simulation flag `-lv=LOG_NLS_NEWTON_DIAGNOSTICS`. Jacobians are obtained using the same functions that are employed to get them for the quasi-Newton solvers used for simulation, which can either use code obtained with symbolic differentiation or resort to numerical finite differences when that is not possible. Hessians are computed numerically from Jacobians by means of finite differences.

Although it would be conceptually possible to use symbolic differentiation also for the Hessian computation, developing the code to do so was not really worth the effort: the second derivatives are used to generate heuristic indicators, so a high precision is not really required, so that the trivial task of computing them by numerical differentiation was chosen instead. Computational times are also not an issue, since all the required computations are only carried out once and normally take much less than a second also for systems with hundreds of unknowns, so simplicity of implementation was favoured over efficiency. This also lead to the choice of always using the LAPACK dense solver DGESV to solve the linear equations of the Newton step, also in case of systems with high sparsity ratio.

As mentioned in Section 2.1, the classification of linear and nonlinear equations and variables when tearing is used must also consider the nonlinearities introduced by the torn equation. This information could have been inferred symbolically by extending the structural analysis algorithm of the OpenModelica backend; however, this would have taken a significant development effort. It was therefore chosen to follow a simpler numerical approach instead.

Linear equations $l(x) = 0$ are therefore identified by checking if their residual after the first Newton step $f^i(x_1) \approx 0$, see Theorem 4. In case a damped Newton step needs to be computed to avoid out-of-range residual evaluations, the following condition is checked:

$$f^i(x_1^*) + (\lambda - 1) f^i(x_0) \approx 0 \tag{31}$$

Linear variables z are instead identified by checking if the corresponding column of the Hessians is close to zero.

4 Test Results

At the time of this writing, the implementation of the method in release 1.25.0 of OpenModelica is nearly complete, except for two features:

- getting numerical Jacobians when symbolically differentiated Jacobians are not available;
- scaling the residuals when computing the nonlinear residual norm $\left\| r(x_0) \right\|_\infty$

This unfortunately still prevents from testing the implemented method on the initialization problems of physical models using SI units. In particular, the steady-state initialization of thermo-hydraulic problems is notoriously prone to convergence failures, so it could benefit immensely from this type of diagnostics, but unfortunately it involves badly scaled variables such as pressures in Pa, as well as medium models such as the IF97 water/steam model, that cannot be symbolically differentiated.

The implementation was therefore tested on the three example cases shown in (Casella and Bachmann 2021), namely a simple thermo-hydraulic system, a nonlinear DC circuit, and an AC circuit. In all the three cases, the exact analytic solution of the system is known, so it is possible to set the start attribute of the unknowns at various distances from the solution, testing the ability of the proposed method to highlight the ones that need to be fixed in order to ensure the convergence of the Newton method. These test problems use well-scaled units with all the unknowns having order of magnitude of unity, so there is no need to scale the elements of $\left\| r(x_0) \right\|_\infty$ to obtain good results.

The computed values of the α_i, Γ_{ijk}, and $\left|\sigma_{jj}\right|$ indicators were very close to the ones that are reported in (Casella and Bachmann 2021), which were computed by ad-hoc, manually written Matlab code, thus validating the C-code implementation in the OpenModelica runtime. In order to obtain the same results, tearing had to be de-activated, so that the raw nonlinear system written in Modelica was passed directly to the diagnostic routine.

The results of one test case are shown here. The test system is the model of an electrical DC circuit, where the series connection of N resistors and one diode is connected to an ideal voltage source, which provides a certain fixed power P. The system is described by the following set of implicit equations:

$$i - i_s \left(e^{v_d / v_t} - 1 \right) = 0 \tag{32}$$

$$vi - P = 0 \tag{33}$$

$$v - \sum_{j=1}^{N} v_j - v_d = 0 \tag{34}$$

$$v_j - Ri = 0, \qquad j = 1 \cdots N \tag{35}$$

where i_s, v_t, P, R are known parameters, $x = \begin{bmatrix} i & v_d & v & v_1 & v_2 & \cdots & v_N \end{bmatrix}'$, $w = \begin{bmatrix} i & v_d & v \end{bmatrix}'$, $z = \begin{bmatrix} v_1 & v_2 & \cdots & v_N \end{bmatrix}'$.

DOI 10.3384/ecp218109

Note that the system has $N+1$ linear equations and only two nonlinear equations: the first is very strongly nonlinear, due to the exponential term in the diode equation, while the second, containing the voltage-current product, is only mildly nonlinear. The system has three nonlinear variables, which are the only ones for which the initial guess value matters, according to Theorem 3.

Taking $i_s = 6.9144 \cdot 10^{-13}$, $v_t = 25 \cdot 10^{-3}$, $P = 10.7$, $R = 1$, $N = 10$, the system has an exact solution $i = 1$, $v_d = 0.7$, $v = 10.7$, $v_j = 1$. If the start attributes of i, v_d, and v are reduced by 10% with respect to the known solution, the quasi-Newton solvers of the OpenModelica runtime fail to solve the system.

When activating the Newton Diagnostics runtime flag, OpenModelica generates the diagnostic output shown in Fig. 1.

The first table shows results by variable, ranked in descending order of potential criticality; for each variable, the largest value of Γ_{ijk} and $\left|\sigma_{jj}\right|$ that involve it are reported. The result unequivocally points out some very serious problem with the start attribute of v_d; indeed, due to the exponential term in the diode equation and to the small value of the v_t parameter, an error of 10% in the initial guess for v_d is enough to cause convergence failure. Conversely, the same 10% error in the start values of i and v, which are involved in the mildly nonlinear equation $vi - P = 0$, is not problematic at all. In fact, increasing the start attribute of v_d from 0.63 to 0.66 is enough to ensure the convergence of the quasi-Newton algorithm used by OpenModelica to solve the nonlinear system, without any need to touch the start attributes of i and v.

The second table shows results by equation, ranked in descending order of potential criticality. The "Eq no." index refers to the ordering of the residuals in the runtime solver, in case one wanted to inspect it in detail, whereas the "Eq idx" index refers to the index of the equations in the equation-based debugger (Sjölund et al. 2014), which displays the solved equations after structural analysis and symbolic manipulation, see Fig. 2. The diode equation is clearly indicated as the one creating trouble, while, the power equation is not creating any significant problem with the selected start attributes for its variables i and v.

For more details about the other test cases, the interested reader is referred to (Casella and Bachmann 2021).

5 Conclusions

The convergence failure of Newton's method during the solution of nonlinear systems of equations for the initialization of Modelica model is a possible critical outcome of the attempt of simulating Modelica models with implicit nonlinear equations, particularly when initializing models in steady state. Such an occurrence is a serious issue for Modelica tool users and can be a show-stopper for inexperienced users that have no idea how to fix the problem.

This paper presents the implementation in the OpenModelica tool of methods originally devised by Casella and Bachmann (2021) to diagnose such failures and help resolving them in a user-friendly manner. The presented implementation outputs lists of potentially problematic start attributes and nonlinear equations, ranked in descending criticality order.

In the authors' opinion, the presented methods provide much needed support in the debugging of failing Modelica models, particularly if coupled with user-friendly equation-based debuggers such as the one presented in (Sjölund et al. 2014).

The implementation was successfully tested in some illustrative test cases taken from Casella and Bachmann (2021). Unfortunately, at the time of this writing it was not yet possible to compute the normalized function residuals, as explained at the end of Section 2.2, because that requires a substantial refactoring of the OpenModelica runtime code. This prevented testing the method on more complex and realistic Modelica models using SI unit variables, whose residuals are usually quite badly scaled. Such a refactoring is currently on-going and planned to be finalized for the next 1.26.0 release of the software.

Future work will also involve a tighter integration of these run-time methods with the equation-based debugger of OpenModelica, which currently only provides static information elaborated at compile time.

Abstract

Tasks involving Modelica models often do not simply investigate the dynamic behavior of a system, but rather also want to characterize possible optimal control strategies according to suitable criteria. Unfortunately, since Modelica does not support out-of-the-box optimization features, users are often forced to use other tools to code again the system model for optimization studies. For this reason, the authors present Modelica2Pyomo, an open-source tool to translate Modelica models into Pyomo optimization programs, leveraging on their flat Base Modelica representation. This work illustrates the main features of Modelica2Pyomo, including automatic variables and constraints normalization, expressions manipulation and initialization via Modelica simulation results. To demonstrate the capabilities of this framework, two examples are showcased, including an industrial-grade open-loop optimal control problem of a solid-oxide fuel cell.

Keywords: Modelica, Model Conversion, Base Modelica, Pyomo, Dynamic Optimization

1 Introduction

Over the years, the Modelica language has established itself as one of the main tools for the formulation of system-level models for dynamic simulation purposes. Even though the size and the complexity of the systems that can be simulated with this language has increased dramatically since Modelica's inception, its object-oriented and equation-based nature, together with its drag&drop flowsheeting feature, significantly tames the challenges faced in the formulation of such models. Moreover, the possibility of highly customizing pre-existing and newly coded models, makes Modelica a suitable choice for academy and industrial R&D users that study bleeding edge technologies (see for example De Pascali and Casella (2024)).

Such studies often do not consist solely of dynamic simulations but they rather aim at characterizing both the system behavior and apply optimization routines to formulate, for example, optimized control strategies according to specific criteria. Since Modelica does not provide out-of-the-box optimization features, this second task requires a different framework. Often, users resort to different software and need to create from scratch a copy of the Modelica model in another programming language. This process requires modeling the same system twice and is prone to *manual translation* errors.

For this reason, the Modelica community spent quite some effort to build a bridge between the simulation and the optimization worlds. The main contributions were initially brought by the open-source software JModelica.org (Åkesson et al. 2010) and OpenModelica (Fritzson et al. 2020), both through the implementation of the Optimica framework (Åkesson 2008). Optimica extends Modelica with language constructs that enable the formulation of optimization problems based on Modelica models. Optimica-enabled tools communicate with optimization solvers such as IPOPT directly or through the CasADi framework (see Wächter and Biegler (2006) and Andersson et al. (2019), respectively).

This approach has several advantages over the *manual translation* approach. Most importantly, the system model is written only once and in an equation-based object-oriented framework: this avoids the possibility of introducing errors and makes it easier to model systems that would be too complex to code in a flat equation-based framework. Moreover, the resulting optimization problem benefits from the pre-processing executed by the Modelica compiler on the original Modelica model before its translation, e.g. alias elimination, index reduction, parameter evaluation, etc., to further reduce the size and the complexity of the problem that is fed to the underlying optimization solver. Finally, Modelica GUIs can support the formulation of complex models with the drag&drop flowsheeting feature mentioned above, easing the user task of connecting different units and components to build the final model to optimally control.

Unfortunately, the open-source JModelica.org development was discontinued in 2019 in favor of the commercial cloud-based software Modelon Impact, which includes the Optimica Compiler Toolkit; the development and maintenance of optimization features in OpenModelica mostly stopped around 2016, so there is currently no available industrial-strength open-source solution to solve dynamic

optimization problems on Modelica models.

To fill this gap, the authors present Modelica2Pyomo, an open-source tool developed in Python that allows to automatically translate a Modelica model into an equivalent Pyomo model, that can be used to formulate and solve optimization tasks with state-of-the-art solvers.

The input of the tool is a Modelica model, possibly using advanced object-oriented features such as inheritance, a-causal connections, hierarchically structured models with parameter propagation, expandable connectors, stream connectors, inner/outer objects, etc. The model is first flattened by the open-source OpenModelica tool into an equivalent Base Modelica (Kurzbach et al. 2023) representation, that basically contains a set of variable declarations and a corresponding set of (implicit) differential-algebraic equations (DAEs). As a matter of fact, the case of the Modelica2Pyomo tool is a nice application of the main aim of Base Modelica, which is *"to provide a much lower barrier of entry to the Modelica world, since writing a Base Modelica compiler or interpreter is a much easier task than writing a full-fledged Modelica compiler"* (OpenModelica Consortium 2025).

Pyomo (see Bynum et al. (2021)) is an established open-source software package for formulating and solving large-scale optimization problems in Python, with a clear to read semantics. Pyomo's modeling constructs can be used to express a wide range of optimization problems, including nonlinear and mixed-integer programs. In particular, the package Pyomo.DAE by B. Nicholson et al. (2018) allows to formulate the differential-algebraic constraint equations of optimal control problems in a declarative way, which is very close to flat Base Modelica code. The optimal control problem is then automatically transformed by Pyomo into a form suitable for optimization solvers by means of direct collocation or finite difference discretization methods, including the automatic generation of sparse Jacobians and Hessians.

The output of the tool is a configurable Python script containing the generated Pyomo model with the same variables and equations as the original Modelica model. The formulation of the actual optimization model, i.e., the objective function, additional degrees of freedom, and constraints of the optimization problem can be subsequently added manually to perform a wide range of tasks and analyses.

The main advantage of the Pyomo framework compared to other solutions (e.g., CasADi and Optimica Compiler Toolbox) lies in the wide range of supported optimization solvers, both open-source and commercial, which allows to pick the best-suited one for the specific case at hand. The approach proposed in this work thus offers more flexibility compared to the available alternatives. In some cases, commercial optimization solvers may be required to tackle particularly challenging problems; on the other hand, the remaining part of the required toolchain is entirely open-source.

A limitation of the current implementation of Modelica2Pyomo is that it does not yet benefit from the symbolic manipulations such as alias elimination and index reduction, since the Base Modelica code can currently only be generated by the OpenModelica front-end, whereas these operations are carried out by the back-end. Nonetheless, the complex examples presented in this work can be successfully run without such manipulations. Recents results on the impact of symbolic manipulation of the model equations on the efficiency and convergence robustness of optimization solvers could also be considered, see e.g., (Naik et al. 2025) and (Parker et al. 2022). Such manipulations could be performed on the Pyomo side, but some of them could also be carried out on the Modelica tool side, if they are already implemented for the optimization of simulation code.

This paper is organized as follows: Section 2 describes the Modelica2Pyomo tool in terms of both usage and implementation. Section 3 describes two test cases, showcasing the flexibility of the tool and demonstrating the level of complexity of the Modelica models that can be successfully handled. Section 4 draws the conclusion of this work and outline possible future developments.

The code of Modelica2Pyomo, together with the code of the examples showed in this paper, is available in (De Pascali and Casella 2025).

2 The Modelica2Pyomo tool

The Modelica2Pyomo tool is a Python script that translates a Modelica model into an equivalent Pyomo model. In its current form, the tool accepts as input the flattened Base Modelica representation of a square Modelica simulation model with as many equations as unknown variables, with all the input variables bound to some expressions that only depend on time. The corresponding generated Pyomo model is a degenerate dynamic optimization model with a trivial objective function, no free inputs, and no inequality constraints, whose solution corresponds to the simulation of the original Modelica model. The comparison between the simulation results of the Modelica model and the solution of this degenerate dynamic optimization problem allows to verify that the DAEs have been correctly transcribed by the whole toolchain.

One can then formulate actual dynamic optimization problems by manually editing the generated Pyomo code:

- replacing the objective function with the desired one;
- removing the equations that determine the time-dependent system inputs, thus freeing the inputs that should be determined as a result of the optimization problem;
- optionally adding inequality constraints to the system variables.

2.1 Tool inputs

To generate the equivalent Pyomo model, Modelica2Pyomo requires as input the flattened Base Modelica code of the Modelica model and optionally the result file

DOI 10.3384/ecp218117

of a Modelica simulation of the model to provide an initial guess to the solver. Employing Base Modelica code as input allows to process a flat representation of the Modelica model which only contains lists of variables, functions and record declarations, equations and initial equations, without bothering about object-oriented features such as modularity, connectors, inheritance, etc. This greatly simplifies the writing of the Modelica2Pyomo tool.

Additionally, in order to minimize the tool development work, the generated BaseModelica code needs to fulfill some additional requirements, which are obtained by flattening the model with OpenModelica and setting some special flags in the compiler:

- `-d=evaluateAllParameters` replaces all parameter instances in the equations with their literal numerical value; this allows to skip the parameter section of the model entirely, as well as the handling of dependencies among parameters enforced by non-trivial parameter-binding expressions; it also prevents conditional equations and expressions depending only on parameters to show up in the equation that will be passed to Pyomo;
- `--frontendInline` enables inlining of functions (i.e., the body of a function is inserted in all places where the function is called, swapping the formal inputs with the actual inputs), to make the resulting model fully equation-based.
- `--baseModelicaOptions=moveBindings` moves all the binding equations of Real variables into the `equation` section, so there is no need to parse binding equations separately from regular equations;
- `--baseModelicaOptions=scalarize` rolls out array variable declarations and array equations (including `for` loops) into their scalar elements, so that each variable declaration corresponds to a scalar variable and each equation is a scalar equation in the Base Modelica code; this also minimizes the tool development effort, because there is no need to handle arrays, slicing, iterators, etc., which are all handled upstream by the OpenModelica tool.

2.2 Tool capabilities and limitations

Modelica2Pyomo can handle Modelica models of arbitrary complexity from an object-oriented point of view: features such as models defined by instantiating components, parameter passing, a-causal connectors, composite connectors, stream connectors, expandable connectors, inner/outer components, inheritance, replaceable classes and components, N-dimensional arrays of variables and components, are all supported. The availablity of a Base Modelica interface with a state-of-the-art compiler such as OpenModelica makes it possible to off-load the processing of all these features onto the Modelica tool, so that the implementation of the Modelica2Pyomo tool can be kept very lean, while remaining always be up-do-date with the latest additions to the Modelica language, as long as an updated version of the Modelica tool is used.

This approach can make Modelica2Pyomo a very attractive tool for the Pyomo community. Pyomo indeed includes several features for the handling of modular, structured models, but they are by no means as powerful as those made available by the Modelica language. In the authors' opinion, it would be a waste of time to re-invent yet another full-fledged object-oriented modelling language for Pyomo – a much more efficient approach is to re-use Modelica as a modelling front-end (including drag-and-drop graphical user interfaces such as OMEdit) and then use OpenModelica for flattening and Pyomo as an optimization back-end. Modelica2Pyomo is meant to be a first step in this direction.

The main limitation on the models that Modelica2Pyomo can handle stems from the capabilities of the Pyomo.DAE tool it is based upon. Pyomo.DAE can only take as input purely equation-based index-1 DAEs, described by scalar variables and equations. Hence, the upstream Modelica tool must be able to reduce the original model to that form. This entails some restrictions in the set of supported models.

First and foremost, the original Modelica model must be purely continuous-time; hence, it should not contain discrete or clocked variables. Additionally, Pyomo.DAE expects the equations to be continuously twice-differentiable; this also rules out conditional expression and equations, which are potentially not differentiable, and which in any case have no counterpart in Pyomo.DAE.

Conditional expression could be supported by Modelica2Pyomo by replacing expressions such as `if a > b then c else d` with analytic expressions such as

$$\frac{1}{2}\left[d+c+\tanh\left(\frac{a-b}{\varepsilon}\right)(d-c)\right], \tag{1}$$

where ε is a suitably small constant; with the same logic, conditional equations such as

```
if a > b then
  x = y;
else
  z = w;
end if;
```

could be approximated with the following smoothed approximation to a complementary condition:

$$z+x-w-y+\tanh\left(\frac{a-b}{\varepsilon}\right)(z+y-w-x)=0. \tag{2}$$

This feature is not yet implemented at the moment, but it could be easily added in the future.

Last, but not least, Pyomo can only handle index-1 DAE models; at the time of this writing this implies that the original Modelica model also has to be index-1, because OpenModelica currently outputs the flat Base Modelica code immediately after the flattening phase, prior to structural analysis and index reduction. It is possible to check that this condition holds by

compiling the Modelica model for simulation with the flags `--preOptModules-=removeSimpleEquations -d=bltdump`, which reports whether index reduction is necessary to obtain an index-1 system. This restriction may be lifted in the future if OpenModelica becomes capable of outputting index-reduced Base Modelica code.

As mentioned at the beginning of Section 2, the originally supplied Modelica model must have prescribed input variables, which will then be freed and determined as the result of the optimization problem. It is possible, and in fact recommended, to also provide a reference simulation result file, obtained with those prescribed input values, which will be employed to provide an initial guess for the optimal solution, considerably improving the chances of convergence of the optimization problem. If no result file is supplied, the variables will be initialized to zero.

As a final remark, the Modelica2Pyomo tool was mainly designed to solve *dynamic* optimization problems, where the constraint equations are DAEs. However, as a special case, it can also solve *static* optimization problems, where all the constraint equations are purely algebraic. This can be helpful in a number of application fields; for example, in the case of thermal power generation systems, it can be first used to compute optimal (i.e., maximum efficiency) steady-state off-design operating points, and later to compute optimal (i.e., fast) transients to move between them at maximum speed while respecting operational constraints such as maximum temperature gradients.

2.3 Notable Modelica2Pyomo features

A crucial feature offered by Modelica2Pyomo is the automatic normalization of variables, constraints and objective function.

One aspect of declarative equation-based modeling is that the use of dimensionally consistent SI units for the physical variables is preferable; however, in many application areas this can lead to systems of equations which are badly scaled from a numerical point of view. As explained by Casella and Braun (2017), even though this is usually not declared explicitly in the literature and in the documentation about optimization solvers, the implicit assumption taken by their developers is that the unknowns of the problem have an order of magnitude close to unity or at least not too far from that, e.g. in the range $10^{-3} - 10^{3}$. The optimization of badly scaled models of significant complexity are inevitably bound to fail, a fact further confirmed by the authors' experience with convergence failures before scaling was included in Modelica2Pyomo.

For these reasons, the normalization procedures described in Casella and Braun (2017) are implemented in Modelica2Pyomo. For the variables, the normalization value is chosen as the maximum value between the assigned nominal value and the initialization value assigned to the variable in the first time instant.

Regarding the constraint residuals and the objective function, again as suggested by Casella and Braun (2017), they are scaled by the factor

$$f_{norm} = \max_j \frac{df}{dx_j} x_{j,norm} \tag{3}$$

where x_j are the unknown variables and $x_{j,norm}$ are their normalization values. The lines of code responsible for the variable normalization are placed after each variable declaration while the code for the constraints and objective function normalization is included in the Pyomo script right before the solver declaration at the end of the file.

Modelica2Pyomo offers also an expression manipulation feature that consists in the replacement of logarithm expressions with a more suited equivalent formulation. Since logarithms are not defined for arguments equal or less than zero, the solvers will encounter issues if their argument become negative during Newton-Raphson iterations. An alternative and equivalent formulation can be introduced to overcome this issue:

$$\begin{cases} \ln(x) \rightarrow u \\ \exp(u) - x = 0 \end{cases} \tag{4}$$

The logarithm is replaced by an auxiliary variable u and the second equation, which does not suffer from the same domain limitations of the logarithmic function, is enforced to replace the logarithm expression.

Concerning the initial guess values for the optimization problem, Modelica2Pyomo offers three options:

1. no initial guesses are employed (all initial guesses are zero);
2. each variable is initialized to a constant value obtained from the results file of the Modelica simulation at a specified time instant;
3. each variable is initialized with the time evolution of the corresponding Modelica variable obtained from the results file of a suitable reference simulation.

Finally, if a dynamic optimization problem is formulated, two different options are provided to specify its initial conditions:

1. employ the initial equations of the Modelica model;
2. fix the initial values of the variables appearing in the Modelica derivative operator according to the values reported in the results file of the simulation.

The first option is in principle more flexible, since it covers those cases where the initial condition is not fixed a priori but is also part of the optimization problem; on the other hand, difficult-to-solve initialization problem could lead to convergence problems of the optimization solver.

The second option only works in the case of initial conditions that are fixed for the optimization problem, with the advantage that it can leverage on advanced features of the Modelica tool (e.g., homotopy) to successfully solve hard initialization problems. This is essential in cases such as the steady-state initialization of thermal power generation systems.

DOI 10.3384/ecp218117

2.4 Modelica2Pyomo script overview

Modelica2Pyomo is organized in several functions, which are all executed through the *m2p()* function. The arguments that should be passed to this function, together with the paths of the Modelica model and the optional results file, are the following:

- a string with the name of the Python file that will contain the Pyomo model;
- a string with the name of the solver to be employed;
- a string specifying whether the generated problem will be *Static* or a *Dynamic* optimization program;
- in case of a dynamic optimization problem, a string specifying whether the initial equation of the Modelica model should be translated or the initial values of the states should be retrieved from the results file;
- in case of a dynamic optimization problem, the start and finish time instants of the simulation;
- in case of a dynamic optimization problem, a dictionary containing information about the discretization method (e.g. finite differences or collocation) and the respective settings (e.g., number of finite elements, discretization scheme, etc.);
- a flag to enforce the *min*/*max* attributes in the imported reference simulation file;
- a flag to enable expressions manipulation, e.g., logarithms transformations;
- a string containing the Pyomo code to specify the objective function;
- optional strings containing additional constraints and utility Python commands to be inserted before and after the solver definition lines of the Pyomo model.

Once it is run, the tool performs the set of operations that is briefly described below. Each step roughly corresponds to a Python function, which adapts to the user requirements according to the input described above.

1. read the Base Modelica file and store each line in a list;
2. store in a Python dictionary with the DyMat Python package by Jörg (2011) the numerical results of a Modelica simulation of the system;
3. remove from the Base Modelica code comments and other characters which are not related to the model description;
4. identify, if present, the lines related to *TimeTables* and *CombiTimeTables* declarations, store the tables and instantiate a string containing their Pyomo code;
5. analyze the variable section of the Base Modelica model and store name, min, max and nominal values of each variable;
6. employ the information of the previous step and the DyMat results dictionary to build a string containing the necessary code to instantiate the variables of the model, setting min/max bounds, initial values and normalization value employing the Pyomo syntax;
7. analyze the equation section of the Base Modelica model and instantiate a string containing the equations of the problem using the proper Pyomo syntax. In addition, look for the following cases:
   - if a variable is set equal to a number, use the Pyomo *fix* variable attribute to model the equation instead of the original formulation;
   - if a logarithm expression is present and the optional flag is enabled, store the logarithm argument and replace the logarithm as shown in Equation (4);
   - if a time derivative operator is present, store the associated variable to create a list of the states;
8. analyze the initial equation section and instantiate a string with additional equations to define the Modelica parameter characterized by the *fixed = true* attribute, which, otherwise, would be missing their defining equation;
9. use the list of state variables created in the previous step to instantiate the respective time derivatives with the Pyomo *DerivativeVar* object;
10. analyze the initial equation section to instantiate a string featuring the initial equations of the Pyomo optimization problem;
11. write on a .py file the Pyomo code contained in the string created in the previous steps together with the objective function, constraints and objective function normalization code, solver settings and other custom lines included as arguments for the tool.

To execute many of the steps listed above, Modelica2Pyomo employs regular expressions through the Python native re and regex (Matthew 2025) packages to search for predefined patterns in the rows of the Base Modelica file and stores information about variables and constraints according to the specification of the Base Modelica language. Moreover, the quoted identifiers used for Base Modelica variables are adapted to remove the quotes, the Modelica dot notation, square brackets and commas, which are all replaced with underscores in the Pyomo model in order to comply with Python syntax rules.

As an example, Appendix A reports a simple, first-order model formulated in Modelica, its Base Modelica flat representation, and the corresponding Pyomo script generated by the Modelica2Pyomo tool.

3 Test cases

In this Section, two examples of Modelica model translation are showcased; both models are converted into open-loop dynamic optimal control problems, which are then successfully solved by the Pyomo framework. The first example is a simple, conceptual model that can be useful to understand how the tool works. The second example, instead, is a full-fledged industrial-grade system model, aimed at demonstrating the capability of the tool to handle real-life complexity models.

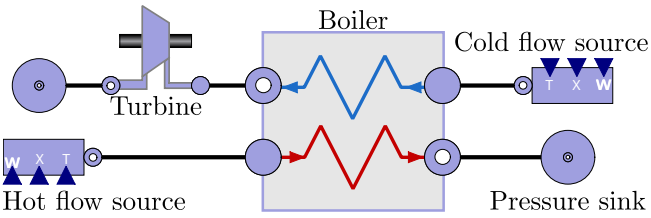

Figure 1. Modelica diagram of the s-CO_2 boiler and turbine model.

The corresponding BaseModelica flat models, which are the actual inputs of the tool, are available in the Examples directory of the Modelica2Pyomo package (De Pascali and Casella 2025).

3.1 Conceptual s-CO_2 boiler-turbine system

The first test features a conceptual Modelica model of a supercritical CO_2 boiler-turbine system. Figure 1 shows the diagram of the model. A hot flue gas stream heats up a cold stream of supercritical CO_2 which is expanded in a turbine with a prescribed outlet pressure to produce electrical power. The two streams are generated by ideal mass flow rate sources and their flow rate and temperatures can be changed arbitrarily. The medium model for supercritical CO_2 is the implicit Peng-Robinson equation of state, written in the equation section of the model.

In the first test case, the flow rates are fixed to constant values and are embedded in the optimization problem with the Pyomo *fix* attribute. The selected simulation time is 500 s and direct collocation with 100 finite elements, each with 3 collocation points, is the employed discretization method. Since the Modelica model is a square system having the same number of variables and equations, the translated optimization problem does not feature degrees of freedom, thus its optimal solution coincides with the simulated Modelica trajectory.

The coincidence of the two solutions demonstrates that the Modelica model was successfully translated into an equivalent Pyomo model, having the same solution.

To formulate a meaningful optimization problem, first two degrees of freedom are introduced, by *unfixing* the two mass flow rate variables (w_{hot} and w_{cold}), then a suitable cost function is chosen to guide the plant along transient conditions, as follows. The system is required to track a time-varying power output P_{turb} setpoint while keeping the turbine inlet temperature TIT constant. To this end, the following objective function is employed, with overbarred variables being the required setpoints, k indicating the simulation time step and coefficients, A_i being suitable weights for the different components of the expression:

$$\begin{aligned}\min \sum_k \; & (A_1 \cdot (P_{\text{turb}}(k) - \overline{P}_{\text{turb}}(k))^2 \\ & + A_2 \cdot (\text{TIT}(k) - \overline{\text{TIT}}(k))^2 \\ & + A_3 \cdot (w_{\text{hot}}(k) - w_{\text{hot}}(k-1))^2 \\ & + A_4 \cdot (w_{\text{cold}}(k) - w_{\text{cold}}(k-1))^2)\end{aligned} \tag{5}$$

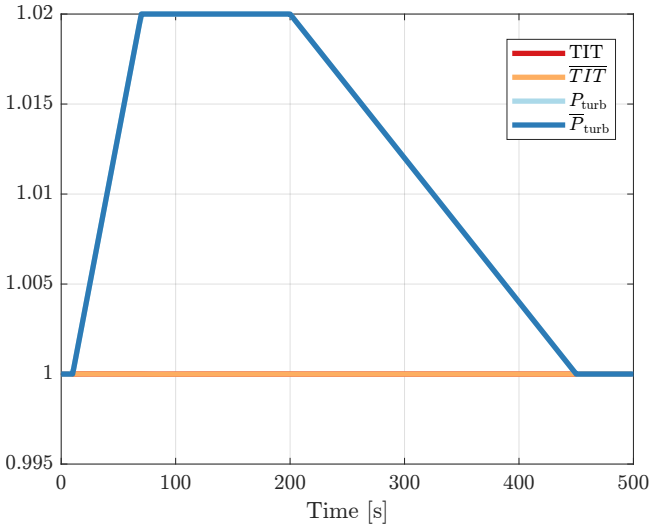

Figure 2. P_{turb} and TIT normalized profiles.

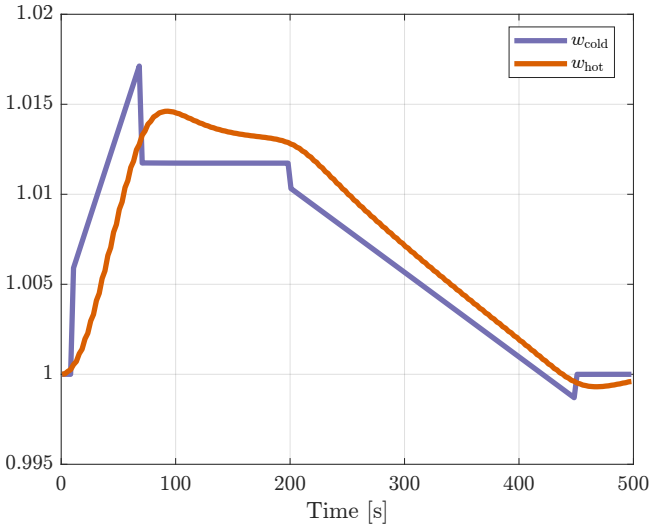

Figure 3. w_{hot} and w_{cold} normalized profiles.

The third and fourth terms of the objective function in (5) limit the rate of change of the optimization variables, moderating the control action.

Figure 2 shows that both P_{turb} and TIT follow accurately their setpoints, while Figure 3 shows the optimization variables w_{hot} and w_{cold}, that, as prescribed by the objective function, do not show abrupt variations. This first example shows that this class of simulation problems can be effectively translated into a nonlinear optimization problem, that features roughly 10000 variables and constraints. The most time consuming operation is the objective function normalization routine, while the Modelica to Pyomo compilation, the variables and constraints instantiation, the constraints normalization and the solver overhead is negligible. Table 1 summarizes these considerations and also shows a comparison between the open-source solver IPOPT and the commercial closed-source solver CONOPT 4.

DOI 10.3384/ecp218117

Table 1. Performance results for the s-CO_2 boiler-turbine test

	Time [s]
Modelica2Pyomo model translation	2.3
Pyomo variables and Constraints instantiation	0.2
Constraints normalization	0.01
Objective function normalization	12
Solver: IPOPT	0.3
Solver: CONOPT 4	0.8

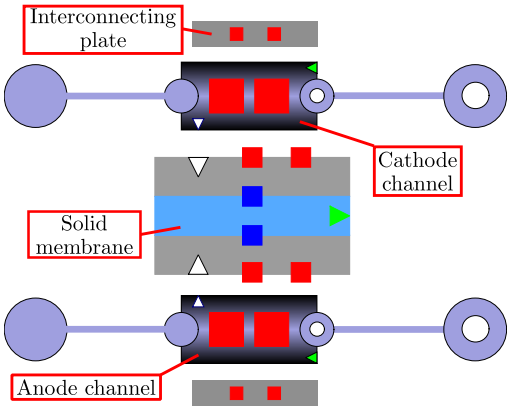

Figure 4. Modelica diagram of the solid-oxide fuel cell model.

3.2 Solid-oxide fuel cell

While the Section above showcased a toy example with relatively few equations, the goal of this Section is to present a relevant industrial case study. To this end, the 1-D solid-oxide fuel cell (SOFC) model presented by De Pascali, Donazzi, et al. (2023) and employed by De Pascali and Casella (2024) to model a complex thermal power generation system, is fed to Modelica2Pyomo to formulate an open-loop optimal control problem. The model has about 9000 variables and equations. Note that the full source code of the model is publicly available on GitHub. The model of the SOFC (see the Modelica diagram in Figure 4) is extremely nonlinear, due to the presence of strongly coupled nonlinear thermal, chemical and electrochemical phenomena. These describe the conversion at high temperatures of natural gas into hydrogen and its oxidation with oxygen ions to produce water, with the final aim of generating electrical power without resorting to fuel combustion.

The extensive use of object-oriented modeling techniques, that are necessary to tame the complexity of the formulation of such a challenging model, would make an hypothetical *manual translation* into an optimization framework such as Pyomo.DAE quite difficult, time consuming, and error-prone. This is exactly the reason that motivated the work presented in this paper: Modelica2Pyomo is capable of *automatically* converting such a complex Modelica model featuring 10000 equations and 160 states into a working Pyomo model.

As in the previous case, to formulate a dynamic optimization problem, direct collocation is used to discretize in time the simulation: for a 120 s simulation with 35 time steps, each with 3 collocation points, a NLP with roughly 850000 equality constraints is formulated. The goal of this test is to evaluate a trajectory for the SOFC extracted current I to optimally follow an electrical power output P_{SOFC} setpoint, while constraining the maximum allowed rate of change of the temperatures T of the fragile ceramic solid membrane of the SOFC. The following constraints is thus added manually to the Pyomo model for all the temperature variables of the SOFC solid membrane:

$$T(k) - T(k-1) < \frac{dT_{max}}{dt} \cdot \Delta t \tag{6}$$

$$T(k) - T(k-1) > -\frac{dT_{max}}{dt} \cdot \Delta t \tag{7}$$

where dT_{max}/dt is the maximum temperature rate of change prescribed by fuel cell manufacturers and Δt is the length of the simulation time step. In this test, dT_{max}/dt is varied to show how the solver is forced to follow less accurately the power setpoint $\overline{P}_{\text{SOFC}}$ when its variation is too steep. The following objective function is chosen:

$$\begin{aligned} \min \sum_k \; & (B_1 \cdot (P_{\text{SOFC}}(k) - \overline{P}_{\text{SOFC}}(k))^2 \\ & + B_2 \cdot (I(k) - I(k-1))^2 \\ & + B_3 \cdot (T(k) - T(k-1))^2) \end{aligned} \tag{8}$$

Also in this case, the coefficients B_i are employed to weight the contributions of the different terms of the objective function and the last two components are employed to moderate the control action.

Figure 5 shows the SOFC power output considering two different values for dT_{max}/dt: in the stricter case, $dT_{max}/dt = 0.2\,\text{K/s}$, while in the milder case, this value is three times higher. As expected, the control performance are worse in the stricter case, and the power setpoint is followed less accurately. Figure 6 shows the trends of the temperature of the solid membrane at the near the outlet of the SOFC, which respect the prescribed maximum rate of variation. Figure 7 shows the current I extracted from the fuel cell, which is the manipulated variable determined by the optimization problem.

Also in this much more challenging test case, Modelica2Pyomo is able to formulate a meaningful and working Pyomo model with no effort by the end user except for the manual inclusion of additional constraints for the membrane temperatures and the objective function. Compared to the previous example, Table 2 shows comparable compilation and instantiation times, while the time required by the solvers is higher, given the increased size of the optimization problem. Notice that the time employed to normalize the objective function is lower, since this simulation features less time steps, compared to the previous one. Moreover, IPOPT was not able to solve this model,

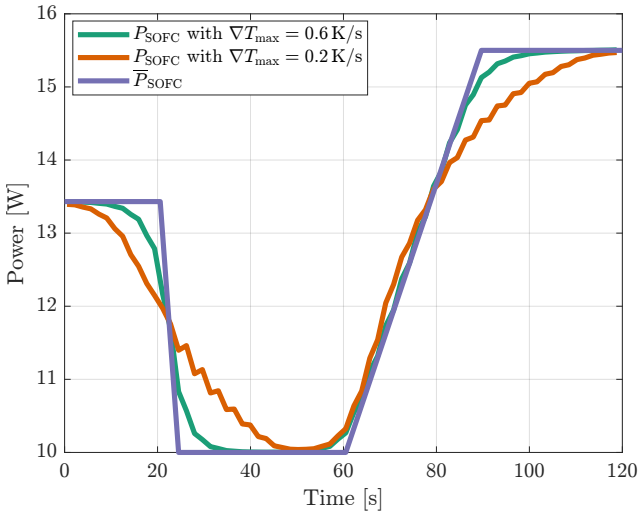

Figure 5. P_{SOFC} at varying dT_{max}/dt.

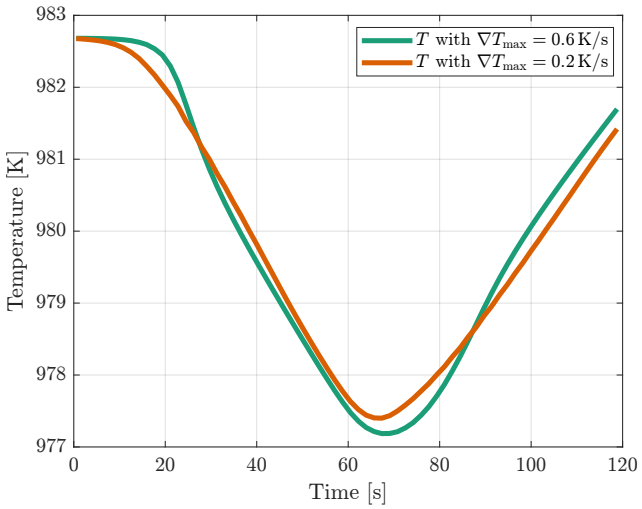

Figure 6. Membrane T at the SOFC discharge at varying dT_{max}/dt.

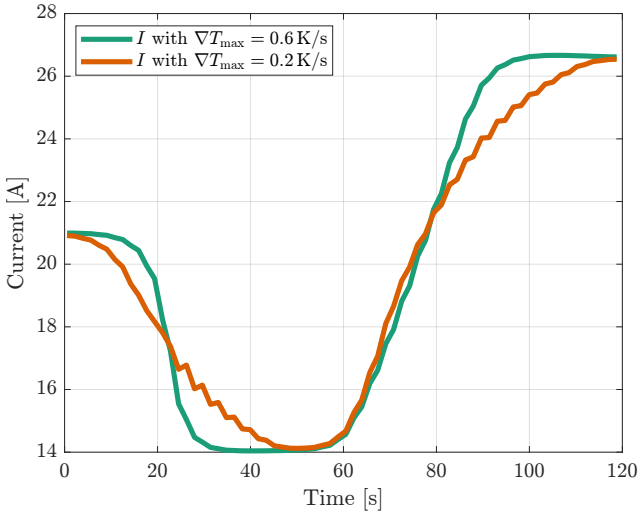

Figure 7. I extracted from the fuel cell at varying dT_{max}/dt.

Table 2. Performance results for the solid-oxide fuel cell test

	Time [s]
Modelica2Pyomo model compilation	3.7
Pyomo variables and Constraints instantiation	6.7
Constraints normalization	1.3
Objective function normalization	0.7
Solver: CONOPT 4	185

possibly indicating that a feasible path, active-set solver like CONOPT might be more suited for this class of problems, compared to an interior point method like IPOPT.

4 Conclusion

In this paper, the Modelica2Pyomo tool was presented. The aim of this tool is to create an open-source, flexible, and lightweight bridge between Modelica and the optimization world.

Modelica2Pyomo is a Python script that translates Modelica models into Pyomo models, exploiting the OpenModelica tool for flattening, the new Base Modelica language for flat Modelica model representation, and the Pyomo.DAE tool for writing DAE constraints for Pyomo in a high-level fashion. The flat, scalarized Base Modelica representation obtained through OpenModelica uses a very nimble set of language constructs, that can be efficiently handled by regular expressions to find Base Modelica language patterns that are converted into Pyomo expressions, without the need of embarking in the traditional workflow of compiler development, with parsers, lexers, abstract syntax trees, etc.

This approach allowed to drastically cut the required development and maintenance effort from the tens of person-years required for the development of a full-fledged Modelica compiler down to a few person-months effort, a nice demonstration of the potential that can be unlocked by the forthcoming Base Modelica standard.

The Modelica2Pyomo tool produces the Pyomo code corresponding to the set of DAE constraint equations, including their proper scaling, the transformation of some expression to more numerically robust equivalent ones, and the capability of importing intial guesses for the NLP solver from reference simulation results. The actual optimization problem (constraints and objective function) is then directly formulated using the Pyomo tool, which allows flexible access to a range of different solvers, both open-source and commercial.

The results obtained in two example test cases were reported, showing the capabilities of the proposed framework, which is able to successfully convert industrially-relevant complex Modelica models into nonlinear optimization programs with satisfying performance.

DOI
10.3384/ecp218117

The code of the tool is available as open source under GPL v3 license. Contributions for its further improvement and developments are welcome.

Future research directions will extend the range of Modelica constructs that can be handled by the tool, e.g., by handling conditional expressions and equations by regularization, improve the numerical robustness of the translated Pyomo.DAE model, as well as test the framework on even more challenging problems, e.g., optimizing transients of an innovative power plant that features the fuel cell model studied in this work as one of its components. One could also experiment with the use of optimization techniques for solving hard steady-state initialization problems, using Pyomo as a protoyping environment. It would also be interesting to explore the optimal control of Modelica systems including time delays and discrete variables, as well as optimization with embedded DAE solvers (shooting methods).

Modelica2Pyomo clearly demonstrates how Base Modelica can successfully enable the development of lean tools that employ Modelica models for uses other than simulation. The authors hope that this example further motivates the standardization effort of the Base Modelica language, as well as its improved support in Modelica tools.

Enhancing Collocation-Based Dynamic Optimization through Adaptive Mesh Refinement

Linus Langenkamp [1] Bernhard Bachmann [1]

[1]Institute for Data Science Solutions, Bielefeld University of Applied Sciences and Arts, Germany,
{first.last}@hsbi.de

Abstract

Direct collocation-based dynamic optimization plays an important role in the optimization of equation-based models. With this approach, continuous problems are transcribed into sparse nonlinear programs (NLPs) that can be solved efficiently. The open-source Modelica environment OpenModelica provides an implementation using Radau IIA collocation, but has major limitations, such as the lack of parameter optimization, no adaptive mesh refinement, and no support for higher-order integration schemes. This paper presents (1) a comprehensive reimplementation that addresses these limitations and (2) a novel h-method mesh refinement algorithm. Implemented in the custom Python / C++ optimization framework GDOPT, the approach demonstrates significant performance improvements, solving typical problems 2 to 3 times faster than OpenModelica under equivalent conditions. Using the proposed mesh refinement algorithm, the framework correctly identifies non-smooth regions and increases resolution accordingly, requiring only a small increase in computation time. The implementation lays the foundation for a future integration into the OpenModelica toolchain.

Keywords: Dynamic Optimization, Direct Collocation, Adaptive Mesh Refinement, Nonlinear Programming

1 Introduction

Dynamic Optimization has application in many different fields, including engineering, systems biology, economics, aerospace engineering and other disciplines where physical models are described by differential-algebraic equations (DAEs). A widely adopted strategy for solving such problems is direct collocation, a method that discretizes the time horizon and replaces the states by polynomials that satisfy the differential equations at discrete nodes. This approach leads to a sparse nonlinear program (NLP) that can be solved with state-of-the-art nonlinear optimizers. The accuracy of the approach relies on a well-designed discretization mesh. While smooth trajectories can be approximated with fewer intervals or higher degree polynomials, non-smooth behavior, e.g. rapid transitions, switching points or nonlinearities, demands high resolution and fine meshes. Adaptive mesh refinement methods, including h- (interval length adjustment), p- (polynomial degree adjustment), and hp-strategies (hybrid), are essential to efficiently obtain accurate solutions and are an active area of research (Liu, Hager, and Rao 2015; M. A. Patterson, Hager, and Rao 2015; Jain and Tsiotras 2008; Y. Zhao and Tsiotras 2009; J. Zhao and Shang 2018).

Several free and commercial tools implement direct collocation methods, including GPOPS-II (M. A. Patterson and Rao 2014), PSOPT (Becerra 2010), SPARTAN (Sagliano et al. 2018), JModelica (Magnusson and Åkesson 2015), and OpenModelica (Ruge et al. 2014; Fritzson, Pop, Abdelhak, et al. 2020). Among them, OpenModelica offers a fully open-source environment that combines expressive equation-based modeling in the Modelica language with optimization capabilities in a single tool. However, its current direct collocation implementation, using Radau IIA methods, has significant limitations, as it lacks support for adaptive mesh refinement, parameter optimization, higher-order collocation schemes and does not use exact second-order derivatives.

To address these limitations, this work proposes a novel h-method mesh refinement algorithm, implemented in a newly developed open-source framework called GDOPT, which is designed for future integration into the OpenModelica toolchain. The primary objective of this paper is to develop a general purpose mesh refinement algorithm that can accelerate the convergence of direct collocation as well as correctly identify non-smooth sections of control trajectories and increase the resolution appropriately.

This paper is organized as follows: Section 2 provides a general introduction and presents the mathematical formulation of dynamic optimization using direct collocation. Based on these considerations, we propose our novel mesh refinement algorithm L2-Boundary-Norm in Section 3, detailing its principal components and properties. Section 4 discusses the direct collocation implementation, focusing on its most important features and workflows. To demonstrate the capabilities of the algorithm and our implementation, Section 5 presents numerical results for a representative control problem, the fuel-optimal start-up of a diesel-electric power train (Sivertsson and Eriksson 2012; Mengist, Ruge, Gebremedhin, et al. 2013; Bachmann et al. 2012), comparing these results with the current OpenModelica implementation. Section 6 examines the limitations of both the framework and mesh refinement algorithm, while Section 7 summarizes the work and pro-

vides an outlook for future work.

2 Dynamic Optimization

2.1 Problem Definition

Consider the dynamic optimization problem

$$\min_{\boldsymbol{u}(t),\boldsymbol{p}} \; M(\boldsymbol{x}(t_f),\boldsymbol{u}(t_f),\boldsymbol{p},t_f) + \int_{t_0}^{t_f} L(\boldsymbol{x}(t),\boldsymbol{u}(t),\boldsymbol{p},t)\,\mathrm{d}t \tag{1a}$$

s.t.

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x}(t),\boldsymbol{u}(t),\boldsymbol{p},t) \qquad \forall t \in T \tag{1b}$$

$$\boldsymbol{x}(t_0) = \boldsymbol{x}_0 \tag{1c}$$

$$\boldsymbol{g}^L \le \boldsymbol{g}(\boldsymbol{x}(t),\boldsymbol{u}(t),\boldsymbol{p},t) \le \boldsymbol{g}^U \qquad \forall t \in T \tag{1d}$$

$$\boldsymbol{r}^L \le \boldsymbol{r}(\boldsymbol{x}(t_f),\boldsymbol{u}(t_f),\boldsymbol{p},t_f) \le \boldsymbol{r}^U \tag{1e}$$

$$\boldsymbol{a}^L \le \boldsymbol{a}(\boldsymbol{p}) \le \boldsymbol{a}^U \tag{1f}$$

over a fixed time horizon $T = [t_0, t_f]$ with time $t \in T$, referred to as the General Dynamic Optimization Problem (GDOP). The goal is to determine optimal control trajectories $\boldsymbol{u}(t) : T \to \mathbb{R}^{d_{\boldsymbol{u}}}$, time-invariant parameters $\boldsymbol{p} \in \mathbb{R}^{d_{\boldsymbol{p}}}$, and states $\boldsymbol{x}(t) : T \to \mathbb{R}^{d_{\boldsymbol{x}}}$ minimizing the cost functional (1a), subject to the constraints (1b) - (1f). The objective is divided into the *Mayer term* $M(\cdot)$, penalizing the final system state, and the *Lagrange term* $\int_{t_0}^{t_f} L(\cdot)\,\mathrm{d}t$, accounting for accumulated cost over time. The constraints include an initial value problem with *dynamic constraints* (1b) and an *initial condition* (1c), along with algebraic *path constraints* (1d), *final constraints* (1e), and *parametric constraints* (1f). All involved functions $M, L : \mathbb{R}^d \times T \to \mathbb{R}$, $\boldsymbol{f} : \mathbb{R}^d \times T \to \mathbb{R}^{d_{\boldsymbol{x}}}$, $\boldsymbol{g} : \mathbb{R}^d \times T \to \mathbb{R}^{d_{\boldsymbol{g}}}$, $\boldsymbol{r} : \mathbb{R}^d \times T \to \mathbb{R}^{d_{\boldsymbol{r}}}$, and $\boldsymbol{a} : \mathbb{R}^{d_{\boldsymbol{p}}} \to \mathbb{R}^{d_{\boldsymbol{a}}}$ with $d := d_{\boldsymbol{x}} + d_{\boldsymbol{u}} + d_{\boldsymbol{p}}$, are assumed to be twice continuously differentiable. The constraint bounds are given by $\boldsymbol{g}^L, \boldsymbol{g}^U \in \bar{\mathbb{R}}^{d_{\boldsymbol{g}}}$, $\boldsymbol{r}^L, \boldsymbol{r}^U \in \bar{\mathbb{R}}^{d_{\boldsymbol{r}}}$, and $\boldsymbol{a}^L, \boldsymbol{a}^U \in \bar{\mathbb{R}}^{d_{\boldsymbol{a}}}$ with $\bar{\mathbb{R}} := (\mathbb{R} \cup \{-\infty, \infty\})$. This formulation extends the Nonlinear Optimal Control Problem (NOCP) implemented in OpenModelica (Ruge et al. 2014) by including static parameters, which may be present in all model functions.

2.2 Direct Collocation

The continuous GDOP is reduced to an NLP by embedding a collocation scheme based on *flipped Legendre-Gauss-Radau (fLGR)* points. This discretization is equivalent to a transcription using the Radau IIA Runge-Kutta method, where the fLGR collocation nodes are scaled from $[-1, 1]$ to $[0, 1]$. For $[0, 1]$, the nodes c_j, $j = 1, \ldots, m$ are the m roots of the polynomial $(1-t)P^{(1,0)}_{m-1}(2t-1)$, where $P^{(1,0)}_{m-1}$ is an $(m-1)$-th Jacobi polynomial. The Radau IIA method has excellent stability properties, since it is A-, B-, and L-stable, and achieves order $2m-1$ for m collocation nodes.

The time horizon $[t_0, t_f]$ is divided into $n+1$ intervals $[t_i, t_{i+1}]$, $i = 0, \ldots, n$ with lengths $\Delta t_i := t_{i+1} - t_i$. On each interval $[t_i, t_{i+1}]$, collocation nodes $t_{ij} := t_i + c_j \Delta t_i$, $j = 1, \ldots, m_i$, along with the first grid point $t_{i0} := t_i + c_0 \Delta t_i$, where $c_0 = 0$, are introduced. Since $c_{m_i} = 1$ is always included in the Radau IIA scheme, the last grid point of interval $i-1$ matches the first of interval i, i.e. $t_{i-1,m_{i-1}} = t_{i0}$.

States and controls are approximated as $\boldsymbol{x}(t_{ij}) \approx \boldsymbol{x}_{ij}$ and $\boldsymbol{u}(t_{ij}) \approx \boldsymbol{u}_{ij}$, with the initial state fixed as $\boldsymbol{x}_{00} := \boldsymbol{x}_0$. In interval i, the state $\boldsymbol{x}(t)$ is replaced by a Lagrange interpolating polynomial $\boldsymbol{x}_i(t) = \sum_{j=0}^{m_i} \boldsymbol{x}_{ij}\, l_j(t)$ of degree m_i, where

$$l_j(t) := \prod_{\substack{k=0 \\ k \neq j}}^{m_i} \frac{t - t_{ik}}{t_{ij} - t_{ik}} \quad \forall j = 0, \ldots, m_i. \tag{2}$$

This polynomial must satisfy the differential equation (1b) at the collocation nodes t_{ij} for $j = 1, \ldots, m_i$ and match the initial condition $\boldsymbol{x}_{i0}$ from interval $i-1$. These conditions yield

$$\boldsymbol{0} = \begin{bmatrix} D^{(1)}_{10} I & \ldots & D^{(1)}_{1m_i} I \\ \vdots & \ddots & \vdots \\ D^{(1)}_{m_i 0} I & \ldots & D^{(1)}_{m_i m_i} I \end{bmatrix} \begin{bmatrix} \boldsymbol{x}_{i0} \\ \vdots \\ \boldsymbol{x}_{im_i} \end{bmatrix} - \Delta t_i \begin{bmatrix} \boldsymbol{f}_{i1} \\ \vdots \\ \boldsymbol{f}_{im_i} \end{bmatrix}, \tag{3}$$

with identity matrix $I \in \mathbb{R}^{d_{\boldsymbol{x}} \times d_{\boldsymbol{x}}}$, $\boldsymbol{f}_{ij} := \boldsymbol{f}(\boldsymbol{x}_{ij}, \boldsymbol{u}_{ij}, \boldsymbol{p}, t_{ij})$, and the first differentiation matrix $D^{(1)}_{jk} := \frac{\mathrm{d}\tilde{l}_k}{\mathrm{d}\tau}(c_j)$, where

$$\tilde{l}_k(\tau) := \prod_{\substack{j=0 \\ j \neq k}}^{m_i} \frac{\tau - c_j}{c_k - c_j} \quad \forall k = 0, \ldots, m_i. \tag{4}$$

Using the formulas provided in (Schneider and Werner 1986), these matrices can be computed efficiently *a priori*.

The Lagrange term is approximated via the corresponding Radau quadrature rule

$$\int_{t_0}^{t_f} L(\boldsymbol{x}(t),\boldsymbol{u}(t),\boldsymbol{p},t)\,\mathrm{d}t \approx \sum_{i=0}^{n} \Delta t_i \sum_{j=1}^{m_i} b_j L_{ij}, \tag{5}$$

where $L_{ij} := L(\boldsymbol{x}_{ij}, \boldsymbol{u}_{ij}, \boldsymbol{p}, t_{ij})$ and the quadrature weights are given by

$$b_j = \int_0^1 \prod_{\substack{k=1 \\ k \neq j}}^{m_i} \frac{\tau - c_k}{c_j - c_k}\,\mathrm{d}\tau \quad \forall j = 1, \ldots, m_i. \tag{6}$$

2.3 Resulting NLP

Discretizing the remaining components of the GDOP is straightforward. The path constraints are replaced by constraints, which are evaluated at all grid points t_{ij} and the Mayer term and final constraints are approximated by an evaluation at the final grid point t_{nm_n}. The time-invariant parameters and their parametric constraints need not be

DOI 10.3384/ecp218127

discretized, since these are discrete. By flattening the collocated dynamics (3), the discretized GDOP becomes

$$\min_{\boldsymbol{x}_{ij},\boldsymbol{u}_{ij},\boldsymbol{p}} M(\boldsymbol{x}_{nm_n},\boldsymbol{u}_{nm_n},\boldsymbol{p},t_{nm_n}) + \sum_{i=0}^{n}\Delta t_i \sum_{j=1}^{m_i} b_j L(\boldsymbol{x}_{ij},\boldsymbol{u}_{ij},\boldsymbol{p},t_{ij}) \tag{7a}$$

s.t.

$$\boldsymbol{0} = \sum_{k=0}^{m_i} D^{(1)}_{jk}\boldsymbol{x}_{ik} - \Delta t_i \boldsymbol{f}(\boldsymbol{x}_{ij},\boldsymbol{u}_{ij},\boldsymbol{p},t_{ij}) \tag{7b}$$

$$\boldsymbol{x}_{00} = \boldsymbol{x}_0 \tag{7c}$$

$$\boldsymbol{g}^L \le \boldsymbol{g}(\boldsymbol{x}_{ij},\boldsymbol{u}_{ij},\boldsymbol{p},t_{ij}) \le \boldsymbol{g}^U \tag{7d}$$

$$\boldsymbol{r}^L \le \boldsymbol{r}(\boldsymbol{x}_{nm_n},\boldsymbol{u}_{nm_n},\boldsymbol{p},t_{nm_n}) \le \boldsymbol{r}^U \tag{7e}$$

$$\boldsymbol{a}^L \le \boldsymbol{a}(\boldsymbol{p}) \le \boldsymbol{a}^U \tag{7f}$$

where the dynamic constraints (7b) and path constraints (7d) must be satisfied for all $i = 0,\dots,n$ and $j = 1,\dots,m_i$.

This sparse, large-scale NLP can be implemented and solved efficiently with state-of-the-art nonlinear optimizers such as Ipopt (Wächter and Biegler 2006) or SNOPT (P. E. Gill et al. 2007; Philip E. Gill, Murray, and Saunders 2005), which require first and second order derivatives of the objective and constraints. By properly sorting the constraint vector, the cyclic block structure in the Jacobian and Hessian can be exploited. A detailed overview of the resulting blocks is given in (Langenkamp 2024).

3 Adaptive Mesh Refinement

An important modeling decision is the choice of grid points, i.e. the mesh $\mathcal{M} = \{t_0, t_1, \dots, t_n\}$, and the number of collocation nodes m_i per interval. Without prior knowledge of the problem, one might use an equidistant mesh $\Delta t_i \equiv$ const and a fixed number of nodes $m_i \equiv$ const. However, this often leads to large errors and unrealistic results, especially when the optimal solution exhibits discontinuities, switches, or steep gradients. Furthermore, the optimization often takes a significant amount of computation time due to poor initial guesses.

To address this, direct collocation methods typically employ adaptive mesh refinement algorithms, which balance accuracy and efficiency. In adaptive refinement, an initial NLP is solved on a coarse mesh, then the mesh is refined, and the NLP is solved again using updated initial guesses. This process continues until a termination criterion is met. The main classes of mesh refinement methods are h-, p-, and hp-methods.

h-methods (J. Zhao and Shang 2018; Y. Zhao and Tsiotras 2009; Jain and Tsiotras 2008; Betts and Huffman 1998) divide the time horizon into many intervals and use low-degree polynomials on each, i.e. $m_i \equiv m$. Convergence is achieved by increasing the number of intervals based on error criteria. These methods are robust and effective for non-smooth solutions but converge only polynomially fast for smooth problems. Several h-methods have been described in the literature. For example, in (J. Zhao and Shang 2018) a *multiresolution technique* is proposed that compares the current solution with a smoothed trajectory using non-oscillatory (ENO) interpolation. It detects non-smooth regions and merges intervals with constant control. Another method, presented in (Y. Zhao and Tsiotras 2009), encodes the curvature of the control trajectory into a density function that governs the distribution of mesh points, effectively capturing irregularities.

p-methods usually use a single interval and high-degree global polynomials. For smooth problems, they achieve *spectral*, i.e. exponential, convergence, but for non-smooth cases, errors grow significantly.

Modern hp- or ph-adaptive methods (M. A. Patterson and Rao 2014; M. A. Patterson, Hager, and Rao 2015; Liu, Hager, and Rao 2015; Sagliano et al. 2018; Garg, M. Patterson, Francolin, et al. 2011) combine both strategies. They adapt both the number of intervals and polynomial degrees. These hybrid methods also provide spectral convergence and are implemented in state-of-the-art tools such as GPOPS II (M. A. Patterson and Rao 2014). However, they may still struggle to detect switches and often generate large meshes with many collocation points (J. Zhao and Shang 2018; M. A. Patterson, Hager, and Rao 2015).

3.1 L2-Boundary-Norm

In this paper, the novel h-method *L2-Boundary-Norm (L2BN)* is proposed, which uniformizes the control trajectory in a similar way to density function-based approaches (Y. Zhao and Tsiotras 2009). L2BN applies consecutive bisection mesh refinement, following a workflow similar to the *multiresolution* technique (J. Zhao and Shang 2018), but without removing mesh points to maintain maximum stability. The method is designed to detect discontinuities, kinks, bends, and steep sections, while requiring limited computation time. L2BN is divided into 2 distinct phases:

3.2 Phase I

Phase I is used to accelerate the optimization by performing a simple multigrid refinement. Here the possibly poor initial guess of the control trajectory $\boldsymbol{u}_{init}(t)$, e.g. constant or linear, is only used for an initial optimization on an extremely coarse mesh. To ensure that the state trajectory guess $\boldsymbol{x}_{init}(t)$ is feasible, i.e. satisfies the initial value problem (1b) - (1c), the initial states are obtained by performing a simulation using the provided guesses $\boldsymbol{u}_{init}(t)$ and $\boldsymbol{p}_{init}$.

The initial optimization is exceptionally fast compared to one using the poor guess on a fine mesh. The optimal solution of the problem is then interpolated onto a mesh, where every interval has been bisected. This interpolated solution is then used as a new, more appropriate initial guess and optimized again. Repeating this process several times, yields a realistic, equidistant optimal solution

that solely suffers from steep sections, kinks or jump discontinuities. Overall, the first phase can be expressed as Algorithm 3.1:

Algorithm 3.1: Phase I: Multigrid Refinement

Input: GDOP, equidistant mesh $\mathcal{M}_0$, number of iterations k_{max}, initial guess on the control trajectory $\boldsymbol{u}_{init}(t)$ and parameters $\boldsymbol{p}_{init}$
Output: Equidistant solutions $\boldsymbol{x}^*(t)$, $\boldsymbol{u}^*(t)$, $\boldsymbol{p}^*$

$\boldsymbol{x}_{init}(t) \leftarrow$ Solve the ODE $\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\cdot), \boldsymbol{x}(t_0) = \boldsymbol{x}_0$ using the guesses $\boldsymbol{u}_{init}(t), \boldsymbol{p}_{init}$
for $k = 0, \ldots, k_{max}$ **do**
  $\boldsymbol{x}_k^*(t), \boldsymbol{u}_k^*(t), \boldsymbol{p}_k^* \leftarrow$ Solve the NLP (7a) - (7f) on $\mathcal{M}_k$ using $\boldsymbol{x}_{init}(t), \boldsymbol{u}_{init}(t), \boldsymbol{p}_{init}$ as initial guesses
  if $k = k_{max}$ **then**
    return $\boldsymbol{x}_k^*(t), \boldsymbol{u}_k^*(t), \boldsymbol{p}_k^*$
  end
  $\mathcal{U}_k \leftarrow \left\{ \frac{t_i + t_{i+1}}{2} \mid i = 0, \ldots, |\mathcal{M}_k| - 1 \right\}$
  $\mathcal{M}_{k+1} \leftarrow \mathcal{M}_k \cup \mathcal{U}_k$
  $\boldsymbol{p}_{init} \leftarrow \boldsymbol{p}_k^*$
  $\boldsymbol{x}_{init}(t), \boldsymbol{u}_{init}(t) \leftarrow$ Interpolate $\boldsymbol{x}_k^*(t), \boldsymbol{u}_k^*(t)$ onto $\mathcal{M}_{k+1}$
end

3.2.1 Illustration of Phase I

To further illustrate phase I, we consider the *Oil Shale Pyrolysis*[1], studied in (Wen and Yen 1977) and (Langenkamp 2024), aiming to find an optimal temperature control. Using a poor, constant initial temperature guess two approaches are compared. The *Default* method involves optimization on a mesh with $|\mathcal{M}_0| = 80$ intervals and $m = 3$ collocation nodes. Alternatively, Algorithm 3.1 (Phase I) starts with a much coarser initial mesh of 5 intervals and performs $k_{max} = 4$ refinement iterations. Both methods ultimately yield the same optimal solution.

Method	$\lvert\mathcal{M}_0\rvert$	m	k_{max}	t_{opt}	Iter
Default	80	3	0	0.3492	161
Algorithm 3.1	5	3	4	0.1242	105

Table 1. Performance Evaluation of Phase I Refinement for an Oil Shale Pyrolysis Optimization

As detailed in Table 1, the optimization using Ipopt and MUMPS demonstrates that Algorithm 3.1 required fewer NLP iterations (Iter) and approximately one-third of the computation time t_{opt} in seconds compared to the default implementation. This significant speedup is attributed to the multigrid refinement strategy: instead of optimizing with a poor initial guess on a large mesh, the guesses progressively improve through successive refinements. Figure 1 depicts this process, showing how the temperature control trajectory evolves and approaches the final solution across refinement iterations.

[1]The GDOPT implementation can be found under `https://github.com/linuslangenkamp/GDOPT/blob/master/examples/oilShalePyrolysis.py`.

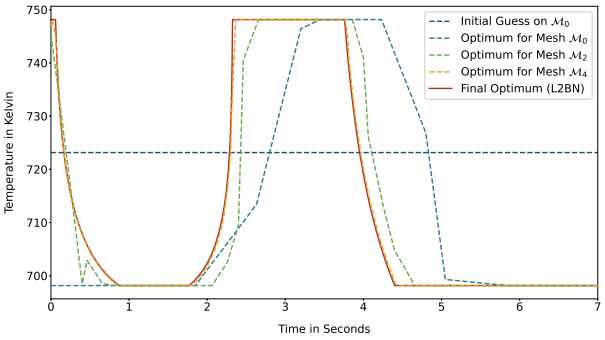

Figure 1. Multigrid refinement applied to an Oil Shale Pyrolysis (Wen and Yen 1977). The optimal solution after performing 3 additional phase II iterations is given as reference.

3.3 Phase II

Phase II addresses the problem of remaining steep sections, kinks or switches and iteratively refines the solution of phase I by investigating certain L^2-norms of the control trajectory (*on-interval condition*) as well as error terms of the trajectories on the boundary (*boundary condition*). It identifies non-smooth behavior and splits intervals, which violate the conditions, such that resolution is increased appropriately and switching times are identified correctly.

3.4 On-Interval Condition

The idea behind the *on-interval condition* is to individually inspect the current solution of the control variables $\boldsymbol{u}_{ij}$ within each mesh interval $[t_i, t_{i+1}]$ of the mesh $\mathcal{M}_k$, and to measure the *slope* and *curvature* of the control variables over the full interval. If these measures exceed a certain threshold, the interval is bisected, and the midpoint $\frac{t_i + t_{i+1}}{2}$ is added to the next mesh $\mathcal{M}_{k+1}$.

Consider an arbitrary interval $[t_i, t_{i+1}]$ from the mesh $\mathcal{M}_k$ and the current optimal solution of the l-th control variable $u^{(l)}$ on this interval. This solution is defined by $m+1$ sample points $u_{ij}^{(l)}$, $j = 0, \ldots, m$. The first step is to construct an interpolating polynomial $p_i^{(l)}(t)$ for the control variable $u^{(l)}$ on the normalized interval $[0, 1]$, such that $p_i^{(l)}(c_j) = u_{ij}^{(l)}$, $j = 0, \ldots, m$, with $p_i^{(l)} \in P^m$. This rescaling is performed because the condition should not be influenced by the length of the interval Δt_i and, moreover, only the magnitude of the controls should be relevant. In order to estimate the change on the interval, it is natural to consider a function norm of $\dot{p}_i^{(l)}$ and $\ddot{p}_i^{(l)}$ such as L^1, L^2 or L^∞. The L^2 norm

$$\|p\| := \sqrt{\int_0^1 p(\tau)^2 \, \mathrm{d}\tau} \tag{8}$$

is chosen, since it is a good middle ground and allows for

DOI 10.3384/ecp218127

a fast computation of the condition. All in all, the *on-interval condition* says:

Condition 3.1 (On-Interval Condition)**.** *If for a given interval* $[t_i, t_{i+1}]$ *there exists at least one control variable* $u^{(l)}$ *such that the interpolating polynomial* $p_i^{(l)}$ *on the nominal interval* $[0,1]$ *satisfies*

$$\left\|\dot{p}_i^{(l)}\right\| > TOL_1^{(l)} \quad \vee \quad \left\|\ddot{p}_i^{(l)}\right\| > TOL_2^{(l)},$$

for specified tolerances $TOL_1^{(l)}, TOL_2^{(l)} > 0$*, then the interval is bisected.*

3.4.1 Fast Computation

The following procedure enables an efficient and exact evaluation of the *on-interval condition* for any number of collocation nodes m. By construction, it holds that $\deg\left(\dot{p}_i^{(l)}(\tau)\right) = m-1$, $\deg\left(\ddot{p}_i^{(l)}(\tau)\right) = m-2$, which implies $\deg\left(\dot{p}_i^{(l)}(\tau)^2\right) = 2m-2$, $\deg\left(\ddot{p}_i^{(l)}(\tau)^2\right) = 2m-4$ for all $m \geq 2$. In the special case of $m = 1$, the second derivative of $p_i^{(l)}$ vanishes and the first derivative is constant. Since Radau quadrature with m collocation nodes integrates all polynomials of degree up to $2m-2$ exactly, both norms can be exactly evaluated using the quadrature rule. For simplicity, the calculations are only shown for the first derivative. These are analogous for the second derivative. Hence

$$\left\|\dot{p}_i^{(l)}\right\| = \sqrt{\int_0^1 \dot{p}_i^{(l)}(\tau)^2 \,\mathrm{d}\tau} = \sqrt{\sum_{k=1}^{m} b_k \dot{p}_i^{(l)}(c_k)^2}, \qquad (9)$$

where b_k are the Radau quadrature weights (6). By writing $p_i^{(l)}(\tau) = \sum_{j=0}^{m} u_{ij}^{(l)} l_j(\tau)$ as a Lagrange interpolating polynomial, we get $\dot{p}_i^{(l)}(c_k) = \sum_{j=0}^{m} u_{ij}^{(l)} D_{kj}^{(1)}$ using the first differentiation matrix. Finally, it follows that

$$\left\|\dot{p}_i^{(l)}\right\| = \sqrt{\sum_{k=1}^{m} b_k \left(\sum_{j=0}^{m} u_{ij}^{(l)} D_{kj}^{(1)}\right)^2}. \qquad (10)$$

Since applying the first differentiation matrix twice yields the second derivatives at the collocation nodes, a similar formula can be calculated for $\left\|\ddot{p}_i^{(l)}\right\|$. Therefore, we obtain Algorithm 3.2 by utilizing matrix-vector notation.

Because the algorithm has to be applied for each mesh interval and control variable, the overall runtime of the condition becomes $O(d_{\boldsymbol{u}} n m^2)$, which is just m times the number of discretized controls $d_{\boldsymbol{u}} n m$. This runtime is neglectable, compared to the several expensive NLP iterations that are performed for each mesh iteration.

3.4.2 Termination

An important idea of the Phase II iteration is that the final solution should satisfy Condition 3.1 for all intervals and control variables. This condition ensures that the local variability (slope and curvature) of the control trajectories remains below specific tolerances across all intervals. When this is achieved, the mesh points become equidistributed relative to this local variability. Since Condition 3.1 takes the same form as conditions used to define mesh density functions (e.g. ensuring an integral of some monitor function over each interval is below a tolerance), the resulting mesh distribution is at least as strong as, and can be characterized by, the density function implicitly defined by the satisfied condition itself. The derivation of this implicit density function is detailed in (Langenkamp 2024). Because of this, it is useful to have a criterion for the termination of a sequence of *on-interval* iterations. A sufficient condition for this termination can be deduced from Lemma 1, where the L^2 norm is again taken on $[0,1]$:

Algorithm 3.2: Fast *On-Interval* Computation

Input: Sample values $\hat{\boldsymbol{u}} = \left(u_{i0}^{(l)}, u_{i1}^{(l)}, \ldots, u_{im}^{(l)}\right)^T$, m-step Radau quadrature weights $\boldsymbol{b}$, differentiation matrix $D^{(1)}$

Output: $\left\|\dot{p}_i^{(l)}\right\|, \left\|\ddot{p}_i^{(l)}\right\|$

$\boldsymbol{p}' \leftarrow D^{(1)} \hat{\boldsymbol{u}}$

$\boldsymbol{q}' \leftarrow \left((p_1')^2, \ldots, (p_m')^2\right)^T$

$\left\|\dot{p}_i^{(l)}\right\| \leftarrow \sqrt{\boldsymbol{b}^T \boldsymbol{q}'}$

$\boldsymbol{p}'' \leftarrow D^{(1)} \boldsymbol{p}'$

$\boldsymbol{q}'' \leftarrow \left((p_1'')^2, \ldots, (p_m'')^2\right)^T$

$\left\|\ddot{p}_i^{(l)}\right\| \leftarrow \sqrt{\boldsymbol{b}^T \boldsymbol{q}''}$

return $\left\|\dot{p}_i^{(l)}\right\|, \left\|\ddot{p}_i^{(l)}\right\|$

Lemma 1. *Let* $p \in P^m$ *be a polynomial and* $p_\varepsilon(t) = p\left(\frac{t}{2}\right) + \varepsilon(t)$ *be a variation of* $p\left(\frac{t}{2}\right)$ *by* $\varepsilon \in P^m$*, then for a given* $\delta \in \mathbb{R}$ *with* $\frac{\sqrt{2}}{2} < \delta < 1$

$$\frac{\|\dot{p}_\varepsilon(t)\|}{\|\dot{p}(t)\|} < \delta, \quad \text{if} \quad \|\dot{\varepsilon}(t)\| < \frac{\sqrt{2}\delta - 1}{2} \left\|\dot{p}\left(\frac{t}{2}\right)\right\|.$$

A proof of Lemma 1 is given in the Appendix. Let $p(t)$ be a polynomial that violates Condition 3.1. The corresponding interval is bisected and both subintervals are examined in the next iteration. Without loss of generality, we consider the first subinterval, while the second follows analogously with $p_\varepsilon(t) = p\left(\frac{t+1}{2}\right) + \varepsilon(t)$. Rescaling the old polynomial from $[0, \frac{1}{2}]$ to $[0,1]$, as required by the *on-interval condition*, yields $p\left(\frac{t}{2}\right)$, so the new polynomial becomes $p_\varepsilon(t) = p\left(\frac{t}{2}\right) + \varepsilon(t)$, with a perturbation ε. By Lemma 1, the new norm on the subinterval is smaller if

$$\left\|\dot{p}_\varepsilon(t) - \dot{p}\left(\frac{t}{2}\right)\right\| = \|\dot{\varepsilon}(t)\| < \frac{\sqrt{2}\delta - 1}{2} \left\|\dot{p}\left(\frac{t}{2}\right)\right\|. \qquad (11)$$

Thus, we get a decreasing sequence of L^2-norms, provided the difference of the new and old polynomial derivatives is suitably bounded proportional to the derivative of the old polynomial itself. Assuming the convergence of the collocation method, the variations $\varepsilon, \dot{\varepsilon}$, and $\ddot{\varepsilon}$ should vanish for smooth problems. Since it is easy to find an analogous lemma for the second derivative with

$$\frac{\|\ddot{p}_\varepsilon(t)\|}{\|\ddot{p}(t)\|} < \delta, \text{ if } \|\ddot{\varepsilon}(t)\| < \frac{2\sqrt{2}\delta - 1}{4}\left\|\ddot{p}\left(\frac{t}{2}\right)\right\| \tag{12}$$

for $\frac{1}{2\sqrt{2}} < \delta < 1$, the same holds for $\ddot{p}$ in both subintervals. Hence, for smooth problems under suitable convergence assumptions, the refinement procedure terminates after finitely many iterations. However, for non-smooth solutions, e.g. bang-bang optimal controls, the method may never terminate, as the identical polynomial can be obtained on one of the subintervals, i.e. $p_\varepsilon(t) - p(t) \equiv 0$.

3.5 Boundary Condition

The described method could be implemented using only the *on-interval condition*. However, this approach has a critical weakness in detecting non-smooth behavior on the boundary of two adjacent intervals.

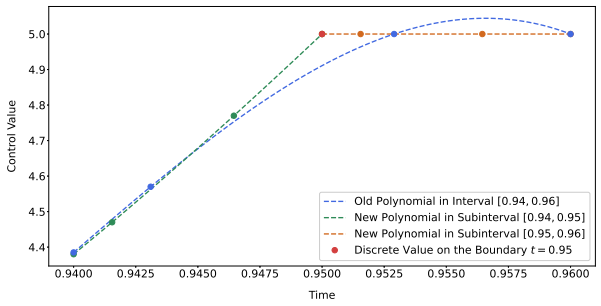

Figure 2. Poor corner detection

Consider Figure 2, where the interval $[0.94, 0.96]$ is split into $[0.94, 0.95]$ and $[0.95, 0.96]$ using the *on-interval condition*. The interpolating polynomials based on the 3-step Radau collocation method are shown. The first subinterval exhibits a steep slope throughout and will likely be bisected again. In contrast, the second subinterval appears nearly constant and will not trigger further refinement. However, this is problematic, as their shared boundary represents a sharp corner. To determine the switching time more accurately, the algorithm should further refine the mesh around this corner.

To resolve this, we introduce the *boundary condition*. It compares the first and second derivatives of adjacent polynomials at their shared boundary point. Rather than using purely relative or absolute error, we adopt the *plus-1 error* with $E(x,y) := \frac{|x-y|}{1+\min|x|,|y|}$, which combines both measures. Overall, the *boundary condition* says:

Condition 3.2 (Boundary Condition)**.** *If for two adjacent intervals i and $i+1$ there exists at least one control variable $u^{(l)}$, such that the interpolating polynomials $p_i^{(l)}, p_{i+1}^{(l)}$ on the nominal interval $[0,1]$ satisfy*

$$E(\dot{p}_i^{(l)}(t_{i+1}), \dot{p}_{i+1}^{(l)}(t_{i+1})) \geq CTOL_1^{(l)} \ \vee$$
$$E(\ddot{p}_i^{(l)}(t_{i+1}), \ddot{p}_{i+1}^{(l)}(t_{i+1})) \geq CTOL_2^{(l)}$$

for the common boundary point t_{i+1} and specified corner tolerances $CTOL_1^{(l)}, CTOL_2^{(l)} > 0$, then both intervals are bisected.

Evaluating the condition is inexpensive, since the values are side products of Algorithm 3.2.

3.6 Algorithm

Based on the previous considerations the full mesh refinement algorithm L2-Boundary-Norm (L2BN) can be formulated. By default, the constant corner tolerances are given as $CTOL_1^{(l)} = CTOL_2^{(l)} = 0.1$, but can be adjusted for a specific problem. The default tolerances for Condition 3.1 are given by

$$TOL_1^{(l)} = \frac{\text{range}(u^{(l)})}{|\mathcal{M}_0|} 10^{-\Lambda} \tag{13a}$$

$$TOL_2^{(l)} = \frac{\text{range}(u^{(l)})}{2|\mathcal{M}_0|} 10^{-\Lambda}, \tag{13b}$$

where $\text{range}(u^{(l)}) := \max_{t\in T} u^{(l)}(t) - \min_{t\in T} u^{(l)}(t)$ and $\Lambda \in \mathbb{R}$ is the level of refinement with default value $\Lambda = 0$.

Altogether we get Algorithm 3.3, which, for the b-th mesh refinement, requires $O(d_{\boldsymbol{u}} m^2 |\mathcal{M}_b|)$ operations. In this version of L2BN, Condition 3.1 enforces a bisection of the interval itself and both neighbors to prevent bisections in future iterations and enhance stability.

4 Implementation

The novel mesh refinement algorithm L2BN is integrated into a newly developed, open source dynamic optimization framework called GDOPT (General Dynamic Optimizer), which is publicly available on GitHub[2]. The framework is split into a Python modeling environment *gdopt*, which allows for expressive and accessible symbolic modeling of dynamic optimization problems and a C++ library *libgdopt* that performs the computationally intensive task of solving the large-scale NLPs with Ipopt (Wächter and Biegler 2006).

The framework offers a range of noteworthy features, of which the most relevant are presented in this paper. A comprehensive description of the GDOPT implementation can be found in (Langenkamp 2024) and an introduction to modeling with the framework is provided in the GDOPT User's Guide[3]. The principle workflows are illustrated in Figure 3. First, users can define their optimization problems in Python using purely symbolic ex-

end
return $\boldsymbol{x}_{b_{max}}^*(t), \boldsymbol{u}_{b_{max}}^*(t), \boldsymbol{p}_{b_{max}}^*$

pressions for differential equations, constraints and objectives. The Python package *SymEngine*[4] is used to efficiently calculate the symbolic first and second derivatives and their common subexpressions to remove redundant calculations. These symbolic expressions are translated into efficient C++ code with exact sparsity patterns. After that, the code is compiled and linked with *libgdopt*, which implements the full collocation-based dynamic optimization pipeline, including discretization, solver interface, L2BN mesh refinement algorithm, and precomputed Radau IIA schemes for $m = 1, \ldots, 70$ accurate to machine precision.

GDOPT separates code generation and optimization, allowing parameters, solver settings, and initial guesses to be modified after compilation. This enables rapid repeated solves without regenerating and recompiling the model. At runtime, the executable reads all parameters, initial values, and solver settings, and solves the resulting NLP using Ipopt (Wächter and Biegler 2006) with a chosen linear solver, e.g. MUMPS (Amestoy et al. 2001) or one from the HSL suite (HSL 2013). Results are written to an output file, which is automatically read by the Python interface for post-processing and visualization using *matplotlib* (Hunter 2007).

4.1 Acceleration of Refinement Iterations

An important note on the implementation is, that Ipopt is an interior-point solver that uses logarithmic barriers. The implementation of L2BN heavily benefits from this concept, by setting the barrier parameter to a minimal value (e.g. $\mu_0 = 10^{-15}$) for repeated solves. This strategy significantly accelerates mesh refinement iterations even further, since the new initial guess, i.e. the previous optimal solution interpolated onto the new mesh, is known to be almost optimal by construction. Thus, Ipopt solves an unperturbed problem, avoiding unnecessary calculations and achieving rapid convergence.

[4] https://github.com/symengine/symengine

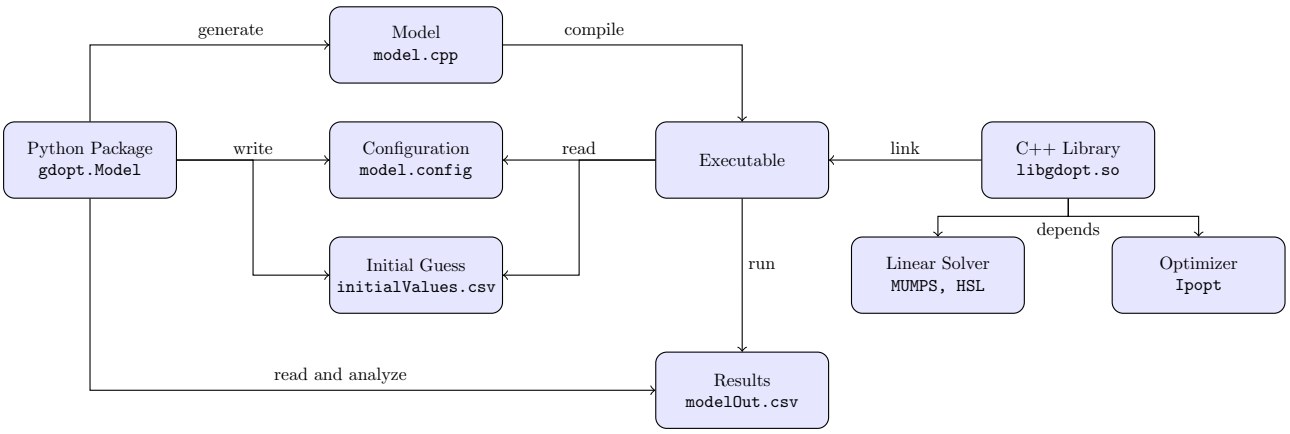

Figure 3. Principle workflows in GDOPT. For a detailed introduction to workflows in GDOPT, please refer to (Langenkamp 2024).

4.2 Optimization of DAEs

Currently, the framework does not support the direct handling of differential-algebraic equations (DAEs). While algebraic variables can be modeled as control inputs, this approach artificially bloats the NLP, making it more numerically unstable and computationally demanding. An integration of *libgdopt* into a proper modeling environment would clearly be beneficial. Previous work on OpenModelica (Ruge et al. 2014) has already demonstrated such an integration by performing a transformation to semi-explicit ODE form and solving for algebraic variables in each optimization step.

5 Results and Performance

To evaluate the performance of the proposed mesh refinement algorithm and the newly developed framework, a relevant dynamic optimization problem from the open literature is considered. For additional benchmarks of GDOPT, including demonstrations of the termination property for smooth problems, we refer to (Langenkamp 2024). All optimizations are performed on a laptop with a Intel Core i7-12800H, 32 GB RAM, running Ubuntu 24.04.2 and using GCC v13.3.0 with flags -O3 -ffast-math for compilation.

5.1 Diesel Electric Power Train

Consider the diesel-electric power train[5] that has been studied extensively in (Sivertsson and Eriksson 2012; Mengist, Ruge, Gebremedhin, et al. 2013; Bachmann et al. 2012). This optimization problem deals with the fuel optimal start-up of a diesel engine from an idling condition to a certain power level. The model features 2 control variables in relative units and 4 states, while each variable is associated with a given box constraint to guarantee physical validity. The diesel-electric power train has the following principle structure:

$$\min_{u_1(t),u_2(t)} \sum_{i=1}^{4} (x_i(t_f) - c_i)^2 \tag{14a}$$

s.t.

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \dot{x}_4 \end{bmatrix} = \begin{bmatrix} f_1(x_1, x_2, x_3, u_1) \\ f_2(x_1, x_2, x_4) \\ f_3(x_1, x_2, x_3, u_1, u_2) \\ f_4(x_1, x_2, x_3, x_4, u_1) \end{bmatrix} \forall t \in [t_0, t_f] \tag{14b}$$

$$\boldsymbol{x}(t_0) = \boldsymbol{x}_0 \tag{14c}$$

$$\boldsymbol{x}^L \leq \boldsymbol{x} \leq \boldsymbol{x}^U \forall t \in [t_0, t_f] \tag{14d}$$

$$\mathbf{0} \leq \boldsymbol{u} \leq \mathbf{1} \quad \forall t \in [t_0, t_f] \tag{14e}$$

$$t_0 = 0, t_f = 0.5, \boldsymbol{c} \in \mathbb{R}^4 \text{ are constants.} \tag{14f}$$

The optimization problem is solved with both GDOPT and OpenModelica v1.24.0 using the same hardware and settings for various configurations. All runs use an Ipopt tolerance of 10^{-14}, the linear solver MUMPS, and identical constant initial guesses. All other solver parameters are left at default and the times are averaged over 5 runs.

[5]The GDOPT implementation can be found under `https://github.com/linuslangenkamp/GDOPT/blob/master/examples/dieselMotor.py`

5.2 Code Generation and Compilation

The code generation and compilation timings for GDOPT are given by: 0.0268 s for the derivative calculations and code generation, 1.1561 s for compiling the generated C++ code and 0.0335 s for obtaining the initial guess by simulating the dynamics. However, the OpenModelica compiler requires just 0.2011 seconds for the translation and compilation. Note that this overhead is independent of the specific configuration.

5.3 Results Without Mesh Refinement

For equidistant meshes with sizes $|\mathcal{M}_0| = 25, 100, 250$, the same optimization has been performed with both implementations and the results are displayed in Table 2.

Alg.	$\lvert\mathcal{M}_0\rvert$	m	$\phi^* \cdot 10^3$	t_{opt}	Speedup
OM	25	3	1.11171326	0.3592	1.0000
GD	25	3	1.11171326	0.1877	1.9136
OM	100	3	1.11155875	0.6730	1.0000
GD	100	3	1.11155875	0.3214	2.0940
OM	250	3	1.11155972	1.8256	1.0000
GD	250	3	1.11155972	0.6086	2.9997

Table 2. Performances of GDOPT (GD) and OpenModelica (OM) on equidistant meshes for the *Diesel Electric Power Train*. The columns are the algorithm (Alg.), initial mesh size ($|\mathcal{M}_0|$), number of collocation nodes (m), scaled final objective ($\phi^* \cdot 10^3$), total optimization time (t_{opt}), and speedup factor relative to OpenModelica.

It is noteworthy that GDOPT is 2 to 3 times faster than OpenModelica without using any mesh refinement. Moreover, both implementations provide the exact same objectives to all digits. This clearly shows that GDOPT efficiently deploys the relevant model information and additionally, performs internal calculations very fast.

5.4 Phase I Refinement

By incorporating $k = 2$ phase I refinements, the same optimal solution for an equidistant mesh size of $|\mathcal{M}| = 100$ is obtained in 0.2291 s as seen in Table 3, compared to 0.3214 s with GDOPT without refinement and 0.6730 s with OpenModelica (Table 2). Therefore, the multigrid refinement (Algorithm 3.1) accelerates the GDOPT procedure by roughly 40%.

5.5 Results Using L2-Boundary-Norm

Additional Phase II iterations enhance accuracy in regions with non-smooth control behavior. Since the optimal control remains constant over large parts of the time horizon, high resolution is not required everywhere. However, the problem also features sharp switching behavior, where accurately resolving the exact timing of the switches is crit-

DOI 10.3384/ecp218127

ical. This is illustrated in Figure 4, which shows the optimal control solution on the final refined mesh:

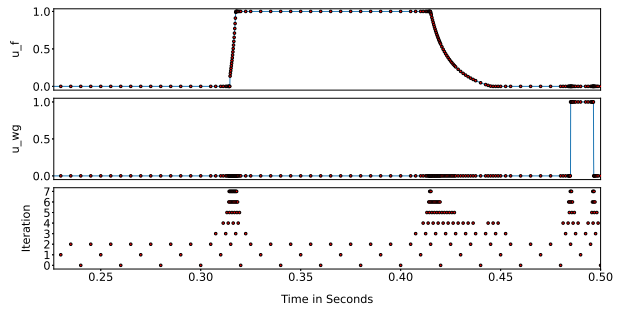

Figure 4. Mesh refinement history of the *Diesel Electric Power Train* for configuration: GDOPT, $k = 2$, $b = 5$, $|\mathcal{M}_0| = 25$, $m = 3$

To further investigate the impact of the refinement iterations, control trajectories in different stages of the refinement process are presented. In Figure 5 the controls are displayed for the configuration $k = 2$, $b = 5$, $|\mathcal{M}_0| = 25$, $m = 3$.

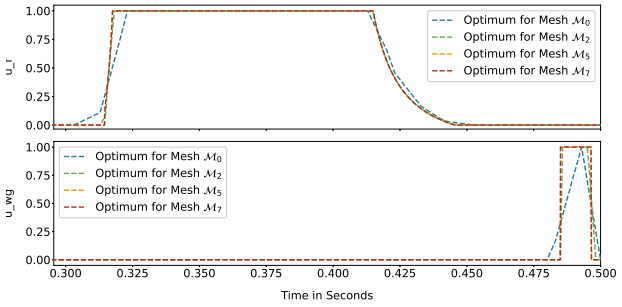

Figure 5. Refinement iterations for both control variables of the *Diesel Electric Power Train* for configuration: GDOPT, $k = 2$, $b = 5$, $|\mathcal{M}_0| = 25$, $m = 3$

Note that in this case the mesh subscript denotes the cumulative mesh iteration. By simply performing 2 multigrid iterations, the solution on $\mathcal{M}_2$ looks almost identical to the final solution using 5 additional phase II iterations. Nevertheless, by increasing the size of the plot, it becomes obvious that the switching times are not precisely located as seen for the second control variable in Figure 6. For this control, the placements of the switches are roughly $t \approx 0.485\,\mathrm{s}$ and $t \approx 0.496\,\mathrm{s}$ for $\mathcal{M}_2$, but the resolution is too low to capture the exact position of the switch. By performing additional iterations, the resolution of the switches increases drastically, such that the final solution on $\mathcal{M}_7$, which was obtained in just 0.9522 s (Table 3), describes a perfect rectangular shape. This final resolution is equivalent to that of an equidistant mesh with 3200 intervals. Performing the optimization on this grid without refinement takes 20.3825 s using GDOPT and 84.6323 s using OpenModelica. Furthermore, OpenModelica did not find the optimal solution but terminated with an oscillating solution.

Alg.	k, b	$\lvert\mathcal{M}_0\rvert$	m	$\lvert\mathcal{M}^*\rvert$	$\phi^* \cdot 10^3$	t_{opt}
GD	2,0	25	3	100	1.11155875	0.2291
GD	2,3	25	3	167	1.11155842	0.4301
GD	2,3	25	5	170	1.11155852	0.6849
GD	2,3	25	7	171	1.11155856	1.1687
GD	2,5	25	3	240	1.11155853	0.9522
GD	2,5	25	5	243	1.11155853	1.5512

5.6 Resolution Under Runtime Constraints

To benchmark resolution efficiency, GDOPT was run on equidistant meshes under a fixed runtime limit of 1 s. The densest such mesh solved within this limit had 400 intervals and required 1.0273 s. In contrast, mesh refinement using L2BN with $k = 2$ Phase I and $b = 8$ Phase II iterations achieved an effective resolution equivalent to 25600 equidistant intervals in just 1.3536 s. For comparison, equidistant meshes with 550 and 600 intervals required 1.2349 s and 2.0783 s, respectively. These resolutions are over 40 times coarser than the refined result. This demonstrates that mesh refinement with L2BN significantly improves resolution, as needed for problems with switching controls, while maintaining low computational cost.

5.7 Discussion of Results

Overall, L2BN enables GDOPT to accelerate convergence from poor initial guesses, efficiently detect non-smooth regions, and adaptively increase resolution, far outperforming traditional equidistant mesh approaches. Combined with its rapid execution under equivalent conditions, GDOPT shows striking advantages over direct collocation in OpenModelica in both speed and solution quality.

6 Limitations

While effective, L2BN and GDOPT have several limitations that should be considered. First, L2BN does not take advantage of the spectral convergence properties of flipped Legendre-Gauss-Radau (fLGR) collocation points. Therefore, it is unable to achieve the convergence rates of hp-adaptive methods and may require excessive mesh iterations or intervals to reach high accuracy, potentially leading to numerical instabilities.

The performance of L2BN also depends on the initial mesh size and refinement parameters, such as the number of phase I and phase II iterations. Clearly, the initial mesh must resemble the principle behavior of the subsequent iterations, otherwise the phase I iterations can have negative effects. Poor choices for these settings can result in unnecessary computational effort or failure to resolve key features of the solution.

Another limitation is the absence of direct error estimation in the algorithm. Since L2BN does not explicitly compute or use error estimates, it may not always refine the mesh optimally. For example, regions with smooth but rapidly changing controls might be over-refined, because of the large change on the interval. This can lead to a lot of unnecessary computations and considerably larger meshes than sufficient.

The most significant limitation, however, is that GDOPT is unable to handle DAEs directly and must model algebraic variables as control inputs. An integration into an elaborate modeling environment like OpenModelica would allow solving for algebraic variables at every step, thus reducing the solver space. Furthermore, direct error estimates could be incorporated by leveraging established simulation capabilities of OpenModelica.

7 Discussion and Future Work

This work presents two significant contributions to direct collocation-based dynamic optimization: (1) a comprehensive re-implementation that addresses significant limitations in optimizing with OpenModelica, and (2) the novel L2BN mesh refinement algorithm. The results demonstrate that GDOPT achieves 2 to 3 times speedups over OpenModelica under equivalent conditions, while introducing additional, essential capabilities such as adaptive mesh refinement, parameter optimization, exact Hessians, and support for higher-order collocation schemes. Tested on a representative optimal control problem, the proposed mesh refinement algorithm proves to be highly efficient. It speeds up convergence from poor initial guesses, correctly detects non-smooth regions, and enhances solution accuracy with low computational effort. Additionally, it reaches a resolution at switching points that would be unrealistic to achieve with equidistant meshes in a reasonable amount of time.

Ongoing work focuses on integrating *libgdopt* into the OpenModelica toolchain to replace its legacy optimization runtime. This integration will bring several substantial improvements, including full parameter optimization capabilities, adaptive mesh refinement as presented in this work, variable polynomial degrees, and exact Hessian computation for improved convergence. Moreover, native DAE support, already available in OpenModelica, will be preserved through algebraic system resolution at each optimization step, expanding the capabilities of GDOPT, which is currently limited to ODEs. The performance gains demonstrated in this paper suggest that such an integration could significantly enhance the optimization capabilities of OpenModelica.

Acknowledgements

This work was conducted as part of the OpenSCALING project (Grant No. 01IS23062E) at the University of Applied Sciences and Arts Bielefeld, in collaboration with Linköping University. The authors would like to express their sincere appreciation to both the OpenSCALING project and the Open Source Modelica Consortium (OSMC) for their support, collaboration, and shared commitment to advancing open-source modeling and simulation technologies.

Appendix: Proof of Lemma 1

Lemma 1. *Let $p \in P^m$ be a polynomial and $p_\varepsilon(t) = p\left(\frac{t}{2}\right) + \varepsilon(t)$ be a variation of $p\left(\frac{t}{2}\right)$ by $\varepsilon \in P^m$, then for a given $\delta \in \mathbb{R}$ with $\frac{\sqrt{2}}{2} < \delta < 1$*

$$\frac{\|\dot{p}_\varepsilon(t)\|}{\|\dot{p}(t)\|} < \delta, \quad \text{if} \quad \|\dot{\varepsilon}(t)\| < \frac{\sqrt{2}\delta - 1}{2}\left\|\dot{p}\left(\frac{t}{2}\right)\right\|.$$

Proof.

$$\begin{aligned} \|\dot{p}(t)\|^2 &= \int_0^1 \dot{p}(t)^2 \,\mathrm{d}t = \int_0^{\frac{1}{2}} \dot{p}(t)^2 \,\mathrm{d}t + \int_{\frac{1}{2}}^1 \dot{p}(t)^2 \,\mathrm{d}t = \frac{1}{2}\left(\int_0^1 \dot{p}\left(\frac{t}{2}\right)^2 \mathrm{d}t + \int_0^1 \dot{p}\left(\frac{t+1}{2}\right)^2 \mathrm{d}t\right) \\ \implies \|\dot{p}(t)\| &= \frac{1}{\sqrt{2}}\left(\int_0^1 \dot{p}\left(\frac{t}{2}\right)^2 \mathrm{d}t + \int_0^1 \dot{p}\left(\frac{t+1}{2}\right)^2 \mathrm{d}t\right)^{\frac{1}{2}} = \frac{1}{\sqrt{2}}\left(\left\|\dot{p}\left(\frac{t}{2}\right)\right\|^2 + \left\|\dot{p}\left(\frac{t+1}{2}\right)\right\|^2\right)^{\frac{1}{2}} \end{aligned} \tag{15}$$

Also $\dot{p}_\varepsilon(t) = \frac{1}{2}\dot{p}\left(\frac{t}{2}\right) + \dot{\varepsilon}(t)$ and by the *Minkowski inequality* $\|\dot{p}_\varepsilon(t)\| \leq \frac{1}{2}\left\|\dot{p}\left(\frac{t}{2}\right)\right\| + \|\dot{\varepsilon}(t)\|$, implying

$$\frac{\|\dot{p}_\varepsilon(t)\|}{\|\dot{p}(t)\|} \leq \frac{\frac{1}{2}\left\|\dot{p}\left(\frac{t}{2}\right)\right\| + \|\dot{\varepsilon}(t)\|}{\frac{1}{\sqrt{2}}\left(\left\|\dot{p}\left(\frac{t}{2}\right)\right\|^2 + \left\|\dot{p}\left(\frac{t+1}{2}\right)\right\|^2\right)^{\frac{1}{2}}} \leq \frac{1}{\sqrt{2}}\frac{\left\|\dot{p}\left(\frac{t}{2}\right)\right\| + 2\|\dot{\varepsilon}(t)\|}{\left\|\dot{p}\left(\frac{t}{2}\right)\right\|} = \frac{1}{\sqrt{2}}\left(1 + \frac{2\|\dot{\varepsilon}(t)\|}{\left\|\dot{p}\left(\frac{t}{2}\right)\right\|}\right). \tag{16}$$

By setting $\frac{1}{\sqrt{2}}\left(1 + \frac{2\|\dot{\varepsilon}(t)\|}{\|\dot{p}\left(\frac{t}{2}\right)\|}\right) < \delta$ for $\delta \in \mathbb{R}$ with $\frac{\sqrt{2}}{2} < \delta < 1$ and rearranging terms, the proposition follows. □

Abstract

As the maritime industry evolves, there is a focus on simulation-driven design, testing, and validation using novel technology solutions. Simulation models designed to represent the behaviour and features of real systems are increasingly available for testing during the early phase of the full development, but in many cases, their testing suffers from the availability of test oracles. Metamorphic testing has become increasingly used in different application domains as an approach to test systems when an explicit test oracle is unavailable. In order to increase its adoption by domain experts, we combine metamorphic testing with Behaviour Driven development for the verification and validation of simulation models. The tool-based approach facilitates automated test generation based on domain-specific custom metamorphic transformations to generate meaningful test inputs for metamorphic input relations. The method also uses features and scenarios extracted from system requirements and domain expertise to define metamorphic output relations. By automating test generation based on system behaviours as features, scenarios, metamorphic transformations, and output candidates for metamorphic relations in a Gherkin-like format, the tool enables practitioners to verify models based on domain-specific constraints and metamorphic relation checks. Our preliminary evaluation shows that the tool can detect metamorphic relations violations in the simulation models under test and that automated test generation provides improved coverage.

Keywords: Metamorphic testing, Validation, Simulation, FMI, FMU

1 Introduction

In recent times, maritime vessels have evolved into complex systems of systems with advanced automation and control systems. This evolution has made the verification and validation of maritime systems more challenging and has increased the demand for new methods for early simulation-based testing. The simulation model of a system is designed based on the properties and behaviour of the real system it represents. The *Functional Mock-Up Interface* (FMI) (Blochwitz et al. 2012) is a standard that defines a container and an interface to exchange dynamic simulation models. The container packs simulation models into an archive file called *functional mock-up unit* (FMU), which contains metadata, interface specification, binary files, data files, documentation and, optionally, the source code of the model. The goal of packing simulation models as FMUs is to exchange them between different stakeholders, such as suppliers and manufacturers, and this opens up the possibility of providing black-box models of the systems and subsystems for acceptance and integration testing. Besides the fact that, in many cases, dynamic simulation models do not come accompanied by explicit test oracles to allow automated testing, this encapsulation complicates the acceptance and integration testing processes.

Metamorphic testing (Tsong Y Chen et al. 2020) is an increasingly popular testing technique for generating test cases and verifying test results based on the properties or functional behaviour of the system. This technique also effectively addresses one of the fundamental challenges in software testing, the test oracle problem (Barr et al. 2014). The test oracle problem is the challenge of determining the expected output or behaviour of the *system under test* (SUT) for a given input. Often, when an explicit test oracle is unavailable to validate the correctness of the execution results of simulation models, they are considered non-testable (Balci 2003; Weyuker 1982).

A recent study about the research directions in metamorphic relation generation (Li et al. 2024) discusses the possibility of extending the applicability of MT in automated test generation to wider application domains that face the oracle problem. Metamorphic testing has been applied to the verification of simulation software (Murphy et al. 2011) and to the verification (Jiang et al. 2014; Lindvall et al. 2017) and validation (M. M. Olsen and M. S. Raunak 2016; M. Olsen and M. Raunak 2018) of simulation models. Recent research on the validation of simulation models using metamorphic testing shows that it has been applied to agent-based and discrete event simulation models, as well as to hybrid simulation models that include combinations of agent-based models, discrete event simulation models, and system dynamics models.

Behaviour-Driven Development (BDD) is a software development approach that extends Test-Driven Development (TDD) by focusing on the behaviour of an applica-

tion from the end user's perspective. The key idea is to write tests in a natural, readable language that describes how the application should behave under specific scenarios. BDD helps teams create a shared understanding of requirements and ensures software is aligned with business goals. BDD uses requirements patterns, such as Given-When-Then, to describe the expected behaviour of a system in a clear, consistent way. It breaks down each scenario into three logical parts: preconditions, action, and expected outcome, allowing domain experts to specify executable testing scenarios.

In this work, we propose the integration of BDD with metamorphic testing to facilitate specifying the test design by domain experts to automate the test case generation, execution, and verdict assignment for the validation of dynamic simulation models. The approach can streamline the testing process by generating the test design documentation in a practitioner-friendly BDD format and automating the different steps of the testing cycle with the following contributions:

- We propose a set of metamorphic input and output relational operators to test system dynamics simulation models.
- We provide a framework to allow domain experts to express test actions and expected behaviour in BDD format by selecting metamorphic transformations and output relations.
- We provide the tool support for automating different steps of the metamorphic testing process: the metamorphic BDD test case generation, input transformation, test execution and test verdict assignment.

The rest of the paper is divided into six sections. Section 2 describes concepts such as metamorphic testing and behaviour-driven development testing. Section 3 introduces the overview of our approach. We exemplify our approach on the simulation model of a lubricating oil cooling system in Section 4 and discuss the results in Section 5. We overview related work in Section 6, and draw the conclusions in Section 7.

2 Prerequisites

This section describes in more detail the metamorphic testing technique and behaviour-driven development testing.

2.1 Metamorphic testing

Metamorphic testing (MT) was introduced by Chen et al. (Tsong Y Chen et al. 2020) as a solution to test systems without explicit specification of the test oracle. In MT, the behavioural or functional properties of the system are defined by posing a hypothesis about using generic relations, known as *metamorphic relations (MRs)*, between different sets of inputs and their expected outputs.

The typical MT process is shown in Figure 1. A *source test case* is the first set of tests performed using *seed inputs (initial inputs)* denoted as x in Figure 1. The *seed inputs* are then transformed into *morphed inputs* denoted as x' based on a defined *metamorphic transformation*. The *follow-up test cases* are performed using the resulting *morphed inputs*.

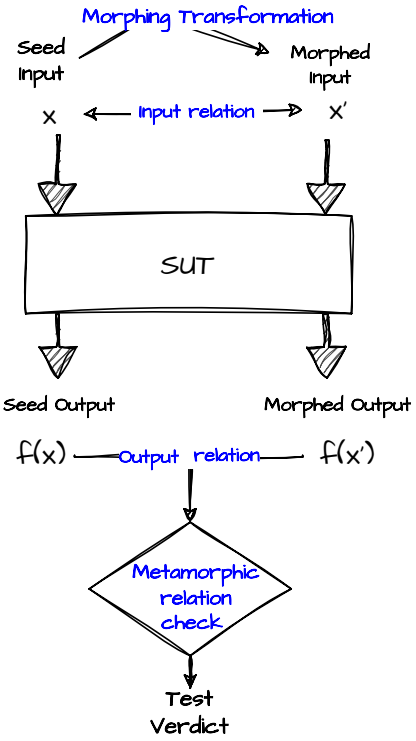

Figure 1. Generic metamorphic testing process

An MR is composed of two parts: an *input relation* and *output relation* (Liu et al. 2012). The *input relation* represents the relation between the inputs of the source test case and a follow-up test case, whereas an *output relation* represents the relation between the expected outputs of the *source and follow-up test cases*. In addition, an *implication* between the outputs of *source and follow-up test cases* is needed to specify the impact of input transformations on their corresponding outputs. The output relation, often specified using a relational operator such as equality, subset, disjoint, complete, and difference (Segura et al. 2017), should hold for any corresponding output of the system. The test verdict is assigned based on the *violation* or *non-violation of output relation*.

Several studies show that metamorphic testing has become a popular choice for testing systems without explicit test oracles and that it has been applied successfully to many application domains, including embedded systems, web applications, computer graphics, and simulation and

DOI
10.3384/ecp218139

modelling (Segura et al. 2016; Tsong Yueh Chen et al. 2018).

2.2 Behaviour Driven Development testing

Behaviour-driven development (Smart and Molak 2023) testing aims to build a development process in which development and testing activities occur concurrently throughout the product life cycle, facilitating faster and more reliable releases. The Gherkin language (Wynne and Hellesoy 2012) serves a key role in BDD and test automation by allowing developers and other stakeholders to describe software behaviour clearly that is both human-readable and executable by machines. As a structured plain-text language, Gherkin uses keywords such as *Feature, Scenario, Given, When, Then* to define the abstract description of the feature or behaviour of the system, scenarios associated with it and the steps that describe the initial conditions, test actions, and acceptance criteria. These steps ensure precise documentation of system requirements and test design as *user scenarios*. An example of a scenario specified using *Given-When-Then (GWT)* patterns is presented in Listing 1.

Listing 1. Example test specified using GWT template

```
Feature: User login
  Scenario: Successful login with valid
      credentials
    Given the user is on the login page
    When the user enters valid credentials
    Then the user should be redirected to
          the dashboard
```

3 Overview of the approach

We propose a metamorphic behaviour-driven development (Metamorphic BDD) approach for testing simulation models. The approach is intended to allow domain experts to formulate easily metamorphic tests for FMUs, by mapping concepts of MT to the GWT templates (as shown in Table 1).

Table 1. Mapping MT concepts to GWT patterns

Metamorphic concept	GWT pattern
Seed input & output	Given
Morphing Transformation Follow-up input	When
Output Metamorphic Relation	Then

Let x be an input to the SUT, and $x' = \mathrm{MT}(x)$ its metamorphic transform. The output of the SUT is $f(x)$. The metamorphic relation is evaluated by a function $\mathrm{MR}_{\mathrm{out}}(f(x), f(x'))$, which checks whether the expected relationship between the outputs holds. Consider the following GWT scenario:

$$\begin{aligned} &GIVEN \quad x \quad with \quad initial \quad value \quad x_0 \\ &WHEN \quad x' = \mathrm{MT}(x) \\ &THEN \quad \mathrm{MR}_{\mathrm{out}}(f(x), f(x')), \end{aligned}$$

In this case, all the inputs and outputs are time series over a specified time interval. As such, a metamorphic test consists of four steps:

1. *Execute source test*, with seed input x;
2. *Apply metamorphic transformation* to seed input $x' = \mathrm{MT}(x)$;
3. *Execute follow-up test* with morphed input x';
4. *Verify the metamorphic relation* between the seed output $f(x)$ and morphed output $f(x')$.

Although the approach can be applied for defining tests for any kind of simulation system, in this paper, we take advantage of the information provided in the FMU package to streamline and automate the tool support. To that extent, we use the interface specification of the SUT extracted from the FMU package and the necessary properties of the system from the requirements specification as input. This will allow us to facilitate MR definitions and to automate test generation, execution, and verdict assignment. Finally, a test report is generated as output.

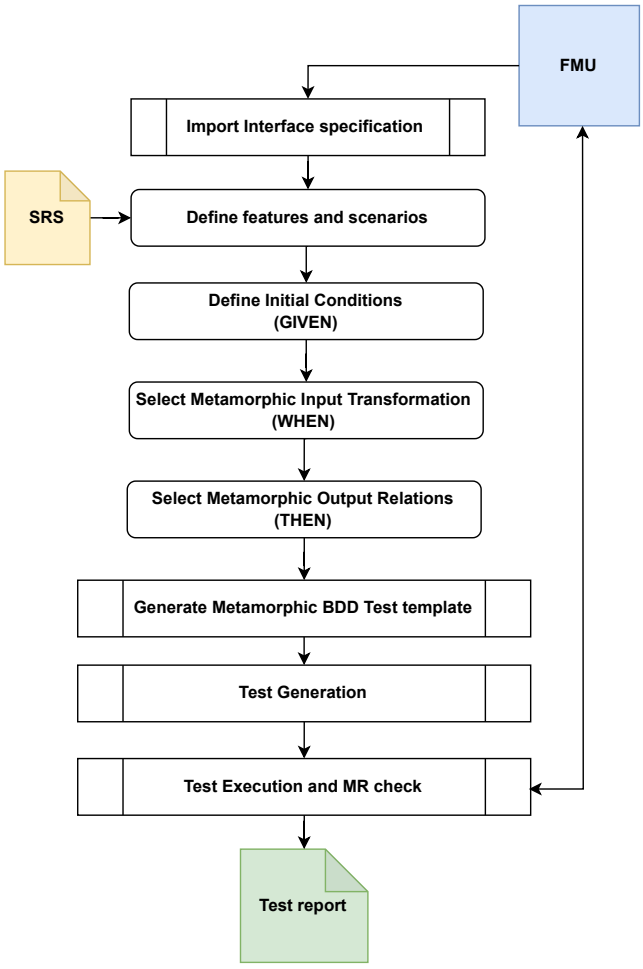

Figure 2. Metamorphic BDD testing workflow

The workflow of the approach is depicted in Figure 2. In the following, we will discuss the main steps of the approach.

Import interface specification. In the first step of our approach, the interface specification of the SUT is imported from the FMU file (*modelDescription.xml*). This includes the input and output signals, the initial values for the inputs and the ranges of the input.

Define features and scenarios. Then, the domain expert defines the features and scenarios for validating the relevant properties of the SUT.

Define initial conditions The user defines the initial condition values for the inputs of the system. These conditions correspond to the GIVEN statement of the GWT pattern.

Select Metamorphic Input Transformation. For the WHEN statement, the user selects the metamorphic transformation that should be applied to each input signal in the scenario defined. A given *metamorphic transformation* is defined as a tuple $(transformation, relation)$. The *transformation* defines the pattern based on which the input signal is changed (e.g., *None*, *Steps*, *Drift*), whereas the *relation* specifies the direction of the change (e.g., *constant*, *increase*, *decrease*). In case of *Drift* transformation, the input signals vary by a *ramp_rate* value selected from the range ± 2 and for *Steps*, they vary from the initial condition value by $\pm(value)$ until it reaches the lower and upper limits of the inputs they are applied upon. The actual value of the *ramp_rate* can be defined manually or generated using a random uniform sampling method, which is used to create the morphed input values for the corresponding input variable.

Metamorphic Output Relation Selection. The output metamorphic relation can be defined in the THEN statement, for one or several of the output signals extracted from the interface specification of the FMU. The output relations that are applicable to validate the expected properties of the output signal can be selected from the list of temporal and relational operator combinations enumerated below:

1. *Always_Greater than*: Implies that morphed outputs of the selected output variable should always be greater than the corresponding seed outputs.
2. *Always_Greater than or equal to*: Implies that morphed outputs of the selected output variable should always be greater than or equal to the corresponding seed outputs.
3. *Always_Less than*: Implies that morphed outputs of the selected output variable should always be less than the corresponding seed outputs.
4. *Always_Less than or equal to*: Implies that morphed outputs of the selected output variable should always be less than or equal to the corresponding seed outputs.
5. *Always_Equal to*: Implies that morphed outputs of the selected output variable should always be equal to the corresponding seed outputs.
6. *Eventually_Increases than*: Implies that morphed outputs of the selected output variable should eventually increase than the corresponding seed outputs.
7. *Eventually_Decreases than*: Implies that morphed outputs of the selected output variable should eventually decrease than the corresponding seed outputs.
8. *Always in given range [lower_limit upper_limit]*: Implies that morphed outputs of the selected output variable should always stay in the range defined as its lower limit and upper limit in the requirements specification.

All these metamorphic relations assume that the seed and morphed outputs will be checked at each time step of the simulation.

Metamorphic BDD test template generation. In this step, a feature file with the metamorphic BDD format is generated based on the metamorphic relations selected for the inputs and outputs in the previous step. This step takes as input the number of scenario instances to be generated and the number of time steps per scenario instance to create the parametrized BDD test file in Gherkin format.

Test Generation. In this step, the morphed test input values are generated for the follow-up tests based on the transformation relation selected and the parametrized values in the BDD test file. These test inputs are also saved to a test suite file in '.json' format.

The test inputs are generated using the *ramp_rate* added as a parametrized value in the BDD test file. The seed input is transformed into morphed input by applying the selected transformation on the initial condition value added in the GIVEN condition for the corresponding input. If the transformation selected is *None*, the value remains the same as the initial condition value throughout the simulation.

Test Execution and MR checking. In this last step, the morphed test inputs are executed on the FMU file. For this case study, the Python package `PyFMI` (Andersson, Åkesson, and Führer 2016) was used to simulate FMUs. The simulations run for the source test execution using the initial condition values for inputs and the follow-up scenario instances using the morphed input values generated. Then, each set of morphed outputs from follow-up test executions is compared with seed outputs from the source test execution, using the output MRs to assign the test verdict. The test verdict of each follow-up test execution and the comparison plots are summarized and presented in a test report for further analysis.

One should notice that each generated scenario instance would require executing a seed test and a follow-up test. However, since the seed test would be identical for each scenario instance, only one execution of the seed test is needed in order to collect the corresponding seed output. That is, if from a given scenario, *n* scenario instances are generated, the number of executions of the SUT equals *n+1*. This considerably reduces the test execution time.

4 Case Study

We will exemplify the approach presented in Section 3 on a simplified version of a *Lubricating Oil Cooling* (LOC) system that transfers heat from the lubrication oil to the cooling water circuit of a ship engine unit (NoviaRDISeafaring 2024). The LOC system has a control valve which controls the lubrication oil temperature at a constant setpoint at the engine inlet using a PI controller. The controller aims to keep the lubrication oil temperature at the outlet within the boundary values specified at all conditions.

To test the LOC system using our approach, we start by importing the interface specification of the system. Then, the relevant features to be tested should be defined in the framework. For instance, a feature and scenario added to test the LOC system can be seen in Figure 3.

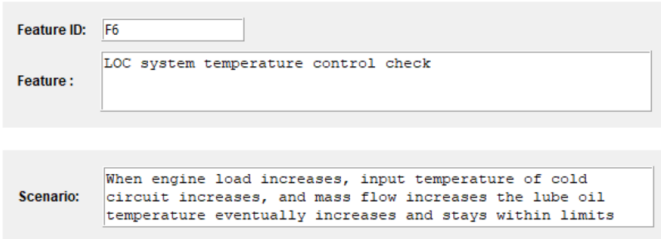

Figure 3. Defining the Feature and Scenario to test LOC system

The tool automatically extracts inputs and outputs from the model description and presents them in the GUI together with predefined data values. The initial condition values for the inputs of the system can be provided in the GIVEN tab, as in Figure 4.

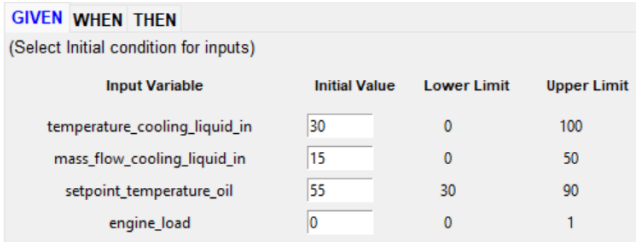

Figure 4. Setting Initial condition values

For the WHEN statement, the user selects the metamorphic transformation that should be applied for all inputs of the FMU (see Figure 5).

Figure 6 shows an example resulting input signal generated upon selecting *Steps_Increase* using a *ramp_rate* of `3.64` at a time interval of `5` for the input *temperature_cooling_liquid_in* with an initial condition value `30`. The transformation will preserve the original limits of the signal, `0` and `100`, respectively.

Figure 7 shows the output signals of the LOC system and the set of predefined output relations that can be selected for each signal. From the listed set of relations, the

ones corresponding to the output variable selected and the input transformation applied can be chosen to facilitate the automatic generation of the metamorphic BDD test file.

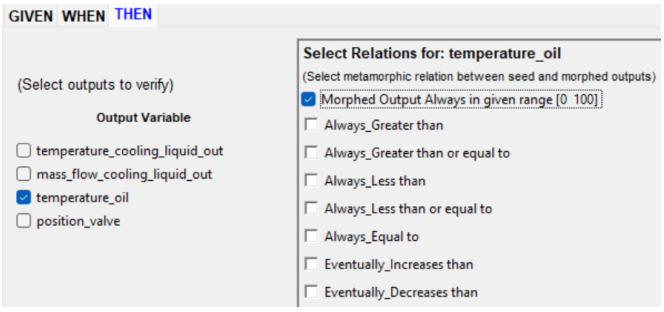

Figure 7. Metamorphic Output Relation Selection options

Figure 8 shows the first few scenario instances of the parametrized BDD test file created based on the inputs and outputs selected in Section 4, and the test generation specific parameters such as number of scenario instances to be generated as `5`, and the number of time steps per scenario instance as `1000`.

For the BDD test scenario in Figure 8, the follow-up test inputs generated for one of the scenario instances are depicted in Figure 9. Figure 10, shows the seed and mor-

phed outputs of the scenario presented in Figure 8 where the expected behaviour of the system is that the lubricating oil temperature at the outlet eventually increases compared to the seed outputs and stays within the boundary limits in response to the input transformations depicted in Figure 9. The verdict is assigned by checking the values of *temperature_oil* from the simulation results of the source and follow-up test execution of the system using the metamorphic output relation.

4.1 Tool support

Tool support has been in Python using the GUI toolkit `Tkinter` (Lundh 1999) for the user interface (see Figure 11). Most of the steps in the metamorphic testing process are fully automated based on the input and output MR selection using the framework. To implement automation, we have used Python, Behave library, a BDD framework for Python (Behave 2012), and `PyFMI`, which interacts with the FMU generated using `Simulink` (MATLAB/Simulink 2024) to perform automated test execution. Allure (Allure 2025), an open-source tool for visualising the results of a test run, is used to generate the test report (see Figure 12), which is integrated with Behave and can also be integrated with task management tools like Jira.

5 Results and discussion

We have defined *6* features and their corresponding scenarios, and provided *1000* time steps to generate the test inputs for each execution of the SUT. The number of steps executed per feature and scenario depends on the number of scenario instances and the number of Given-When-Then templates in the BDD test file. The execution time of the tests was *1m14.584s*. The test results, comprising the features and behaviours tested, and the test verdict, are summarised in a test report in HTML format. The test suite with test inputs and outputs is saved in *'.json'* format. A domain expert performs further analysis to fix the defects identified by the failed tests, based on the details in the test report and test inputs that caused the system to fail. The failed scenario instance of *Feature 6* highlighted in Figure 12 checks if the output relation, *Always in given range [lower_limit upper_limit]*, is satisfied for the *temperature_oil*. Based on the evaluation of observed outputs, the MR is not satisfied, and the input transformations and the ramp_rates used in the scenario instance can be further analysed to fine-tune the model parameters to fix the issue.

6 Related work

Yao, Deng, et al. (Deng et al. 2021) proposed a declarative metamorphic testing approach, BMT, for testing autonomous driving models. The approach designed for generating MRs using custom traffic behaviours is primarily applied to image processing to verify deep learning models on their erroneous predictions. Their work also used behaviour-driven development based domain-specific language to build the metamorphic relation and to generate a test template similar to our approach. However, they target image processing systems for autonomous driving models, whereas our work focuses on testing the dynamic simulation models exported as FMUs in the maritime application domain.

7 Conclusions

We proposed a metamorphic testing approach combined with behaviour-driven development for the validation of simulation models. The main contributions of our approach were: specifying the metamorphic tests as scenarios using GWT patterns, and defining a set of metamorphic transformations and metamorphic relations to validate dynamic simulation systems. Tool support for the approach has been provided in the form of a GUI-based tool that allows the domain expert to import FMU specifications and to formulate metamorphic tests as parametrizable scenarios. The tool also allows the generation of additional tests from these scenarios. Currently, the input-output combinations in metamorphic relations are selected based on domain expertise to facilitate the test generation process. However, this can be done semi-automatically based on the availability of artefacts such as SysML diagrams, causal graphs or cause-effect diagrams (Clark et al. 2023).

Future work will focus on customizing the framework to utilize information mined from causal modelling approaches for the systematic generation of metamorphic relations. At the moment, the test generation uses random generation, but future work will replace it with a guided approach, based on our previous work on combining metamorphic testing and generative adversarial networks (Sudheerbabu et al. 2024). Future work also includes a study with practitioners on the usability and practical effectiveness of the tool to both researchers and practitioners in the context of acceptance and integration testing.

The Value of Enforcing a Strict Modeling Methodology within Modelica

Dirk Zimmer[1]

[1]Institute of Robotics and Mechatronics, German Aerospace Center (DLR), Germany,
dirk.zimmer@dlr.de

Abstract

Self-restriction to a certain modeling style can enable the modeling of large-scale systems and the robust modeling of complex system architectures. This paper discusses how such a self-restriction can be achieved within the Modelica language and provides a corresponding example.

Keywords: Modeling Methodology, Language Design, Object-Oriented

1 Motivation

Modelica provides the modelers with a lot of freedom on how to create and compose their models. This freedom contributed significantly to the appeal of the language. It enabled many modelers to solve even exotic problems while the powerful algorithms for symbolic index-reduction in Modelica compilers still enable the generation of efficient simulation code. Hence Modelica has become the language of choice for many experts in their fields, especially in thermal and energy related fields where many specialized solutions are needed.

As always, this freedom is associated with a price to be paid for it. First, what is appealing to an expert maybe overwhelming for a novice. Beginners in Modelica often struggle with decrypting the error-messages and often yearn for more guidance. Even after 25 years, the entry barrier to the world of equation-based modeling is high. Second, since equations can be entered in any form, the code generation has to be relegated to the very last stages in processing. For monolithic simulation code, this is fine but code for large-scale systems on GPUs or for variable structure systems require differently structured code that becomes available before final system assembly. This is difficult to fulfill for current Modelica models, despite notable efforts from (Benveniste 2023, Neumayr 2023).

Being self-aware of its flaws, the Modelica community has always remained open to take inspiration from new language developments. Whether these are experimental languages like MOSILAB (Nytsch-Geusen 2006), SOL (Zimmer 2010) or larger efforts such as Modia (Elmqvist 2021). However, these developments also revealed how strong the Modelica legacy is and that maybe a new language or a major extension is not what is needed.

Indeed, this paper argues that not an extension of the Modelica language is needed but that a self-imposed restriction would benefit a significant set of applications. The conflict between an expert and a novice does not need to exist. We can formulate basic models by restricted means and then let the experts extend from this giving them free choice of their tools. The conflict between different possible compile paths also does not need to exist. We can provide models in a restricted form that enable local analysis and local compilation and when these restrictions are lifted, full global analysis for elaborate index-reduction is enabled.

We shall remind ourselves that it is the strength of a declarative language that it does not stipulate its computational realization. When we are stricter about the declarative form, we typically gain freedom on how to process the content.

2 Robust Modeling Methodology

The greatest source of complexity in the processing of equation-based models are systems that are over-idealized. Over-idealization means that the system has been idealized so strongly that the information on how to solve this system has been lost in the process of modeling. A great educational collection of such examples has been provided by Peter Junglas (Junglas 2025):

- A singular model of gear shift for a car transmission: the over-idealization neglected the necessary synchronization during the shift.
- A singular model of an RS Flip-Flop: the over-regularization neglected the signal delays within the components
- A model for the distribution of compressed air with unsolvable non-linear equations: the over-idealization neglected the kinetic energy of the fluid that would lead to the flow balance.
- etc.

Unfortunately, the formulation of over-idealized systems has a strong legacy in text-books and modeling. To make matters worse the awareness of this phenomenon is often little to none. Over-idealized systems not necessarily lead to singular systems but often also to structural regular systems involving non-linear equation system in implicit

form and states with non-linear constraints between potential state variables.

Because the information on how to solve these models has been removed, a compiler for such Modelica models has essentially to perform blunt guessing (often euphemistically formulated as "applying clever heuristics"). No matter how elaborated such guesswork may be, it involves severe disadvantages:

- It needs be performed on a global level to exploit the full context and hence a global analysis of the model is needed.
- It does not scale. While guessing may work for system of low dimensions, it will eventually fail for increasingly large dimensions.
- The compile process becomes non-deterministic. Different compilers may have different guessing strategies.

It is important to emphasize that this is not a problem of the compiler's algorithms or of any of the simulation tools. It is a problem of the input to the compiler. If the information entering the system is incomplete, no algorithm can magically retrieve this missing information. This is basic information theory.

The only solid solution to this problem is thus to insist on input that is information complete, meaning models that are idealized (as all models are idealizations) but not over-idealized.

Fortunately, a suitable model class has been recently identified. We call them Linear Implicit Equilibrium Dynamics (LIED), (Zimmer 2024)

A DAE system with potential state derivatives $\dot{\boldsymbol{x}}$, time t and algebraic variables $\mathbf{w}$

$$\mathbf{0} = \boldsymbol{F}(\dot{\boldsymbol{x}}, \boldsymbol{x}, \mathbf{w}, t)$$

is defined as LIED system when it can be transformed into the following form:

$$\begin{bmatrix} \mathbf{w}_E \\ \dot{\boldsymbol{x}}_E \end{bmatrix} = \mathrm{g}(\boldsymbol{x}_I, \boldsymbol{x}_E, t)$$

$$\mathbf{A}(\boldsymbol{x}_I, \boldsymbol{x}_E, \mathbf{w}_E) \begin{bmatrix} \mathbf{w}_I \\ \dot{\boldsymbol{x}}_I \end{bmatrix} = \mathrm{f}(\boldsymbol{x}_I, \boldsymbol{x}_E, \mathbf{w}_E, t)$$

We see that both the algebraic variables as well as the state derivatives can be split into a fully explicit part $(\dot{\boldsymbol{x}}_E;\ \mathbf{w}_E)$ and a part $(\dot{\boldsymbol{x}}_I;\ \mathbf{w}_I)$ with a linear system in implicit form expressed by the regular matrix $\mathbf{A}$. Furthermore, the following conditions shall hold true:

$$\dot{\boldsymbol{x}}_E \cap \dot{\boldsymbol{x}}_I \subseteq \dot{\boldsymbol{x}}$$

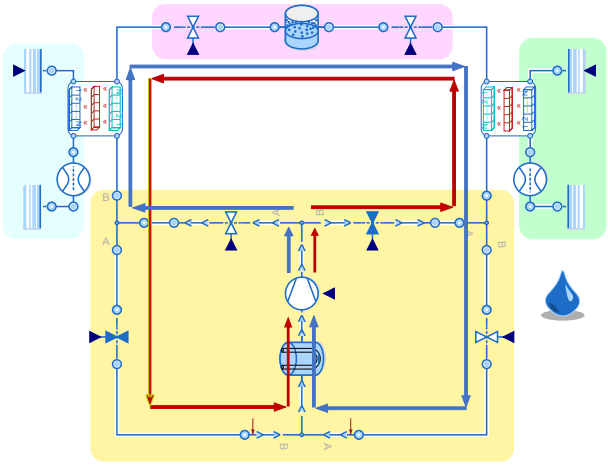
$$\mathbf{w}_E \cap \mathbf{w}_I \supseteq \mathbf{w}$$

$$\dot{\boldsymbol{x}}_E \cap \dot{\boldsymbol{x}}_I \cap \mathbf{w}_I \supseteq \dot{\boldsymbol{x}}$$

$$\dot{\boldsymbol{x}}_E, \dot{\boldsymbol{x}}_I, \mathbf{w}_E, \mathbf{w}_I \text{ are all disjoint}$$

These conditions essentially mean that it is allowed to perform certain symbolic mechanism of index reduction such as the dummy derivative method (Mattsson1993) originating from Pantelides (Pantelides 1988). Using this method, states variables of $\boldsymbol{x}$ can be transformed to algebraic variables in $\mathbf{w}_I$ and further derivatives may be added to $\mathbf{w}_I$ or $\mathbf{w}_E$. In practice, this is important because it means that the linear implicit dynamics can be expressed by far fewer states than suggested by the vector $\boldsymbol{x}$ of the original DAE formulation.

Whereas this model class may seem to be overly restrictive in the first place we could demonstrate that it is not only applicable but also highly attractive for the modeling of stiff mechanical systems as in Figure 2 (Zimmer 2023) and complex thermo-fluid architectures (Zimmer 2022, Junglas 2023) as in Figure 1. Further library development for energy and electric systems is currently ongoing.



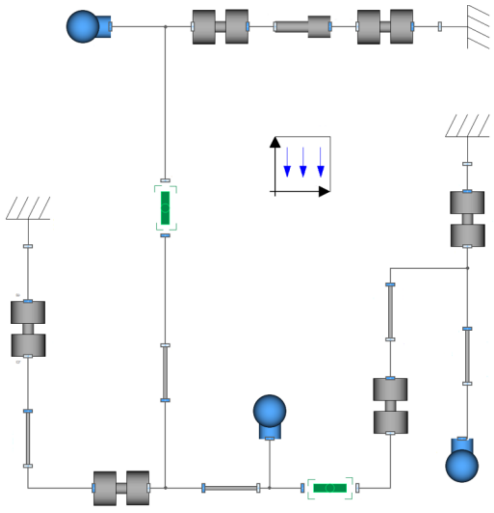


Figure 1. Model diagram of a heat pump using the DLR ThermoFluid Stream library (Zimmer 2022)

DOI 10.3384/ecp218147

Figure 2. Model diagram of a mechanical system for a kinematic using the Dialectic Mechanics library (Zimmer 2023).

The goal is now to define a language that is restricted for such LIED systems and that also represent valid Modelica code. The expected advantages are naturally contrarian to the previous bullet list for over-idealized models:

- Models can be analyzed locally and early compilation of components is enabled.
- It scales. The dimension of the system will principally not impact its solvability barring other issues such as numerics or memory consumption.
- The compile process can be formulated in fully deterministic way increasing the value of a reference implementation.

3 Demonstration Example

Whereas the two preceding sections made very abstract arguments, we shall now provide a concrete example and then discuss the design ideas based on this code. Listing 1 was placed in the Appendix and presents the model of a 2D multibody library implementing components according to dialectic mechanics. The code has been stripped from most annotations, occasionally shortened and simplified for presentation purposes.

3.1 Assumed Causality

A key point of the robust modeling approach is that models are formulated under the assumption of causality. This enables two major benefits:

1. Code generation for individual components is enabled.
2. Error messages point to a single line holding either a equation whose causality is not correct or to a variable definition that is not causalized.

To achieve this, the connectors need to have an assumed causality and what derivates are needed. Also, we need to be able to formulate what is a state and what variables can be used to tear a linear equation system. Let us go through each of these points:

Connectors with assumed causality

Input and outputs are the natural way to formulate a causal connector. Whenever inputs and outputs are used we will use them as indicator of causality: the input is assumed to be known to its component and the output is unknown (and the reverse is true to the outside).

For the modeling of physical systems, conjugated pairs of potential and flow variables have proven to be useful. In order to formulate these pairs with an assumed causality, they are not allowed to stand on their own but need to be associated with a signal connector.

A potential variable may be declared in a connector after a signal and then inherits the assumed causality from this signal. The flow variable must then be declared after the potential variable and is assumed to be of inverse causality.

Two examples of such connectors are found in Listing 1, lines 35-51. The `FlangeOn` is supposed to be on the root side of a kinematic chain and hence its variable for position forms an output signal. The corresponding potential is the velocity and shares this causality. The flow is the force (or torque respectively and of inverse causality). The `FlangeTo` forms then the connector of opposite sex.

The example demonstrates another feature defined on Listing 1, line 14 and used in lines 30-34. A new special predefined type called `RealWithDerivative` that indicates that not only the potential variable is available in the connector but also its derivative. Providing this information means that differential index-reduction can be performed on the component level.

For a standard Modelica compiler, it is not necessary to have such a special type hence the definition on line 15 simply defines a `Real`. The definition exists so that other compilers or a compliance checker can replace this default definition by a special inner representation.

Given such causalized connectors, the model equations can now be provided in partially ordered form: each equation can be causalized based on the previous equations. A simple example for this is the body model in Listing 1, lines 130 – 150. It assumes the position and the derivatives to be known and calculates the forces and torques from the acceleration.

Declaring Tearing of Linear Equation Systems

Since the modeler shall formulate everything under the assumption of causality, this also impacts how implicit linear equation systems across components have to be formulated. Often the modeler expects the model to react to a variation by a linear response. This observation enables to formulate such a system in causalized and torn form. To indicate a tearing of a linear equation system, a special predefined model is being declared and then applied. The model is called `LinearResponse`.

The revolute joint element shows how to use it. The modeler expects that a linear response in force results from a change in acceleration. He formulates it accordingly by declaring the model `LinearResponse`. The assumed causality of the model now naturally follows from this.

Within Modelica the `LinearResponse` model can be formulated as in Listing 1, line 6-12. This definition ensures that the model will be correctly understood by any existing Modelica tool. Special tools for this modeling

methodology may replace this definition with an internal representation.

Declaring States of the System

A predefined type is also used to select the state of the system. In this case the state variable is declared as `ContinuousState`.

The obvious question is why using this mechanism and not the already available `StateSelect` attribute? The reason is to enable an orthogonal mechanism for state selection.

The special model is used for the restricted modeling methodology presented here and aims to enable component-wise compilation. The state-select attribute is to be set by an expert for full complex (non-restricted) Modelica models. The motives for selecting states can be quite different and hence it seems a good idea to avoid any potential conflict.

When translating a model, the state variable is assumed to be known and the derivative is assumed as unknown. If you take the derivative of any non-state variable than this variable has to be known at this point and the derivative is derived from this. The `Body` component is an example from this. Its derivative does not define a state.

3.2 No Look-ahead

In our restricted modeling methodology, we shall declare or define items before we use them. Basically, a compiler or a compliance checker for this restricted set shall be able to "understand" each line without having to read ahead. This concession significantly reduces the complexity of a compiler since many processes can now be performed directly on the stack instead of having to work on intermediately stored parts. Far less internal data-structures are thus needed.

One result of this requirement is that packages must not be mutually depending on each other anymore. The common pattern that is used by many existing Modelica libraries does not match this requirement. We have to abandon this pattern and separate interfaces from components from examples in order to shed unnecessary dependencies.

We can see this in Listing 1 where packages for interfaces, planar components and examples are separated and all encapsulated. Import statements are restricted to encapsulated packages. By separating interfaces, components and examples the interdependencies are reduced.

While providing a short-term inconvenience, this restriction leads to code that is better maintainable in the long-term and avoids "spaghetti" packages. Even a modern language like Go enforces such a rule for good reasons.

3.3 Feature Elimination

When we restrict ourselves to a certain modeling style, this also offers an opportunity to trim the feature set of the language. There are a number of small features which have only very specific purpose or application in the standard Modelica language that we shall abandon for this modeling methodology:

- connections.branch/root (used mostly in MultiBody)
- stream (used in Modelica.Fluid)
- operator overload
- expandable connectors
- delay
- homotopy
- inline
- etc.

As the reader can see from the above list of abandoned language features, it is back to basics again. Another significant simplification is that annotations can be part of the code but are completely ignored for the process of compliance checking or compiling. The information within the annotation is hence only regarded as auxiliary meta-information for non-compilation processes as it was the original intention in early Modelica (this is also an additional reason why to use special predefined types and models such as in lines 2-19 rather than custom annotations)

For the moment, the focus is also on continuous systems but of course, discrete events also need to be handled. This shall follow the same guidelines yielding a fully deterministic process that can be locally analyzed. However, this is still upcoming work.

3.4 Compatiblity to Modelica

Evidently, the restrictions that are imposed to the modeler are significant. The Modelica Standard Library clearly does not comply to these restrictions and other existing libraries are also unlikely to do so.

We hence need new libraries developed under this methodology. This is no surprise because there was previously no sufficiently practical guidance on how to model in an object-oriented way that is also information complete.

What is important however that libraries that are developed under these restrictions are fully usable with any tool supporting the Modelica standard. Even if these tools do not exploit the special characteristics of the restricted modeling methodology, they still profit from the fact that these models are information complete. Not only shall these libraries work in any Modelica tool, they shall also be (automatically without further tool support) be very robust in their usage.

DOI 10.3384/ecp218147

We currently engage in the development of 4 libraries:

1. Signal Blocks
2. Dialectic Mechanics
3. Controlled Energy Flows
4. ThermoFluid Stream Lite

4 Implementation

To support the development of these new libraries, a Compliance checker is being implemented. It serves two functions:

1. The implementation formalizes the restrictions that have been informally stated above.
2. It provides instant feedback to modelers whether their library abides to these restrictions.

Formalizing the restricted modeling methodology will ultimately result in a new language that forms a sub-set of Modelica. The compliance checker is thus not developed from an existing Modelica compiler or tool but as a new tool from scratch. This is the most effective way to shed complexity and question all the existing requirements.

The compliance checker is implemented as a stand-alone console application in C++17 using only the Standard Template Library (STL). Given that the portability of C++ code between operating systems and compilers has significantly improved over the last decade the application may be applied on different operating systems.

We can use the compliance checker to keep track of the complexity of the new restricted language. Figures 3 and 4 measure the complexity of the C++ code compared to the Modelica specification which is written in English language. The counting for the code includes comments and the counting for the specification includes also the examples.

Although we compare an executable code against a mere description in natural language, we still have far less complexity. This shows that (at least for now) the reduction in complexity is very effective.

How is this compliance checker supposed to be used? As a console application it runs next to the Modelica development environment of your choice and automatically checks whenever a modification is saved whether the file(s) comply to the restricted modeling methodology. Otherwise it provides an error message that always refers to a specific line of code.

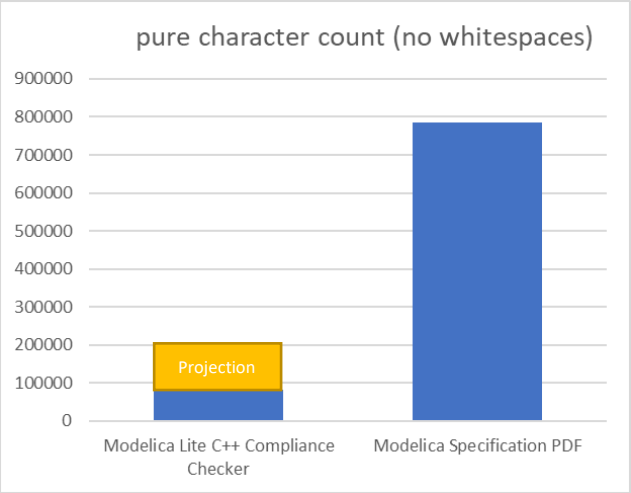

Figure 3. Complexity of the compliance checker implementation in C++ for a restrictive Modelica vs Modelica Specification PDF version in character count. Projection indicates an estimate for the complete compliance checker.

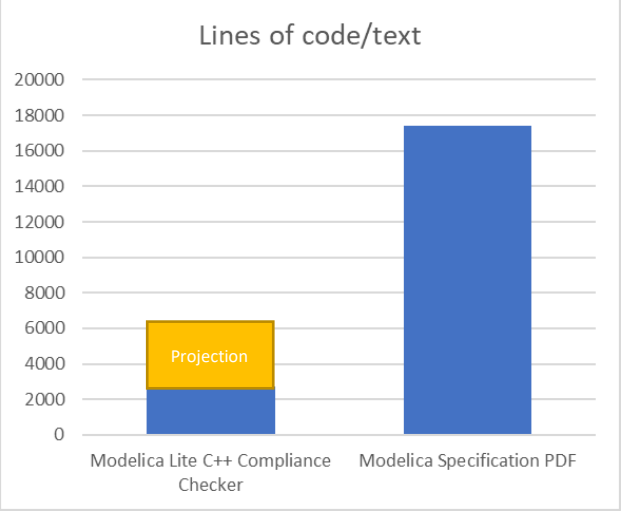

Figure 4. Complexity of the compliance checker in C++ for a restrictive Modelica vs Modelica Specification PDF version in lines of code.

In this way, the existing IDEs for Modelica can be effectively reused but the modeler is restricted with instant feedback. In future, the compliance checker can be extended to enable different compile paths. After all the compliance checker already performs many processing steps of a full compiler such as: lexer, parser, type generation, identifier resolution, partial casualization, etc.

5 Conclusions

Modelica has gained its popularity by providing the modeler ample freedom in the formulation of its models.

However, there are many applications that profit from a more restrictive modeling methodology:

- For complex architectures, (especially when modeled across different organizational entities) the robustness of the model often becomes the limiting factor in model development. If a strict modeling methodology allows stronger a-priori statements on solvability and pinpoint error messages, it will be highly welcome.
- For large scale systems or variable structure systems, a global analysis of the system increasingly becomes infeasible. If a strict modeling methodology requires only a local analysis and enables compilation of components, it will be of high value.
- Modern compute architectures like GPUs (Kirk 2022) demand different forms of code generation. Modern numerical methods such as multi-derivative methods (Krivovichev 2024) also require different compilation schemes. If a strict modeling methodology eases the compiler development by massively reducing complexity, it will find quick adaptation.

As shown in the previous section, it is possible to support such a strict methodology fully within the current version of Modelica without demanding any changes to the existing language. It is basically an act of self-discipline. Some models may seem unusual for a Modelica purists but in view of the listed advantages, one should advocate for pragmatism.

The currently undergoing implementation of a compliance checker will ease this discipline, formalize the restrictions and open up the development of independent compile paths. We plan to release the compliance checker as open-source software.

In this way, we can have the best of both worlds. Confined modeling efforts for special systems can be performed by experts using the full feature-set of Modelica. Modeling efforts of larger architectures or with versatile compute architectures can be performed using a strict modeling methodology such as the one presented here.

Abstract

Cyber-physical systems are self-adaptive, changing their behavior at run time to adapt to their context. Hence, their simulations must also handle variability at run time. The lack of support for variability in industrial equation-based modeling languages, such as Modelica, causes problems when simulating self-adaptive systems, e.g., they only limitedly support structural variability, and state transitions are based on if-then-else conditions that can cause conflicts, especially for complex control mechanisms.

We present a modeling technique for equation-based models containing variability by implementing concise and dedicated language constructs to express state space and transitions via contextual modeling. Contextual modeling abstracts the modeled world and allows the definition of constraints that reduce the risk of reaching conflicting states. We demonstrate the feasibility of our approach on a case study, presenting the advantages of our modeling technique regarding the definition of state control and the reduction of risk for reaching conflicting states.

Keywords: Cyber-physical systems, Self-Adaptive Systems, Contexts, VSS, Julia, Simulation

1 Introduction

The 5C architecture of cyber-physical systems (CPSs) (Lee, Bagheri, and Kao 2015) includes a configuration level that implies system behavior variability. Therefore, when simulating CPSs, their simulations must also handle variability. Variability at simulation time is supported only partially by the equation-based modeling (EBM) language Modelica (Fritzson and Engelson 1998), e.g., Modelica does not support conditional definitions of components during simulation (Zimmer 2010) and has limitations with switching equations at simulation time if the DAE index changes (Benveniste, Caillaud, and Malandain 2020). Even if these limitations are bypassed, Modelica supports only if-then-else or when conditions based on Boolean expressions. These expressions become complex and incomprehensible for complex state spaces and transitions. This lack of expressiveness results in an inconvenient definition of variability in simulation models.

In this paper, we present context-oriented equation-based modeling (COEBM), a modeling technique for EBM containing variability by implementing concise and dedicated language constructs to express state space and transitions via contextual modeling. Contexts abstract the simulated world and possible control actions. Constraints between contexts are checked during runtime, preventing reaching conflicting states, e.g., simultaneously charging and discharging a battery. During simulation, context changes imply transitions between models to achieve structural variability. We further develop *Contexts.jl*, presented in our previous work (Gutsche et al. 2024), to achieve better applicability of context-oriented programming (COP) and context modeling in EBM.

For our implementation, we use the EBM language *ModelingToolkit.jl* (MTK) (Ma et al. 2021). MTK is implemented as a library-based embedded domain-specific language (DSL) for the general-purpose programming language Julia (Bezanson et al. 2015; The Julia Project 2023). This enables utilizing Julia's features for extending the modeling language (Rackauckas and Nie 2019) and using the expressiveness of a programming language in callbacks during simulation time. We present how to extend MTK with syntax suitable for COEBM.

The main contributions of this paper are:

1. Integrating COP in EBM for concise syntax for variable reinitialization
2. Integrating *Contexts.jl* language constructs in MTK to define structural variability
3. Using context modeling with constraints to prevent conflicting states in EBM and implementing state control mechanism

We present a case study to evaluate the contribution's feasibility for simulating self-adaptive systems. Therefore, we model an energy park for green hydrogen production with COEBM. We port Modelica models to MTK and implement the control logic with contextual modeling. Simulation speed is crucial when using simulations to support CPS operation. Therefore, we also provide performance measurements for our COEBM implementation.

In section 2, we present background information on Julia and context modeling, followed by an overview of related work about variable structure system (VSS) simulations in EBM in section 3. In section 4, we present the concept of COEBM and how to simulate systems containing variability with COEBM. The evaluation, consisting

of the mentioned energy park case study and performance measurements, is presented in section 5. To conclude, we provide a discussion in section 6 and a conclusion and outlook for future work in section 7.

2 Background

2.1 Julia and ModelingToolkit.jl

Julia (Bezanson et al. 2015; The Julia Project 2023) is a just-in-time compiled general-purpose programming language. A major difference from other commonly used programming languages is the multiple dispatch paradigm. Instead of defining functions within classes and dispatching over the function's object, the dispatch relies on the types of the function's arguments. Some of the advantages of this design choice are discussed later. Besides this, Julia has powerful metaprogramming capabilities.

In addition, Julia provides the rich ecosystem of scientific machine learning (SciML) containing libraries for mathematical computation and optimization (Lubin et al. 2023), numerical equation solvers (Rackauckas and Nie 2017), and EBM (Ma et al. 2021). The implementation in Julia enables utilizing multiple dispatch, which allows developers to, thanks to design choices of *DifferentialEquations.jl*, extend the functionality of the SciML ecosystem (Rackauckas and Nie 2019).

MTK is an embedded DSL implementing Modelica-like object-oriented EBM in Julia. MTK components consist of variables, parameters, equations, sub-components, callbacks, and Julia code. Models defined with the macro `@mtkmodel` are translated to equation systems. Depending on the mathematical structure, MTK provides, among others, `ODESystem` and `PDESystem`. These systems are used to define `ODEProblem`s containing initial values and a time span. `ODEProblem`s are solved with an implemented `solve` function where different solver algorithms are available. MTK benefits from support for extensibility of the SciML ecosystem (Rackauckas 2021). We implement our modeling technique in MTK because of this support for extensibility and the possibilities for combining Julia language features with EBM.

2.2 Context Modeling

Contexts describe the situation and environment in which a program is executed as discrete categories. Context-awareness (Abowd et al. 1999) enables software to achieve dynamic adaptation of its behavior to the current situation by specifying behavior for different contexts. Contexts are activated and deactivated based on the global state of the program or its environment. We call this state activeness. A programming paradigm based on this principle is called COP (Keays and Rakotonirainy 2003; Hirschfeld, Costanza, and Nierstrasz 2008). In COP, developers can specify contextual variants of a function. During the program's run time, the current activeness of contexts is evaluated, calling the function defined for this context. Therefore, dynamic adaptivity is achieved.

In our previous work (Gutsche et al. 2024), we presented a COP implementation in Julia. We introduced the library *Contexts.jl*, which provides concise syntax based on metaprogramming to define contexts and achieve context-dependent behavior for functions by utilizing Julia's multiple dispatch. In (Gutsche et al. 2024), we also already showed that combining *Contexts.jl* and MTK to implement variability in equation-based models with contexts is possible.

As presented in (Gutsche et al. 2024), context modeling in *Contexts.jl* is based on singleton objects representing contexts. The activeness of contexts can be constrained by an approach based on context Petri nets (Cardozo et al. 2012). The Petri nets defined in *Contexts.jl* are Dynamic Feature Petri nets (Muschevici, Clarke, and Proença 2010) that represent the constraints from (Cardozo et al. 2012). For example, an exclusion constraint prevents two specific contexts from being active simultaneously, and weak inclusion constraints imply that the activation of one context causes the activation of another context. This reduces the risk of reaching conflicting states.

3 Related Work

Several approaches aim to increase functionalities for specifying and simulating variability in EBM. As (Wang et al. 2025) show, these approaches focus on enabling EBM to simulate models containing structural variability, called VSSs (Utkin 1977).

Several new languages were designed, heavily inspired by Modelica, including Sol (Zimmer 2010), Hydra (Giorgidze 2012), and Modelyze (Broman and Siek 2012). While they support structural variability, advanced modeling techniques to specify state spaces and control mechanisms are not implemented. The already mentioned MTK and *Modia.jl* (Elmqvist, Neumayr, and Otter 2018) are new EBM implementations, implemented as embedded DSLs in Julia. In contrast to MTK, *Modia.jl* has dedicated support for VSS simulation (Neumayr and Otter 2023) but also lacks advanced modeling techniques.

DySMo (Mehlhase 2014), MoVaSe (Esperon, Mehlhase, and Karbe 2015), and PyVSM (Stüber 2017) rely on scripts that orchestrate the simulation. DySMo and PyVSM use Python to simulate different models, defining variants, e.g., modeled with Modelica. While they enable VSS simulation, they lack modeling techniques for constructing state space and transitions. MoVaSe, later called MoVaSim, is implemented in the Eclipse ecosystem and includes modeling techniques to specify model variants. However, the only available references to MoVaSim are a Work-in-progress paper (Esperon, Mehlhase, and Karbe 2015) and a dissertation (Gómez Esperón 2017). The editor itself is not available. In these approaches, variability modeling and state control are performed in non-EBM technical spaces, namely Python and Eclipse, creating a hurdle for users.

OM.jl (Tinnerholm, Pop, and Sjölund 2022) is a Mod-

DOI 10.3384/ecp218155

elica compiler written in Julia. *OM.jl* adds syntax for VSS allowing specifying different modes and their transitions. However, also *OM.jl* lacks advanced modeling to specify mode transitions. An approach that aims to improve this modeling is presented in (Wang et al. 2025), where a preprocessor is used to implement syntax for specifying contexts that control the modes. The preprocessed code is then compiled by *OM.jl*. However, only one context can be active at a time, and context activeness is controlled by Boolean conditions based on the time value. Therefore, the advantage of using contexts is lost.

We identify a gap: none of them supports both VSS simulation and advanced modeling of the state space and control mechanisms with dedicated syntax.

4 Context-Oriented Equation-based Modeling

We use contexts in COEBM to achieve behavior variability. Therefore, a well-defined context model is the base of COEBM. This section first describes the modeling of such context models. Afterwards, we present two ways to use contexts and COP for variability: variable reinitialization and structure change.

4.1 Contexts in Equation-based Modeling

We classify contexts into measurable and control contexts. Measurable contexts change their activeness based on measured values of observables, e.g., a temperature. Those observables cannot be directly influenced. Control contexts describe states or variables controlled by operators, e.g., a variable voltage. By changing the context, the operational mode changes.

In (Gutsche et al. 2024), we presented how *Contexts.jl* enables the definition of contexts with concise syntax based on metaprogramming and how constraints based on (Cardozo et al. 2012) are used to describe the state space. Using primarily measurable contexts to imply the activation and deactivation of control contexts via constraints enables the definition of control mechanisms while minimizing the risk of reaching conflicting states.

We introduce a new constraint for contexts, the `alternative`. This constraint implies that out of N contexts, exactly 1 context must be active at any time. This constraint occurs frequently in modeling but was not described by (Cardozo et al. 2012) or (Gutsche et al. 2024). We implemented the constraint in *Contexts.jl* using a Petri net like the library's other constraints. The constraint checks two things when a context's activeness is changed. If the currently only active context gets deactivated, this deactivation will be undone, and if a context $C1$ gets activated, but an alternative context $C2$ was active before, $C2$ becomes deactivated.

Another concept that we introduce is context groups. A context group implies an `alternative` constraint between the contexts that compose the group. Calling the group object will return the currently active context of this group. Context groups should describe orthogonal context dimensions to prevent conflicts. We also implemented context groups in *Contexts.jl* to improve the applicability for COEBM. An example of how to define contexts within a context group is shown in Listing 1.

```
1 @newContext Cold, Medium, Warm
2 activateContext(Medium)
3 Temp = ContextGroup(Cold, Medium, Warm)
4 Temp() # returns Medium
```

Listing 1. Example for defining contexts `Cold`, `Medium`, and `Warm` as well as a context group `Temp`. These contexts describe the Temperature as a discrete classification.

Modeling the context space should consist of four steps. First, identify relevant contexts. Second, cluster contexts to context groups. Third, classify contexts as measurable or control contexts. Fourth, define constraints between contexts of different groups. The activation and deactivation of measurable contexts may imply the activation and deactivation of control contexts, but not vice versa.

An example is a temperature control system. For the sake of simplicity, we assume that the system either activates heating or cools the system by activating the air conditioning (AC). These two possible operations create four contexts: `HeatingOn` and `HeatingOff`, composing the group `Heating`, and `ACOn` and `ACOff`, composing the group `AirConditioning`. For a basic control mechanism, the activeness of heating and AC might only automatically depend on the temperature. We define a context group `Temperature` consisting of the contexts `Cold`, `Medium`, and `Warm`.

While the temperature contexts are measurable, the contexts for heating and AC are control contexts. We model the control contexts' activeness based on the activeness of the temperature contexts. Therefore, we specify the following constraints:

- `Cold` weakly includes `HeatingOn`
- `Medium` weakly includes both, `HeatingOff` and `ACOff`
- `Warm` weakly includes `ACOn`

Note that because `Cold` and `Warm` exclude each other, `ACOn` and `HeatingOn` will never be activated automatically at the same time. To also prevent manual simultaneous activation of `ACOn` and `HeatingOn`, we define an exclusion rule between those two contexts. A visualization of the specified context model is shown in Figure 1.

We use context models within EBM in MTK to control simulation variability. MTK allows the definition of discrete and continuous events. We use events to call callback functions that include the functionalities of *Contexts.jl* to activate or deactivate contexts. Based on the defined constraints, other contexts change their activeness, and the simulation model adapts based on these changes. Hereby, adaptation can be implemented by variable (or parameter) reinitialization or structural changes.

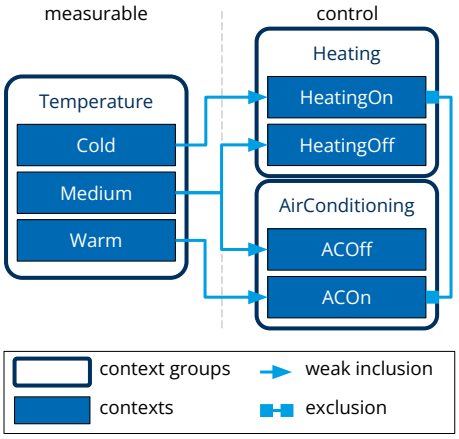

Figure 1. Context model for a heating system consisting of three contextual groups. The implicit alternative constraints between contexts of one group are not separately visualized.

4.2 Context-Oriented Variable Reinitialization

MTK supports variable reinitialization to achieve discrete changes of variable values. We extend this by using the COP features of *Contexts.jl* to control the reinitialization based on changes in the context activeness. Again, we explain this mechanism with the example from above. Therefore, we assume heating can be simulated as on or off by reinitializing a voltage value. We model possible context transitions within one context group as a state machine. For example, the temperature context transitions from `Cold` to `Medium` if $T \geq 15\,°\text{C}$ and from `Medium` to `Cold` if $T \leq 14\,°\text{C}$. The difference between temperature thresholds prevents cyclic event calls. Accordingly, transitions between `Warm` and `Medium` are defined, but transitions between `Warm` and `Cold` are not foreseen. Callback functions in MTK are Julia functions, i.e., Julia's complete expressiveness is available. In Listing 2, a callback function is defined on lines 9 to 26, and computational logic representing the state machine is shown on lines 10 to 24. In line 25, a context-oriented function is called to reinitialize the voltage value if the previously performed context changes influenced the activeness of the heating context. The two context-specific definitions for the function are shown in lines 1 to 7.

In this explanatory example, the voltage values could be reinitialized directly based on temperature values instead of activating the temperature contexts. However, for spaces containing multiple measurable context groups or when activating control contexts also depends on the activeness of other control contexts, separating the state machines for measurable contexts from the activation of control contexts is advantageous. Such an example will be presented in section 5.

4.3 Contextual Views for Structural Changes

A case not natively supported in MTK (or Modelica) is variability due to changing, adding, or deleting variables,

```
1  @context HeatingOn function setV(integ, u)
2    integ.u[u.V] = 12
3  end
4
5  @context HeatingOff function setV(integ, u)
6    integ.u[u.V] = 0
7  end
8
9  function tempChange!(integ, u, p, ctx)
10   if isActive(Warm)
11     if integ.u[u.T] <= 24
12       activateContext(Medium)
13     end
14   elseif isActive(Medium)
15     if integ.u[u.T] <= 14
16       activateContext(Cold)
17     elseif integ.u[u.T] >= 25
18       activateContext(Warm)
19     end
20   elseif isActive(Cold)
21     if integ.u[u.T] >= 15
22       activateContext(Medium)
23     end
24   end
25   @context Heating() setV(integ, u)
26 end
```

Listing 2. Example for a callback function. The computational logic from lines 10 to 24 represents a state machine changing the temperature context based on the current temperature value. The function call on line 25 is a context-oriented call of the function defined on lines 1 to 7, performing a variable reinitialization.

equations, and whole components. We realize the simulation of such VSS by defining distinct differential equation systems that are represented by `ODESystem` objects in MTK. When simulating the whole system, the solving algorithm must switch between those `ODESystem` objects and perform state migration. The algorithm must transfer the end values of all variables to the initial values for the respective variables in the new `ODESystem`. This workflow, realized in Python and not for MTK, was already applied in DySMo (Mehlhase 2014) to simulate VSS. We implement an adapted version of this workflow where contexts decide which model is simulated next.

In our modeling technique, when to switch the model and which model should be simulated next is decided based on the context model, called contextual VSS (CVSS). Therefore, every model variant is assigned to a context or multiple contexts linked with logical operators. Every context must be unambiguously mapped to a model to ensure systems have a well-defined behavior.

To simulate CVSS in MTK without performing the state migration manually, we implemented multiple features. As described in (Rackauckas and Nie 2019), we implement this extension based on Julia's type system and multiple dispatch paradigm.

1. We defined a new problem type for contextual VSS, `CVSSProblem`, as a Julia `struct`. Instead of a single `ODESystem` object, the `struct` contains a dictionary, here called `f`, for the perviously men-

DOI
10.3384/ecp218155

tioned mapping of contexts to `ODESystems`.

2. We specify a new implementation of the `solve` function of *DifferentialEquations.jl* for `CVSSProblem` types with multiple dispatch. This `solve` function checks the keys of `f`, which are the contexts `ODESystems` are mapped to. If a context is active, the respective `ODESystem` will be used for simulation. Therefore, an `ODEProblem` and a respective `Integrator` object are created. The initial values `u0` and simulation start time `t0` are set to either the original start values or the end values of the previous partial solving process. Then, the `ODEProblem` is solved, and its `ODESolution` is saved. If the simulation is restarted, the process is repeated. The simulation ends if the specified ending time is reached, the function `terminate!` is called, or an error occurs. The workflow is visualized in Figure 2
3. We define a new function `restart!`. It calls the `terminate!` function to stop the solving process. If a termination with `restart!` is detected by the `solve` function, the activeness of contexts is checked again, followed by solving the respective `ODESystem`.
4. We define `VSSSolution` as a subtype of `SciMLBase.AbstractODESolution`. The `VSSSolution` contains all the attributes of ODE solution `structs` but also contains a vector of the `ODESolution` objects obtained during the solving. We implement the `getindex` function for the `VSSSolution` objects so that the solutions are obtained as usually done in MTK.

```
1  function tempChange!(integ, u, p, ctx)
2    ACContext = AirConditioning()
3    ## State machine as shown in
4    ## Listing 1, lines 10 to 25
5    if ACContext != AirConditioning()
6      restart!(integ)
7    end
8  end
9
10 f = Dict(ACOn => system_acOn,
11           ACOFF => system_acOff)
12 prob = CVSSProblem(f, [], (0, 60))
13 sol = solve(prob, RadauIIA5())
```

Listing 3. Example for a callback function (lines 1 to 8) and the code to simulate the system (lines 10 to 13). The function `restart!` (line 6) is used to stop the simulation and restart it with a new mode based on the context activeness of the AC context. In lines 10 and 12, the dictionary `f` is defined that maps context to `ODESystem` objects that are used for simulation. With `f`, we define a `CVSSProblem` (line 12) and simulated by solving the `CVSSProblem` (line 13).

We assume the heating example from above is modeled as a VSS system where there is one model for active AC and one model for inactive AC. Accordingly, we create two `ODESystems`, that we call `system_acOn` and `system_acOff`. Both `ODESystems` contain events that call the callback function `tempChange!` as we defined in Listing 2, but we extend it with the model switching logic as shown in Listing 3 on lines 1 to 8. In line 2 in Listing 3, we save the AC context before changing the temperature context. If the AC context was changed due to changes in the temperature context, the `restart!` function is called to perform the model switch. The definition of the context to feature map `f` is shown on lines 10 and 11. Line 12 shows `CVSS` definition and line 13 the solve call, recreating MTK syntax.

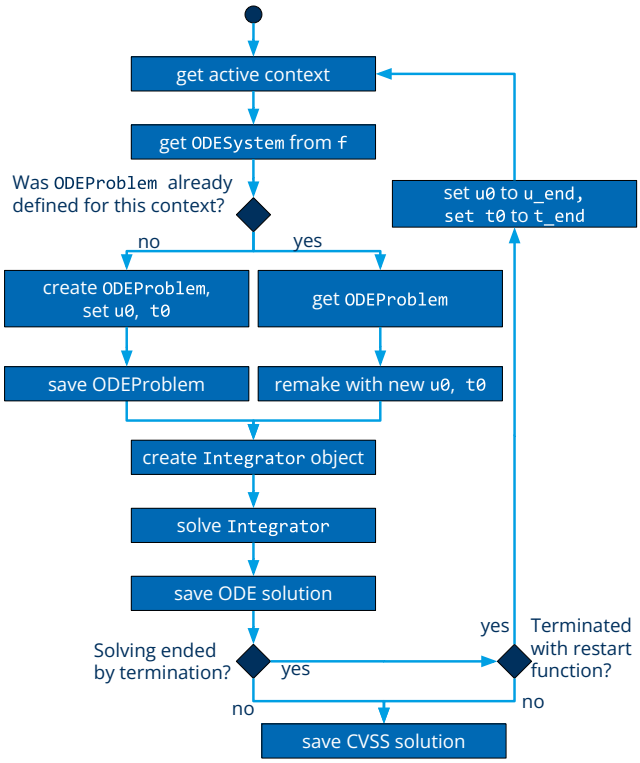

Figure 2. Workflow for solving a CVSS problem. The algorithm checks which contexts mapped to `ODESystems` are active. If this `ODESystem` is solved for the first time, a respective `ODEProblem` is created with the initial values `u0` and start time `t0` and saved. If the `ODESystem` is used another time during solving the `CVSSProblem`, this `ODEProblem` is obtained again and newly initialized with `remake` using the new `u0` and `t0`. An `Integrator` object is created from `ODEProblem` and the `ODESystem` is solved, and the solution is saved. If the simulation was stopped with the `restart!` function, the end values of variables are used to restart the simulation within another context. In the end, the solution is returned as a `VSSSolution` object.

5 Evaluation

We show the feasibility of our modeling process by presenting a simulation of an energy park where hydrogen is produced from renewable energy sources as a case study. After presenting the modeling process and simulation results, performance measurements are provided.

5.1 Case Study: Modeling of an Energy Park

The energy park model consists of wind turbines and photovoltaic (PV) modules for producing electricity, a battery, and an electrolyzer to produce green hydrogen. Also, the park is connected to the electricity grid. Because only green hydrogen should be produced, hydrogen production must be stopped when renewable electricity is unavailable. Also, excess electricity should be stored in a battery to power the electrolyzer with green electricity, even if the weather conditions would not allow it. The energy park should adapt its behavior based on its state, Hence, it is self-adaptive, and context awareness is advantageous.

One of the disadvantages of MTK compared to Modelica is the relatively low availability of libraries. Therefore, most of the needed components have been modeled by us. The models are inspired by Modelica libraries like the Modelica Standard Library, PhotoVoltaics (Brkic et al. 2019), and Wind Power Plants (Eberhart et al. 2015). The electrolyzer model and system design are inspired by (Migoni et al. 2016). A scheme of the system is shown in Figure 3.

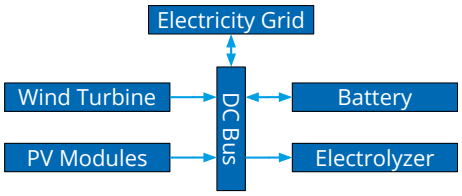

Figure 3. Scheme of the simulation model. Wind turbines and PV modules supply electricity, and an electrolyzer consumes electricity. A battery is used for storing excess electricity. The system can also exchange electricity with the grid.

As this simulation does not aim to give detailed insight into the technical properties of an energy park, the model contains numerous simplifications. We simplified the components themselves compared to the implementations in Modelica. We modeled the system completely in DC with a constant voltage, and converters are neglected. The hydrogen has no physical properties besides mass. Nevertheless, the electricity and hydrogen output are in the correct order of magnitude, and their behavior is modeled reasonably. Because these properties are significant for the presented control via COEBM, the model is suited to show the feasibility of COEBM.

To only produce green hydrogen, two variation points can be controlled: First, the battery can be charged and discharged, and second, the electrolyzer can be put into active and standby mode. Battery charging and discharging is controlled by variable reinitialization, while the electrolyzer operation mode is controlled with a structural change. The active electrolyzer is modeled inspired by (Migoni et al. 2016), while we model standby mode as a resistor representing a constant electrical load. When to switch modes depends on different variable values and the system's state itself.

The variation points are directly translated to contexts. The control contexts `BatteryCharging`, `BatteryDischarging`, and `BatteryIdle` form the context group `BatteryChargingMode`. The contexts `ElectrolyzerActive` and `ElectrolyzerStandby` form the context group `ElectrolyzerOperation`. The measurable contexts represent three properties. First, the power that is fed into or drawn from the grid. We define 4 contexts, `GridOutput` when power is drawn from the grid and `GridInputLow`, `GridInputHigh`, and `GridInputHighWithElectrolyzer`, representing different quantities of power supply to the grid. `GridInputHighWithElectrolyzer` got its name because it can only be reached if the electrolyzer is operated with maximal power. The second context group represents the state of charge (SoC) of the battery containing the contexts `BatterySoCMin`, `BatterySoCMedium`, and `BatterySoCMax`. And third, we define two contexts `ElectrolyzerMaxPower` and `ElectrolyzerMinPower` that are activated based on the voltage with which the electrolyzer is operated. Note that those contexts are not part of a context group because they can be deactivated simultaneously. The context model is visualized in Figure 4.

The lower part of Figure 4 represents the weak inclusion constraints, which implement the control logic. We define seven constraints. Every constraint realizes a specific control step. If the electrolyzer is not operated with maximal power and the battery is charging, charging is stopped (C1). If the electrolyzer is not operated with maximal power and the battery is in idle mode and not empty, the battery gets discharged (C2). Those constraints increase hydrogen production. If the battery discharges but becomes empty, it is set to idle mode (C3). Respectively, if the battery charges but becomes fully charged, it is set to idle mode (C4). If the electrolyzer is active and at minimum power, but grid input is low or we have grid output, the electrolyzer is set to standby mode (C5). This constraint prevents producing hydrogen from grid electricity. If the electrolyzer is in standby mode and the grid input is high, the electrolyzer is set to active mode (C6). If the electrolyzer is operated with maximal power and a certain amount of power is supplied to the grid, the battery is charged if it is not already fully charged (C7).

We define events and callback functions to activate measurable contexts during simulation time. For each of the two context groups `GridState` and `BatterySoC`, we define one callback similarly designed as the one shown in Listing 2. Again, we implement a state machine to control the activation of measurable contexts, and constraints imply the activation of control contexts. We use the `restart!` function and context-oriented functions for variability control. We also define two callback functions for each context: `ElectrolyzerMaxPower` and `ElectrolyzerMinPower`. One function activates the context, and one deactivates it. One of those callback

DOI
10.3384/ecp218155

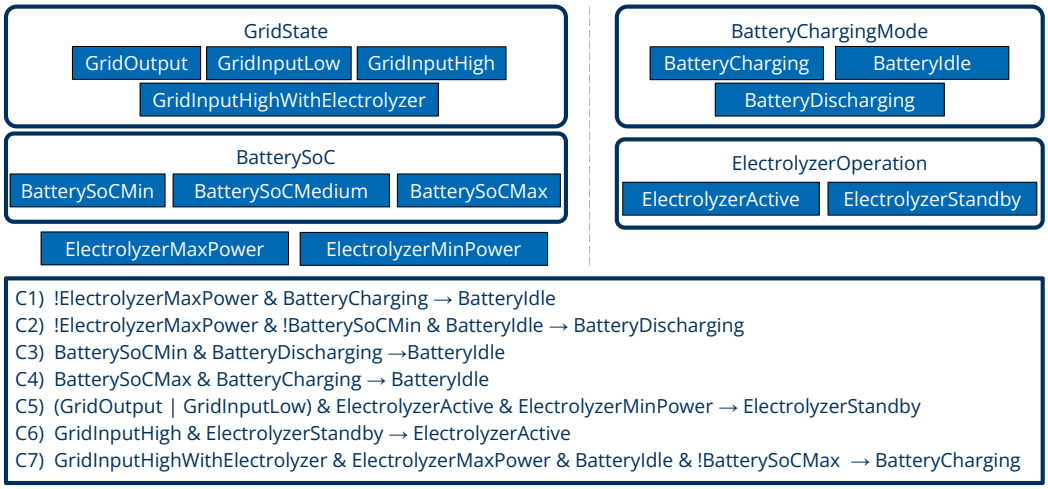

Figure 4. Context model of the energy park simulation. It defines a total of 14 contexts and 4 context groups. The grid state, battery SoC, and electrolyzer power are used for measurable contexts. The battery's charging mode and electrolyzer activeness are implemented as control contexts. The seven constraints that control the system are shown in the lower part of the scheme.

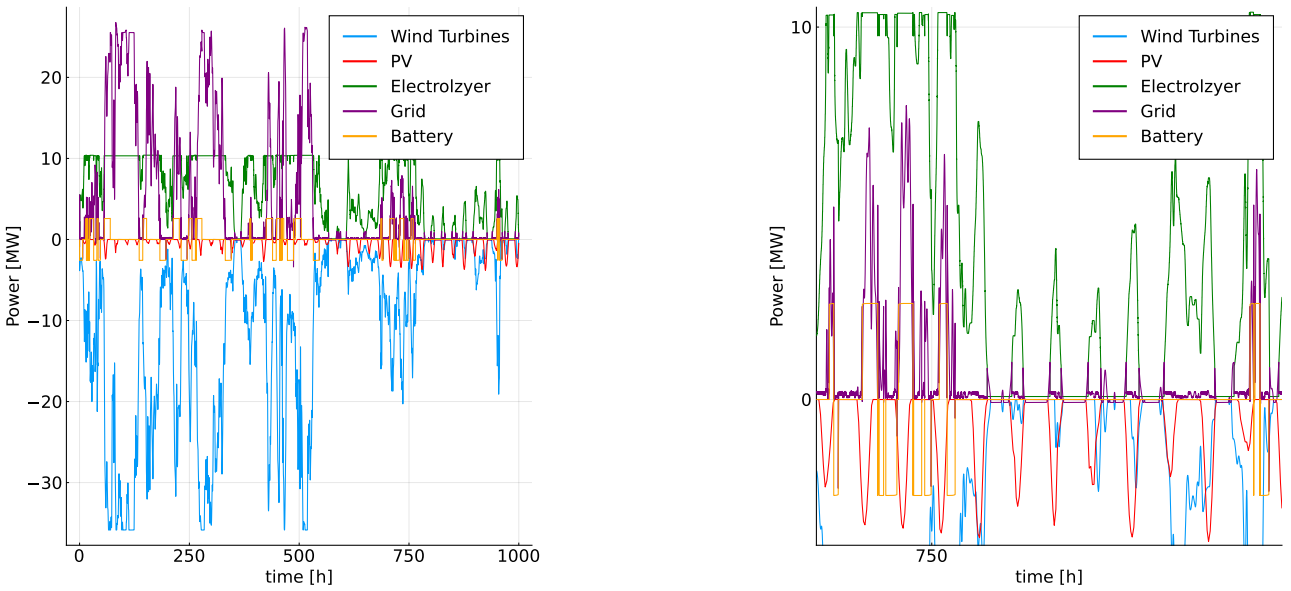
functions is shown in Listing 4, and the rest can be viewed in the code example in the Git repository[1]. The events that call these functions are also shown in the repository. The call on lines 5 and 6 in Listing 4 changes the battery's activation mode. Here, the advantage of using COP is noticeable. Without COP, if-then-else conditions would be needed to check the wanted operation mode. This would result in 7 lines instead of the one presented. In line 8, the restart function is called. The `solve` function automatically chooses the correct next simulation model. It is not needed to specify explicitly to which model to switch.

```
1  function electrolyzerMin!(integ, u, p, ctx)
2    oldContext = ElectrolyzerOperation()
3    if !(isActive(ElectrolyzerMinPower))
4      activateContext(ElectrolyzerMinPower)
5      @context BatteryChargingMode() (
6              batteryMode(integ, u))
7      if oldContext != ElectrolyzerOperation()
8        restart!(integ)
9      end
10   end
11 end
```

Listing 4. Example of a callback function that checks if the context `ElectrolyzerMinPower` must be activated. If the control contexts change after that, variable reinitialization and model switches are performed.

We use solar irradiation data from (Krähenmann et al. 2016b) and wind speed data from (Krähenmann et al. 2016a) as input data. We simulate the system for 1000 h. Figure 5a shows the power of the wind turbines, PV, electrolyzer, battery, and the power exchange with the grid. Positive power values indicate power consumption, while negative values indicate power supply. For the grid, positive values indicate power fed into, and negative values indicate power drawn from the grid.



[1] github.com/cgutsche/ContextualEBM.jl

The effects of context control are better visible in Figure 5b. We achieved control of the electrolyzer and battery by activating measurable contexts. The positive values of the battery power curve show that the battery is only charged if the electrolyzer is operated with maximal power. The negative values show that the battery is discharged if the electrolyzer can not be operated with maximum power because the power generated by renewable energy systems is insufficient. The results show that for multiple days, electricity is barely produced by wind power plants. Then, only the PV provides electricity during the day to operate the electrolyzer, while the electrolyzer is set to standby at night. Therefore, by properly defining the context model, we achieved the goals of producing hydrogen only with energy supplied by renewables and increasing the hydrogen output with battery control. In total, the model switched 32 times during the simulation. The electrolyzer was active during 826.3 h from a total 1000 h simulated.

5.2 Performance

One advantage of simulating VSS is to switch between more and less detailed models depending on the needed accuracy under different input conditions. Also, one possible use case for CVSS simulation is to support the operation of CPS where simulation time becomes crucial. However, computing the context control logic, callback functions in events, and the system switches are expected to have a computational overhead. Therefore, we provide performance measurements to evaluate its impact.

We compare 7 different scenarios. First, the CVSS simulation of the energy park as it was presented (*CVSS*). Second, the `restart!` functions are removed from the callbacks, and the system is simulated as an `ODEProblem` (*Active* and *Standby*). Hence, the events are still triggered, and contexts are activated, but the simulation model is not switched. Third, the events are kept, but the callback functions contain no action, i.e., the context activeness is un-

(a) Complete Simulation results.

(b) Detailed view.

Figure 5. Simulation results of the energy park model.

changed (*ActiveEmptyCB* and *StandbyEmptyCB*). Fourth, the events are entirely removed from the simulation models (*ActiveNoCB* and *StandbyNoCB*). The measurements are performed 10 times, and the simulations not based on `CVSSProblem` are performed for the model with the electrolyzer in active and standby mode. The results are shown in Figure 6

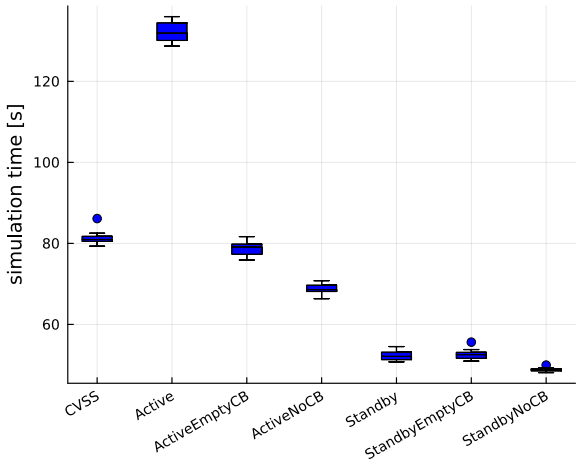


Figure 6. Boxplot that shows the simulation time for seven different simulations. Every model was simulated 10 times.

The comparison of the models that do not contain any events shows that the active electrolyzer model increases the simulation time, which is explainable by the model's increased complexity. Adding empty callbacks also increases simulation time. This effect is stronger for the model with an active electrolyzer, which is explainable by a larger number of events. Adding the context control logic to the callbacks significantly increases the simulation time for the model with an active electrolyzer. Using profiling showed that computing the constraints between contexts is the main reason for this increase.

To estimate the additional computation time of the COEBM simulation, we compare the mean simulation time of the CVSS simulation with a weighted sum of the mean simulation time for the active and standby models with empty callbacks that do not activate contexts. The weights are calculated as $826.3\,\mathrm{h}/1000\,\mathrm{h}$ for the active model and $1 - 826.3\,\mathrm{h}/1000\,\mathrm{h}$ for the standby model, so that they represent the share of the respective models in the total simulation time. The mean CVSS simulation took 81.4 s, and the weighted sum of the active and standby simulation results in 74.2 s. Hence, the increase in simulation time is approximately 10 %.

6 Discussion

The presented approach of COEBM allows simulating VSS that can not be simulated in standard Modelica or MTK without external tools or manually concatenating simulations and their results. COEBM enables specifying control mechanisms based on contextual modeling with concise syntax provided by *Contexts.jl*. Instead of manually (de-)activating components or reinitializing variables based only on if-then-else conditions, constraints between contexts can be used to control the system, and context-adaptive behavior is achieved. Defining constraints within the context model prevents reaching conflicting states. As discussed in (Gutsche et al. 2024), context control in *Contexts.jl* provides the basis for model-checking.

The case study shows that using the context model sim-

DOI 10.3384/ecp218155

ulation control is feasible and advantageous. COP reduces the code complexity. Instead of if-then-else-cascades, only a context-oriented function call is used to check how to operate the battery. The remaining if-then-else conditions are comprehensible as they represent state machines and contain Boolean expressions that depend on one or a few variables. The goals of the variability were achieved.

Contexts discretize continuous variables and, therefore, are activated based on threshold values. Therefore, the choice of threshold values influences the control. In the case study, the threshold values were defined meaningfully. However, changing them can, e.g., change when the electrolyzer gets activated and influences the amount of produced hydrogen. Future research could investigate obtaining optimal values via optimization.

The performance measurements show that computing context control is time-consuming. However, *Contexts.jl* was not optimized for performance. Julia gives developers many tools to improve performance. The context control computation can be optimized. For example, the library uses normal Julia arrays for computing constraints, but static arrays can improve the performance [2].

Context activeness must be initialized before the simulation. If initial activeness does not fit the initial variable values, the control mechanisms could work faulty. MTK allows the calculation of initial variable values, which can be used to initialize the context activeness correctly.

The presented case study has several simplifications. Some simplifications are only relevant for getting technical insights and could be resolved by adding or replacing components in the model. However, other simplifications would also influence the control logic. The model does not include an intermediate state between active electrolyzer and standby, resulting in discrete jumps within the simulation. Also, shutdown is not implemented. Adding models for deactivated and ramp-up states would create additional models and contexts and, therefore, more complexity, but the modeling technique is still applicable.

While we focused on modeling variable behavior, another interesting use case for variability in simulation is the use of surrogate models. If the needed accuracy allows surrogates, contexts can switch between more and less detailed models or data-driven components. Using neural networks within EBM models is supported by MTK.

7 Conclusion and Outlook

We presented how COEBM enables simulating equation-based models containing variability. Therefore, we described a modeling technique based on contexts. Contextual modeling is used to abstract the simulated world and specify control mechanisms. Constraints in the contextual model prevent reaching conflicting states. This is advantageous when modeling self-adaptive systems, e.g., cyber-physical systems, with complex state spaces.

We presented a case study of an energy park for hydrogen production, showing the feasibility of the modeling process in more complex scenarios. We achieve VSS simulation by switching between different simulation models and performing state migration. Performance measurements show that the context control negatively impacts simulation time but can be improved by changing the *Contexts.jl* implementation of computing context control.

We are currently working on implementing additional modeling tools in Julia to simplify the generation of model variants using a single underlying model (Atkinson, Stoll, and Bostan 2010; Seifert 2011). This will improve code reuse and maintainability. Additionally, concise syntax for defining variability not located in the simulation model's top-level would improve modeling.

Another interesting topic for future research is investigating the combination of the presented approach and *OM.jl* to achieve COEBM in Modelica. Additionally, MTK provides an experimental feature to use Functional Mock-up Units (FMUs) within MTK models. This could pave the way for coupling FMUs and Modelica models to COEBM.

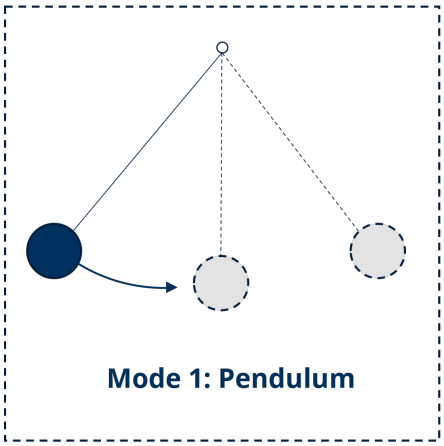
Abstract

Context-aware systems are crucial in modern cyber-physical systems (CPS), enabling dynamic adaptation to changing conditions. Many such systems involve complex variability. Modelica, a leading equation-based language for modeling and simulating physical systems, struggles to manage this complexity. As variability management becomes more complex, traditional Modelica constructs such as conditional statements, state machines, and state graphs become increasingly inadequate and difficult to maintain. This work introduces a **context-oriented modeling paradigm for Modelica** by integrating Petri Net-based context control with FMI-based Variable Structure Systems (VSS). Specifically, we present Context Petri Nets (CoPN) as a formal mechanism for representing and managing contextual dependencies. By combining CoPN with VSS, our approach enables advanced variability management, supporting the modeling and simulation of complex, context-aware CPS.

Keywords: Modelica, variable structure systems, FMI, Context Petri Nets, context-aware systems, variability management, context-oriented modeling and simulation

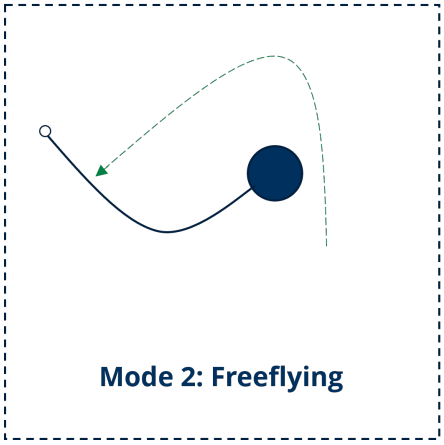
1 Introduction

Context-aware systems exist everywhere in daily life. According to Dey and Abowd 2000, the context refers to conditions that influence a system's behavior or state. A typical example is the smartphone, where different operation modes (e.g., `do not disturb`, `power saving`, `gaming`) dynamically adjust software and hardware configurations based on active contexts (e.g., battery level). More importantly, these modes often have contextual relationships. For example, when the battery level drops below 20%, `power saving` mode activates, reducing the screen refresh rate and limiting CPU/GPU performance. If `gaming` mode attempts to activate at that moment, it fails, which demonstrates an **exclusion** relationship between the two modes. Another example is the iPhone's crash detection feature. When a car crash occurs, the iPhone detects the event and activates the `emergency` context, automatically dialing emergency services. In this case, `crash` and `emergency` have an **inclusion** relationship, as one triggers the other. More specifically, this represents a **weak inclusion** relationship, where `crash` triggers `emergency`, but not vice versa.



Modelica, a state-of-the-art equation-based modeling language, along with its various tools and libraries, is widely used in industry for modeling and simulating multi-domain and multi-physical systems. For simple context expression and variability management, conditional statements (e.g., `if-else` and `when` clauses) are sufficient. However, for more advanced context modeling and management, especially when dealing with complex contextual relationships, traditional conditional statements become inadequate. They not only lack expressiveness but also lead to unreadable and hard-to-maintain code. Addressing advanced contextual relationships in Modelica remains an open research challenge. This work addresses this challenge by introducing **context-oriented Modelica**, an approach inspired by context-oriented programming (Hirschfeld, Costanza, and Nierstrasz 2008), tailored to fit the Modelica modeling paradigm.

The structure of this work is as follows: Section 2 introduces the foundational concepts. Section 3 explores a novel and efficient solution for enabling VSS through FMI. Section 4 focuses on Context Petri Nets (CoPN) and their integration into Modelica for advanced variability management. Section 5 brings together CoPN and VSS into a more generalized approach. A proof of concept demonstrates how this enables the development of context-aware systems. Finally, Section 6 concludes the work and highlights future directions.



2 Background

2.1 Variable Structure Systems in Modelica

One significant challenge for realizing advanced context relationships is Variable Structure Systems (VSS), which was first introduced by Utkin 1977. VSS consist of various subsystems with proper switching logic for switching between these subsystems. In the context of Modelica, VSS mean to switch between different submodels and equation systems based on conditions, as Figure 1 shows. The challenge is that, because of Modelica's static nature (everything must be defined before simulation), the switching of submodels and equation systems is limited. Wang et al. 2024 details the conditions under which VSS works and where it fails. In a summary, when equation systems have different variables and/or differential indexes, the structural transition will fail.

```
model Pendulum
  Real phi(start=0); // Pendulum angle
  Real dphi(start=-2); // Angular velocity
  parameter Real m = 1; // Bob mass
  parameter Real g = 9.81; // Gravity
  parameter Real L = 2; // Pendulum length
  Real x, y, dx, dy, F;
equation
  x = L * sin(phi);
  y = -L * cos(phi);
  dx = der(x); dy = der(y);
  dphi = der(phi);
  der(dphi) = -g/L * sin(phi);
  F = m * (g * cos(phi) + L * dphi^2);
end Pendulum;
```

```
model Freeflying
  Real x;
  Real y;
  Real vx;
  Real vy;
  parameter Real m = 1;
  parameter Real g = 9.81;
  parameter Real L = 2;
equation
  vx = der(x);
  vy = der(y);
  m * der(vx) = 0;
  m * der(vy) = -m * g;
  r = sqrt(x^2 + y^2);
end Freeflying;
```

Figure 1. Two modes with their corresponding equation systems. Modelica cannot handle the transition, thus, at the moment of switching from mode 1 to mode 2, the simulation fails.

2.2 Variability Management in Modelica

Modelica supports several constructs for managing variability, the most basic being conditional statements like **`if-else`** and **`when`**. While suitable for simple systems, these constructs quickly become unwieldy and error-prone in complex systems, making the logic hard to maintain and debug. Modelica also offers **state machines** (as defined in the *Modelica Language Specification*) and **state graphs** (`Modelica.StateGraph`, as defined in the *Modelica Standard Library*). These introduce hierarchy and parallelism, improving clarity compared to raw conditionals. However, their reliance on directed transitions limits flexibility, since state activation typically follows predefined, sequential paths, making it difficult to handle highly dynamic, condition-driven context changes. For more advanced variability management in complex systems, a more flexible and expressive mechanism is needed. Petri Nets offer a powerful alternative. Their token-based, condition-driven structure allows non-directional context activation, supporting complex, concurrent, and non-sequential behaviors without rigid state progression. This enables precise control over context interdependencies while maintaining system reliability through strong formal analysis, which is essential for robust orchestration of complex, dynamic behaviors.

2.3 Petri Nets

Petri 1962 introduced Petri Nets as a formal modeling approach in his PhD dissertation *Kommunikation mit Automaten* (English: Communication with Automata). A Petri Net consists of four fundamental components: **places** (P), which denote system states and are typically represented as circles; **transitions** (T), which represent events or actions that drive state changes and are depicted as rectangles or bars; **tokens**, shown as dots inside places, which indicate the current system state and move between places; and **arcs**, drawn as arrows, which connect places and transitions, directing token flow. The token distribution across all places is called a marking and represents the current state of the Petri Net. The system's behavior is determined by firing rules, where a transition is enabled if all its input places contain the necessary number of tokens. Upon firing, the transition consumes tokens from its input places and generates tokens in its output places, updating the system state accordingly. Their later-introduced graphical nature also makes them intuitive for visualizing complex dynamic behaviors in distributed or reactive systems. Figure 2 shows how a Petri Net works. This Petri Net consists of three places, P_1, P_2, and P_3, and one transition T. The diagram shows the system both **before** and **after** firing.

2.4 Functional Mock-Up Interface

Functional Mock-up Interface (FMI) (Blochwitz et al. 2011) is an open standard for the exchange and co-simulation of dynamic models across different modeling languages and platforms. It defines a container and a set of APIs that allow models, packaged as Functional Mock-up Units (FMUs), to be shared and executed consistently in various simulation environments. FMI is widely adopted in cyber-physical systems engineering for enabling interoperability. FMI 1.0, 2.0, and 3.0 were released in 2010, 2014, and 2022, respectively. FMI supports three FMU types: Model Exchange, Co-Simulation, and the newly introduced Scheduled Execution in FMI 3.0.

3 Advancing VSS with FMI

3.1 State of the Art

Many approaches have been developed to realize VSS in equation-based modeling environments. Based on timeline and design concepts, these can be broadly categorized into four groups. The **first group** includes early works based on new languages/frameworks, such as Mosilab (Nytsch-Geusen et al. 2005), Sol (Zimmer 2010), Hydra (Giorgidze 2012), and Modelyze (Broman and Siek 2012). These support true structural changes and enable VSS modeling but are incompatible with the Modelica ecosystem and cannot reuse existing Modelica libraries. The **second group** focuses on integrating VSS support directly into Dymola, as proposed by Elmqvist, Mattsson, and Otter 2014 and Mattsson, Otter, and Elmquvist 2015. These extensions were only validated with simple examples and have not been included in stable Dymola releases due to limited robustness and generality. The **third group** involves frameworks that orchestrate VSS simulations externally, such as DySMo (Mehlhase 2015), MoVaSim (Gómez Esperón 2017), and PyVSM (Stüber 2017). These do not support true structural changes, and thus only simulate VSS. However, since the models remain in Modelica, modelers benefit from the Modelica ecosystem. The **fourth group** features recent Julia-based approaches, such as Modia (Elmqvist, Neumayr, and Otter 2018), OM.jl (Tinnerholm et al. 2020), and ModelingToolkit (Ma et al. 2021). Julia's dynamic type system and multiple dispatch enhance VSS support. However, like the first group, they require porting Modelica libraries and generally lack the graphical interfaces.

The goal is to remain within the Modelica ecosystem. In DySMo, conditions must be defined within each model. If conditions are managed externally, DySMo can only evaluate them after each time step. For example, if the time step is 1 second and a condition is met at 0.5 seconds, it will still be evaluated at 1 second, not immediately at 0.5 seconds when the condition occurs. This limitation makes DySMo unsuitable for our work. MoVaSim, while more flexible, is implemented on the JModelica compiler. Since JModelica has not been maintained since late 2019, MoVaSim is effectively obsolete unless it is ported to another Modelica compiler. PyVSM lacks sufficient public documentation, with only a single mention available, making detailed evaluation infeasible. To overcome these limitations, we propose an approach for realizing VSS using FMI. This approach resolves DySMo's conceptual issues, improves performance, and leverages FMI's standardized APIs for simulation and management of VSS.

3.2 Concept

The concept, inspired by DySMo, coordinates different simulations by detecting transition points, recording necessary variable values, and using them to initialize the subsequent modes. Simulation results from different submodels are then combined. Using FMI streamlines this process, with Python libraries like FMPy (Sommer 2017) and PyFMI (Andersson, Åkesson, and Führer 2016) providing efficient APIs that avoid costly data serialization and external tool calls, significantly speeding up execution.

This concept was implemented with examples such as the *Pendulum-Freeflying* example mentioned earlier in Figure 1. The simulation result is shown in Figure 3. The first mode (*Pendulum*) will stop when the string loses force on the bob. The system detects this, records the stop time and variable values, and then starts the second mode (*Freeflying*) at the stop time of the first mode, initializing the model with the recorded values. The second mode stops when the string holds the bob again. Other examples can be found at GitHub | FMUVSS.

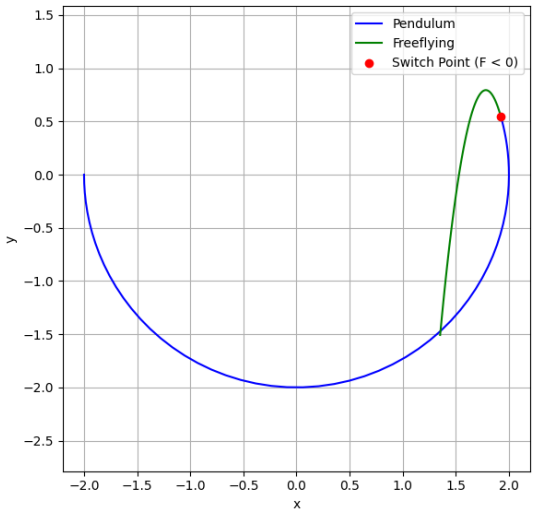

Figure 3. Trajectory of the *Pendulum-Freeflying* example

3.3 The Framework FMUVSS

Based on this concept, the FMUVSS framework was developed to automate the process and provide a user-friendly interface, eliminating the need for manual prototyping. It streamlines the simulation of VSS and supports both FMI 2.0 and 3.0 by leveraging their low-level APIs for finer control over the simulation process (e.g., retrieving specific variable values during simulation). Stop conditions can be defined directly without the need to modify the original models, ensuring a clean separation of concerns: model design remains intact while variability management and switching logic are handled externally. Compared to FMI 2.0, FMI 3.0 offers significant advantages by introducing **event mode** and **early return** in Co-Simulation FMUs, enabling the master algorithm to respond to zero-crossings or mode switches precisely when they occur. In contrast, FMI 2.0 only evaluates events after each simulation step, preventing events from being triggered at their exact time of occurrence. In critical systems, such timing inaccuracies can lead to unstable or incorrect simulation outcomes.

Listing 1. Example of mode configuration in FMUVSS

```
'SlidingBall': {
    'fmu_path': './Ball.fmu',
    'monitored_vars': ['y'],
    'outputs': ['x', 'y', 'vx', 'vy'],
    'stop_condition': lambda vars:
        vars['y'] < 10,
    'transition_mapping': {
        'FlyingBall': {
            'x' : 'x', 'y' : 'h',
            'vx' : 'vx', 'vy' : 'vy'}
            },
    'next_mode': 'FlyingBall'},

'FlyingBall': {
    'fmu_path': './FlyingBall.fmu',
    'monitored_vars': ['h', 'r'],
    'outputs': ['x', 'h', 'vx', 'vy'],
    'stop_condition': lambda vars:
        vars['h'] < vars['r'],
    'transition_mapping': {
        'BouncingBall': {
            'x' : 'x', 'h' : 'h',
            'vx' : 'vx', 'vy' : 'v'}
            },
    'next_mode': 'BouncingBall'},

'BouncingBall': {
    'fmu_path': './ContactBall.fmu',
    'monitored_vars': ['mass.s', 'r'],
    'outputs': ['x', 'h', 'vx', 'v'],
    'stop_condition': lambda vars:
        vars['mass.s'] > vars['r'],
    'transition_mapping': {
        'FlyingBall': {
            'x' : 'x', 'h' : 'h',
            'vx' : 'vx', 'v' : 'vy'}
            },
    'next_mode': 'FlyingBall'}
```

To illustrate the framework in practice, Listing 1 shows part of the configuration interface used to define modes for a *SlidingBall–FlyingBall–BouncingBall* system: The ball begins by sliding down an inclined surface in the `SlidingBall` mode. After reaching a certain height, it leaves the surface and transitions into the `FlyingBall` mode. When it hits the ground, it switches to the `BouncingBall` mode, where damping reduces its bounce height. The system continues alternating between flying and bouncing until the simulation ends.

Compared to DySMo, FMUVSS eliminates the need for modifications to the Modelica models. In DySMo, stop conditions and a `transitionID` must be inserted into the original models to trigger the transition logic. The `transitionID` is initialized to 0, and when the transition condition is met, it changes to 1, signaling the framework to stop the current simulation and switch to the next mode. In contrast, FMUVSS allows developers to export unmodified Modelica models as FMUs. Transition conditions are defined externally and managed centrally, enabling advanced variability handling such as nested conditions and inter-condition relationships.

Experiments demonstrate that FMUVSS runs significantly faster than DySMo, as shown in Table 1. This comparison was conducted using the same models, the DASSL solver proposed by Petzold 1982, a tolerance of `1e-4`, and identical hardware for three VSS models: the Pendulum and SlidingBall models, as well as a clutch model from Benveniste et al. 2022, where two clutches engage and disengage. Compilation time for compiling each model with DySMo was excluded.

Table 1. Performance comparison: FMUVSS vs DySMo

VSS Model	Framework	Time (s)
Pendulum	FMUVSS	0.53
	DySMo	18.69
SlidingBall	FMUVSS	3.34
	DySMo	81.08
Clutch	FMUVSS	2.43
	DySMo	339.4

Profiling with Python tools, such as `cProfile`, reveals that DySMo's slow performance is due to its heavy reliance on Python interpretation, text-based file parsing, and high-overhead interprocess communication (IPC) for executing Modelica simulations. Additionally, DySMo uses dynamic list growth, leading to memory allocation inefficiencies. In contrast, FMUVSS achieves superior performance by using direct binary access through the FMI standard, which avoids the overhead of text parsing and IPC. By leveraging preallocated arrays and zero-copy buffers, FMUVSS minimizes both Python overhead and memory allocation delays, resulting in faster and more efficient execution. More details are available at: GitHub | FMUVSS | Performance Evaluation.

4 Context-Oriented Petri Nets

4.1 Petri Nets for Context-Aware Systems

Gutsche, Wang, et al. 2023 presents using Petri Nets as a control mechanism for state transitions in Modelica. However, if the contexts become more complicated, e.g., if some of the contexts are dependent, such as activating one context (de)activates the other, or activating one requires the other to be active. Using original Petri Nets is not easy for describing these dependencies. Thus a more powerful form of Petri Nets is needed. Petri Nets have many extensions and they have also been extended in different forms to model context-aware systems. Gutsche, Prokopets, et al. 2024 summarized four main extensions in this field: Contextual Petri Nets from Baldan, Corradini, and Montanari 2001; Feature Petri Nets from Muschevici, Clarke, and Proenca 2010; Context Petri Nets from Cardozo et al. 2012; Adaptive Petri Nets from Mai et al. 2018. Context Petri Nets are explicitly designed for context-aware systems, where different contexts (de)activate parts of the model. For this reason, CoPN were chosen for this work.

4.2 Context Petri Nets in Modelica

In CoPN, contexts are represented as places, each guarded by its activation and deactivation conditions. When a condition is met, the corresponding transition fires, adding/removing a token to/from the place. A token count of **one** indicates an active context; zero means inactive. This token-based representation makes dependencies clear and supports modular control logic and formal verification.

If no VSS is involved, CoPN can be directly applied to existing Modelica models without modifying the original structure. The separation of concerns ensures that the control layer and system layer remain separate, allowing for better maintenance. To achieve it, we can utilize the Petri Nets library *PNlib* (Proß and Bachmann 2012)[1]. Through careful design with the use of the inhibitor arc (which inhibits a transition from firing if the connected place has tokens), CoPN and their four types of context relationships can be effectively represented in Modelica. As shown in Figure 4, different dependencies can also be composed together. However, due to the nature of PNlib, the number of input and output ports for each place and transition must be explicitly defined, and connections between them must be unique: each port can be connected only once, and all ports must be used. Otherwise, the model becomes unbalanced. As the number of context places and their relationships increases, modeling and debugging CoPN becomes increasingly complex. Even with only a few contexts and relationships, debugging can be highly challenging, as demonstrated in Figure 4.

The original CoPN work proposed four relationships between contexts: **weak/strong inclusion**, **exclusion**, and **requirement**. These are explained in detail in Figure 5.

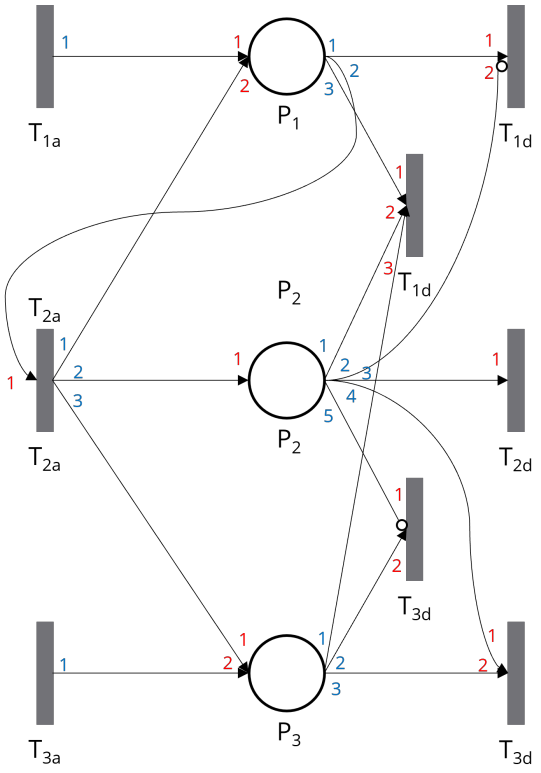

Figure 4. A CoPN containing both requirement and strong inclusion relations. P_2 requires P_1, meaning P_2 can only be active if P_1 is active. P_2 and P_3 are connected by a strong inclusion relation, so they are always activated and deactivated together.

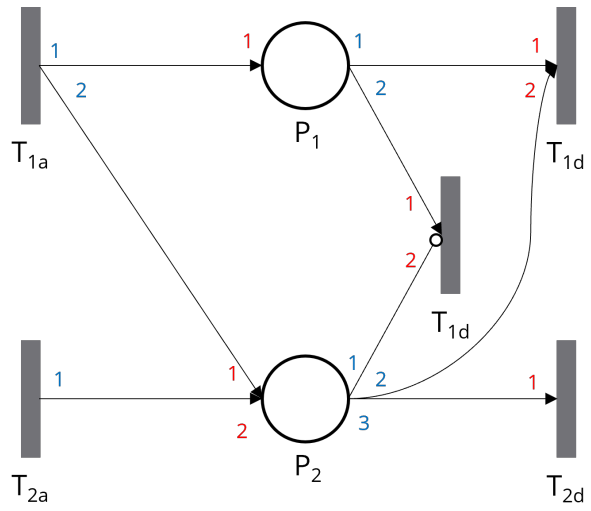
4.3 Composition with CoPNCompositor



To address this growing complexity with context relationships, the Python-based tool `CoPNCompositor`[2] was developed. It utilizes the Python template engine `Jinja`, where basic components such as places, transitions, and arcs (normal or inhibitor arcs) are defined as templates. Based on specific goals, components are automatically created and connected. Developers can then define contexts, their (de)activation conditions (time-based or event-based), and any context relationships in natural language, as shown in Listing 2. The tool automatically composes the CoPN and generates the corresponding Modelica code.

Listing 2. Configuration interface of CoPNCompositor

```
contexts = ["A", "B", "C", "D", "E"]
weak_inclusions = [("A", "B")]
strong_inclusions = [("B", "C")]
exclusions = [["A", "E"]]
requirements = [("D", "E")]
event_definitions = {
    "A":{"activation": "",
         "deactivation": ""}
    "B":{"activation": "",
         "deactivation": ""}
    ...}
```

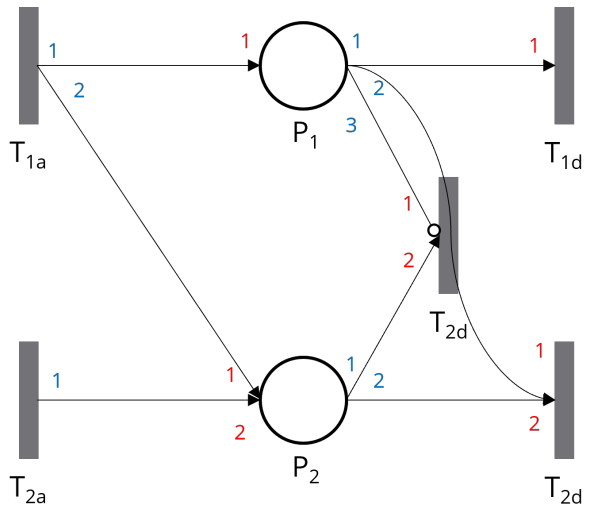
[2] https://github.com/wangzizhe/CoPN

Weak Inclusion

P: Discrete Place



T_a: Activation Transition

T_d: Deactivation Transition

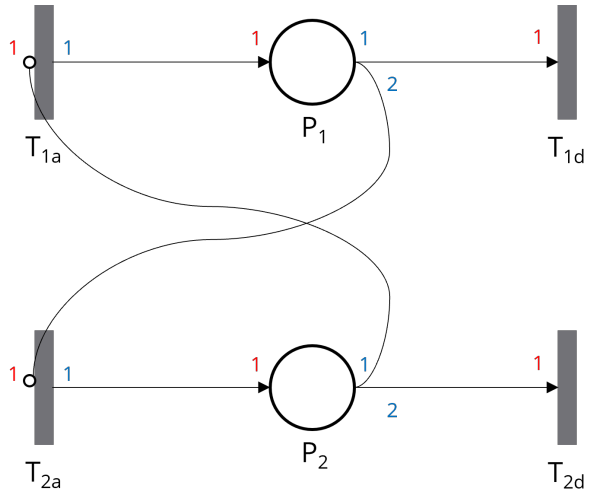
Normal / Inhibitor Arc

1, 2... / 1, 2... Input / Output Ports

(a) Contexts P_1 and P_2 are weakly included (from P_1 to P_2), meaning the (de)activation of P_1 also (de)activates P_2.

Strong Inclusion

P: Discrete Place



T_a: Activation Transition

T_d: Deactivation Transition

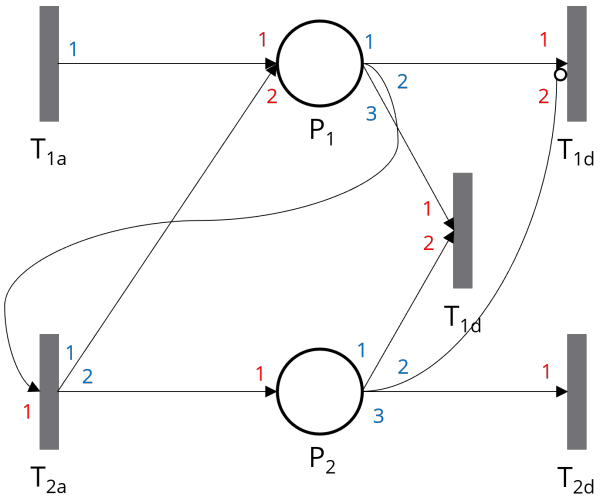
Normal / Inhibitor Arc

1, 2... / 1, 2... Input / Output Ports

(b) Contexts P_1 and P_2 are strongly included (bidirectionally), meaning the (de)activation of one also (de)activates the other.

Exclusion

P: Discrete Place



T_a: Activation Transition

T_d: Deactivation Transition

Normal / Inhibitor Arc

1, 2... / 1, 2... Input / Output Ports

(c) Contexts P_1 and P_2 are mutually exclusive, meaning one can only be activated if the other is not active.

Requirement

P: Discrete Place

T_a: Activation Transition

T_d: Deactivation Transition

Normal / Inhibitor Arc

1, 2... / 1, 2... Input / Output Ports

(d) Contexts P_1 and P_2, where P_1 is a prerequisite for P_2; activating P_2 requires P_1 to be active, and deactivating P_1 also deactivates P_2.

Figure 5. Four context relationships of CoPN modeled with PNlib in Modelica

DOI 10.3384/ecp218165

5 Context-Oriented Modelica

In Section 3, we introduced how to realize VSS with FMI. In Section 4, we discussed how CoPN can be applied in Modelica. By combining these two approaches, we can achieve advanced variability management in a more generalized manner and realize context-oriented Modelica.

5.1 ContextModelica

In systems without structural change, CoPN can be directly integrated into the model, as described in the previous section. For systems involving structural change, CoPN act as the central context manager, while FMUVSS handles VSS. As shown in Figure 6, each mode or context (i.e., submodel) is represented as a place in the CoPN. The token count of each place indicates whether the mode/context is active (1) or inactive (0). Each place is guarded by activation and deactivation transitions, and may include context dependencies spanning the entire net. These (de)activation conditions are typically linked to variable values during simulation. CoPN observe and evaluate these values at runtime. When all conditions and dependencies are satisfied, the corresponding transition fires, thereby (de)activating the relevant mode/context.

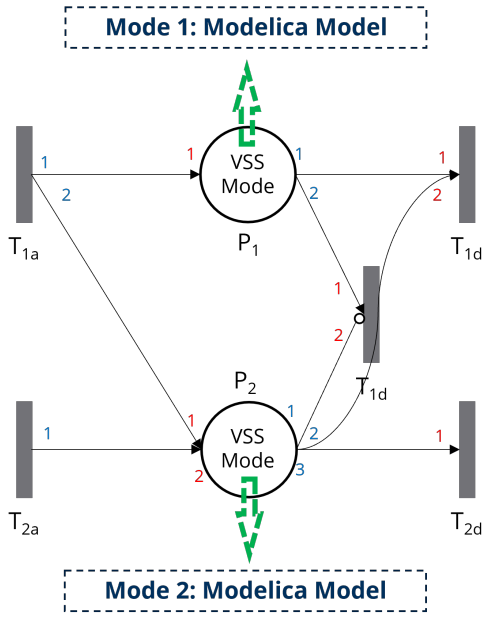


Figure 6. The corresponding Modelica submodels are represented as places in the CoPN. Activating a place triggers FMUVSS to coordinate the simulation of the associated submodel. As a result, the overall model dynamically activates specific submodels based on the currently active contexts. The final output reflects the complete simulation result of the entire system.

Building CoPN outside of Modelica is more flexible, as it avoids the need to manually define the number of ports and their exact connections. Any Python-based Petri Net library that supports inhibitor arcs can be utilized for building the CoPN. In this work, the SNAKES library (Pommereau 2015) has been used to construct the CoPN, as it offers a compact syntax and support for inhibitor arcs.

The framework `ContextModelica` was developed based on this concept to unify the functionality and configuration interfaces of the CoPN compositor and FMUVSS described earlier. Through this framework, developers can define configurations such as various VSS modes, context (de)activation conditions, and their interdependencies. In essence, ContextModelica enables context-oriented modeling in Modelica, allowing for flexible and modular simulation of systems with structural variability.

5.2 Proof of Concept

A simplified IT system model has been applied. To focus on demonstrating the underlying mechanism, the complexity of each submodel has been intentionally reduced. The goal is to validate the proposed concept through a minimal working example.

The system includes two energy supply modes: `greenSupply`, powered solely by green hydrogen, and `hybridSupply`, which combines hydrogen and grid electricity. "H_2ProducedPower" and "loadDemand" are input variables that change over time. Depending on load demand and energy availability, the system switches between three operation modes: `energySaving`, `normal`, and `highPerformance`. Each mode adjusts CPU core count and frequency to reflect the desired performance. (De)activation conditions are based on variable thresholds during simulation, as summarized in Table 2.

Table 2. (De)activation conditions of different modes

Mode	(De)activation Condition
greenSupply	H_2ProducedPower $\geq$ loadDemand
hybridSupply	H_2ProducedPower $<$ loadDemand
energySaving	loadDemand $<$ 150 kW
normal	150 kW $\leq$ loadDemand $<$ 200 kW
highPerformance	loadDemand $\geq$ 200 kW

In addition to conditions, the system enforces **contextual relationships** between modes, as illustrated in Figure 7. Both energy supply modes and operation modes are *mutually exclusive*, ensuring that only one mode from each category is active at any given time. Moreover, some modes depend on others: for instance, `energySaving` requires `greenSupply` to be active, while `highPerformance` depends on `hybridSupply`. Therefore, even if the activation condition is satisfied, these modes will not activate unless their required contexts are also active.

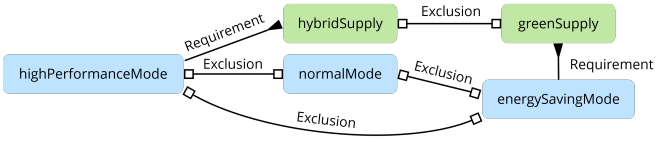

Figure 7. Context relationships of the IT system model

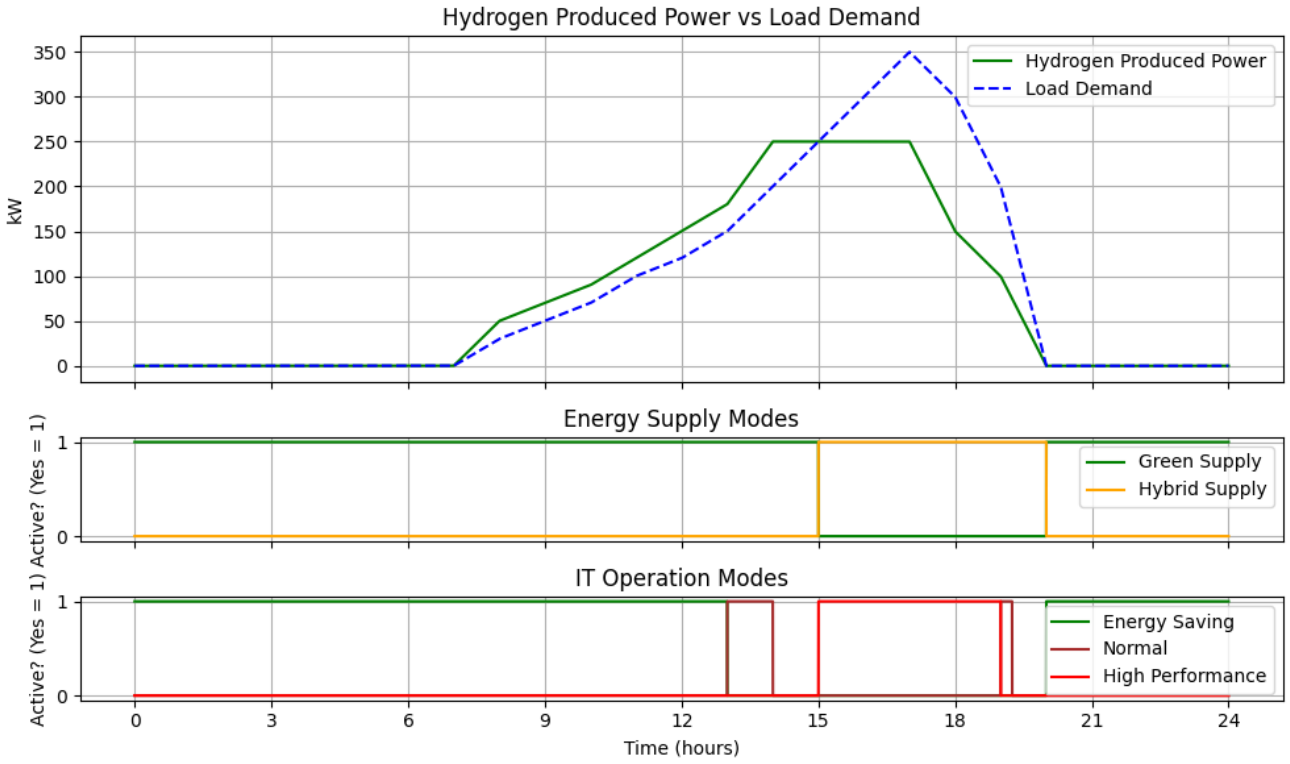

Figure 8. Simulation result of the IT system example

Each mode maps to a specific Modelica submodel. During simulation, the CoPN monitors relevant variables and manages transitions based on defined relationships and guard conditions. The IT system model was simulated over a 24-hour period. Figure 8 illustrates the results. At hour 13, `loadDemand` reached 200 kW, satisfying the activation condition for `highPerformance`. However, since it depends on `hybridSupply`, it only became active at hour 15 when `hybridSupply` was also activated. Likewise, `energySaving` met its condition at hour 19.25 but could not activate until `greenSupply` was active. The delayed activation of `energySaving` and `highPerformance` highlights the importance of context-aware coordination, showcasing the net's ability to synchronize mode interactions safely.

5.3 Managing Submodels

Each mode in a VSS system corresponds to a distinct submodel. Therefore, effectively managing these submodels is essential. The most conventional approach is to export a separate FMU for each VSS mode. While straightforward, this method can become inefficient in systems with tightly coupled components or a large number of modes. In such cases, developers often have to duplicate parameters, variables, and equations across multiple models, which increases maintenance overhead. To address these challenges, we turn to software composition techniques for developing more scalable and maintainable methodologies for managing submodels.

One approach is **model composition**, where individual FMU components are combined dynamically during the VSS simulation based on the active context. FMI supports **hierarchical FMUs**, which allows communication between FMU components via defined input and output ports. However, a major limitation of this approach is the requirement to modify each submodel to expose appropriate ports, which increases maintenance overhead.

Another approach is to encapsulate all submodels within a single unified model and activate only relevant parts based on the active context. This is known as the **Single Underlying Model (SUM)** methodology, as illustrated in Figure 9.

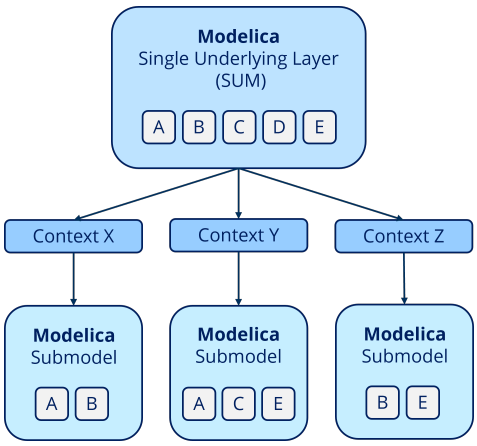

Figure 9. Modelica SUM to submodels based on contexts

DOI
10.3384/ecp218165

In this case, a single model or FMU contains all potential subcomponents, and the active ones are selected at runtime according to the simulation context. The new **Scheduled Execution** FMU type from Gomes et al. 2021 introduced in FMI 3.0 aligns well with this concept. It allows different partitions (representing different modes) within a single FMU to be activated or deactivated based on events. However, as of August 2025, no existing Modelica tools support exporting FMUs using the Scheduled Execution type.

To bridge this gap, the module **ModeGen** was developed as an intermediate solution. ModeGen embraces the core idea of SUM by encapsulating the full system structure in a single Modelica model. It then dynamically generates mode-specific submodels by selectively including or excluding components based on the active context, and exports them as corresponding FMUs. To remain consistent with standard Modelica syntax, a lightweight labeling system/syntax has been introduced to annotate the elements of the Modelica SUM. ModeGen includes a **parser** that reads these labels, interprets them in relation to the active mode or context, and automatically composes the corresponding submodels. A minimal example of a Modelica SUM based on the *Pendulum–Freeflying* scenario is shown in Listing 3. After generation, ModeGen invokes a Modelica compiler to perform model checking for all generated submodels and return the visualized results.

Listing 3. SUM of the *Pendulum-Freeflying* example

```

  m * der(vx) = 0; m * der(vy) = -m * g
```

6 Conclusion and Outlook

6.1 Conclusion

Managing variability in Modelica is challenging due to its static nature and lack of native VSS support, which limits switching between modes and submodels. Constructs like `if-else` and `when` handle only simple cases, while state machines and state graphs offer greater expressiveness but depend on sequential paths, making them less suitable for highly dynamic context-driven changes.

To address these challenges, we introduced CoPN as an advanced variability management pattern for Modelica. CoPN allow for the efficient representation of complex contextual dependencies and dynamic transitions between system states. Additionally, we presented FMUVSS as a framework for realizing VSS within the Modelica ecosystem, offering a comparison with DySMo and identifying DySMo's bottlenecks. With its user-friendly configuration interface, FMUVSS provides a seamless approach to managing variability and dynamic transitions.

By combining CoPN with FMUVSS, we proposed a generalized approach for context-oriented Modelica, where simulations are composed of submodels activated by current contexts. This forms the foundation of a **context-oriented modeling paradigm for Modelica**. The proof of concept demonstrates the potential for advanced variability management in dynamic and adaptive systems. Specifically, we showed that CoPN can be implemented directly in Modelica for systems without structural change and introduced the CoPNCompositor for automated CoPN construction using PNlib. For systems with structural change (VSS), we introduced ContextModelica, which integrates CoPN and FMUVSS.

We further explored submodel management, discussed how hierarchical FMUs can assist in managing submodels, and highlighted the potential of the new Scheduled Execution FMU type introduced in FMI 3.0. This FMU type aligns well with the SUM concept by enabling event-driven mode transitions within a unified FMU. However, since this functionality is not yet widely supported, we proposed an intermediate solution: managing VSS submodels through the SUM, which encapsulates all model information and can be dynamically composed into submodels based on active contexts and modes.

Overall, we demonstrated how context-oriented modeling and programming can be integrated into Modelica, presenting a scalable framework with a unified configuration interface. Its key modules are summarized in Table 3.

Table 3. Key modules for context-oriented Modelica

Module 1: FMUVSS
Module 2: ContextModelica
Module 3: ModeGen
Supporting Tool: CoPNCompositor

6.2 Outlook

Future work aims to further refine and expand the framework, focusing particularly on improving scalability and usability. We plan to integrate the Scheduled Execution FMUs into the framework, once they become widely supported in Modelica tools. Additionally, we plan to explore further collaborations to apply our framework to real-world models, particularly in industries where variability management and dynamic system behavior are critical. These collaborations will provide valuable feedback to help improve the framework.

Benchmarking the Modular Structural Analysis Algorithm

Benoît Caillaud[1] Albert Benveniste[1] Mathias Malandain[1]

Abstract

In a 2023 Modelica Conference paper, we proposed a novel method for the *modular structural analysis* of DAE systems, in which the structural analysis is not performed on flattened models, but rather at the class level. A new notion of *structural interface* was proposed, in which classes are enriched with context information. That paper developed our approach based on a few illustrative examples.

In this paper, we provide the details of our algorithm. Its performance depends on the system architecture: the analysis of models having a small number of classes (possibly instantiated many times), with a low treewidth system architecture, scales up very efficiently with this approach. We then present additional benchmarks, among which a urban heating network, a representative real-life example on which a near-logarithmic scaling up is shown.

Keywords: DAE, Modelica, object-oriented modeling, structural analysis, index reduction, block-triangular decomposition, interface theory, Difference Bound Matrices

1 Introduction

Modelica advocates an *object-oriented style of programming* (Fritzson 2015), in which subsystem or component models are encapsulated as classes, and instantiated to form large system models. Unfortunately, state of the art structural analysis proceeds by, first, flattening the structured model, and then performing the analysis (Pop et al. 2019). This impedes the storage of model components as executable code or in a format similar to it, which is an crucial feature of compiled programming languages. Additionally, it poses a challenge when attempting to extend DAE-based modeling to higher-order modeling or dynamically changing systems (Broman and Fritzson 2008; Broman 2021). Moreover, as pointed out in (Höger 2015), there are situations in which modeling capabilities are limited by the structural analysis itself, as performance issues arise because of model flattening. Finally, an index-reduction method for DAE systems defined as array equations is proposed in (Otter and Elmqvist 2017). In the same direction, (Fioravanti et al. 2023) proposes an array-aware matching algorithm that scales up to large systems of equations with arrays and loops.

In our previous work (Benveniste et al. 2023) a *structural analysis-aware interface* for components was introduced, thanks to which:

1. structural analysis is performed at the class level;
2. the results of this structural analysis are then instantiated for each component, knowing its context;
3. these component-level structural analyses are composed to derive system-level structural information.

Our approach was presented with the help of a few illustrative examples. In this paper, we provide a formal description of our algorithm. Its performance relates to the following two features of the (otherwise very large) system model: a small number of classes (possibly instantiated many times), and a close-to-tree-shaped system architecture. The urban heating network we present as a benchmark exhibits these features.

The paper is organized as follows. Section 2 provides a background on structural analysis. In Section 4, we introduce Σ-systems, the abstraction of DAE components that this work builds upon, and every function needed to perform the modular structural analysis of models built from these systems. Section 5 presents the core result of this paper, namely, the algorithms used for modular structural analysis. Finally, in Section 6, after addressing implementation details that are key to the performance of the algorithm, we present experimental results obtained from several benchmark models of variable sizes, including an industrial-strength model of the heating network mentioned above.

The full structural analysis also includes the construction of a block-triangular form for the index-reduced system of equations. To simplify our presentation, we ignore this aspect.

2 Background on DAE systems and their structural analysis

We consider square DAE systems, of the form:

$$S \quad : \quad f_j(\text{the } x_i\text{'s and their derivatives}) = 0 \qquad (1)$$

where $X =_{\text{def}} \{x_1, \ldots, x_m\}$ is the set of dependent variables and $F =_{\text{def}} \{f_1, \ldots, f_n\}$ is the set of functions. Throughout this section, we only consider square systems, meaning that $m = n$. Instead of the Pantelides algorithm (Pantelides 1988) for structural index reduction, we will use the Σ-method developed by John Pryce (Pryce 2001). This method is recalled next.

To S as in (1), we associate its (bipartite) *incidence graph* $\mathscr{G}_S = (F \cup X, E)$ having $F \cup X$ as set of vertices, and

having an edge $(f,x) \in E$ if and only if x occurs in function f, regardless of its differentiation degree. To account for differentiations, we augment $\mathscr{G}_S$ to

$$\mathscr{G}_S \quad = \quad (F \cup X, E, \sigma) \tag{2}$$

by adding $\sigma =_{\text{def}} \{\sigma_{f,x} \mid (f,x) \in E\}$, the set of nonnegative integer-valued *weights*, where $\sigma_{f,x}$ is equal to the maximal differentiation degree of variable x in function f. This yields a *weight* for any perfect matching $\mathscr{M}$ of $\mathscr{G}_S$[1] through $\sigma(\mathscr{M}) = \sum_{(f,x)\in\mathscr{M}} \sigma_{f,x}$. The Σ-method consists in solving the following pair of dual linear programming problems:

$$\begin{array}{rll} \text{maximize} & J = \sum_{(f,x)\in E} \sigma_{f,x}\, \xi_{f,x} & \\ \text{subject to} & \sum_{f:(f,x)\in E} \xi_{f,x} = 1 & \forall x \in X \\ \text{and} & \sum_{x:(f,x)\in E} \xi_{f,x} = 1 & \forall f \in F \\ \text{and} & \xi_{f,x} \geq 0 & \forall (f,x) \in E \end{array} \tag{3}$$

$$\begin{array}{rll} \text{minimize} & K = \sum_x d_x - \sum_f c_f & \\ \text{subject to} & d_x - c_f \geq \sigma_{f,x} & \forall (f,x) \in E \\ \text{and} & c_f \geq 0 & \forall f \in F \end{array} \tag{4}$$

Problem (3) is the *primal* and Problem (4) is the *dual*. The former encodes the search for a *maximum weight perfect matching* $\mathscr{M}$ of $\mathscr{G}$, also called *optimal matching* in the sequel. It is proved in (Pryce 2001, Theorem 3.6) that, if a solution exists to the index problem, then a unique element-wise minimal solution for Problem (4) exists. Furthermore, this solution does not depend on the choice of the optimal matching solving the primal problem. The following procedure is proposed in (Pryce 2001) to solve (3,4):

Procedure 1 (Σ-method)

1. *Solve LP* (3)*, which gives an optimal matching* $\mathscr{M}$ *of* $\mathscr{G}$*, described as* $(f,x_f)_{f\in F}$ *or* $(f_x,x)_{x\in X}$*;*

2. *Using* $\mathscr{M}$ *found in step 1, solve for* $(d_x)_{x\in X}$ *the following constraint system:*

$$\begin{array}{rrcl} \forall x \in X: & d_x & \geq & \sigma_{f_x,x} \\ \forall (f,x) \in E: & d_x - d_{x_f} & \geq & \sigma_{f,x} - \sigma_{f,x_f} \end{array} \tag{5}$$

   whereas $c_f = d_{x_f} - \sigma_{f,x_f}$ *yields the equation offsets. Index reduction then consists in differentiating* c_f *times equation* f=0*.*

Notations 1 *We denote by* $\mathscr{L}^{\mathsf{p}}$ *the primal problem* (3) *associated to S, by* $\mathscr{L}^{\mathsf{d}}$ *the problem* (5) *in which matching* $\mathscr{M}=(\xi_{f,x})_{(f,x)\in E}$ *is a solution of primal problem* (3)*, and we write* $\mathscr{L} = (\mathscr{L}^{\mathsf{p}}, \mathscr{L}^{\mathsf{d}})$. □

[1] A perfect matching is a one-to-one assignment of variables to equations, obtained by selecting edges of the incidence graph $\mathscr{G}_S$. The existence of a perfect matching is a criterion for structural nonsingularity.

Using DBMs for the dual problem: In (Pryce 2001), an iterative procedure is proposed to compute the element-wise minimal solution of the dual problem, which is unique. However, handling Problem (5) in a modular way requires additional algebraic manipulations, which are beyond the applicability of the Σ-method. However, we found that Difference Bound Matrices (DBM) (Dill 1989; Miné 2001) turn out to be a subclass of linear programs to which problem (5) belongs.

DBMs are matrices of integer or real coefficients encoding constraint systems like $\mathscr{L}^{\mathsf{d}}$. We generically denote them by A in the sequel. The composition of dual problems $A_i, i = 1,2$ is then encoded by the element-wise minimum of the DBMs: $\mathsf{A}_1 \wedge \mathsf{A}_2$. Eliminating variables from the dual problem is encoded by a matrix denoted by $\Pi_Z(\mathsf{A})$, and the complementary operation (reconstructing after the elimination) is denoted by $\amalg_Z(\mathsf{A})$. Both matrices are easily computed from A.

3 A coupled pendulums model

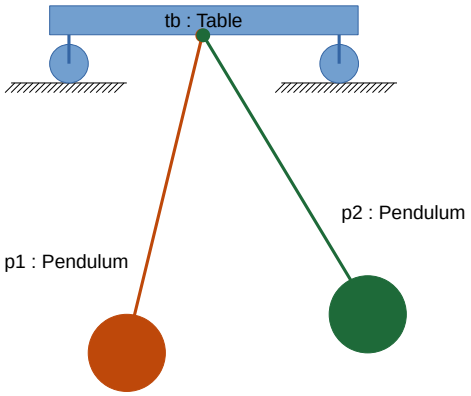

Figure 1. Coupled pendulums, attached to a sliding mass.

Concepts and algorithms introduced presented in the sequel of the paper are illustrated on a model of two 2D coupled pendulums, attached to a mass that can slide on the ground with zero friction, in one dimesion only. The mechanical assembly is depicted Fig. 1, and the Modelica model is defined Fig. 2.

To demonstrate the modularity of the structural analysis method, the model has been as modular as it can be: model `CoupledPendulums` consists of an instance of model `Table`, two instances of model `Pendulum`, and three connecting equations. Two of these connecting equations are trivial, that amount to a variable renaming. Among the three equations, only the third, line 37, a force balance equation, needs to be considered as an equation in the structural analysis. Equations line 9, 26, and 27 are also considered as defining synonyms for the first order derivatives of some state variables. They are not to be considered as equations during the structural analysis.

An important feature of this model is that most variables of models `Table` and `Pendulum` are protected, meaning that they can not be referenced from outside of the model

DOI 10.3384/ecp218175

they belong to. The only variables that remain public are those that are necessary for assembling together the components of the mechanical system, namely: the position of the table `x` and `f`, the projection along the x axis of the forces exerted on the pivot linking the table to each pendulum. As this is explained in the sequel of the paper, this is crucial to the performance of the modular structural analysis.

4 Open DAE systems, Σ-systems, and Σ-interfaces

So far, we focused on closed systems, i.e., systems that operate in isolation. In contrast, open systems are designed to operate in different, yet unspecified environments or contexts. They are the appropriate notion when dealing with modularity. In this section, we introduce open DAE systems and their abstraction for structural analysis, called Σ-systems.

4.1 Open DAE systems and Σ-systems

An *open DAE system* (*oDAE* for short) is a pair $S=(F,X)$, where F is a set of equations $f=0$ and X is a set of variables and their derivatives $x'^k, x \in X$. We require that the cardinalities of these sets satisfy $|X| \geq |F|$. The excess of variables with respect to equations allows capturing interactions with yet unspecified contexts, as shown by the following notion of composition.

Given S_1 and S_2 two oDAEs such that $F_1 \cap F_2 = \emptyset$, their *composition* $S_1 \,\|\, S_2$ is the oDAE $S=(F,X)$ defined by $F = F_1 \uplus F_2$ and $X = X_1 \cup X_2$. Let $S_i, i=1,2$ be two oDAEs. Two solutions $(\mathscr{M}^i, c^i, d^i), i=1,2$ for their respective oDAE index problems are called *complementary* if the union $\mathscr{M}^1 \uplus \mathscr{M}^2$ is a matching, and if variable offsets agree on common variables: $\forall x \in X_1 \cap X_2, d^1_x = d^2_x$. When this holds, matching $\mathscr{M} =_{\text{def}} \mathscr{M}^1 \uplus \mathscr{M}^2$ is equation-complete.

Lemma 1 *Let $S_i, i=1,2$ be two oDAEs, with composition $S = S_1 \,\|\, S_2$. The following properties hold:*

1. *Every solution $(\mathscr{M}, c, d)$ to the oDAE index problem for S projects to a pair of complementary solutions $(\mathscr{M}^i, c^i, d^i), i=1,2$ for the oDAE index problems of $S_i, i=1,2$, where*

$$\mathscr{M}^i = \mathscr{M} \cap (F_i \times X_i),\ c^i = \Pi_{F_i}(c),\ d^i = \Pi_{X_i}(d)\,.$$

2. *Conversely, every pair of complementary solutions $(\mathscr{M}^i, c^i, d^i), i=1,2$ for the oDAE index problems of $S_i, i=1,2$ yields a solution to the oDAE index problem for S by setting*

$$\mathscr{M} = \mathscr{M}^1 \uplus \mathscr{M}^2;\ c_f = c^i_f \text{ if } f \in F_i;\ d_x = d^i_x \text{ if } x \in X_i\,.$$

To account for the fact that the structural analysis of DAEs and oDAEs works on weighted incidence graphs only, we introduce the adequate abstraction for this, called Σ-system. To this end, we distinguish between shared and local variables,[2] by enforcing the following assumption:

Assumption 1 *For $S=(F,X)$ an oDAE, we assume a decomposition $X = X^s \uplus X^\ell$ of its set X of variables into its subsets of* shared *and* local *variables. By convention, local variables of* **S** *are never shared with any other oDAE.*[3]

Local variables are determined locally, by the oDAE equations, whereas shared variables can be determined, depending on the cases, either locally, by the oDAE system, or externally, by the equations of its environment. Interaction with the environment occurs through shared variables only.

Since the structural analysis of oDAE S is built on top of its incidence graph $\mathscr{G}_S$ only, we consider an abstraction of S as $\mathscr{G}_S$, now called a Σ-system:

1. A Σ-*system* is a tuple $\mathbf{S} = (F, X^\ell, X^s, E, \sigma)$, where:

[2] For instance, local variables are declared using the `protected` modifier in Modelica, while shared variables are declared using the default `public` modifier.

[3] We ensure that local variable identifiers are chosen unique, e.g., by performing appropriate renaming to avoid local variable identifier clashes.

- F is a set of functions; X^ℓ and X^s are two disjoint sets of *local* and *shared* variables; we set $X{=}X^s{\uplus}X^\ell$ (the cardinality of F is greater than, or equal to, that of X^ℓ);
- $E \subseteq F \times X$ is the set of *edges*; and
- $\sigma : E \to \mathbb{N}$ is the *weight function*.

2. Given two Σ-systems $\mathbf{S}_1$ and $\mathbf{S}_2$, their *composition* $\mathbf{S}_1 \,\|\, \mathbf{S}_2$ is only defined if $F_1 \cap F_2 = \emptyset$ and yields the Σ-system $\mathbf{S} = (F_1 \uplus F_2, X_1^\ell \uplus X_2^\ell, X_1^s \cup X_2^s, E_1 \uplus E_2, \sigma^1 \uplus \sigma^2)$.

3. Given $x \in X^s$, the *hiding* of x in $\mathbf{S}$ is the Σ-system denoted by $\mathbf{S}{\downarrow_x}$ and obtained by replacing, in $\mathbf{S}$, the pair (X^ℓ, X^s) with $(X^\ell \cup \{x\}, X^s \setminus \{x\})$.

4. Given $x{\in}X^s$ and $y{\notin}X$, the *renaming* of x by y in $\mathbf{S}$ is the Σ-system denoted by $\mathbf{S}[y/x]$ and obtained by replacing x by y everywhere in $\mathbf{S}$.

The combined use of these operators allows to define all Modelica constructs as macros (with the exception of *inner/outer* variable declarations, which imply complex name scoping rules).

Using Section 2, we can associate to a Σ-system $\mathbf{S}$ its oDAE index problem, which, reusing Notations 1, we denote by $\mathscr{L}_\mathbf{S} = (\mathscr{L}_\mathbf{S}^\mathsf{p}, \mathscr{L}_\mathbf{S}^\mathsf{d})$, or simply $\mathscr{L} = (\mathscr{L}^\mathsf{p}, \mathscr{L}^\mathsf{d})$. Its solutions take the form $(\mathscr{M}, c, d)$, where matching $\mathscr{M}$ is equation-complete. The variables matched in $\mathscr{M}$ are determined by the system itself, therefore we call them *dependent variables* and denote the resulting set by X^dep. There are generally several possible choices for $X^\mathsf{dep} \subseteq X$, depending on which variables from X^s are chosen to be part of it.

This choice is parametrized using the notion of selector. Let $\mathbf{S} = (F, X^\ell, X^s, E, \sigma)$ be a Σ-system. Call *selector* any subset $Y \subseteq X^s$, and consider:

- $X^\mathsf{dep} = X^\ell \uplus Y$ and $E^Y = E \cap (F \times X^\mathsf{dep})$;
- σ^Y, the restriction, to E^Y, of the weight function σ;
- $\mathscr{G}^Y = (F \cup X^\mathsf{dep}, E^Y, \sigma^Y)$, the incidence graph; and
- any optimal matching $\mathscr{M}^Y$ for $\mathscr{G}^Y$, if it exists.

Call $\mathscr{M}^Y$ the *selected optimal matching* (SOM) for $\mathbf{S}$ with Y, and *selected optimal weight* its associated weight.

The following result will be instrumental in identifying the appropriate notion of interface required for structural analysis:

Theorem 1 *Let $\mathbf{S}_1$ and $\mathbf{S}_2$ be two Σ-systems, and let $\mathbf{S} = \mathbf{S}_1 \,\|\, \mathbf{S}_2$ be their composition. The following formula holds, where Y is any selector for $\mathbf{S}$ and Y_i is any selector for $\mathbf{S}_i, i{=}1,2$:*

$$\mathsf{J}^Y = \max \left\{ \mathsf{J}_1^{Y_1} + \mathsf{J}_2^{Y_2} \;\middle|\; Y_1 \cap Y_2 = \emptyset \text{ and } Y_1 \cup Y_2 = Y \right\}. \quad (6)$$

We now move to considering the dual problem. For $\mathbf{S}$ a Σ-system and $Y \subseteq X^s$ a selector for it, we denote by $\mathscr{L}^{Y\mathsf{d}}$ the dual problem (5) with $X^\mathsf{dep} = X^\ell \uplus Y$ and $X^\mathsf{free} = X^s \setminus Y$. The following result relates the dual problem of a composition to the dual problems of each of the composed open systems:

Theorem 2 *Let $\mathbf{S}_1$ and $\mathbf{S}_2$ be two open systems and $\mathbf{S} = \mathbf{S}_1 \,\|\, \mathbf{S}_2$ their composition. Denoting by $\mathscr{L}_i^{Y_i\mathsf{d}}, i{=}1,2$ the dual problem of $\mathbf{S}_i$ with selector Y_i, then, for* any *choice of (Y_1, Y_2) achieving the max in (6):*

$$\mathscr{L}^{Y\mathsf{d}} \equiv \mathscr{L}_1^{Y_1\mathsf{d}} \cup \mathscr{L}_2^{Y_2\mathsf{d}}, \quad (7)$$

$$\mathsf{A}^Y = \mathsf{A}_1^Y \wedge \mathsf{A}_2^Y. \quad (8)$$

In (7), the $\cup$ on the right hand side indicates the union of sets of constraints, whereas the symbol $\equiv$ means that the two sides possess identical sets of solutions.

4.2 Σ-interfaces

The Σ-interface is *precisely what is required for interactions with the outside world* — no more, no less. We complement it with the notions of local decomposition and extension, which summarize the missing information in the Σ-interfaceneeded to reconstruct solutions to the structural analysis of the Σ-system.

Notations 2 *In the sequel, given a relation $R \subseteq W \times W$ or a function $f : W \to Z$, and $V \subseteq W$, we denote by*

$$\Pi_V(R) \text{ and } \Pi_V(f)$$

the restriction *of R to $V \times V$ and of f to V.*[4] *We will use this notation with some liberty. For $Y \subseteq X^s$ a selector, we will write $\Pi_Y(\mathsf{J})$ instead of $\Pi_{\mathscr{P}(Y)}(\mathsf{J})$ to mean the restriction of function J to $\mathscr{P}(Y)$, the set of all subsets of Y.*

For the following definition, we reuse the DBM associated to the dual problem introduced in Section 2.

Definition 1 (interface) *To Σ-system $\mathbf{S} = (F, X^\ell, X^s, E, \sigma)$, we associate its* Σ-interface

$$\mathbf{I}_\mathbf{S} = \left(X^s, \mathsf{J}, \Pi_{X^s}(\mathsf{A})\right), \quad (9)$$

where J and $\Pi_{X^s}(\mathsf{A})$ are functions that respectively map any selector $Y \subseteq X^s$ to:

- J^Y*, the optimal weight of $\mathbf{S}$ for the primal problem with selector Y;*
- $\Pi_{X^s}(\mathsf{A}^Y)$*, the projection, over X^s, of the DBM A^Y associated to the dual problem with selector Y.*

In our modular algorithm, we use the following function:

$$\text{INTERFACECOINTERFACE}(\mathbf{S}) = \left(\mathbf{I}_\mathbf{S}, \amalg_{X^s}(\mathsf{A})\right) \quad (10)$$

[4] Our notation is reminiscent of a projection, on purpose.

DOI 10.3384/ecp218175

where $\amalg_{X^s}(\mathsf{A})$ is a function that maps each selector $Y \subseteq X^s$ to $\amalg_{X^s}(\mathsf{A}^Y)$, the extension of A^Y from X^s. Function (10) splits $\mathbf{S}$ as its Σ-interface $\mathbf{I_S}$ and an object $\amalg_{X^s}(\mathsf{A}^Y)$ that makes up for the loss of information in $\mathbf{I_S}$. The latter is stored for subsequent reuse when "reverting the Σ-interface", as we shall see.

To illustrate the concept of Σ-interface, let us consider model `Table` (Fig. 2). It has two public variable, `x` and `f`. Protected variable `u` (line 5) should be seen as a synomym for the first order derivative of `x` (equation line 9). This means that for the structural analysis, this model has two variables and one equation (line 8). As a consequence, the interface $I_t = (\{x,f\}, J_t, A_t)$ of this model admits two valid selectors: $\{x\}$ and $\{f\}$. The optimal weight J_t and the DBM A_t are given in the table below, for each of the two valid selectors:

Y	J_t	A_t
$\{f\}$	0	$A_t^{\{f\}}$
$\{x\}$	2	$A_t^{\{x\}}$

where:

$$A_t^{\{f\}} = \begin{array}{c} \\ 0 \\ x \\ f \end{array} \begin{array}{c} \begin{array}{ccc} 0 & x & f \end{array} \\ \begin{bmatrix} & -2 & 0 \\ & & \\ & -2 & 0 \end{bmatrix} \end{array} \qquad A_t^{\{x\}} = \begin{array}{c} \\ 0 \\ x \\ f \end{array} \begin{array}{c} \begin{array}{ccc} 0 & x & f \end{array} \\ \begin{bmatrix} & -2 & 0 \\ & 0 & 2 \\ & & \end{bmatrix} \end{array}$$

Matrix elements that are left blank have the value $+\infty$, and impose no constraint on the corresponding offset variables. Therefore, DBM $A_{\{f\}}$ is equivalent to the system of inequalities $d_x \geq 2, d_f \geq 0, d_x \geq 2 + d_f$. The second DBM $A_{\{x\}}$ encodes $d_x \geq 2, d_f \geq 0, d_f \geq d_x - 2$.

Theorem 3 (hiding) *Let* $\mathbf{S}$ *be a* Σ*-system, with* Σ*-interface* (9). *Let* $\mathbf{T} =_{\text{def}} \mathbf{S}{\downarrow_Z}$*, where* $Z \subseteq X^s$*, and define* $Z^s = X^s \backslash Z$*. Then, the* Σ*-interface of* $\mathbf{T}$ *is*

$$\mathbf{I_T} = \left(Z^s, \Pi_{Z^s}(\mathsf{J}), \Pi_{Z^s}(\mathsf{A})\right),$$

where $\Pi_{Z^s}(\mathsf{J})$ *and* $\Pi_{Z^s}(\mathsf{A})$ *are functions mapping any selector* $Y \subseteq Z^s$ *to* $\Pi_{Z^s}(\mathsf{J}^Y)$ *and* $\Pi_{Z^s}(\Pi_{X^s}(\mathsf{A}^Y))$.

As a direct consequence of the properties of the projection, note that, for every selector Y,

$$\Pi_{Z^s}(\mathsf{A}^Y) \quad = \quad \Pi_{Z^s}(\Pi_{X^s}(\mathsf{A}^Y)) \tag{11}$$

In our modular algorithm, we will use the following function, where $\mathbf{I_S}$ is as in (9):

$$\text{HIDEEXPOSE}(\mathbf{I_S}, Z) = \left(\mathbf{I_T}, \amalg_Z(\mathsf{A})\right) \tag{12}$$

In (12), $\amalg_Z(\mathsf{A})$ is the function mapping each selector $Y \subseteq X^s$, to $\amalg_{Z^s}(\mathsf{A}^Y)$, the extension of A^Y from Z^s. Function (12) replaces the pair $(\mathbf{I_S}, Z)$ by its Σ-interface $\mathbf{I_T}$, and object $\amalg_{Z^s}(\mathsf{A}^Y)$ that makes up for the loss of information in $\mathbf{I_T}$. The latter is stored for subsequent reuse when "reverting the hiding".

Theorem 3 and (11) show that HIDEEXPOSE can be evaluated through the Σ-interfaces $\mathbf{I_S}$ and $\mathbf{I_T}$ only.

Theorem 4 (composition) *Let* $\mathbf{S}_1$ *and* $\mathbf{S}_2$ *be two* Σ*-systems, with* Σ*-interfaces* $\mathbf{I}_{\mathbf{S}_i} = (X_i^s, \mathsf{J}_i, \mathsf{A}_i), i = 1,2$.

1. *We have* $\mathbf{I}_{\mathbf{S}_1 \| \mathbf{S}_2} = (X^s, \mathsf{J}, \mathsf{A})$*, where:*

$$\begin{aligned} X^s &= X_1^s \cup X_2^s, \text{ and, for } Y \subseteq X^s, \\ \mathsf{J}^Y &= \max \left\{ \mathsf{J}_1^{Y_1} + \mathsf{J}_2^{Y_2} \;\middle|\; \begin{array}{l} Y_i \subseteq X_i^s, i{=}1,2 \\ Y_1 \cap Y_2 = \emptyset \\ Y_1 \cup Y_2 = Y \end{array} \right\} \qquad (13) \\ \mathsf{A}^Y &= \mathsf{A}_1^{Y_1} \wedge \mathsf{A}_2^{Y_2} \qquad (14) \end{aligned}$$

2. *The resulting* A^Y *in* (14) *is independent from the chosen optimizing pair.*

The right-hand sides of (13, 14) depend only on the Σ-interfaces of $\mathbf{S}_1$ and $\mathbf{S}_2$. Hence, we will denote by $\mathbf{I_{S_1}} \| \mathbf{I_{S_2}}$ the so defined operation on Σ-interfaces.

Call *optimizing pair* the function $Y \mapsto (Y_1, Y_2)$, mapping any Y to a pair (Y_1, Y_2) achieving the maximum in (13). In our modular algorithm, we use the following function:

$$\text{COMPOSEDECOMPOSE}(\mathbf{I_{S_1}}, \mathbf{I_{S_2}}) = \begin{pmatrix} \mathbf{I_{S_1}} \| \mathbf{I_{S_2}} \\ Y \mapsto (Y_1, Y_2) \end{pmatrix} \tag{15}$$

computing the optimizing pair as its second component, for subsequent reuse when "reverting the composition".

To illustrate the composition operator, let us consider the composition of model `Table` with the equation "`der(f) + x = 0`". The interface of the former is given above, while the latter has for interface $I_e = (\{x,f\}, J_e, A_e)$, where J_e and A_e are defined as follows:

Y	J_e	A_e
$\{f\}$	1	$A_e^{\{f\}}$
$\{x\}$	0	$A_e^{\{x\}}$

where:

$$A_e^{\{f\}} = \begin{array}{c} \\ 0 \\ x \\ f \end{array} \begin{array}{c} \begin{array}{ccc} 0 & x & f \end{array} \\ \begin{bmatrix} & 0 & -1 \\ & & \\ & 1 & 0 \end{bmatrix} \end{array} \qquad A_e^{\{x\}} = \begin{array}{c} \\ 0 \\ x \\ f \end{array} \begin{array}{c} \begin{array}{ccc} 0 & x & f \end{array} \\ \begin{bmatrix} & 0 & -1 \\ & 0 & -1 \\ & & \end{bmatrix} \end{array}$$

The composition $(I_t \parallel I_e) = (\{x,f\}, J, A)$ is as follows: it admits only one valid selector $Y = \{x,f\}$, which optimal partitioning is $Y_t = \{x\}$ and $Y_e = \{f\}$. This gives a weight $J^Y = J_t^{Y_t} + J_e^{Y_e} = 3$. DBM A^Y is the pointwise minimum of $A_t^{Y_t}$ and $A_e^{Y_e}$:

$$A^Y = \begin{array}{c} \\ 0 \\ x \\ f \end{array} \begin{array}{c} \begin{array}{ccc} 0 & x & f \end{array} \\ \begin{bmatrix} & -2 & -1 \\ & 0 & 2 \\ & 1 & 0 \end{bmatrix} \end{array}$$

4.3 Reverting the Σ-interface

In this section, we formalize what was meant above by "reverting" interfaces, hiding, and composition.

Consider a Σ-system $\mathbf{S} = (F, X^\ell, X^s, E, \sigma)$. Call Σ-*solution of* $\mathbf{S}$ any tuple

$$\nu \quad = \quad \big(Y, (d_x)_{x\in X}, (c_f)_{f\in F}\big)\,, \tag{16}$$

where $Y \subseteq X^s$ is a chosen selector such that $\mathsf{J}^Y > -\infty$, and variable offsets $(d_x)_{x\in X}$ are solution of A^Y, whereas equation offsets $(c_f)_{f\in F}$ are computed as in Procedure 1. We denote by $\mathsf{sol}(\mathbf{S})$ the set of all Σ-solutions of $\mathbf{S}$. We equip $\mathsf{sol}(\mathbf{S})$ with the partial order $\leq$ defined by

$$\nu \leq \nu' \quad \text{iff} \quad Y = Y' \text{ and } \forall x \in X : d_x^Y \leq d_x'^Y\,. \tag{17}$$

The term "minimal" will be referring to this order.

Let $\mathbf{I}$ be a Σ-interface following (9). Call *local solution* of $\mathbf{I}$ any tuple

$$\mu \quad = \quad \big(Y, (d_x)_{x\in X^s}\big)\,, \tag{18}$$

where $Y \subseteq X^s$ is a chosen selector such that $\mathsf{J}^Y > -\infty$, and variable offsets $(d_x)_{x\in X^s}$ are solution of $\Pi_{X^s}(\mathsf{A}^Y)$. Minimality is defined as in (17).

Nota: Σ-solutions are the wanted solutions of the index reduction problem. They are large objects since their cardinality relates to the size of X. In contrast, local solutions are small objects, whose cardinality relates to the size of X^s. Local solutions are the minimal objects from which Σ-solutions for the considered Σ-system can be rebuilt. Our overall objective is to compute Σ-solutions in a modular way, by manipulating only local solutions.

When composing Σ-interfaces, their local solutions fuse into local solutions of the composed interface. Local decomposition is the reverse operation.

Theorem 5 (local decomposition) *Let $\mathbf{I}_i, i{=}1,2$ be two Σ-interfaces and let $\mathbf{I}{=}\mathbf{I}_1 \,\|\, \mathbf{I}_2$ be their composition.*

1. *Let $\mu_i, i{=}1,2$ be a local solution of $\mathbf{I}_i, i{=}1,2$. Say that μ_1 and μ_2 are* compatible *if, with reference to Theorem 4:*

   (a) (Y_1, Y_2) is the optimizing pair for $Y{=}Y_1{\cup}Y_2$, and

   (b) for every $x, y \in X_1^s{\cap}X_2^s$, we have: $d_{1,x} = d_{2,x}$.

   If μ_1 and μ_2 are compatible, we can define their join

$$\begin{array}{rcl} \mu_1 \sqcup \mu_2 & =_{\text{def}} & (Y, (d_x)_{x\in X^s})\,, \text{ where:} \\ Y & = & Y_1 \cup Y_2 \\ d_x & = & \text{if } x \in X_1^s \text{ then } d_{1,x} \text{ else } d_{2,x} \end{array} \tag{19}$$

2. *Conversely, any Σ-solution μ of $\mathbf{I}{=}\mathbf{I}_1 \,\|\, \mathbf{I}_2$* decomposes *as $\mu = \mu_1 \sqcup \mu_2$, where μ_i is a Σ-solution of $\mathbf{I}_i$ and*

   (a) Y decomposes as $Y = Y_1{\cup}Y_2$, where (Y_1, Y_2) is the pair returned by the function COMPOSEDECOMPOSE *defined in (15), and*

   (b) $(d_{i,x})_{x\in X_i^s}$ is the restriction of $(d_x)_{x\in X^s}$ to X_i^s.

The important step in this decomposition is 2a. Step 2b is just a restriction and does not need any side information.

Nota: The decomposition $\mu = \mu_1 \sqcup \mu_2$ may not be unique, since optimizing pairs of selectors can be several. However, step 2b always yields the same result.

We now focus on how to revert the effect of hiding on Σ-interfaces. We use macro (12) together with objects and notations of Lemma 3.

Theorem 6 *Let $\mathbf{I}$ be a Σ-interface as in (9), and let $Z \subseteq X^s$ and $Z^s = X^s \setminus Z$. Consider the interface $\mathbf{J}$ of the hiding $\mathbf{I}{\downarrow_Z}$.*

1. *Let $\mu = (Y, (d_x)_{x\in X^s}, \preceq)$ be a local solution of $\mathbf{I}$ such that $Y \cap Z = \emptyset$. The* hiding of Z in μ, *defined by*

$$\mu{\downarrow_Z} \quad = \quad (Y, (d_x)_{x\in Z^s})\,, \tag{20}$$

   is a local solution of $\mathbf{J}$ and every local solution of $\mathbf{J}$ is obtained in this way. Say that $\mu{\downarrow_Z}$ extends to *μ.*

2. *Conversely, every local solution μ of $\mathbf{J}$ extends to a unique local solution $\mu^\star$ of $\mathbf{I}$, which is minimal among the set of all local solutions of $\mathbf{I}$ extending μ. This minimal extension is computed by using only $\amalg_Z(\mathsf{A})$, stored as the second component of the function* HIDEEXPOSE *introduced in* (12).

Theorem 7 *Let $\mathbf{S}$ be a basic Σ-system with Σ-interface $\mathbf{I}_\mathbf{S}$, and let $\nu = \big(Y, (d_x)_{x\in X}, (c_f)_{f\in F}\big)$ be a Σ-solution of $\mathbf{S}$.*

1. *The* hiding of X^ℓ in ν, *defined by*

$$\nu{\downarrow_{X^\ell}} \quad = \quad (Y, (d_x)_{x\in X^s})\,,$$

   is a local solution of $\mathbf{I}_\mathbf{S}$ and every local solution of $\mathbf{I}_\mathbf{S}$ is obtained in this way. Say that $\nu{\downarrow_{X^\ell}}$ extends to *ν.*

2. *Conversely, every local solution μ of $\mathbf{I}_\mathbf{S}$ extends to a unique Σ-solution $\nu = \mu^\star$ of $\mathbf{S}$, which is minimal among the set of all Σ-solutions of $\mathbf{S}$ extending μ. This minimal extension is computed by using only the pair $\amalg_{X^s}(\mathsf{A})$, which was stored as the second component of the function* INTERFACECOINTERFACE *in* (10).

This completes the toolbox for computing a Σ-solution of the Σ-system in a modular way. With the exception of basic Σ-systems, only shared variables are involved. Hence, these concepts remain as small as the set of shared variables of the associated Σ-systems.[5]

[5] Referring to the Modelica taxonomy, we expect all programs to have a set of *public* variables of small cardinality. In addition, we expect basic classes to possess a small set of variables.

DOI 10.3384/ecp218175

5 Modular algorithm

This section contains the most significant and practical contribution of this work, namely: a term algebra for the modular definition of Σ-systems, and a modular algorithm performing their structural analysis.

While the structural interface theory developed in Section 4.2 provides the needed pillars, it is not sufficient to construct an efficient and scalable algorithm, taking advantage of certain assumptions regarding the DAE systems we target.

Indeed, the large DAE systems that are typically seen in the digital twins of industrial systems are sparse. In addition, they generally result from a composition of a large number of instances of basic models in much smaller number, e.g., taken from libraries. Said differently, our targeted DAE systems contain a large number of structurally identical components, in which only parameter values may differ.

Our modular algorithm ensures that structural analyses are computed only once for each representative component, and then properly fused to get the global analysis. Achieving this relies on the interface theory developed in Section 4.2, complemented with adequate algorithmic techniques and data structures that we explain in this section.

Algorithm 1 Upward sweep: computing interfaces and cointerfaces with memoization

global $\mathscr{I}C : \mathscr{A} \to \mathscr{I} \times \mathscr{C}$ ▷ memoization table
▷ initially empty
function INTERFACE(a)
  if $\mathscr{I}C(a)$ is defined **then** ▷ if already memoized
    $(i,\cdot) \leftarrow \mathscr{I}C(a)$ ▷ then retrieve interface
  else
    if $a = (a_1 \parallel a_2)$ **then** ▷ composition
      $i_1 \leftarrow$ INTERFACE(a_1) ▷ compute interfaces
      $i_2 \leftarrow$ INTERFACE(a_2) ▷ of operands
      $(i,c) \leftarrow$ COMPOSEDECOMPOSE(i_1,i_2)
    else if $a = a'\downarrow_x$ **then** ▷ hiding
      $i' \leftarrow$ INTERFACE(a') ▷ interface of operand
      $(i,c) \leftarrow$ HIDEEXPOSE(i',x) ▷ compute hiding
    else if $a = [y/x]a'$ **then** ▷ renaming
      $i' \leftarrow$ INTERFACE(a') ▷ interface of operand
      $(i,c) \leftarrow$ RENAMEREVERSE(i',y,x)
    else if $a = b$ **then** ▷ basic Σ-system
      $(i,c) \leftarrow$ INTERFACECOINTERFACE(S_b)
    end if
    $\mathscr{I}C(a) \leftarrow (i,c)$ ▷ memoize (co-)interface
  end if
  return i ▷ return interface
end function

Algorithm 2 Downward sweep: computing local solutions

global $\mathscr{I}C$ ▷ initialized by function INTERFACE
  $\mathscr{S}ol \subseteq \mathscr{A} \times \mathscr{S}$ ▷ set of local solutions
  ▷ initially empty
procedure SOLUTION(a,μ)
  if $(a,\mu) \notin \mathscr{S}ol$ **then** ▷ visited yet ?
    add (a,μ) to $\mathscr{S}ol$ ▷ mark visited
    $(\cdot,c) \leftarrow \mathscr{I}C(a)$ ▷ retrieve cointerface
    if $a = (a_1 \parallel a_2)$ **then** ▷ composition
      $(\mu_1,\mu_2) \leftarrow c(\mu)$ ▷ compute local solutions
      ▷ of both operands
      SOLUTION(a_1,μ_1) ▷ propagate local solutions
      SOLUTION(a_2,μ_2) ▷ to the operands
    else if $a = a'\downarrow_x$ **then** ▷ hiding
      $\mu' \leftarrow c(\mu)$ ▷ compute local solution
      ▷ of the operand
      SOLUTION(a',μ') ▷ propagate to operand
    else if $a = [y/x]a'$ **then** ▷ renaming
      $\mu' \leftarrow c(\mu)$ ▷ compute renamed solution
      SOLUTION(a',μ') ▷ propagate to operand
    else if $a = b$ **then** ▷ basic Σ-system
      $\nu \leftarrow c(\mu)$ ▷ compute Σ-solution
      generate reduced index system of
      S_b for Σ-solution ν
    end if
  end if
end procedure

5.1 A term algebra $\mathscr{A}$ of Σ-systems

In this section, we consider a term algebra of Σ-systems, defined by the following grammar:

$$\mathscr{A} \quad ::= \quad \mathscr{B} \mid (\mathscr{A} \parallel \mathscr{A}) \mid \mathscr{A}\downarrow_{\mathscr{X}} \mid \mathscr{A}[\mathscr{X}/\mathscr{X}] \tag{21}$$

where $\mathscr{B}$ is a predefined set of symbols b denoting basic Σ-system S_b, and $\mathscr{X}$ is a set of variable names x, y, or z. The semantics of $\mathscr{A}$ is a mapping that associates a Σ-system $[\![a]\!]$ to term a. It is defined inductively on the term:

$$\begin{aligned} [\![b]\!] &= S_b \\ [\![(a_1 \parallel a_2)]\!] &= \rho_1[\![a_1]\!] \parallel \rho_2[\![a_2]\!] \\ [\![a\downarrow_x]\!] &= [\![a]\!]\downarrow_x \\ [\![a[y/x]]\!] &= (\rho[\![a]\!])[y/x] \end{aligned} \tag{22}$$

where ρ_k, $k = 1,2$ are any injective renamings of the vertices of $[\![a_k]\!] = (F_k, X_k^\ell \uplus X_k^s, E_k, \sigma_k)$, $k = 1,2$, such that $F_1 \cap F_2 = \emptyset$, $X_1^\ell \cap X_2^\ell = \emptyset$, and ρ_k, $k = 1,2$ are identity functions on X_k^s. Renaming ρ is any mapping such that it is the identity on the shared variables of $[\![a]\!]$ and y is not a variable of $\rho[\![a]\!]$. Our central problem is the following:

Problem 1 *How can one perform the structural analysis of $[\![a]\!]$ without computing $[\![a]\!]$, that is, by considering only term a and the Σ-systems S_b of the basic terms b appearing in a?*

A solution to this problem is developed in this section. The following notations are used in the sequel:

Notations 3 *In the sequel, symbols a, a', a_1, a_2 are use to represent terms; i, i', i_1, i_2 denote Σ-interfaces; c denotes cointerfaces and μ, μ', μ_1, μ_2 represent local solutions, while symbol ν is used to represent Σ-solutions. Also, we will use the generic term of* Cointerface *to denote the complementary components computed by the functions* INTERFACECOINTERFACE, HIDEEXPOSE, *and* COMPOSEDECOMPOSE, *introduced in (10,12,15).* □

5.2 A modular algorithm for the structural analysis of $\mathscr{A}$

In this section, we propose an algorithm solving Problem 1. This algorithm consists in traversing the sub-term graph, by first performing an *upward sweep* using Algorithm 1, followed by a *downward sweep* using Algorithm 2, which we comment next.

Upward sweep Algorithm 1 Σ-interfaces are computed inductively, starting from basic Σ-systems. A *memoization* table $\mathscr{I}C: \mathscr{A} \to \mathscr{I} \times \mathscr{C}$ is used to store the local interface and cointerface for each sub-term. Memoization (Cormen et al. 2022, Section 14.3) is an algorithmic technique that consists in ensuring that a function $f(x)$ is evaluated at most once for each parameter value x. This relies on a data structure that stores $f(x)$ for each value x encountered so far during program execution. Table $\mathscr{I}C$ has a double purpose: it is both used to prevent the evaluation of function INTERFACE(a) whenever this has already been done, and to store the local cointerface associated to a term. This cointerface is used in the downward sweep.

Downward sweep Algorithm 2 Local solutions are computed for each sub-term. In procedure SOLUTION(a, μ), a is a term and μ a local solution, seen as its context. This procedure computes the local solutions of the sub-terms of a, in the context of μ. To do this, the local cointerface c of term a, computed during the first phase, is retrieved from table $\mathscr{I}C$.

In the sequel, we call *modular structural analysis* the successive execution of Algorithms 1 and 2.

5.3 Back to the coupled pendulums example

The coupled pendulums model, introduced Section 3, can be expressed as the following component algebra term:

$$
\begin{aligned}
\text{CoupledPendulums} \;=\; & (\,\text{Table}[tb.f/f] \parallel \\
& \quad (\,\text{ConnectingEquation} \parallel \\
& \qquad \text{Pendulum}[p1.f/f] \parallel \\
& \qquad \text{Pendulum}[p2.f/f] \\
& \quad)\downarrow_{p1.f,p2.f} \\
&)\downarrow_{x,tb.f}
\end{aligned}
$$

where Table and Pendulum are the Σ-systems obtained from the classes `Table` and `Pendulum` defined Fig. 2, and ConnectingEquation is the Σ-system obtained from the connecting equation, line 37.

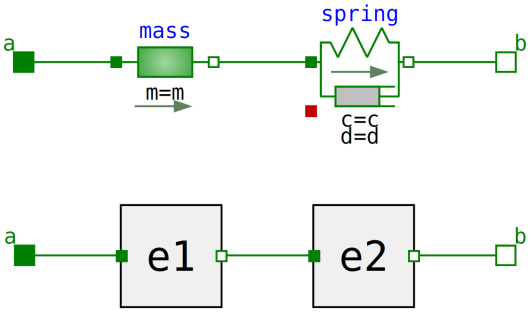
The execution of Algorithm 1 is detailed Fig. 9. The figure displays the term as an acyclic directed graph where each node represents a subterm of term CoupledPendulums, and each edge represents the containment relation. The algorithm starts with basic Σ-systems, and propagates Σ-interfaces in the opposite direction of the edges. Each time the Σ-interface of a term is computed, its corresponding cointerface is stored in the memoization table.

Figure 10 details the downward sweep of Algorithm 2: partial Σ-solutions are propagated down the subterm graph. The end result consists of Σ-solutions for each basic Σ-system instance, that can be used to perform the index reduction of each of these oDAE systems.

6 Implementation and benchmarking

In this section, we address an important implementation aspect of our modular method, then we benchmark our prototype implementation on several examples: a vibrating string model, an industrial-strength thermofluid model of a urban heat network, and a Heat Equation model defined with arrays and a *for* loop.

6.1 Avoiding the combinatorial explosion due to selectors



A difficulty in our interface theory is the consideration of selector-dependent structural analysis problems. The primal and dual problems are functions of the selector, that can be numerous, except for systems with only a few public variables. With a mere enumeration of selectors, composition operators can result in an exponential growth of the number of valid selectors.

Indeed, the number of valid selectors usually remains rather small, as the maximum number of shared variables for all the subsystems of a given system is small (below 20 or so). In such cases, enumerating valid selectors is not costly. It is however possible that, for some subsystems, the set of shared variables is larger, and enumerating selectors may become too costly. In Modelica, this typically happens whenever a class has public variables of array types.

In such cases, the set of valid selectors can be represented by its Boolean *characteristic function*. The primal and dual interfaces can also be represented as tuples of Boolean functions In this approach, efficient representations exist, namely Binary Decision Diagrams and their extensions; we use the Reduced-Ordered variant (ROBDD) introduced by (Bryant 1986). In our implementation, we adopted a hybrid approach, where selectors are enumerated for systems with a number of public variables below a given threshold, while the characteristic function approach is used when this threshold is exceeded (Benveniste et al. 2022).

The experimental comparison of the enumerative and symbolic approaches, presented in Section 6.2, turns in

Figure 3. A mass-spring-damper system; the element (top left) is assembled from the 1-D translational mechanical components of the Modelica Standard Library. An assembly of two elements is shown at the bottom left. A chain of mass-spring-damper elements of length n is defined by the recursive Modelica-like class shown on the right. Although Modelica does not allow for recursive classes, our software prototype allows recursion, provided conditional statements can be evaluated at compile time.

favor of the enumerative approach. Nevertheless, the symbolic approach should not be ruled out, as subsystems with a large number of shared variables may occur, and the enumerative approach would fail on these particular instances.

6.2 Benchmarking

Our implementation has been benchmarked on two academic examples and an industrial strength model. The former are a vibrating string model, and a 1-D finite element model of the Heat Equation; the latter is an industrial-strength model of a urban heat network system. All three models have been made parametric so that one can adjust their size, in terms of numbers of equations and variables. For these examples, the performance of the modular structural analysis is compared with a global reference implementation of the Σ-method.

6.2.1 The Vibrating String example

This example is a lumped model of a vibrating string, consisting in a chain of mass-spring-damper elements. The Modelica diagrams and code of this model are given by Figure 3. The mass-spring-damper element is built using the translational mechanics package of the Modelica Standard Library (MSL). The chain is defined by dichotomy, using a recursive class. , exactly like the chain circuit example.

The performance of the modular method was compared with a classical implementation of the Σ-method, where the primal problem is solved using an implementation of the Hungarian method (Munkres 1957), the dual problem is solved by a fixed point iteration, as advocated in (Pryce 2001). This reference implementation also puts the equations in Block Triangular Form (BTF), based on the computation Strongly Connected Components, using Tarjan's

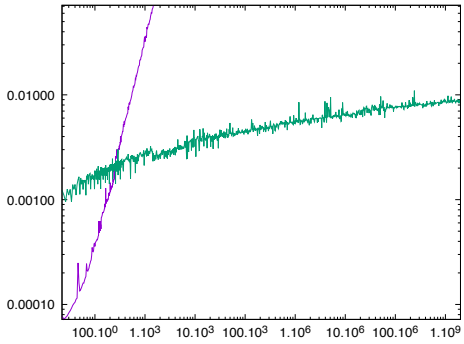

Figure 4. CPU times (seconds) of the modular (in green) and global (in purple) methods for the Vibrating String, as a function of the number of equations.

algorithm (Tarjan 1972). Figure 4 gives the computation times of both methods, for a range of instances of Vibrating String model, up to about 10^9 equations. The computation times for the modular method are logarithmic in the number of equations, because the number of interfaces to be computed is logarithmic in the model parameter value. The modular method runs faster than the global one, except for small models with less than a few hundred equations.

6.2.2 The Urban Heat Network model

This is an industrial-strength thermofluidic model of a urban heat network system, inspired by (Mans et al. 2022). The complete network comprises hot and cold water pipes, heat exchangers and circulation pumps, expansion tanks, and heat sources and sinks. Pipes and heat exchangers are lumped models, consisting in several elements connected in series. Figure 5 shows the variables-to-components incidence graph of the model for parameter value $n = 10$, and

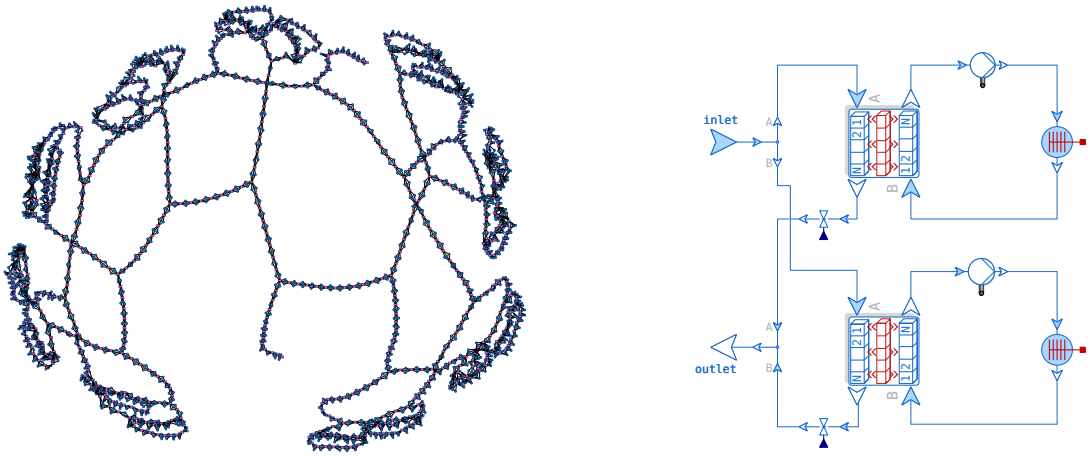

Figure 5. (a) Variables-to-components graph of the Urban Heat Network model for $n = 10$. Blue circles represent variables that are shared between two components; purple boxes represent instances of the basic thermofluidic components. (b) Modelica model of a substation, instantiated n times in the model and interconnected with a network of pipes.

  Real T[N](each start=Tright);
equation
  c*der(T[1]) = g * (2*Tleft - 3*T[1] + T[2]);
  for i in 2:N-1 loop
    c*der(T[i]) = g*(T[i-1] - 2*T[i] + T[i+1]);
  end for;
  c*der(T)[N] = g*(T[N-1] - 3*T(N) + 2*Tright);
end Thermal1D;
```

Figure 7. Modelica code of the 1-D Heat Equation, with an array and a loop of equations.

the Modelica model of a substation, that is instantiated n times and connected to a tree-shaped network of hot and cold water pipes. Figure 6 gives the computation times of the global and modular methods for instances of this model up to about 10^6 equations.

Although its measured time complexity is not logarithmic in the size of the model, the modular method runs faster than the global method for instances of the model with more than about $7,000$ equations. This is due to the fact that the model has a low treewidth (Bodlaender 1988), as evidenced by Figure 5a.

6.2.3 The Heat Equation model

Figure 7 shows the Modelica code of a finite element model of the 1D Heat Equation. This model, taken from (Fioravanti et al. 2023), consists of an array of real variables and a set of equations defined thanks to a *for* loop. This is a challenging benchmark for two reasons. First, it is a system of ordinary differential equations, on which each of the three steps of the global structural analysis method (primal and dual problems, then BTF decomposition) has a computation time that is linear in the size of the model. Second, this model does not provide a class instantiation tree decomposition of the system of equations; this decomposition has to be defined manually, or computed automatically.

As a reference, we performed the structural analysis using a manually-defined balanced binary tree decomposition of the system of equations, very similar to that of the Vibrating String example. Unsurprisingly, the performances (Figure 8, top graph) show that, above a certain threshold in the size of the system, the modular structural analysis takes only a fraction of the computation time required for the global (classical) structural analysis. As a matter of fact, it should be noticed that the empirical time complexity is logarithmic in the number of equations.

To our knowledge, computing an almost-balanced tree decomposition, that minimizes the number of shared variables between subtrees, is an open problem, in the general case of (possibly nested) loops of equations. It is nevertheless possible to compute tree decompositions, not necessarily balanced, using the heuristics implemented in Snowflake (Thibault 2024; Thibault 2022). Because

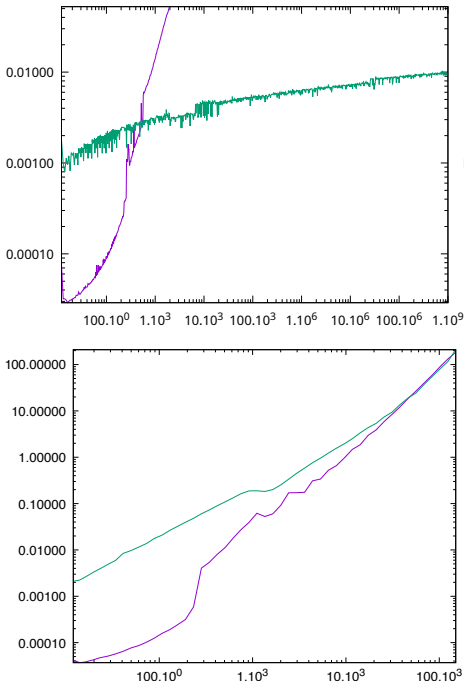

Figure 8. CPU times (seconds) of the modular (in green) and global (in purple) methods for the Heat Equation model, as a function of the number of equations, with balanced (top graph) and unbalanced (bottom graph) tree decompositions.

Snowflake implements a greedy decomposition algorithm, it results in an unbalanced, comb-shaped tree. The performances obtained with this tree decomposition are shown in the bottom graph of Figure 8. Although the modular structural analysis also has a linear time complexity for this model, it can be observed that, for large instances of the model, the computation times of the global and modular methods are almost the same. This examplifies the importance of a balanced tree decomposition for the performance of the modular method.

7 Conclusion and perspectives

Only square and structurally nonsingular DAE models are suitable for simulation. Such models correspond to *closed* systems, considered in isolation. In contrast, *open component models*, possessing more variables than equations, constitute the adequate framework to deal with model composition. Variables in open models are either local (*protected* variables in Modelica, i.e., private to the class), or public (possibly shared with other component models). Open models can be made aware of assumptions on their (unspecified yet) context. Overall, open models address the system view of physical modeling.

In this paper, we propose a notion of Σ-*interface* for open component models. Σ-interfaces involve only shared variables, thus abstracting away equations and local variables. The Σ-interface of an open model carries the information needed to perform modular structural analysis. We propose a hierarchical and modular algorithm that performs the interface-based structural analysis for DAE systems composed of possibly many open component models. Our algorithm exploits the sparsity of the underlying system as reflected in its incidence graph. Furthermore, very much like message passing, its efficiency relates to the model treewidth: the lower, the better.

The modular structural analysis algorithm was benchmarked on two academinc examples and an industrial-strength model of a urban district heating network. We succeeded in performing the structural analysis of DAE systems comprizing from 10^6 to 10^9 equations, depending on the model. Except for small instances of the models, computation times of the modular algorithm were a fraction of the computation times of state-of-the-art global structural analysis algorithms. As expected, sublinear execution times have been measured for several of the use cases.

This Σ-interface theory breaks one of the acknowledged obstacles to the scalability of DAE-based modeling languages, such as Modelica. Our contribution thus provides an important step towards the modular compilation of Modelica.

Of course, some issues remain open. In particular, models with higher treewidth are not handled well by our approach. Such unstructured models typically involve arrays of variables and components, with square regular grids being an example. While our notion of Σ-interface remains a useful candidate abstraction in this case, alternative algorithms for solving the Σ-method in a modular way still have to be found.

Resizable Arrays in Object-Oriented Modeling

Martin Otter[1] Hilding Elmqvist[2]

Abstract

The Modelica language (Modelica.org) makes it easy to build large, complex models by allowing the instantiation of reusable component models. Modelica tools typically expand arrays of variables, equations and components and perform symbolic transformations on the scalar elements. This reduces the efficiency of the translation process and makes it difficult to change array dimensions after translation.

This paper describes modest enhancements of standard algorithms to avoid scalarization. As a result, arrays can be resized both after translation and during simulation. The new technique does, however, impose certain restrictions on the way models are written. It is also sketched how to provide more meaningful diagnostics for erroneous models. Several examples demonstrate the new algorithms using the Web App Modiator.

Keywords: Modelica, array equations, compilation

1 Introduction

The Modelica language[1] makes it easy to build large, complex models by allowing the instantiation of reusable component models. Modelica tools typically expand arrays of variables, equations and components and perform symbolic transformations on the scalar elements. This reduces the efficiency of the translation process especially for models with fine discretization of partial differential equations or for handling arrays of parametric data. In many cases, this scalarization can be omitted, which will be explored in this paper.

Furthermore, avoiding scalarization of arrays allows changing array sizes without recompilation. This is important since it's essential to check the fidelity of the discretization for partial differential equations to ensure sufficient accuracy, i.e. to allow quick comparison of simulation results without recompilation with different numbers of segments. The technique also enables changing array dimensions during simulation, i.e., a model modifies its discretization depending on the model's behavior, for example increasing the number of segments when a transient occurs.

This paper outlines the modest enhancements to standard algorithms required for this new approach. A tool can verify whether the model complies with the required restrictions. If so, the new technique is employed, otherwise the current scalarization approach is used. The new approach imposes certain restrictions on models. These restrictions and how to rewrite the model equations to fulfill them are described. The alternative is to scalarize the equations internally, and then try to combine them into array equations and for-loops after the symbolic algorithms have been applied. Such an approach is much more involved.

The new approach and all the examples in this article have been tested with the Web App *Modiator* which supports a subset of Modelica. The current features, restrictions and future plans of Modiator are discussed in the companion paper (Elmqvist and Otter 2025).

Previous work on avoiding scalarization includes the following articles: (Otter and Elmqvist 2017) show that scalarization of array equations is needed for index reduction when using the standard algorithms, e.g., for multibody systems. They scalarize array equations internally and reconstruct arrays after sorting. (Pop et al. 2019) describe a new high-performance frontend to OpenModelica[2] (Fritzson et al. 2020) to convert arrays of component models to array equations and to keep arrays during flattening. (Zimmermann et al. 2020) propose set-based graph algorithms to avoid unrolling of for-loop equations of Modelica models. (Abdelhak et al. 2023,2025) map indices of array variables and equations, as well as iterator values of for-equations to unique scalar indices, apply standard algorithms for matching and sorting on these internally scalarized systems and reconstruct array equations and for-loops afterwards. They tested this approach with an extension to OpenModelica. (Marzorali et al. 2024) propose a matching algorithm for repetitive structures with for-loops over vectors of unknowns and test the implementation as part of the ModelicaCC compiler[3].

2 Model Restrictions

This section explores the restrictions that are needed to be imposed on Modelica authoring to avoid scalarization with the new method and achieve compile times that are independent of array sizes (*O(1) rather than O(n) or worse*).

Restriction 1: *The model must be balanced with regards to non-scalarized variables and equations. The equation*

[1] https://specification.modelica.org/maint/3.6/MLS.html

[2] https://openmodelica.org/

[3] https://github.com/CIFASIS/modelicacc

number of a for loop is the number of equations in the loop.

This restriction is illustrated using the CascadedFirstOrder model from the ScalableTestSuite[4] (Casella 2015):

```
tau*der(x[1]) = u - x[1];
for i in 2:N loop
  tau*der(x[i]) = x[i-1] - x[i];
end for;
```

Equations for tau and u are provided elsewhere. This equation set violates **Restriction 1** and needs to be modified since the number of unknowns is one (der(x)) but there are two equations. It can, for example, be rewritten as:

```
for i in 1:N loop
  tau*der(x[i]) = (if i == 1 then u else x[i-1]) - x[i];
end for;
```

or more compactly using the concatenation operator cat:

```
tau*der(x) = cat(1, {u}, x[1:N-1]) - x;
```

The cat function concatenates the array arguments, in this case along the first dimension. It means that the x vector is shifted upwards (x[N] omitted) and u is inserted as first element. Yet another possibility is to use a reduction expression.

```
tau*der(x) = {(if i == 1 then u else x[i-1]) - x[i] for i in 1:N}
```

Restriction 2: *All elements of an array must be of the same kind (algebraic or differentiated).*

This means that a model such as a variant of the CascadedFirstOrder model from above:

```
x[1] = u;
for i in 2:N loop
  tau*der(x[i]) = x[i-1] - x[i];
end for;
```

violates **Restriction 2** because x[1] is an algebraic variable and variables x[2:N] are variables appearing differentiated. Such a model needs to be rewritten in one of the forms shown above. In similar cases, arrays need to be split in different pieces so that all elements of an array are either algebraic or states.

An equivalent model to the CascadedFirstOrder model can be made with an array of components:

```
model FiltersInSeries
  model Filter
    input Real u;
    output Real x;
    parameter Real tau = 0.1;
  equation
    tau*der(x) = u-x;
  end Filter;
  parameter Integer N = 10 "Number of filters";
  Filter f[N](each x(start=0, fixed=true),
              u=cat(1, {1}, f[1:N-1].x));
end FiltersInSeries;
```

If all components in an array of components have the same causality, all component equations can be sorted together, i.e. that each equation in an array of components can be translated to a for loop over that equation (it is not important in this simple case since there is only one equation in each component).

The outputs f.x[1:N-1] are shifted to form the inputs f.u together with the input 1 to the first filter. Handling acausal connectors is somewhat more complex. See the *Transmission Line* example in section 4.3.

In section 5 more *restrictions* are discussed and there might be still more. Modiator never performs scalarization (also not internally) and therefore *valid Modelica models might be rejected.* The user should be able to understand how to rewrite the model equations from the error messages. The benefit is that generated code never contains scalarized equations or enrolled for-loops, translation is faster and error messages are more compact since the elements of an array are not shown.

3 Assignment without Scalarization

This section gives an overview how to symbolically process array equations so that arrays can be resized after compilation - both for translated Modelica models and Functional Mockup Units (≥ version 3.0)[5]. The details of the new algorithms are presented in **Appendix A**.

3.1 Model Unification

In order to make symbolic processing simpler, the Modelica model is transformed by a model unification process similar to what is done in OpenModelica (Pop et al. 2019):

- For-equations with multiple equations in the body are converted to potentially nested for-equations with *one* equation in the body:
  ```
  for index-expression, … loop
    equation
  end for;
  ```
- Non-constant variables of arrays of components are transformed to array variables with outer indices according to the component array indices.
- Each equation of an array of components is transformed to a for-loop over the equation.

3.2 Structurally Assignable Property

Afterwards, standard symbolic algorithms are used that operate, with some modifications on variable symbols. The following notation is used:

- All variable symbols v_j are collected in a variable vector $\boldsymbol{v}$. A symbol v_j may represent a scalar or an array of one or more dimensions. The first variable v_0 has index $j = 0$ (as it is common in programming languages such as C, C++, Javascript).

[4] https://github.com/casella/ScalableTestSuite

[5] https://fmi-standard.org/docs/3.0.2/

DOI 10.3384/ecp218189

- All equations e_i are collected in an equation vector $\boldsymbol{e}$. An equation e_i may be a scalar or an array equation of one or more dimensions with potentially a for-loop around it, as sketched above. The first equation e_0 has index $i = 0$.
- The relationship between the equations e_i and the variables v_j is defined by a sparse representation of the incidence matrix that is defined as vector $\boldsymbol{G}$, where each entry G_i is a vector consisting of the indices of the variable symbols appearing in equation e_i. $\boldsymbol{G}$ can also be interpreted as a representation of a bi-partite graph.
- The relationship between variable symbols is defined by the variable association vector $\boldsymbol{A}$:
  $A_j = \textbf{if } \dot{v}_j = v_k \textbf{ then } k \textbf{ else } -1.$
- The relationship between the equations is defined by the equation association vector $\boldsymbol{B}$:
  $B_i = \textbf{if } \dot{e}_i = e_k \textbf{ then } k \textbf{ else } -1.$

Additionally, the following *new property* needs to be defined for every variable in every equation:

Definition 1: *A variable v_j is called structurally assignable with respect to an equation e_i, if a complete assignment is possible for all (scalar) elements of v_j with respect to all (scalar) elements of e_i, provided v_j and e_i are expanded to scalars and this property holds, independently of the common dimensions and dimension sizes of v_j and e_i.*

In general, **Definition 2** is difficult to apply. The following sufficient condition is easier to use:

Theorem 1: *A variable v_j is structurally assignable with respect to an equation e_i, if*

- *v_j is a scalar and e_i a scalar equation, or if*
- *v_j is an array and e_i can be expressed as $0 = s \cdot v_j + w$, where s is a scalar expression and w is a vector expression and neither s nor w are a function of v_j.*

Proof: (a) A scalar variable/equation is already expanded and therefore the scalar variable can be assigned. (b) If e_i is expressed as $0 = s \cdot v_j + w$, the k-th element of v_j can be assigned to the k-th element of e_i. ■

The (new) structural assignable property is defined with vector $\boldsymbol{G_a}$, a companion vector of $\boldsymbol{G}$, such that $G_{a,i,j} =$ true, if variable $v_{G_{i,j}}$ is structurally assignable with respect to equation e_i and otherwise $G_{a,i,j} =$ false. Note, every vector $G_{a,i}$ must have at least one true value, since otherwise no variable can be assigned for equation e_i.

The underlying DAE (Differential Algebraic Equations) of a model is defined as:

$$\boldsymbol{e}(\boldsymbol{v}(t), t) \tag{1}$$

where t is time, the independent variable.

The central goal in this section is to provide an algorithm, so that by differentiating equations and variables, appending them to $\boldsymbol{e}$ and $\boldsymbol{v}$, and updating $\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{G}, \boldsymbol{G_a}$, a *complete assignment* of the *structurally assignable* highest derivative variables is provided for all highest derivative equations, that is, every highest derivative equation is uniquely assigned to a structurally assignable highest derivative variable:

$$e_i(v_j, t);\ \frac{\partial e_i}{\partial v_k} \text{ is structurally regular for } (B_i = -1,\ A_k = -1, G_{a,i,v_k} = \text{true}) \tag{2}$$

The result of the assignment is reported in vector ***assign***, such that $assign_k = i$, where i is the index of a highest derivative equation, that is $B_i = -1$, and v_k is a structurally assignable highest derivative variable, i.e., $A_k = -1$, and $G_{a,i,v_k} =$ true ($,v_k$ is the index of variable k in $G_{a,i}$). If all variables and equations are scalarized, so $G_{a,i,v_k} = true$ for all the scalarized variables and equations, then there are several (standard) algorithms to derive (2) from DAE (1), see for example (Otter, Elmqvist 2017, section 3.1).

The notation above is clarified with the cascaded first order model in vector notation from section 2, where the equation u = 1 is additionally added:

Table 1: Notation for vectorized CascadedFirstOrder model (T means true, F means False).

e_0	u = 1
e_1	tau*der(x) = cat(1, {u}, x[1:N-1]) - x
$\boldsymbol{B}$	[-1,-1] // no equation appears differentiated
v_0	u
v_1	x
v_2	der(x)
$\boldsymbol{A}$	[-1,2,-1] // the derivative of x is der(x)
G_0	[0] // e_0 is a function of u
G_1	[0,1,2] // e_1 is a function of u, x, der(x)
$G_{a,0}$	[T] // e_0 is structurally assignable for u
$G_{a,1}$	[F, F, T] // e_1 is struct. assignable for der(x)

Using the algorithm given in **Appendix A.1**, a complete assignment (2) for the problem formulation in **Table 1** is derived, yielding the following result:

assign = [0, -1, 1] // v_0 assigned to e_0, v_2 to e_1

This assignment holds for any valid dimension N (for N=1, the model is not valid due to x[1:N-1]). With the algorithms sketched in **Appendix A.4**, the following sorted and solved assignment statements can be derived:

```
u := 1
der(x) := (cat(1, {u}, x[1:N-1]) – x)/tau
```

and corresponding code generated. The translation time is independent of dimension N and N can be changed after translation!

3.3 Differentiation of Equations

In order to derive (2) from DAE (1), equations might need to be differentiated. For scalarized variables and equations several (standard) algorithms are available, see for example (Otter, Elmqvist 2017, section 3.1). These algorithms need to be extended to take the new structurally assignable property $\boldsymbol{G}_a$ into account. In **Appendix A.1**, it is shown how to extend the algorithm of Pantelides (1988) in this respect.

Consider the following simple yet non-trivial example:

Model 1: Model that needs to be differentiated.

```
Model ModelThatNeedsToBeDifferentiated
  Real n[3]; L, e[3]; r[3];
  Real s(start=1, fixed=true);
equation
    L = sqrt(n*n);
    e = 2*n/L;
    r = e*s;
    e*der(r) = der(s) - s;
    n = {1, 2, sin(time)};
end ModelThatNeedsToBeDifferentiated;
```

This model has the following structurally assignable properties:

equations	*structurally assignable*
L = sqrt(n*n);	L
e = 2*n/L;	e, n
r = e*s;	r, s
e*der(r) = der(s) - s;	der(s)
n = {1, 2, sin(time)};	n

With the enhanced Pantelides algorithm of **Appendix A.1** the following complete assignment of differentiated equations can be derived:

assigned	*highest derivative equations*
der(L)	der(L) = 0.5*(n*n)^-0.5*(der(n)*n + n* der(n))
der(e)	der(e) = (2* der(n)*L - 2*n* der(L))/L^2
der(r)	der(r) = der(e)*s + e* der(s)
der(s)	e*der(r) = der(s) - s
der(n)	n = {0,0, cos(time)}

In section **4**, several application examples are given that demonstrate the usefulness of the new approach.

3.4 Improved Error Diagnostics

If a Modelica model is erroneous, in many cases tools provide error messages that make it difficult to figure out the reason for the problem. For example, Modelica tools could provide an error message of the following kind which is quite useless: *The problem is structurally singular. It has 2046 scalar unknowns and 2045 scalar equations*. The error messages have improved over time, but they are often still not helpful enough. In **Appendix A.3**, a new, simple algorithm is sketched to significantly improve error diagnostics. Take for example the following model which contains several errors:

Model 2. Model having several errors.

```
model SeveralErrors
  Real v1,v2,v3,v4,v5,v6,v7,v8,v9,v10,v11;
equation
  der(v1) = -v1;
  der(v2) = -v3;
  v3 = -1;
  v3 = 3 + v2;

  der(v4) = -v4 + v1;
  der(v5) = -v5 - v4;
  v5 = 2;

  der(v6) = -v6 + v7;
  der(v7) = -v8 + v9;
  0 = v7 + v8 + v9;
end SeveralErrors;
```

Modiator provides the following error message.

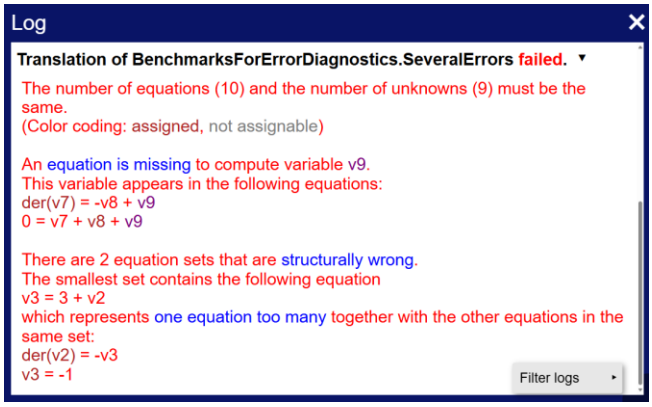

Figure 1. Modiator error message for **Model 2**.

The first message states, that one equation is missing to compute variable v9 and the equations are listed in which this variable appears. All of these equations are already assigned, so it is impossible to assign for v9. Most likely, just an equation for v9 is missing and should be added. Modiator lists these types of error messages first, because little output is expected, since a variable typically only appears in a few equations.

The second message states that two equation sets are wrong. Since many equations might be involved, more information is only given for the set with the smallest number of equations. For this set, first the equation is listed that makes the following set of equations overdetermined. This equation cannot get an assignment because there is one equation too many in this set. Afterwards, all the other (already assigned) equations are listed together with their assignment.

Note, the output of the error messages is not unique and a different initial ordering of the equations can display a different message (e.g. instead of v9, variable v8 could be listed). However, the important point is that the error message either points to *one* problematic *variable* or to *one* problematic *equation*, to help the user identifying the issue.

4 Application Examples

4.1 Heat Exchanger

The ScalableTestSuite and LargeTestSuite[6] of (Casella, 2015) contain cocurrent heat exchanger models with different numbers of segments from 10 to 81920. The compilation time in Modiator is essentially independent of n: about 11 milliseconds. The simulation results for n=10 are shown in Figure 1, and n can be changed after compilation.

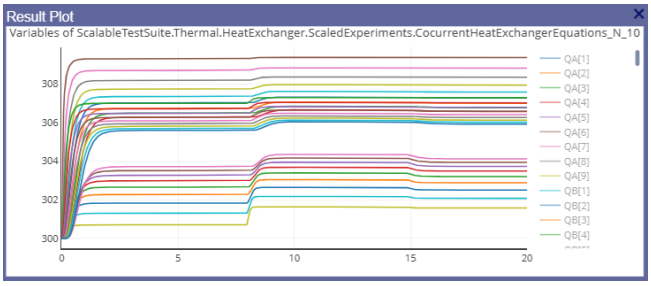

Figure 2. Simulation results for the cocurrent heat exchanger model with 10 segments from the ScalableTestSuite.

A small modification of the model was needed. The equations:

```
TA[1] = if time < 8 then 300 else 301;
TB[1] = 310;
for i in 2:N loop
  TA[i] = TAtilde[i - 1];
  TB[i] = TBtilde[i - 1];
end for;
```

were replaced by:

```
TA = cat(1, {if time < 8 then 300 else 301}, TAtilde)
TB = cat(1, {310}, TBtilde)
```

in order to comply with **Restriction 1**.

4.2 Shock Waves

Capturing shock waves typically needs a large number of grid points, i.e. benefits substantially by using the described array preserving technique. Consider the water hammer model, **Model 3**, using only array equations. The valve at the end of the pipe closes at time=0.01 inducing a shock wave. The number of grid points n can be changed after compilation.

Model 3: Modelica Water Hammer model capturing shock waves from Clément Coïc.

```
model WaterHammer
  parameter Integer n=10;
  parameter Real L=100 "Length of the pipe (m)";
  parameter Real A=3.1415*D^2/4 "Cross-sect. area of pipe (m^2)";
  parameter Real rho=1000 "Density of water (kg/m^3)";
  parameter Real B=21e8 "Bulk modulus of water (Pa)";
  final parameter Real c=sqrt(B/rho) "Speed of sound in water (m/s)";
  parameter Real tClose=0.01 "Time at which the valve closes (s)";
  parameter Real Q0=0.0002 "Initial flow rate (m^3/s)";
  final parameter Real dx=L / n "Length of each pipe segment (m)";
  final parameter Real dt=dx / c "Time step for stability (s)";
  parameter Real f=0.05 "Darcy-Weisbach friction factor (dim.less)";
  parameter Real D=0.05 "Pipe diameter (m)";
  Real p[n+1](start=fill(3e5, n+1), fixed=true) "Press. at each node (Pa)";
  Real Q[n] "Flow rate in each segment (m^3/s)";
  Real V[n](start=fill(0.1, n), fixed=true) "Speed of flow (m/s)";
  Real Qend "Flow rate at the end of the pipe (m^3/s)";
  Real QPlusEnds[n+2];
  Real valveOpen "1 if valve is open, 0 if closed";
equation
  Q = V*A;
  valveOpen = if time < tClose then 1 else 0;
  Qend = Q0 * valveOpen;
  der(V) = -(p[2:n+1] - p[1:n]) / (rho * dx) - (f / (2 * D)) .* V .* abs(V);
  QPlusEnds = cat(1, {Q[1]}, Q, {Qend});
  der(p) = B*(-(QPlusEnds[2:n+2] - QPlusEnds[1:n+1]) / (A * dx));
 annotation(experiment(StopTime=0.3));
end WaterHammer;
```

Figure 3 plots the pressures against time.

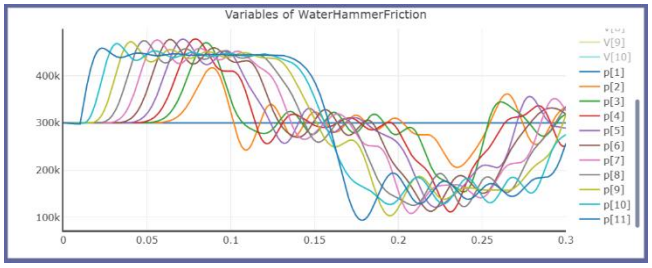

Figure 3. Pressures of WaterHammer model.

Such time plots do not convey the wave behavior very well. It is better to show the pressure profile over the pipe at different times, **Figure 4**. Spline interpolation is used to smooth the curve over the 51 spatial points (n=50). The pressure wave traverses from right to left. After about 72 milliseconds, the wave starts returning (green curve):

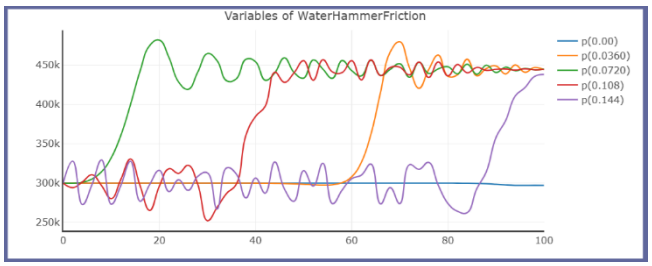

Figure 4. Spatial plot of pressures of WaterHammer model.

4.3 Transmission Line

Consider the transmission line element of **Figure 5**. It is a regular structure of connected electrical components (Resistor, Inductor, Conductor and Capacitor). Such a device can be modeled in Modelica using arrays of components and a for-loop for connections. A voltage source is connected to the first segment and a resistance load to the last segment:

[6] https://github.com/casella/ScalableTestSuite

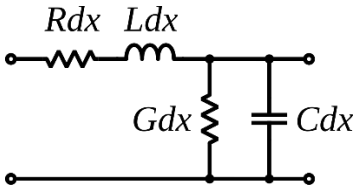

Figure 5. Image of transmission line element from Wikimedia[7]

Model 4: TransmissionLine
modeled with arrays of components.

```
model TransmissionLine
  import Modelica.Electrical.Analog.Basic;
  model TransmissionLineSegment
    parameter Real dx = 1 "Length of the segment in meters";
    parameter Real resistancePerMeter = 0.01;
    parameter Real inductancePerMeter = 0.001;
    parameter Real capacitancePerMeter = 1e-9;
    parameter Real conductancePerMeter = 1e-6;

    Modelica.Electrical.Analog.Interfaces.Pin p;
    Modelica.Electrical.Analog.Interfaces.Pin n;

    Basic.Resistor r(R=resistancePerMeter*dx);
    Basic.Inductor l(L=inductancePerMeter*dx);
    Basic.Capacitor c(C=capacitancePerMeter*dx);
    Basic.Conductor g(G=conductancePerMeter*dx);
    Basic.Ground ground;
  equation
    connect(p, r.p);
    connect(l.n, g.p);
    connect(g.p, c.p);
    connect(c.p, n);
    connect(r.n, l.p);
    connect(g.n, c.n);
    connect(c.n, ground.p);
  end TransmissionLineSegment;

  parameter Integer N = 10 "Number of segments";
  parameter Real length = 1000 "Length of in meters";

  TransmissionLineSegment segments[N](dx=fill(length/N, N));

  Basic.Ground ground;
  Basic.Resistor load(R=100);
  Modelica.Electrical.Analog.Sources.ConstantVoltage
      source(V=10);
equation
  // Connect the segments in series
  for i in 1:N-1 loop
    connect(segments[i].n, segments[i+1].p);
  end for;

  // Connect the first segment to the source
  connect(source.p, segments[1].p);
  connect(source.n, ground.p);

  // Connect the last segment to the load
  connect(segments[N].n, load.p);
  connect(load.n, ground.p);
end TransmissionLine;
```

In order to avoid recompilation of this model when N is changed, the connect statements are manually expanded. Since segments[N].n is connected to a capacitor having a state, the voltages are copied to the right (n to p) with the first element coming from source.p via a node nSource (since source.p needs to be connected, otherwise source.p.i would be zero). The currents are copied from p to n with the last current coming from load.p.i via the node nLoad.

```
segments.p.v = cat(1, {nSource.v}, segments.n.v[1:N-1]);
segments.n.i = -cat(1, segments.p.i[2:10], {nLoad.i});

nSource.i = segments.p.i[1];
nLoad.v = segments.n.v[N];

connect(source.p, nSource);
connect(source.n, ground.p);

connect(load.p, nLoad);
connect(load.n, ground.p);
```

The compilation time is about 50 milliseconds independent of n. The resulting voltages over the capacitors are shown in **Figure 6**.

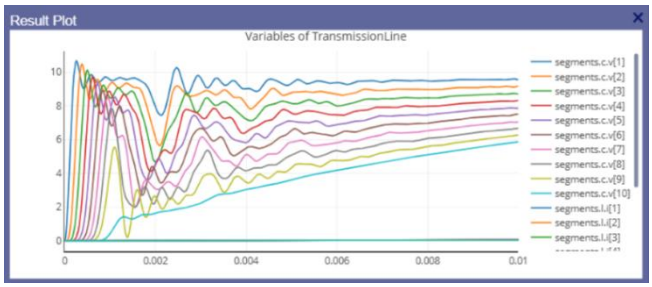

Figure 6. Capacitor voltages.

It should be noted that enabling changes to the discretization after compilation relied on certain specific properties of the model. The capacitor to the right of the TransmissionLineSegment enabled simultaneous copying of all voltages to the right in one array equation. Correspondingly due to the inductor to the left, all currents could be copied simultaneously in one array equation to the left.

4.4 Adaptive Grid

An important advantage of not recompiling when array dimensions change is that a model can refine itself, as shown in the example of this section.

An insulated rod model is shown below and a plot of a simulation in **Figure 7**. It changes the number of segments at time=2000 and time=4000. The changes could also be triggered by detecting some transient behavior.

[7] https://commons.wikimedia.org/wiki/File:Transmission_line_element.svg

DOI
10.3384/ecp218189

Model 5: Insulated rod model with adaptive grid.

```
model InsulatedRod_gradient "Insulated rod with gradient"
  import SI = Modelica.Units.SI;
  parameter SI.Length L=1 "lenght of rod";
  parameter SI.Area A=0.0004 "area of rod";
  parameter SI.Density rho=7500 "density of rod material";
  parameter SI.ThermalConductivity lambda=74
                              "thermal conductivity of material";
  parameter SI.SpecificHeatCapacity c=450
                              "specifc heat capacity";
  parameter SI.Temperature T0=293 "initial temperature";
  parameter Integer nT(min=2)=4 "number of inner nodes";
  SI.Temperature T[nT](start={300, 297.5, 295, 292.5},
              each fixed=true) "temperatures at inner nodes";
  SI.HeatFlowRate Q_flow[nT+1];
  Real dx;
  Real k1;
  Real k2;
  Real k3;
  Real port_a_Q_flow;
  Real port_b_Q_flow;
  SI.Temperature port_a_T;
  SI.Temperature port_b_T;
equation
  dx = L/nT;
  k1 = lambda*A/dx;
  k2 = rho*c*A*dx;
  k3 = 2*k1;

  // Connection equations
  port_a_T = if time<2000 then 300 else 320;
  port_b_Q_flow = 0;

  // Acausal part (assignment depends on connection)
  port_a_Q_flow = k3*(port_a_T - T[1]);
  port_b_Q_flow = k3*(T[nT] - port_b_T);

  // Causal part (assignment does not depend on connection)
  Q_flow = cat(1, {port_a_Q_flow}, k1*(T[1:nT-1] - T[2:nT]),
                  {port_b_Q_flow});
  der(T) = (Q_flow[1:nT] - Q_flow[2:nT+1])/k2;
  when time > 2000 then
    ast.setParameter("nT", 8);
    ast.setStart("T", interpolate(8, T));
  end when;
  when time > 4000 then
    ast.setParameter("nT", 6);
    ast.setStart("T", interpolate(6, T));
  end when;
  annotation(experiment(StopTime=5000));
end InsulatedRod_gradient;
```

A new function ast.setParameter is used to change the grid resolution. Since the state vector changes, new start values for the states are given using ast.setStart. A function *interpolate* is interpolating the temperatures from 4 points to 8 and back to 6. This function considers how the grid points are distributed along the staggered grid. This explains why the curves have discontinuities since T[i] refers to different positions along the rod when nT changes.

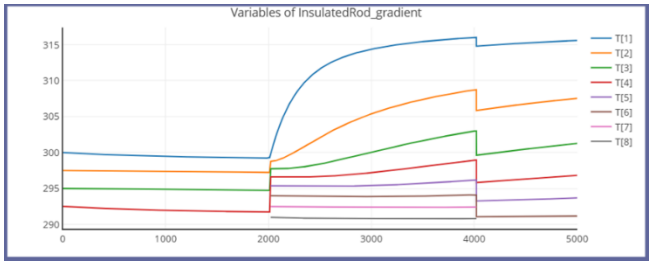

Figure 7. Simulation results of the temperature nodes along an insulated rod. At time=2000 and time=4000 the number of segments is changing from 4 to 8 to 6.

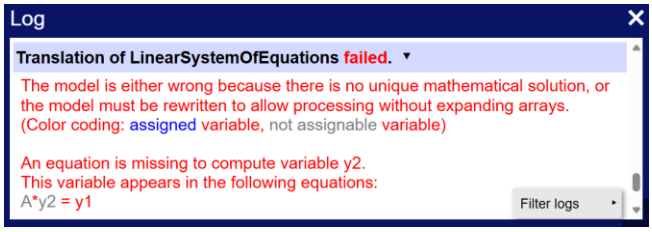
5 Reformulation of Array Equations

In this section, valid Modelica models are presented that are rejected by the algorithm of **Appendix A.1**. It is shown how to reformulate the equations in order that code can be generated.



5.1 Linear Equation Systems

Consider the following valid Modelica model that contains a linear system of equations

Model 6: Model with a linear system of equations.

```
model ModelWithLinearSystemOfEquations
  parameter Real n[2] = {1,2};
  parameter Real A[2,2]= [1,2;3,4];
 Real y1[2];
 Real y2[2];
equation
  y1 = n*time;
  A*y2 = y1;
end ModelWithLinearSystemOfEquations;
```

Modiator prints the following error message:

The listed equation must be reformulated, since (a) an equation is missing to compute variable y2, (b) variable y2 appears only in this equation and no variable is assigned to this equation. Note, that y2 is not structurally assignable according to **Theorem 1**. The remedy is to explicitly solve the linear equation system in the model:

```
equation
  y1 = n*time;
  y2 = Modelica.Math.Matrices.solve(A,y1);
```

5.2 Models That Must Be Scalarized

There are various kinds of Modelica models that can only be processed if array variables and equations are scalarized in the generated code. A simple example is shown in the following model:

Model 7: Model where array variables and equations need to be scalarized.

```
model ModelThatRequiresScalarization
  parameter Real n[:]={1,2,3};
  Real s(start=1, fixed=true);
  Real r[3];
equation
    r = n*s;
    der(r)*n = -s;
end ModelThatRequiresScalarization;
```

Modiator prints the following error message:

Translation of ModelThatRequiresScalarization failed.

Equation differentiated 10 times which is too much (most likely processing would be successful if arrays would be expanded, which is not done):
der(r)*n = -s

So, the error message states that the listed equation is differentiated too often and that the likely reason is that array variables in this equation must be scalarized, which is not done in Modiator. If the array variables and equations are scalarized, the following assignment is possible:

assigned	*highest derivative equations*
der(s)	der(r[1]) = n[1]*der(s)
der(r[2])	der(r[2]) = n[2]*der(s)
der(r[3])	der(r[3]) = n[3]*der(s)
der(r[1])	der(r[1])*n[1]+der(r[2])*n[2]+der(r[3])*n[3]=-s

However, it is not possible to convert the scalarized variables and equations back into array variables and equations. One remedy is to split variable r1 and the first equation in two pieces:

Model 8: Reformulation of **Model 7** in order that array variables and equations can be kept without expansion in the generated code.

```
model ChangedModelThatRequiredScalarization
  parameter Real n1 = 1;
  parameter Real n2[:] = {2,3};
  Real s(start=1, fixed=true);
  Real r1;
  Real r2[size(n2,1)];
equation
    r1 = n1*s;
    r2 = n2*s;
    der(r1)*n1 + der(r2)*n2 = -s;
end ChangedModelThatRequiredScalarization;
```

An assignment is now possible without expanding array variables and equations:

assigned	*highest derivative equations*
der(s)	der(r1) = n1*der(s)
der(r2)	der(r2) = n2*der(s)
der(r1)	der(r1)*n1+der(r2)*n2 = -s

5.3 Mechanical Systems

In the following simple model, a mass is sliding along a given direction in 3D space:

Model 9: 3D sliding mass model that requires scalarization.

```
model SlidingMass3DrequiringScalarization
  parameter Real m=1 "Mass of body";
  parameter Real n[3] = {1,0,1}/sqrt(2) "Sliding direction";
  parameter Real g[3] = {0,0,-9.81} "Gravity acceleration";
  Real r[3] "Position";
  Real v[3] "Velocity";
  Real f[3] "Constraint force of prismatic joint";
  Real s "Generalized coordinate of prismatic joint";
equation
  r = n*s;
  v = der(r);
  m*(der(v)-g) = f;
  0 = n*f;
end SlidingMass3DrequiringScalarization;
```

Modiator prints the following error message:

Translation of SlidingMass3DthatRequiresScalarization failed.

The model cannot be processed without exanding arrays because the following equation with arrays does not have at least one unknown variable that appears linearly in the form scalar*variableSymbol:
0 = n*f

The reason is that the *scalar* equation 0 = n*f contains only *array* variables and therefore none of these variables is structurally assignable.

In (Elmqvist and Otter 2017, section 3), it is shown that array variables and equations of mechanical systems must be at least internally expanded in order that processing is possible. After symbolic processing, it is usually possible to recover the non-expanded forms. Since the algorithm in **Appendix A.1** does not expand array variables and equations, *existing* 3D mechanical models, such as those from the Modelica.Mechanics.MultiBody[8] library, cannot be processed by Modiator. For tree-structured mechanical systems it is easy to fix this issue in the following way:

A tree-structured mechanical system with $\boldsymbol{q}$ the vector of generalized minimal coordinates (= generalized coordinates in the joints) and $\boldsymbol{u}$ the generalized forces (= generalized forces in the joints) is described by the following equation:

$$\boldsymbol{M}(\boldsymbol{q})\ddot{\boldsymbol{q}} + \boldsymbol{h}(\boldsymbol{q}, \dot{\boldsymbol{q}}) = \boldsymbol{u}; \quad \boldsymbol{M} = \boldsymbol{M}^T \geq 0 \qquad (3)$$

In object-oriented modeling, where bodies, joints and other objects can be connected together in a nearly arbitrary fashion, it is easy to define a system where the symmetric mass matrix $\boldsymbol{M}$ is positive semi-definite (that is, it is singular) instead of positive definite as postulated by mechanical principles. Examples:

- A non-zero mass and a *zero inertia-matrix* is defined for a body, and the connection structure allows rotations of the body.

[8] https://doc.modelica.org/Modelica%204.0.0/Resources/helpDymola/Modelica_Mechanics_MultiBody.html

DOI 10.3384/ecp218189

- A chain of mechanical objects ends with a joint and not with a body.
- More as 3 revolute joints are connected directly together, without having a body between the joints.

Let's subtract a small term $\varepsilon_m \ddot{\boldsymbol{q}}$ from the generalized forces $\boldsymbol{u}$, where the scalar $\varepsilon_m \geq 0$:

$$\boldsymbol{M}(\boldsymbol{q})\ddot{\boldsymbol{q}} + \boldsymbol{h}(\boldsymbol{q}, \dot{\boldsymbol{q}}) = \boldsymbol{u} - \varepsilon_m \ddot{\boldsymbol{q}} \quad (4)$$

or

$$\big(\varepsilon_m \boldsymbol{I} + \boldsymbol{M}(\boldsymbol{q})\big)\ddot{\boldsymbol{q}} + \boldsymbol{h}(\boldsymbol{q}, \dot{\boldsymbol{q}}) = \boldsymbol{u} \quad (5)$$

where $\boldsymbol{I}$ is the unit-matrix. The new mass matrix is positive definite (that is, regular) if $\varepsilon_m > 0$. This follows from its positive quadratic form:

$$\boldsymbol{x}^T(\varepsilon_m \boldsymbol{I} + \boldsymbol{M})\boldsymbol{x} = \varepsilon_m \boldsymbol{x}^T\boldsymbol{x} + \boldsymbol{x}^T\boldsymbol{M}\boldsymbol{x} > \boldsymbol{0}, \text{if } |\boldsymbol{x}| > \boldsymbol{0} \quad (6)$$

since $\varepsilon_m \boldsymbol{x}^T\boldsymbol{x} > \boldsymbol{0}$ and $\boldsymbol{x}^T\boldsymbol{M}\boldsymbol{x} \geq \boldsymbol{0}$. Therefore, the mentioned issues can no longer occur if $\varepsilon_m > 0$ and a mechanical model in Modelica becomes more reliable against user errors. Note, the original multibody system is unchanged, if $\varepsilon_m = 0$. Processing with unexpanded arrays becomes possible by adding a corresponding term to the joints of a Modelica model, as shown exemplarily by the following modified version of the sliding mass model:

Model 10: Changed **Model 9** in order that assignment is possible without expanding arrays.

```
model SlidingMass3D
  ...
  parameter Real eps_m(min=0) = 0 "Small mass in joint";
equation
  r = n*s;
  v = der(r);
  f = m*(der(v)-g);
  sd = der(s);
  0 = n*f + eps_m*der(sd); // der(sd) structurally assignable
end SlidingMass3D;
```

The last (scalar) equation is now structurally assignable for the scalar der(sd). With the algorithm of **Appendix A.1** the following assignment can be derived:

assigned	*highest derivative equations*
der(der(r))	der(der(r)) = n* der(der(s))
der(v)	der(v) = der(der(r))
f	f = m*(der(v)-g)
der(der(s))	der(sd) = der(der(s))
der(sd)	0 = n*f + eps_m*der(sd)

When sorting these highest derivative equations, an algebraic loop is identified that corresponds to (5). The equations can be, for example, transformed in the following linear equation in one unknown:

```
input: der(sd)  // tearing variable
output: residue
der(der(s)) := der(sd)
der(der(r)) := n*der(der(s))
der(v) = der(der(r))
f := m*(der(v)-g)
residue := n*f + eps_m*der(sd)
```

Inserting all terms in the last equation and setting residue=0, results in one linear equation with der(sd) as unknown:

```
(eps_m + m*(n*n))*der(sd) = m*(n*g)
```

Note, if arrays are no longer expanded for mechanical systems, the number of modes of *analytically described elastic bodies*, such as *beams* or *plates*, can be changed after translation!

6 Conclusions

The Modelica Web-App Modiator (Elmqvist and Otter, 2025) does not expand arrays of equations, for loops or arrays of components in order to speed up translation and avoid recompilation when array changes are made. The needed restrictions have been described, translation techniques have been outlined, and several presented model examples show the benefits of this new method. As a result, the Modiator Web-App has compilation times independent of array sizes (O(1) instead of O(n) or worse) and arrays can be resized after compilation.

Special emphasis has been put on enabling index reduction without scalarization for models described by array equations. The developed extensions of the Pantelides algorithm are utilized in Modiator and allow index reduction directly on array equations without expanding arrays (also not internally). The algorithm is described and the proofs of its properties are given. The needed changes to the symbolic processing of a Modelica tool are modest and reasonable diagnostics can be given if index reduction and/or assignment fails by pointing to the equations and arrays that need to be changed, in order that processing is possible without expanding array equations and arrays.

The enhanced algorithms presented in the **Appendix**, together with tests for some of the models in this paper, are also provided in Javascript format in file *assign-highest-derivatives-test.html* in the accompanying zip-file. *Dragging this file into a web browser will execute the tests* and display the test results in the web browser window.

Appendix A

In this appendix, the enhancements of standard algorithms are sketched to find a complete assignment (2) for a DAE (1) without expanding array variables and equations.

A.1 Assign Highest Derivatives

Starting point is the algorithm of Pantelides (1988). The modified algorithm is provided in Javascript format (which is nearly the same as C/C++ format here) in the following listing. The yellow parts are deviations from (Pantelides, 1988) and are discussed below:

Listing 1: Function assignHighestDerivatives in Javascript format to determine highest derivative equations that have a complete assignment with respect to *structurally assignable* highest derivative variables. Yellow parts are deviations from (Pantelides, 1988).

```
a1  function assignEquation(i,
                            G,Ga,assign,vColor,eColor,vInspect){
      const Gi = G[i]
      const Gai = Ga[i]
      eColor[i] = true
      for (let j=0; j<Gi.length; j++) {
        const v = Gi[j]
        if(vInspect[v] === -1 && assign[v] === -1 && Gai[j]){
          assign[v] = i;
          return true}}
      for (let j=0; j<Gi.length; j++) {
        const v = Gi[j]
        if (vInspect[v] === -1 && assign[v] > -1 && !vColor[v]
                                                 && Gai[j])  {
          vColor[v] = true
          if (assignEquation(assign[v],
                             G,Ga,assign,vColor,eColor,vInspect)) {
            assign[v] = i;
            return true}}
      }
      return false
    }
a2  export function assignHighestDerivatives(G,Ga,A) {
      let nA  = A.length
      let nB  = G.length
      const assign = Array(nA).fill(-1)
      const B      = Array(nB).fill(-1)
      const eColor = Array(nB)
      const vColor = Array(nA)
a3    function colorEquation(i) {
        eColor[i] = true
        for (const v of G[i]) {
          if (A[v] === -1 && assign[v] > -1 && !vColor[v]
                          && B[assign[v]] === -1) {
            vColor[v] = true
            colorEquation(assign[v])}
        } // end for
      }
a4    const nB_initial = nB
      for (let k = 0; k < nB_initial; k++) {
        let i = k
        while (true) {
          eColor.fill(false)
```

```
    vColor.fill(false)
    if (assignEquation(i,G,Ga,assign,vColor,eColor,A)) break
a5  for (let j=0; j<nB; j++) {
      if (eColor[j] && Ga[j].some(val=>val===false)){
        colorEquation(j)}}}
a6  for (let j=0; j<nB; j++) {
      if (eColor[j]) {
        nB++; B.push(-1); B[j]=nB-1;
        for (const v of G[j]) {
          if (A[v] === -1) {
            nA++; A.push(-1); A[v]=nA-1; assign.push(-1)}}
        G.push( Gj.map(m => A[m]) )
        Ga.push( Ga[j] )}}
    for (let j = 0; j < nA; j++) {
      if (vColor[j]) assign[A[j]] = B[assign[j]]}
a7  i = B[i]
    eColor.length = nB
    vColor.length = nA
  } // end while
a8 } // end for
   return [assign,B]}
```

Utility function assignEquation(i,...), see code block (a1), is basically function AUGMENTPATH of (Pantelides, 1988). The function inspects all variables v of equation i that are *structurally assignable* and have vInspect[v] = -1. It returns true if a v is assigned to equation i and otherwise it returns false. If false is returned, the following property holds:

Theorem 2: *If* assignEquation *returns with* false, *the equations with* eColor[k] = true *are minimally structurally singular with respect to the variables with* vColor[k] = true *(these variables are structurally assignable with respect to the assigned equations).*

Proof: Follows from the proof of Lemma 3.3 of (Pantelides, 1988), with the only difference that a subset of the variables is inspected (variables that are structurally assignable and have vInspect[v] = -1, i.e. are highest derivative variables since A is passed to the function as vInspect). ■

This property means that the colored equations are the smallest subset that need to be differentiated. This subset has more equations than variables and therefore differentiating this subset will introduce more new equations as it will introduce more new variables.

The core function assignHighestDerivatives, see code blocks (a2-a9), inspects all equations in sequence. For every equation, function assignEquation is called with vInspect = A, that is only highest derivative variables are inspected, see last statement in code block (a4). If the function returns true, the next equation is inspected. Otherwise, a while loop iterates over the function call, until an assignment is found. If assignEquation returns false, the colored set of equations needs to be differentiated.

Colored equations that have at least one highest derivative variable that is *not* structurally assignable are inspected by calling the function colorEquation on them, see code blocks (a5,a3). This function colors additional equations that need to be differentiated. Assume for example, that equation j colored by assignEquation has a highest derivative variable v that is not structurally assignable with respect to equation j, is already assigned, is not colored and the equation to which v is assigned is a highest derivative equation. If equation j is differentiated, then v is also differentiated, but without differentiating the highest derivative equation assign[v], because this equation was not colored by assignEquation. The construction of code blocks (a5,a3) ensures, that these assigned equations are also colored and are thus differentiated. Note, this additional equation coloring appears, for example, in **Model 1** from section 3.3.

In code block (a6), the data structures G,Ga,A,B,assign are appended with new entries that include the incidences of the equations and the highest derivative variables that will appear when the equations are differentiated. This part is nearly identical to code block (3b-5) of ALGORITHM 4.1 of (Pantelides, 1988). The essential difference is that in (3b-5) of (Pantelides, 1988) first all colored variables are appended to A before G,B are updated. However, this is not possible here, because a colored equation j may have a variable v that is not structurally assignable and that is not assigned. When differentiating equation j, v is differentiated as well, but the differentiated v may not yet exist because it was not colored. For this reason, A is updated when the incidence of the differentiated equation j is appended to G. The remaining part of the code is identical to ALGORITHM 4.1 of (Pantelides, 1988). Function assignHighestDerivatives returns the newly constructed arrays assign,B via the return statement, and the updated arrays G,Ga,A via the argument list.

A.2 Assign Extended System

Since assignHighestDerivatives has a while loop, the question arises whether this loop will terminate for all inspected equations. In (Pantelides, 1988) an *extended* system $\boldsymbol{EG} = \begin{bmatrix} \boldsymbol{G} \\ \boldsymbol{G}_h \end{bmatrix}$ is analyzed consisting of $\boldsymbol{G}$ and of the incidence matrix $\boldsymbol{G}_h$ of additional equations $0 = h_i(v_i, \dot{v}_i)$ for every variable v_i appearing differentiated. A corresponding matrix $\boldsymbol{EG_a} = \begin{bmatrix} \boldsymbol{G}_a \\ \boldsymbol{G}_{h,a} \end{bmatrix}$ defines whether the elements of $\boldsymbol{EG}$ are structurally assignable or not. Hereby, all elements of $\boldsymbol{G}_{h,a}$ representing the new equations h_i are true.

Theorem 3: *If* $\boldsymbol{G}_a$ *has only true values then the* while *loop in function* assignHighestDerivatives *terminates for all inspected equations after a finite number of iterations if and only if the extended system* $\boldsymbol{EG}$ *is structurally nonsingular. In such a case, the highest derivative equations of* $\boldsymbol{G}$ *have a complete assignment with respect to the highest derivative variables. If* $\boldsymbol{EG}$ *is structurally singular, then the underlying DAE (1) has no solution since it is impossible to find a set of consistent initial conditions.*

Proof: This is Theorem 4.2 of (Pantelides, 1988) formulated with the notation of this paper. ■

Unfortunately, this strong property does no longer hold, if one or more elements of $\boldsymbol{G}_a$ are false, that is, not all variables are structurally assignable. This is demonstrated with the simple example of **Model 7** of section 3.3. A complete assignment of the extended system $\boldsymbol{EG}$ with respect to all structurally assignable variables is possible:

assigned	*equations of extended system*
r	r = n*s
s	der(r)*n = -s
der(r)	0 = h(r, der(r))

Analyzing the equations of **Model 7** with function assignHighestDerivatives results in the following sequence of assignments: Function assignEquation returns false for r = n*s because r is not a highest derivative variable and s is not structurally assignable. Therefore, this equation is differentiated leading to the new highest derivative equations:

assigned	*highest derivative equations*
der(r)	der(r) = n*der(s)
---	der(r)*n = -s

Function assignEquation returns false for der(r)*n = -s because der(r) is not structurally assignable and s is no highest derivative variable. Differentiating this equation and additionally the first equation due to code block (a5), results in the following new highest derivative equations:

assigned	*highest derivative equations*
der(der(r))	der(der(r)) = n*der(der(s))
---	der(der(r))*n = - der(s)

A similar situation as in the previous step occurs: The second equation needs to be differentiated, because der(der(r)) is not structurally assignable and der(s) is no highest derivative variables. Also, the first equation is differentiated due to code block (a5). As a result, an infinite number of differentiations occurs.

If instead, variables r and n are expanded, the highest derivative equations are identified and assigned as shown in section 3.3. As can be seen, it is not possible for this model to have an assignment of structurally assignable variables without expanding array variables and array equations. ■

The consequence is that the number of iterations of the while loop in function assignHighestDerivatives must be explicitly limited and when this limit is reached, the function either returns with an error or the model is processed again with all arrays expanded. Assume that the following assumption holds (which is checked before function assignHighestDerivatives is called):

Assumption 1: *The number of equations e_i of the underlying DAE (1) is identical to the number of highest derivative variables, so variables v_j that have $A_j = -1$.*

then the following theorem states the property of the return result of function *assignHighestDerivative*:

Theorem 4: *The highest derivative equations of $\boldsymbol{G}$ have a complete assignment with respect to their structurally assignable highest derivative variables, if Assumption 1 holds and the while-loop in function assignHighestDerivatives terminates after a finite number of iterations for all inspected equations.*

Proof: If the function returns successfully, then all underlying equations have been inspected once, due to the for-loop of code block (a4). Since every equation gets an assignment for a structurally assignable highest derivative variable that is not yet assigned, due to code block (a1), all equations are assigned for highest derivative variables that are structurally assignable. This assignment does not influence already assigned equations, because otherwise these equations would have been colored and then differentiated together with the not-yet assigned equation and their assigned variables would have been differentiated correspondingly. Due to **Assumption 1**, all highest derivative variables or derivatives of them are assigned because the same number of equations get an assignment. ■

If the *while*-loop does not terminate, then either the DAE (1) has no unique solution, or a complete assignment with respect to *expanded* arrays is possible.

In order that meaningful diagnostics can be given, the following theorem is utilized:

Theorem 5: *If the extended System $\boldsymbol{EG}$ is structurally singular with respect to the structurally assignable variables, the while-loop does not terminate for at least one of the inspected equations.*

Proof: Follows from the proof of Theorem 4.2 in (Pantelides, 1988), Part B until "the algorithm will keep differentiating until infinitum". ■

Note, if the extended System **EG** is structurally singular with respect to the structurally assignable variables, it is still possible that the DAE is solvable if the array variables and array equations are expanded. This can be easily seen from **Model 6** in section 5.1. The extended System **EG**

assigned	*equations of extended system*
y1	y1 = n*time
--	A*y2 = y1

is *structurally singular* with respect to the structurally assignable variables because the first equation can be assigned to y1 and the second equation can be also assigned to y1 but not to y2, because y2 is not structurally assignable according to **Theorem 1**. Therefore, the while loop does not terminate, but this can be detected beforehand. If arrays are expanded, the elements of the second equation can be assigned to the elements of y2 and the extended system is *structurally regular*. ■

DOI 10.3384/ecp218189

Listing 2 shows the code for function assignExtendedSystem that builds and checks the extended system for structurally assignable variables.

Listing 2: Function assignExtendedSystem in Javascript format to determine a complete assignment of the extended system with respect to the *structurally assignable* variables. Yellow parts are deviations from (Pantelides, 1988).

```
b1  export function assignExtendedSystem(G,Ga,A) {
      // Build extended system
      const EG  = [...G]
      const EGa = [...Ga]
      const nA  = A.length
      for (let i=0; i<nA; i++) {
        const Ai = A[i];
        if (A[i] > -1) {
          EG.push([i, A[i]]); // h-equation
          EGa.push([true, true])}
      }
b2    // Assignment of extended system
      const assign   = Array(nA).fill(-1)
      const vColor   = Array(nA)
      const eColor   = Array(EG.length)
      const vInspect = Array(nA).fill(-1)  // inspect all variab.
      const unassignedEquations = []
      for (let i=0; i<nA; i++){
        eColor.fill(false)
        vColor.fill(false)
        if ( !assignEquation(i,EG,EGa,
            assign,vColor,eColor,vInspect) && i<G.length){
          unassignedEquations.push(i)}
      }
b3    // Collect unassigned variables
      const unassignedVariables = []
      for (let j=0; j<assign.length; j++) {
        if (assign[j] === -1) unassignedVariables.push(j)
      }
      return [unassignedEquations, unassignedVariables]
    }
```

In code block (b1) the extended system for G and Ga is constructed. In code block (b2), function assignEquation is called for all equations of the extended system and for *all* of its variables (due to vInspect = Array(nA).fill(-1)). If assignEquation returns false, and the inspected equation is no h-equation, it is pushed on stack unassignedEquations. (beause h-equations should not be reported to the user and if a h-equation is not assigned, there is also an unassigned variable). In code block (b3) the unassigned variables are collected in stack unassignedVariables. Both stacks are returned. If one of them is not empty, the complete assignment of the extended system failed and the unassigned equations and unassigned variables are returned and reported to the user.

The practical application of the theorems requires additionally the following small extension:

Function assignHighestDerivatives(G, Ga, A, maxDer =-1) gets an additional optional argument that defines the maximum number of allowed differentiations for an equation (if maxDer =-1, the number of differentiations is not limited) . If this limit is reached, the function terminates. It returns [assign,B,eqDiffTooMuch]. If the maximum number of differentiations is reached, eqDiffTooMuch is the equation of the underlying DAE that was differentiated too often. This equation can be reported in the error message.

A.3 Improved Error Diagnostics

The information for the error messages presented in section 3.4, is deduced from assignExtendedSystem(…) of **Listing 2** by extending this function a bit:

- The function already collects all unassigned variables. For every unassigned variable, all equations are inspected where this variable appears and then these equations are printed together with their assignments.
- The function also collects all unassigned equations which is not very useful. Instead, when no assignment can be found, *all colored equations* are collected together because they constitute the set of equations that, together with the unassigned equation, creates an overdetermined system. This combined set is stored. If more overdetermined sets of equations appear, only the one with the smallest number of equations is kept.

A.4 Further Symbolic Processing

A tool could call the presented functions in the following order:

1. Call assignExtendedSystem. If the function returns with unassigned equations and/or unassigned variables either print an error message showing the unassigned equations/variables ("*Either DAE is not solvable or processing not possible without expanding arrays, which is not supported*") or expand all arrays and equations and perform the standard processing of the tool for expanded equations/arrays.
2. If assignExtendedSystem returns successfully, call assignHighestDerivatives. If the function terminates because the maximum number of differentiations reached, either print an error message showing the equation that was differentiated too often ("*Equation eqDiffTooMuch differentiated until the limit of maxDer differentiations reached. Either DAE is not solvable or processing is not possible without expanding arrays, which is not supported.*") or expand all arrays and equations and perform the standard processing of the tool for expanded equations/arrays.
3. If assignHighestDerivatives returns successfully, a full assignment of the highest derivative equations with respect to the structurally assignable highest derivative variables was found and standard processing continues with only symbol information (so with unexpanded equations/arrays).

After the complete assignment of the highest derivative equations with respect to the structurally assignable highest derivative variables is determined with function

assignHighestDerivatives the standard approach of object-oriented modeling can be used for further processing and code generation by using basically only the symbol information (without expanding arrays):

1. *Analytically differentiating the equations*
   The equations are analytically differentiated based on the information provided in $\boldsymbol{G}, \boldsymbol{A}, \boldsymbol{B}, \boldsymbol{assign}$.
2. *Equation sorting*
   $\boldsymbol{G}$ and ***assign*** of the highest derivative variables $\boldsymbol{A}$ with $A_k = -1$ define a directed graph where the nodes are the highest derivative equations together with the assigned highest derivative variables. The edges are defined by the rows of the incidence matrix $\boldsymbol{G}$ that correspond to the highest derivative equations. With the algorithm of (Tarjan, 1972) the strong components (algebraic loops) in the directed graph are determined and the equations are sorted.
3. *State selection*
   From the sorted highest derivative equations, the constraint equations are determined by the algorithm of (Mattsson and Söderlind, 1993) based on the highest derivative equation systems determined in step 2. From this information states are statically and/or dynamically selected.
4. *Code generation*
   Code is generated. Arrays with small, fixed dimensions and corresponding array equations with small, fixed dimensions might be expanded. If arrays are kept unexpanded, then the generated code must support array operations where dimension sizes might be only known at run-time and can be changed after translation to object code. Typically, Modelica tools support this already, because code generation for Modelica functions need a similar infrastructure to operate on arrays.

Constant Time Causalization using Resizable Arrays

Karim Abdelhak[1] Bernhard Bachmann[1]

[1]Institute for Data Science Solutions, Bielefeld University of Applied Sciences and Arts, Germany,
{karim.abdelhak, bernhard.bachmann}@hsbi.de

Abstract

Equation-based modeling that utilizes reusable components to represent real-world systems can result in excessively large models. This, in turn, significantly increases compilation time and code size, even when employing state-of-the-art scalarization and causalization techniques. This paper presents an algorithm that leverages repeating patterns and uniform causalization to enable array-size-independent constant time processing. Allowing structural parameters that govern array sizes to remain resizable during and after the causalization process enables the formulation of an integer-valued nonlinear optimization problem. This approach identifies the minimal model configuration that preserves the required structural integrity, which can subsequently be resized as needed for simulation. The proposed method has been implemented in OpenModelica and builds upon preliminary work aimed at preserving array structures during causalization, while still resolving the underlying problem in a scalarized manner.

Keywords: Equation-based modelling, Array-preserving, Causalization, Resizable, Nonlinear programming, Integer programming

1 Introduction

Current state-of-the-art approaches for compiling large-scale models with scalable structures typically rely on full scalarization. Although this method yields correct results, it often incurs substantial compilation times and leads to significantly larger code sizes. *OpenModelica*'s (Fritzson, Pop, Abdelhak, et al. 2020) pseudo-array compilation algorithm (Abdelhak, Casella, and Bachmann 2023) addresses the challenges of large code sizes and prolonged compilation times by enabling array-size-independent symbolic manipulation, while still performing causalization on scalarized graphs. Building on this foundation, this paper presents an algorithm that systematically reduces scalable structures to a theoretical minimal form, allowing causalization to be performed efficiently. Following compilation, the resulting model can be resized to any desired scale suitable for simulation.

Thematically related research exploring the exploitation of resizable array structures includes the work presented in (Neumayr and Otter 2023), which introduces predefined acausal components as a means of enabling flexible array configurations. Additionally, an alternative to the pseudo-array compilation algorithm has been proposed in (Marzorati, Fernández, and Kofman 2024), where a set-based graph approach is employed. This method is inherently designed to operate independently of array sizes, representing a structurally distinct approach to addressing the challenges associated with scalable model compilation. Although the paper does not explicitly address the resizability of set-based nodes within the set-based graph, the algorithms presented in this paper for determining the general resizability of for-loop equations should be equally applicable, given that the underlying model remains unchanged.

1.1 Resizable Parameters

First and foremost, structural parameters that determine the array sizes within a model must be preserved and not evaluated throughout the flattening process. These parameters are *resizable* but will be simply referred to as *parameters* in all subsequent discussions. While the concept of minimizing model size may appear to align directly with minimizing the values of these parameters, such a correlation is not guaranteed. The modeling language *Modelica* permits array sizes to be defined by any expression that yields a non-negative integer (Modelica Association 2023). As a result, the relationship between parameter values and overall model size can even be nonlinearly correlated. Additionally, a single parameter may influence multiple array sizes, and conversely, multiple parameters may contribute to determining a single array size. *OpenModelica* offers two different ways to indicate that a parameter is *resizable*, which will be described in detail in Section 3.3.

1.2 Resizable Equations

Any equation whose size is determined by a resizable parameter is itself considered resizable. In the modeling language *Modelica*, there are two primary constructs for expressing such equations: *array equations* and *for-equations*. While array equations are a conventional method for representing multidimensional relationships, the latter are more specific to Modelica. For-equations employ a surrounding for-loop construct—similar to those used in algorithmic programming—to define a set of structurally similar relationships using array variables indexed by one or more iterator variables.

The primary advantage of identifying resizable equations lies in the ability to reduce their size as much as pos-

sible during the process of causalization. This enables the transformation of the flattened model into target code to be performed independently of the resizable array sizes defined within the model. It is important to note that in order to keep the system structure parameters and equations must satisfy specific conditions and cannot be resized arbitrarily.

Assumption 1 *The following discussion operates under the assumption that the model remains balanced for every feasible combination of parameter values. In other words, each parameter is assumed to influence variable dimensions and corresponding equation sizes in a consistent manner.*

Example 1 *As an example of an invalid resizable parameter, consider the following model. While the original definition with $p = 2$ yields a balanced and valid model, any other value of p results in an invalid configuration.*

```
model invalid_resizable
  parameter Integer p = 2;
  Real[p*p] x
equation
  for i in 1:2*p loop
    x[i] = sin(time) * i;
  end for;
end invalid_resizable;
```

2 The Optimization Problem

The primary objective of the optimization is to minimize the overall model size. Owing to Assumption 1, this objective can be simplified to minimizing either the total number of variables or equations, as their sizes are assumed to be proportionally aligned. In the following, the optimization problem is formulated with a focus on minimizing the sizes of the equations. As will be demonstrated in the following sections, the decision variables are integer-valued, and the objective function is inherently nonlinear. The constraint set includes both inequalities and equalities, which—although infrequently—may also exhibit nonlinear characteristics.

2.1 Objective Function

Let $x \in \mathbb{Z}^n$ denote the vector of decision variables representing resizable parameters. The goal is to determine the values of x that minimize the total number of equations, subject to structural and semantic constraints.

$$\arg\min_{x} \quad F(x) = \sum_{k} f_k(x) \tag{1}$$

where $F(x)$ is the total model size and f_k being the local size objectives of equation k as product of their dimension objective functions:

$$f_k(x) = \prod_{j} d_j^k(x) \tag{2}$$

The dimension objective function evaluates whether the j-th dimension D satisfies condition (a_j), namely, that it is defined by an iterator within a for-loop whose range $D_{\text{start}} : D_{\text{step}} : D_{\text{stop}}$ is governed by one or more resizable parameters. If (a_j) holds, the objective is set to the number of elements traversed by the iterator. Otherwise, if the size is not explicitly defined by an iterator, the equation must be an array-based equation whose dimensions can be inferred from the array variables it contains. This inference is performed by the function $\dim_j^k(x)$ which may either yield a constant size or, in the case of parameterized array equations, represent a function dependent on one or more resizable parameters.

$$d_j^k(x) = \begin{cases} (D_{\text{stop}}(x) - D_{\text{start}}(x))/D_{\text{step}} + 1 & \text{if } (a_j) \\ \dim_j^k(x) & \text{else} \end{cases} \tag{3}$$

2.2 Constraints

This optimization problem is subject to several constraints, which can be classified into three main categories:

equation dimension constraints. The first set of constraints arises from the requirement that each resizable equation must have a size of at least one to ensure its representation in the underlying bipartite graph. Consequently, each dimension associated with an equation must be of minimum size one. For every iterator i with a range defined as $D^i_{\text{start}} : D^i_{\text{step}} : D^i_{\text{stop}}$, this requirement can be expressed through the following constraint:

$$0 \leq (D^i_{\text{stop}}(x) - D^i_{\text{start}}(x))/D^i_{\text{step}} \tag{g_1}$$

Furthermore, the same condition must hold for each j-th dimension of the k-th array equation that depends on resizable parameters imposing the following constraint:

$$1 \leq \dim_j^k(x) \tag{g_2}$$

structural variable constraints. For each resizable parameter $x_p \in x$ the minimum and maximum value constraints (if given by the underlying model) have to be taken into account:

$$x_p \geq x_p^{\min} \tag{g_3}$$
$$x_p \leq x_p^{\max} \tag{g_4}$$

In addition to being box-constrained by their minimum and maximum values, parameters may also impose mutual restrictions. When a resizable variable is indexed using a resizable parameter, it is essential to ensure that this indexing operation does not result in an out-of-range access.

Example 2 *Let y be a resizable variable whose size is determined by the parameter x_1. Additionally, consider a component reference to y in the model as*

DOI 10.3384/ecp218203

$y[x_2]$, where x_2 is another parameter. This imposes a constraint on x_2, requiring that $x_2 \leq x_1$ to prevent out-of-range access.

The same logic applies to non-parameter indexed variables, constant valued restrictions have to be collected as well. For each component reference that references a resizable variable in the model, each dimension has to be checked if it imposes a constraint.

$$\text{sub}_c^j(x) \leq \text{cdim}_c^j(x) \qquad (g_5)$$

where c refers to c-th component reference and j to the j-th dimension $\text{cdim}_c^j(x)$ with $\text{sub}_c^j(x)$ being the subscript of c in dimension j. If a constraint does not involve any parameters or if the parameters cancel out, its validity must be verified. If the constraint is valid, it can be safely omitted; otherwise, an error should be raised, as this indicates an issue with the underlying model.

structural equation constraints. The final set of constraints is derived from array equations and, in contrast to the previous inequality constraints, consists of equality constraints. For each array equation k, the j-th dimension on the left-hand side, represented by the function $\text{lhs}_j^k(x)$, must be equal to the corresponding right-hand side dimension rhs_j^k. This ensures consistency between both sides of the equation and results in the following equality constraint:

$$\text{lhs}_j^k(x) = \text{rhs}_j^k(x) \qquad (h)$$

3 Solving the Problem

Solving the general integer-valued nonlinear optimization problem is known to be NP-hard (Kannan and Monma 1981). However, for the majority of practical models, the problem structure is predominantly linear and can be efficiently addressed under typical conditions. Moreover, obtaining the global optimum is not strictly necessary. Any method that consistently yields a feasible, finite solution—while maintaining computational complexity independent of the values of resizable parameters—successfully achieves the objective of array-size-independent compilation time. For the results presented in Section 4, a simple greedy hill-climbing algorithm was implemented as a proof of concept, using the original model-defining parameter configuration as the initial starting point.

3.1 Utilization of Optimization Results

Once a feasible parameter configuration has been identified—yielding a sufficiently small, array-size-independent model—all affected model sizes must be updated accordingly. In addition, auxiliary structures must be generated and stored to enable recovery of the original array sizes. The bipartite graph used for equation-variable matching, as well as the directed graph used for equation sorting, are both constructed based on these reduced model sizes. This results in a causalization problem that is independent of array sizes. After the causalization is completed, the original array structures are reconstructed using the three-step sorting procedure described in (Abdelhak, Casella, and Bachmann 2023). Notably, the third sorting step differs for resizable equations, as these do not require resolution through the underlying graph. Instead, it is sufficient to analyze the indexed variables they contain and their usage patterns.

resizable array-equation If a resizable array equation is solved for the same variable instance in each of its scalar sub-equations, it poses no additional challenge, as the equation body can be resolved using established techniques. However, when explicit solving is not possible, or when different variable instances are involved, the equation should be reformulated in residual form and handled implicitly during simulation.

resizable for-equation Let $0 = f(X,Y,I)$ denote the for-equation expressed in residual form, where $\hat{x} \in X$ is the component reference to be solved for, and X is the set of all component references corresponding to the same variable x as $\hat{x}$. The set Y contains all other component references appearing in the equation, and I represents the set of for-equation iterators along with their respective ranges. To determine the execution order of the individual scalar sub-equations within f, one examines the elements of X and compares their positions relative to $\hat{x}$, using the indexing information provided by I. The component references in Y do not influence the execution order and can therefore be disregarded for this purpose. If multiple variable instances are intended to be solved, the current implementation does not support retaining the equation in resizable form (see Section 3.2). The complete method is presented in Algorithm 1, which determines the execution order for each iterator. The execution order for a given iterator can fall into one of three categories:

a) in the original order (forwards)
b) reverse to the original order (backwards)
c) in any order (arbitrary)

Once determined, the inner equations do not need to be sorted based on the underlying scalar dependency graph, as their execution order is fully defined by the enclosing structure. As shown in Algorithm 1, the algorithm may revert the resizable status of variables used to determine the size of the observed equation. In such cases, this behavior must either be reported to the modeler via an error message—aborting compilation to allow for appropriate model adaptation—or issued as a warning, allowing compilation

Algorithm 1 Execution Order

Input: component reference to solve for $\hat{x}$
Input: set of component reference of the same variable X
Input/Output: set of iterators, their ranges and markings I
if there is only one component reference $X = \{\hat{x}\}$ **then**
    Mark all iterators in I with **arbitrary**
else
    for each dimension d in x **do**
        Find the set O of all subscripts in dimension d for all elements of X
        Let I be the set of all iterators occuring in O
        if there is only one iterator $I = \{i\}$ **then**
            compute the set of partial derivatives $D \leftarrow \{\delta o/\delta i | o \in O\}$
            if $|D| = 1$ **then**
                compute the set of all offsets F for the elements of O
                let $\hat{f} \in F$ be the offset for the occurence of $\hat{x}$
                if $\hat{f} \leq f \; \forall f \in F$ and i is not marked **forwards then**
                    Mark i with **backwards**
                else if $\hat{f} \geq f \; \forall f \in F$ and i is not marked **backwards then**
                    Mark i with **forwards**
                else
                    Mark i with **arbitrary**
            else
                The equation is not resizable
                return
        else
            The equation is not resizable
            return

to proceed. In the latter case, the resizable status of the affected variables is reverted, the modified optimization problem is resolved, and the causalization pipeline is subsequently executed again.

Example 3 *In the trivial case where a for-equation is solved for a variable and no other instances of that variable appear within the equation, the execution order is arbitrary. The following example illustrates a non-trivial case involving two possible scenarios. The equation may be solved either for $x[i]$ or for $x[i+1]$:*

```
for i in 1:p loop
  x[i+1] = x[i]*2;
end for;
```

If $\hat{x} \equiv x[i+1]$, the structure of the equation body remains unchanged after solving, and the iterator i can be traversed in its original forward order, since each computed element depends only on a previously computed one. Conversely, if $\hat{x} \equiv x[i]$, the iterator range must be traversed in reverse order, as each element otherwise would depend on a value that is computed in a later iteration.

Expanding the idea by adding a third indexed instance of x leads to following examplary for-equation:

```
for i in 1:p loop
  x[i] = x[i+1]*2 + x[i+2]*3;
end for;
```

If $\hat{x} \equiv x[i+2]$, the execution order is forward, and if $\hat{x} \equiv x[i]$, it is backward—consistent with the behavior described previously. However, if $\hat{x} \equiv x[i+1]$, the computation would depend on both a preceding and a subsequent value, resulting in an algebraic loop. In such cases, since residual equations in an implicit system do not require a specific execution order, the iterator traversal is considered arbitrary.

3.2 Limitations and Future Work

Although this approach is designed to be broadly applicable to general *Modelica* models, certain limitations in its current implementation remain, warranting further investigation and development.

connect equations The modeling language *Modelica* allows the construction of complex models through hierarchical composition, using sub-components interconnected via specialized connectors. These connectors implicitly define a set of equations that are incorporated into the model during the flattening process, which transforms the component-based structure into a single mathematical representation suitable for symbolic manipulation and simulation. A

DOI 10.3384/ecp218203

graph-based algorithm has been developed to determine these connection equations. As with other *Modelica* equations, connect-equations can be enclosed within for-equation constructs, potentially depending on resizable parameters. To enable array-size-independent compilation of such models using the optimization approach presented in this paper, the graph-based connection algorithm must be extended to handle undetermined array sizes during compilation.

split equations If a multi-dimensional equation must be solved for multiple distinct variable instances, it is partitioned into several slices, with each slice being solved for one of the targeted variables. The current implementation of the optimization does not guarantee that the original equation is of sufficient size to ensure that all resulting slices are fully represented in the minimal version of the model. In principle, additional constraints could be incorporated into the optimization problem to guarantee slice-safety; however, doing so would likely require a comprehensive prior analysis to anticipate all potential slicing operations.

entwined equations The concept of entwined equations refers to the evaluation of two or more, potentially multi-dimensional, equations in an alternating sequence (as detailed in (Abdelhak, Casella, and Bachmann 2023)). While, in principle, it is feasible for one or more of these equations to be resizable, the current implementation requires structural enhancements to support the generation of correct and efficient code.

non-trivial index accessing The proposed method supports only linear index access, requiring a consistent multiplicative factor for all accesses to solved variables and their occurrences within resizable equations. This constraint is necessary to ensure a clear and strict dependency structure, which is essential for classification into one of the defined execution order categories. While the algorithm could be extended to handle certain fringe cases, such enhancements are generally unnecessary, as the majority of practical *Modelica* models do not demand a more comprehensive approach.

3.3 Implementation in OpenModelica

As previously mentioned, the proposed approach has been integrated into the OpenModelica compiler and can be activated using the `--newBackend` compiler flag. Resizable array-defining parameters can be specified individually by applying the annotation
`__OpenModelica_resizable=true`.
Alternatively, all array-defining parameters can be treated as resizable by enabling the `--resizableArrays` compiler flag.

4 Results

All experiments were conducted on a laptop with a 12th Gen Intel® Core™ i7-12800H x 20 @ 4.80GHz, 31 GB RAM and a 1TB NVMe SSD, running Ubuntu 20.04.6 LTS. The evaluation was conducted using OpenModelica version 1.24.5-dev, compiled from source.
The `--newBackend` and `--resizableArrays` compiler flags were enabled for the relevant tests.

The presented proof-of-concept implementation was evaluated on several scalable models and consistently produced satisfactory results. The model illustrated in Figure 1, originally developed by Martin Otter, is a simplified variant of the model presented in (Neumayr and Otter 2023). It represents an insulated rod discretized into an array of segments, with the level of discretization controlled by a single parameter, nT, which can be designated as resizable. Specifically, nT determines the sizes of the variables T and Q_{flow}, and also defines the bounds for two for-equations, with iterators i in $2 : nT$ and i in $1 : nT$, respectively. As illustrated, Assumption 1 holds, since the resizable parameter nT uniformly influences both variable and equation sizes. The objective function can be derived from Equations 1, 2, and 3, based on the two iterators that define the sizes of the corresponding for-equations. The sizes of all other equations are omitted from the formulation, as they remain constant.

$$\underset{nT}{\arg\min} \quad F(nT) = 2 \cdot nT - 1 \tag{4}$$

The equations and variables impose a variety of constraints on the optimization problem, the majority of which can be omitted due to being trivially satisfied. However, they are presented in the following as illustrative examples of the method. The resizable parameter nT is restricted by a minimal size, therefore a constraint g_3 can be formulated:

$$nT \geq 1 \tag{5}$$

which is not the only variable constraint in this model. The equation

```
port_a.Q_flow = 2*k1*(port_a.T-T[1]);
```

does not pose a restriction itself, but the indexed variable $T[1]$ results in a constraint g_5:

$$1 \leq nT \tag{6}$$

The same holds for all remaining equations, which involve indexed variables but can be evaluated as trivially satisfied. As such, they do not provide additional illustrative value for the purposes of this example. Each of the two for-equations introduces one constraint, both derived from Equation g_1:

$$0 \leq nT - 2 \tag{7}$$

$$0 \leq nT - 1 \tag{8}$$

(a) Linear Comparison

(b) Logarithmic Comparison

Figure 2. Comparison of causalization times across three configurations: the old backend, the new backend, and the new backend with support for resizable variables. Nodes marked with a strikethrough indicate that causalization was successfully performed and timed; however, subsequent model building or simulation failed.

DOI 10.3384/ecp218203

Since the model does not contain any array equations, no constraints of the form described in Equation h are present. After omitting all trivially satisfied conditions, the resulting optimization problem can be formulated as follows:

$$\arg\min_{nT} \quad F(nT) = 2 \cdot nT - 1 \tag{9}$$

$$0 \leq nT - 2 \tag{10}$$

The minimal solution to this optimization problem, $nT = 2$, is straightforward to derive and is effectively identified and applied by the *OpenModelica* implementation.

The model presented in Figure 1 has been compiled using different versions of *OpenModelica* to highlight the improvements introduced by the research in this paper. Three configurations are compared: the old backend, the new backend, and the new backend with support for resizable variables. The results of this comparison are presented in Figures 2a and 2b. Figure 2a illustrates the impact of the new backend implementation on causalization time using a linear scale, showing an improvement by a factor of nearly three. Additionally, the updated backend enabled the compilation of larger models, overcoming the scalability limitations of the old backend, which failed to generate code for large models due to memory exhaustion (indicated by 'x' markers in the plots).

While these improvements appear significant, a logarithmic comparison (Figure 2b) reveals that scalability challenges persist: causalization time still increases with array size, despite the reduction of overhead[1]. However, with the introduction of resizable variable support, a fully array-size independent causalization process was achieved, as demonstrated in Figure 2b.

5 Conclusions

This work presents an extension to the OpenModelica compiler backend, introducing enhanced support for resizable equations and improving causalization performance for complex array-based models by ensuring that compilation time no longer depends on array sizes. This is accomplished by formulating and solving an integer-based nonlinear optimization problem to determine the minimal feasible model size, which is then treated as resizable prior to simulation, allowing the final model to adapt to arbitrary sizes before runtime.

The method has four key limitations: first, the graph-based connection algorithm needs extension to handle undetermined array sizes during flattening. Second, the optimization may not fully represent all slices when partitioning multi-dimensional equations, requiring additional constraints. Third, entwined equations need structural improvements for efficient code generation. Finally, the method currently supports only linear index access, which is sufficient for most practical *Modelica* models but could be extended for more complex patterns. Despite these, the current implementation is robust enough for most feasible *Modelica* models.

Although the presented algorithm remains in a proof-of-concept stage—with potential improvements in the choice of optimization strategy and possible relaxation of the underlying problem formulation—the results obtained are highly promising. The algorithm has been evaluated on a wide variety of representative Modelica models, including both synthetic benchmarks and simplified real-world industrial examples. In the case of synthetic benchmarks, full resizability was assumed to stress-test the algorithm's capabilities, while for real-world industrial models, only selected array sizes were treated as resizable to reflect practical usage scenarios.

The development of the new OpenModelica backend has led to substantial performance enhancements. Experimental evaluations demonstrate an almost threefold reduction in causalization time, alongside improved scalability that enables the successful compilation of significantly larger models. The principal contribution of this work, however, lies in the introduction of an optimization-based approach for handling resizable variables. This method effectively decouples compilation time from array sizes, yielding additional performance benefits and paving the way for more efficient large-scale model compilation.

In summary, the integration of resizable variable support marks a significant step forward in improving both the robustness and efficiency of the OpenModelica compilation pipeline. Future work may explore more generalized access patterns, improved diagnostic capabilities, and broader support for dynamic model structures.

Acknowledgements

This work was conducted as part of the OpenSCALING project (Grant No. 01IS23062E) at the University of Applied Sciences and Arts Bielefeld, in collaboration with Linköping University. The authors would like to express their sincere appreciation to both the OpenSCALING project and the Open Source Modelica Consortium (OSMC) for their support, collaboration, and shared commitment to advancing open-source modeling and simulation technologies.

Abstract

The Modelica language (www.modelica.org) has become a de facto standard for systems modeling and many tools exist. This paper describes certain modern enhancements and a static web app implementation called *Modiator (Modelica Instant Simulator)*. It allows an improved immediate first-time user experience since the web app is available in seconds and simulations can be done directly in the browser. State of the art numerical solvers from the Sundials suite have been compiled into WebAssembly. The Modelica model is translated into Javascript code using techniques such as sorting, tearing, index reduction, state selection, etc. A subset of Modelica is supported with some extensions, for example, support for self-modifying models. This paper also presents the Stream and Model3D prototype libraries.

Keywords: Modelica, Modia, Modia3D, compilation, web app, WebAssembly, simulation in the browser, cloud computing, serverless functions, Monte Carlo simulation

1 Introduction

The Modelica language (Modelica Association 2023) makes it easy to build large, complex models since instantiation of reusable component models is possible. However, current tools[1] usually make full expansion of the equation sets including scalarization of arrays for all instances and transform the equations to C-Code that is compiled and linked. This means that translation time can be minutes. There is also a need for self-modifying models for example to support adaptable grid for finite volume models, variable model structures such as multi-stage rockets or just turning on and off subsystems. This means that separate translation would be beneficial, i.e. only translating the parts of the model that has been changed. This will also speed up experiments involving variant selection by simulation when certain subsystems are redeclared to analyze alternative designs.

Web technology allows an improved immediate first-time user experience since the web app needs no installation (and also no administrator rights), is available in seconds and faster separate translation and simulations done directly in the browser means less waiting. This will also make object-oriented modeling and simulation more accessible to students, hopefully increasing the popularity of Modelica.

Mobile phones are becoming more popular than computers and they have sufficient computing power for simulation. The drawback of mobile phones is the limited screen size (except for foldable phones). One possible solution is to use an *infinite canvas* and convenient and fast zooming, scrolling, and panning.

For multi-simulations for variant selection or Monte Carlo simulations, cloud should be possible to utilize, for example by serverless lambda functions, and there are needs to visualize results in different ways than just trend plots, such as scatter diagrams and histograms.

Many of the innovations and findings in this paper regarding translating models come from the experiences from the Modia project[2], see, e.g., (Elmqvist et al. 2021). Modia is a language with many similarities to Modelica. However, the language is much simpler than the Modelica language, and implementation of the Modia environment is based on Julia[3] (Bezanson et al. 2017). The effort is now moved from the Modia language to the Modelica language for three reasons: (1) It takes too long to get the first plot when using Modia (installing Julia and many used packages, as well as compiling generated Julia model code the first time). (2) There are many existing Modelica model libraries in wide-spread use and it is too much effort to develop and maintain a thorough translator from Modelica to Modia. (3) New technologies with WebAssembly [4] and fast just-in-time compilation of Javascript enables immediate and fast simulations.

The paper introduces *Modiator (Modelica Instant Simulator)*, a static web-app implemented with Javascript and WebAssembly providing support for a sub-set of the Modelica language with some extensions of Modelica based on experience with Modia/Julia and taking advantage of modern web technology.

The commercial Modelica environment *Modelon Impact*[5] *(Elmqvist et al. 2018)* also provides a browser GUI. However, compilation and simulation of models are not performed in the browser but via a cloud service that has to be paid for. The default behavior of Modiator is that models are compiled and simulated locally in the browser.

[1] https://modelica.org/tools/
[2] https://github.com/ModiaSim/Modia.jl
[3] https://julialang.org/
[4] https://webassembly.org/
[5] https://modelon.com/modelon-impact/

This requires different techniques, e.g., to generate model code directly in Javascript, instead of in C or C++ (as done by other Modelica tools).

Compiling and simulating a Modelica model in a web browser has been proposed by (Franke 2014) and demonstrated with a tiny, very partial prototype. (Short 2014) demonstrates a tool chain to translate Modelica models to Javascript based on the OpenModelica [6] compiler and Emscripten[7] and run the Javascript code locally in the browser. (Kulhánek et al. 2023) provide the Bodylight.js 2.0 toolchain to build in-browser web simulators by translating a Modelica model into an FMU[8] (Functional Mockup Unit), use Emscripten to transform the C-source code inside the FMU into WebAssembly format and embed this code in a web page with a specific user-friendly GUI for this particular Modelica model.

2 A Modernized Modelica Syntax

There are trends concerning the syntax of new programming languages (e.g. C#, Go, Julia, Python, Swift) which have been adopted by Modia. The following proposals for the Modelica language are inspired by Modia, based on these new trends:

- Using Greek letters in identifiers is natural for users making mathematical models.
- Semicolon is becoming optional which makes models easier to read. Traditionally, semicolons were used to enable resynchronization after the first error in order to continue parsing. The speed of parsing is now much faster, so it is better to abort after the first error is found.
- Type and unit inference and checking can be introduced if a notation is utilized to associate units to numeric literals. In the example below, units are appended to parameters and start values enclosed in single quotes. Most type specifiers are omitted since all parameters are Real and the states must be Real.
- The class identifier after end is made optional.

Below is shown a second order model utilizing the simplified, more readable syntax in Modiator:

Listing 1. Modelica model with the proposed condensed syntax and Greek identifiers.

```
model SecondOrder
  τ = 1.0 's'  // instead of: parameter Real tau(unit="s") = 1.0;
  ζ = 0.5
  input u
  x1(start=0)
  x2(start=0 '1/s')   // instead of: Real x2(start=0, unit="1/s");
  output y=x1
equation
  der(x1) = x2
  τ*τ*der(x2) + 2*ζ*τ*x2 + x1 = u
end   // instead of: end SecondOrder;
```

3 Self-Modifying Models

A much-wanted Modelica feature is to be able to change array dimensions without recompiling when, for example, higher fidelity of discretization is needed. Other needs are to be able to redeclare component classes or start and stop subsystems. These scenarios can be achieved by scripting repeated simulations where the start value for the next simulation is set to the end value of the previous simulation. At certain conditions, parameters can be changed, redeclarations made and some transformation algorithm is applied between final state and new state. Writing such scripts is not object oriented though. To make it reusable, the transformations should be made in the model classes.

A similar situation exists when updating HTML pages. The HTML DOM (Document Object Model) is a tree of various kinds of nodes which can be modified by Javascript functions which are called when different kinds of events occur. The DOM tree can also be traversed and a node id can be search for. Nodes can then be modified either by changing attributes or making a new subtree by providing an *innerText* definition. Nodes can also be added or removed by built-in JavaScript function calls.

The ModelManagement.Structure.AST functions of Dymola[9] can manipulate the AST (Abstract Syntax Tree) from Modelica scripts (not from Modelica models). This functionality can serve as inspiration for models manipulating themselves.

For this feature, Modelica needs to have an event detection mechanism (c.f. addEventListener in HTML). Modelica already has a when-statement which can be generalized. The model below shows some of the functions which can be used to manipulate the **ast** (reserved Modiator identifier for the Abstract Syntax Tree) of a model.

Listing 2. Model that modifies its definition during simulation.

```
model TestSelfModifications
  parameter Real T=1;
  Real x(start=0);
equation
  T*der(x) + x = 1;
  when x>0.3 then
    ast.setParameter('T', 0.1);
  end when;
  when time>0.5 then
    ast.setStart('x', 2);
  end when;
  when time>0.7 then
    ast.addEquation('0.1*der(y) + y = 1');
  end when;
end TestSelfModifications;
```

If a significant event occurs, the modified model ast is translated to Javascript code which is just-in-time compiled before the simulation continues.

[8] https://fmi-standard.org/
[9] https://www.3ds.com/products/catia/dymola

DOI 10.3384/ecp218211

The semantics of the above function calls are explained by the plot below.

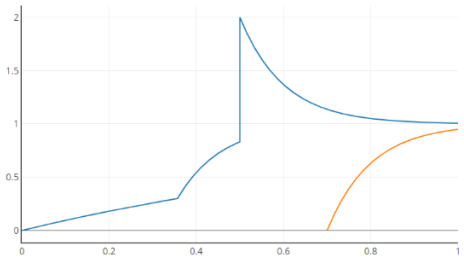

Figure 1. Plot of model TestSelfModifications

Note, that when the equation was added, also a new variable was introduced, y. By default, all state variables are currently plotted, i.e. y was also plotted during its existence. Adopted from Modia, Modiator does not require declaration of variables and the start value is 0 by default.

Array dimensions and the number of states can also be changed at events which is illustrated by the following model:

Listing 3. Model that modifies array dimensions and number of states during simulation.

```
model VaryingDimensions
   Integer n=2;
   Real x(start=1:n, fixed=true);
equation
   der(x) = -diagonal(1:n)*x;
   when time > 0.1 then
      ast.setParameter('n', 3);
      ast.setStart('x[3]', (x[1]+x[2])/2);
   end when;
   when time > 0.2 then
      ast.setParameter('n', 2);
      ast.setStart('x[1]', (x[1]+x[3])/2);
      ast.setStart('x[2]', (x[2]+x[3])/2);
   end when;
end VaryingDimensions;
```

Note, the new start values defined with ast.setStart(…) are calculated before the model is evaluated at the event. This gives a nice mechanism for transferring the state information to a new state representation. See the results below.

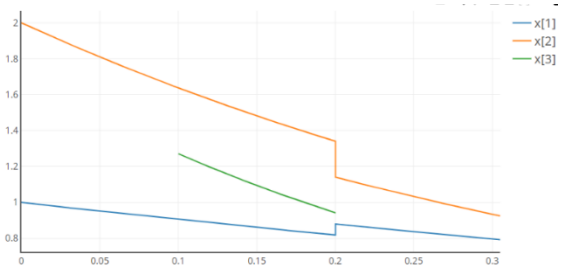

Figure 2. Plot of model VaryingDimensions.

In the companion paper on resizable arrays (Otter et al. 2025), this technique is used for adaptive grid modeling of an insulated rod.

4 Web App for Immediate Results

Web technology allows an immediate first-time user experience since a web app is available in seconds and simulations can be done directly in the browser.

Mobile phones are becoming more popular and powerful than laptop computers and they have sufficient computing power for simulation. The drawback is the limited screen size. One possible solution is to use an *infinite canvas* (inspired by Apple Photos) and convenient and fast zooming, scrolling, and panning. The DOM/CSS-feature *style.transform* [10] provides the fundamental rendering functionality to implement infinite canvas in the browser. Modiator uses two-finger touches on touch screens to zoom and move around.

The Modiator User Interface is based on a set of widgets (text editor, plots, 3D animator, model diagrams, parameter dialog, etc.) which can be freely placed and sized on the *infinite model board*, see Figure 3:

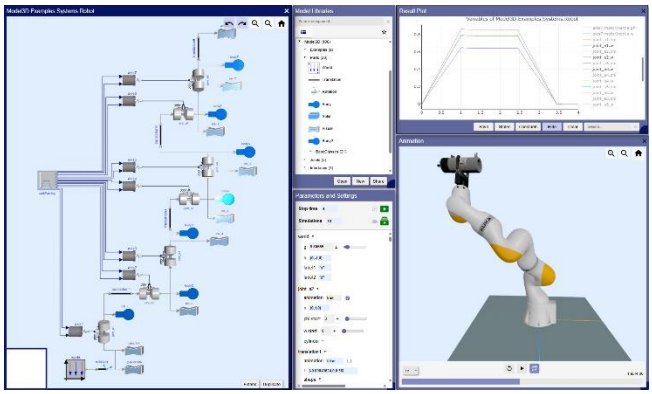

Figure 3. Example of Modiators User Interface.

The model diagram rendering is inspired by the 2.5D look of Playmola (Elmqvist et al. 2015), i.e., that icons have a 3D representation which are placed in a 2D diagram.

Multiple plot widgets can be used to visualize simulation results in different ways such as line plots, scatter diagrams, etc.

To enable AI techniques for Modelica authoring, external text editors such as VS Code with Github Copilot plug-in, can be used. When the external file is changed, Modiator will load and simulate the updated model.

The Modiator web app is a PWA (Progressive Web App), i.e., it can be installed on your device and by using service workers it can be used offline without internet connection.

[10] https://www.w3schools.com/jsref/-prop_style_transform.asp

5 Simulation in the Browser

Modiator uses a mixed execution model for simulation. Modelica models are translated to JavaScript functions which calculate the derivatives given time, states and parameters. The integration of the differential equations is performed by CVODE from the SUNDIALS suite [11] (Hindmarsh et al. 2005, Gardner et al. 2022). CVODE has been translated from C to WebAssembly [12] utilizing Emscripten [13] and is called from Javascript when simulation starts. When derivatives need to be calculated, a Javascript callback function is called from CVODE. Special considerations had to be taken especially regarding allocation and transfer of arrays.

Modiator translates the model equations to a JavaScript function by using the *new Function()* concept[14]. The Function constructor takes two arguments. The first one is a string of comma-separated arguments of the function and the second is the body of the function as a string, for example:

```
const func = new Function('a,b', 'return a + b')
console.log(func(1, 2)) // 3
```

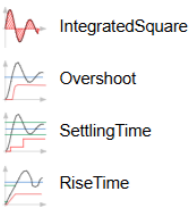
Such functions are usually Just-In-Time-compiled. Array and matrix equations are not expanded (Otter et al. 2025), but evaluated by calls to run-time functions and math.js[15].

In order not to disturb user interactions, parsing, translation and simulations are performed in concurrent web workers.

6 Simulation on the Cloud

For multi-simulations for variant selection or Monte Carlo simulations, it should be possible to utilize cloud computations. So far, *Netlify functions* [16] have been utilized. They are based on Amazon Web Services Lambdas.

Essentially the same simulation code as for web workers can be used. Instead of posting simulation data to a web worker, *fetch* requests are made to a simulate API function with a *body* of simulation data. The simulation data contains parameters and the JavaScript function string for calculating derivatives. To support multi-simulations with redeclares or self-modifying models, the Modelica translator module is also available in the serverless functions.



So far, limited testing has been made. 10000 simulations have been performed on the cloud. The startup time for each simulation was less than a second.

7 Monte Carlo Simulation

Model-based product design involves determining product topology, component selection, component sizing, and parameters (tuners) in such a way that the product has good performance, low production cost and low cost of ownership (objectives) while being robust with regards to variations in its environment and insensitive to variations in parameters (uncertainties). Since topology, component selection and component sizing are important, gradient based optimization tools can't be used.

Modiator uses Monte Carlo simulation and randomly selects tuner values typically from uniform distributions and selects uncertainties typically from truncated normal distributions. Redeclarations to model design selections or discrete environment variations have associated discrete distributions.

A set of Modelica *Objective* blocks is available for inserting into a model to define what are good designs. A subset of these blocks is shown on the right.

Since several possibly conflicting objectives can be defined, the *Pareto frontier* in scatter diagrams can help with compromise decisions and the *parallel axis coordinates plot* can help with assigning different weights to the objectives.

Equality and inequality constraints are enforced by including assert statements that cause simulations to fail if the specified conditions are not met. Functions of the following kind are provided for defining tuners and uncertain parameters:

```
p=uniform(default, minimum, maximum, tuner)
```

Such expressions can be used in modifiers. The *default* value is used for tools that do not provide Monte Carlo simulation in this way. *Minimum* and *maximum* gives the range and *tuner* is true for a tuner, otherwise an uncertainty is defined. The user interface has built-in menus for defining such function invocations (± button).

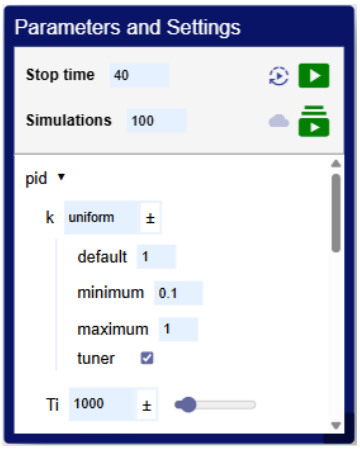


Figure 4. Tuner and Uncertainty definitions.

7.1 Design Example – Servo

To illustrate the design method used by Modiator, a well-known control problem will be employed: PID control of a double integrator. The motor consists of an ideal torque generator and an inertia and behaves like a double integrator.

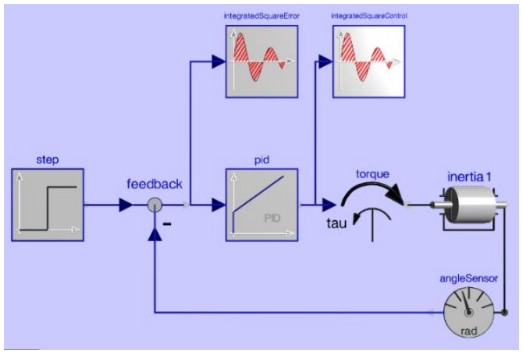

Figure 5. Controlled double integrator.

Two integral square objectives are defined. In addition to the usual objective of small control error, it is desired to keep the control effort small to save energy. The gain, k, and derivative time constant, Td, should be tuned, i.e. uniform distributions are defined and tuner is set to true for them:

```
pid(k=uniform(1, 0.1, 1, true), Td=uniform(2, 0.5, 5, true))
```

By running 100 simulations, the following spaghetti plot is obtained if angleSensor.phi and step.y were plotted during a previous single simulation:

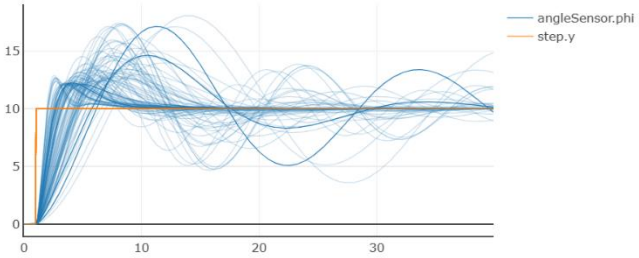

Figure 6. Spagetti plot for 100 simulations.

The time to make one thousand simulations is 2.24 seconds on a HP ZBook Ultra G1a laptop with an AMD RYZEN AI MAX+ PRO 95 3.0 GHZ CPU with 16 cores/32 threads. The corresponding time for MacBook Pro M4 is 1.56 seconds and for iPad Pro 11" M4 is 2.71 seconds. Amazingly, the same task takes only 4.32 seconds on a Samsung Galaxy Z Fold6 mobile phone.

In addition, Modiator presents a matrix of plots, see **Figure 7**. The rows and columns represent the variables: integratedSquareError.y, integratedSquareControl.y, pid.k and pid.Td. The diagonal shows the histograms for the variables (objectives: blue, tuners: green. Plot 1,2 shows the scatter plot for the objectives. The Pareto frontier is marked in red. Plot 1,3 shows that increasing gain is good for the first objective and plot 2,3 shows that decreasing gain is good for the second objective. The plots of the forth column shows that Td needs to be above 3. This is consistent with the well-known fact that the derivative term is needed for stabilization when controlling a double integrator with a PD controller.

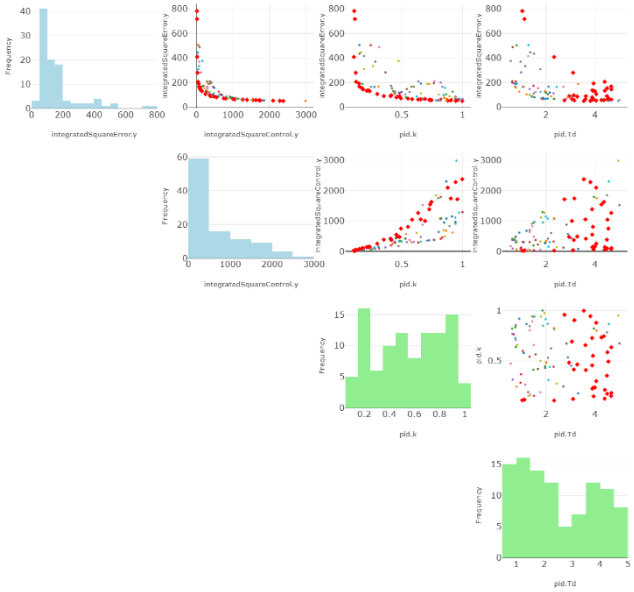

Figure 7. Multi-plot matrix with histogram and scatter plots.

By hovering over the plots, the actual values of objectives and tuners are presented:

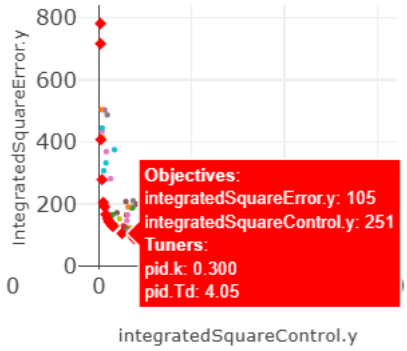

Figure 8. Tool tips showing objectives and tuners.

By zooming in on the Pareto frontier, the corresponding runs are plotted:

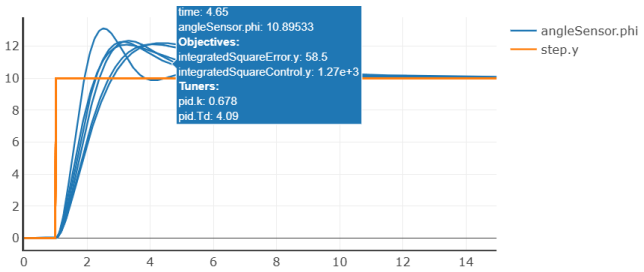

Figure 9. Selected responses.

If uncertainties are defined, for example, as a range of loads:

```
inertia1(J=uniform(1, 0.1, 1))
```

the plots include error bars and the tooltip shows the variations:

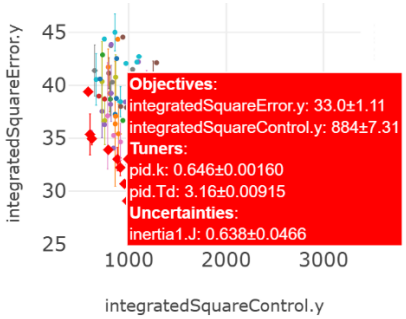

Figure 10. Scatter plot with error bars for uncertainties.

The error bars are obtained by defining bins for the tuner values and for each bin, the mean and standard deviation are presented. For accurate analysis of uncertainty influences many simulations are needed. The use of serverless functions on the cloud fits this use case.

8 Separate Translation of Models

The object-oriented modeling approach of Modelica allows building large models with millions of equations. However, the semantic specification is based on flattening, i.e., recursive cloning of variables and equations of each component instance. Typically, Modelica tools also expand matrix equations to scalar equations. Flattening means that a lot of memory is needed for variables and equations during translation of the Modelica code. It also means that translation time is long since the same analysis (flattening, symbolic processing, etc.) is performed repeatedly for each instance. Furthermore, the C-code becomes large, and compilation takes a long time. In addition, the execution of the C-code gets slower since the code might be larger than the size of the code cache.

However, parts of the equations of a component are always executed in the same order and with the same causality independently of how the component is connected. Such sequences of equations can be put into functions: less code gives shorter compilation time; less machine code gives shorter simulation time.

Finding such sequences can be made once for each model class. The technique is based on forming the most general environment to a model class as illustrated in **Figure 11**.

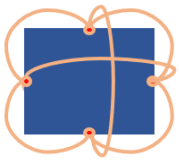

Figure 11. Generic environment of a model.

The generic environment is constructed by adding a set of dummy equations, env, which all depend on all connector variables (c_p: potential variables, c_f: flow variables) All inputs u are assumed to be known. The number of equations of env is the number of flow variables.

The Block Lower Triangular (BLT) form obtained during structural analysis of the model plus the generic environment has the structure shown in **Figure 12**.

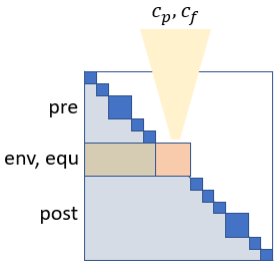

Figure 12. BLT structure of model plus generic environment.

The block in the middle contains the env equations since they all have the same incidences. It also contains certain equations, equ, which are related to the variables of the environment.

An example is given in the Appendix which shows how the equations are partitioned for a second order low pass filter.

9 Technology and Development Environment

The implementation of Modiator relies on *ECMAScript* modules[17]. Type inference and checking is done by *Visual Studio Code* [18] with *TypeScript* engine. Module dependency diagrams are generated by a *Visual Studio Code* plug-in, *Dependency Cruiser*.

The Modiator parser for Modelica is generated with the PEG-parser generator Peggy [19]. The handling of extends and merging of modifiers is done by deep merging of Javascript objects in a way inspired from merging in Modia.

Modelica model diagrams and 3D animations are created with three.js[20]. Plotting is done with Plotly[21].

Alias handling, tearing, index reduction, state-selection, BLT, symbolic processing of expressions, etc. have been ported from Modia (Julia code) to Javascript and some parts significantly improved. This has in some cases been done with a semi-automatic process using AI techniques with tool *Code Converter*[22] and the ChatGPT-4 tools *Microsoft Copilot*[23] and *Perplexity*[24]. Overall, the automatic translation reduced significantly the work to transform Modia functions to Javascript functions.

[24] https://www.perplexity.ai/

DOI 10.3384/ecp218211

In order to enable building a full Modelica compiler and simulator running in the browser, C-code must be handled since Modelica has an interface to C-functions. Successful experiments have been made to use clang running under Wasmer[25] in the browser to compile C-functions into WebAssembly.

Modeling and simulation workflows typically involve scripting, for example with Python. For this reason, successful experiments have been made to use PyScript[26] and Pyodide[27] which enables running Python in the browser together with Modiator.

10 Stream with Media Propagation

When simulating fluid systems, there is currently the inherent drawback in Modelica that a medium has to be defined *at every component* and that every change of the Medium requires *recompilation* of the model. A prototype Modelica package called *Stream* does no longer has these drawbacks.

In this new approach, all media are defined with *external functions* and the internal memory of the functions by *ExternalObjects*[28] (so pointers to memory allocated inside the functions). An ExternalObject is constructed at one component and then propagated through connections. Below, first the principle of the approach is explained based on media *C-functions* and afterwards it is sketched how media *Javascript-functions* are supported in current Modiator.

Stream is a small subset of Modelica package *ThermofluidStream*[29] (Zimmer 2020, Zimmer et al. 2022) but with (a) different handling of the media inspired by (Otter et al. 2019) and (b) equations of the thermodynamic state formulated with *Linear Implicit Equilibrium Dynamics* (LIED) as proposed by Zimmer (2024, 2025). The latter means that all states are fixed in the library and no nonlinear equations appear in Modelica models due to Stream (but might be present inside the external functions). Separate translation, as proposed in section 8, becomes particularly easy in this case. A simple example of a system with boundaries, flow resistances and a volume are shown in the next figure.

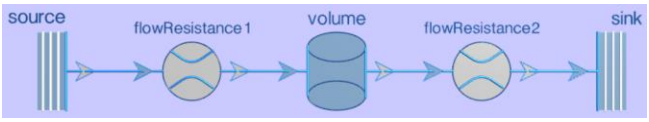

Figure 13. Simple Stream model in Modiator. The *medium* and its variables are defined in the *source* and propagated through the connections. The medium variables are changed in every component. *Media states* are defined in the *volume*. *Mass flow rate states* are defined in the *source* and in the *volume*.

The core LIED equations of the volume are shown in the next Listing.

Listing 4. Stream model of a volume with fixed size.

```
model Volume "Volume of fixed size"
  Interfaces.Inlet  inlet; Interfaces.Outlet outlet;
  parameter SI.Volume V_par "Fixed volume";
    ...
  Real xs[2](each fixed=false, each unit="1")
                                        "Scaled pair (p,T), (p,h), ...";
  Real Xi[size(Xi_start,1)](start=Xi_start, each fixed=true,
                    each unit="1") "Independent mass fractions";
protected
  parameter Integer mediumID(fixed=false);
  functions.Media.MediumAndState obj =
                    functions.Media.MediumAndState(mediumID);
  Real obj_r "Dummy, for correct sorting of obj";
initial equation
  mediumID = functions.Media.mediumID_from_obj(inlet.obj);
  xs       = functions.Media.get_xs(obj,p_start,T_start,...);
equation
  // Update obj with xs, Xi
  obj_r = functions.Media.updateThermodynamicState(obj, xs, Xi);
  outlet.obj = obj;  outlet.obj_r = obj_r;

  // Mass balance
  der_M = inlet.m_flow - outlet.m_flow ;
  der_d = der_M/V_par;

  // Energy balance
  d_in  = functions.Media.density(inlet.obj, inlet.obj_r );
  h_in  = functions.Media.specificEnthalpy(inlet.obj, inlet.obj_r );
  u_out = functions.Media.specificInternalEnergy(
                                          inlet.obj,inlet.obj_r );
  d_out = functions.Media.density(obj, obj_r);
  h_out = functions.Media.specificEnthalpy(obj, obj_r);
  M     = V_par*d_out;
  der_u = (inlet.m_flow*h_in - outlet.m_flow*h_out -
                                          der_M*u_out)/M;
  der(xs) = functions.Media.get_der_xs(obj, obj_r,der_d, der_u);

  // Mass fraction balance
  Xi_in   = functions.Media.massFractions(obj, obj_r);
  der(Xi) = (Xi_in*inlet.m_flow - Xi*(outlet.m_flow - der_M))/M;

  // Mass flow rate and inertial pressure (as in ThermofluidStream)
  ...
end Volume;
```

The state vector of a single substance compressible fluid medium is defined by two intensive quantities. In Modelica.Media, the state pairs (p,T), (p,h), (p,s), (d,T) are used. The pair selected for a particular medium in Stream is *hidden* and is implicitly defined by the medium name. In **Listing 4**, vector xs[2] is defined as a scaled pair, so that the two elements have magnitudes around 1 which means no nominal values need to be set for xs. For example, Modelica.Media.Air.SimpleAir uses the scaling xs[1] = p/10^5, xs[2] = T/273.15.

For a *multi-substance medium*, additionally the independent mass fractions Xi[:] are used as states. The dimension of Xi is identical to the dimension of its start value vector, i.e., Real Xi[size(Xi_start,1)].

[29] https://github.com/DLR-SR/ThermofluidStream

The internal medium states and the internal medium equations are defined by the declaration of the ExternalObject:

```
MediumAndState obj = MediumAndState(mediumID);
```

The input argument to the constructor is the Integer parameter mediumID – a unique identification of a Medium. It is deduced from the inlet input variable obj that references the medium and the medium variables in the connector:

```
parameter Integer mediumID(fixed=false);
initial equation
  mediumID = functions.Media.mediumID_from_obj(inlet.obj);
```

Since inlet.obj is formally a time varying variable propagated through connectors, the mediumID is determined during initialization via the given initial equation. This is not strictly Modelica compliant because alias equations for an ExternalObject are present (such as outlet.obj = obj). This tiny issue is not detected by Dymola[30] and by Modiator. The implementation of the ExternalObject constructor is (media.c contains the C-functions of the media):

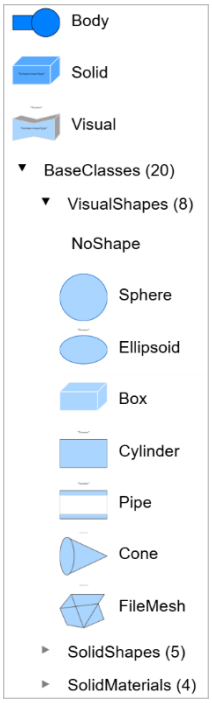
```
class MediumAndState
  extends ExternalObject;
function constructor
  input Integer mediumID "ID of medium";
  output MediumAndState obj;
  external "C" obj = MediumAndState_constructor(mediumID)
    annotation(IncludeDirectory=
                  "modelica://Stream/Resources/C-Sources",
      Include="#include \"media.c\"");
end constructor;
```

Since der(xs) and der(Xi) appear in the volume model, xs and Xi are treated as known. With statement

```
obj_r = functions.Media.updateThermodynamicState(obj, xs, Xi);
```

the states xs and Xi are copied into obj. The function returns the Real dummy variable obj_r (short for obj_ready). Whenever, an access function is called with obj, obj_r must be provided as well to guarantee that obj is used after it was updated. The derivative of xs – der(xs) – is computed with the external function call

```
der(xs) = get_der_xs(obj, obj_r, der_d, der_u);
```



which has obj, obj_r, der_d (derivative of density) and der_u (derivative of specific internal energy) as arguments.

Modiator can currently not utilize C-functions. Therefore, Javascript functions that are equivalent to the functions in media.c are provided in file media-functions.js. This file is included whenever Modiator is started. During parsing of a Modelica model, all function names that start with "functions." are interpreted to be Javascript functions and the look-up is not done in the Modelica model but internally in Modiator.

11 Model3D with 3D Geometries

The prototype Modelica package *Model3D* enables incorporation of 3D geometries into Modelica models. Currently, this capability is applied only to 3D mechanical systems but is intended to extend to other domains in the future. The design of Model3D is inspired by Modia3D[31] (Neumayr and Otter 2018, Neumayr 2025) and Modelica.Mechanics.MultiBody[32] (Otter et al. 2003). It utilizes the new approach "Dialectic Mechanics" introduced in (Zimmer and Oldemeyer 2023) and further developed in (Zimmer 2024, 2025). In particular, the states of a multibody system are fixed in the library and are the generalized joint coordinates of the spanning tree. Kinematic loops can be optionally modelled with elastic cut-joints. By introducing "kinetic velocities" which are filtered position derivatives, very stiff elastic joints can be reasonably simulated. The *analytic* handling of many kinematic loop types supported by the MultiBody library, will be ported to Model3D.

Primitive geometries, such as box, sphere etc. as well as meshes (.stl, .obj/mtl, .dae, .glb format) can be used in a model both for visualization and to compute properties such as mass and inertia, similarly as it is done in Modia3D. A screenshot from Modiators parameter menu of the basic parts of Model3D are shown at the right side. BaseClasses are replaceable models that can be utilized in Body and Visual (VisualShapes) as well as in Solid (SolidShapes, SolidMaterials). An example of a double pendulum with object diagram and animation is shown in **Figure 14**.

Model3D stores layout and settings parameters no longer in the World and other models, but in an external hierarchical JSON file. Standard Modelica tools read this file and extract content via Modelica package *ExternData*[33] (Beutlich and Winkler 2021).

Modiator accesses the settings JSON file directly from Javascript. In order that both approaches work seamlessly together, a few access routines of ExternData are replicated in Model3D as functions.getJSONxxx. If the Modiator parser recognizes function names starting with "functions", it utilizes its Javascript implementation.

[33] https://github.com/modelica-3rdparty/ExternData

DOI 10.3384/ecp218211

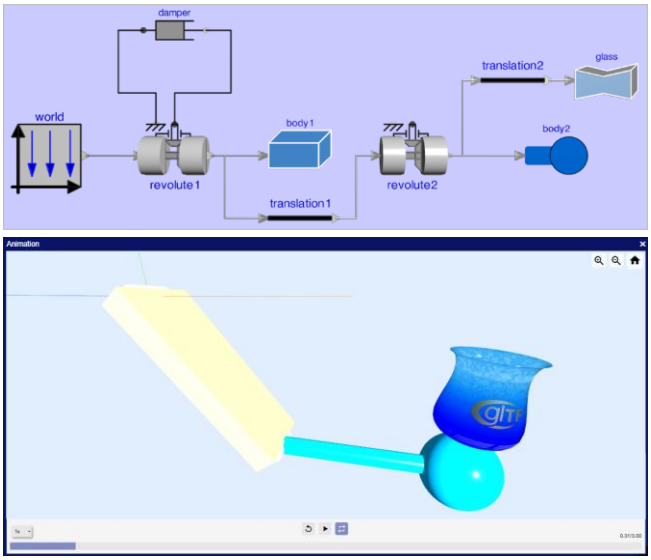

Figure 14. Model of a double pendulum in the diagram and animation widget of Modiator: *body1* is a "Solid" (here: Box) where mass properties are computed from the geometry and from the selected material, *body2* is a "Body" defined by mass, inertia and center of mass together with a "Visual" object (default: Cylinder) and optional marking of the center of mass with a sphere; *glass* is a "Visual" object (here: FileMesh).

As an example, part of the layout parameterization of a Revolute joint is shown in the next Listing.

Listing 5. Layout parametrization of Revolute joint.

```
constant String resource = Modelica.Utilities.Files.loadResource(
                  "modelica://Model3D/Resources/settings.json");
constant Real length = functions.getJSONReal(resource,
                                    "shape_in_m.jointLength",0.1);
constant Real diameter = functions.getJSONReal(resource,
                                   "shape_in_m.jointWidth",0.05);
constant Integer color[3] = functions.getJSONIntegerArray1D(
                               resource,"color.Revolute",3,{255,0,0});
  …
// settings.json file
  {"shape_in_m" : {
       "jointLength": 0.1,
       "jointWidth" : 0.05,
       "forceLength": 0.1,
       "forceWidth" : 0.05,
       "bodyDiameter": 0.11},
    "color": {
       "Revolute" : [255,0,0],
         …}
```

The functions.getJSONxxx act as a thin layer over the ExternData API. They have an additional default argument which is used if the settings file is unavailable. This technique results in much cleaner menus. Notably, all the many parameters of the World object are removed, except for the gravity definition which remains in the World object and is propagated via the connections. Consequently, global data is no longer present, so the inner prefix of World is removed.

12 Limitations and Future Work

The status of Modiator can be categorized as a Proof-Of-Concept for a complete Modelica compiler and simulator running in a web browser. So far, the focus has been to investigate an entire tool chain for the fundamental semantics of Modelica: model classes, component declarations with modifiers and redeclare, and connections.

It is sometimes assumed that the Modelica model is correct since many checks are not performed in the interest of translation speed. Scalability has not been in focus yet, i.e. only models with less than 1000 states and 5000 variables have been tested. The translator can be optimized in many ways, for example, by introducing caching and the separate translation technique outlined in section 8.

Only models which don't have nonlinear algebraic equation systems or mixed simultaneous equations with Real and Boolean unknowns can currently be simulated. Only very limited event handling is currently available. Other features not supported yet are:

- Modelica functions and external C-functions
- inner/outer
- complete set of matrix expressions
- algorithms
- initial equations/algorithms
- stream connectors (not planned)
- overconstrained connections (not planned)
- …

There are no plans to support the following parts of the Modelica Standard Library because they shall be replaced by better approaches:

(1) Modelica.Media shall be replaced by the Stream library sketched in section 10.

(2) Modelica.Fluid shall not be supported but instead the Stream library shall be used, and/or a future version of the ThermofluidStream library based on the Stream media handling and on LIED equations.

(3) Modelica.Mechanics.MultiBody shall be replaced by Model3D. Potentially, a nearly MultiBody compliant library will be provided as thin layer over Model3D to allow reasonable conversion of the many libraries and models that are based on the MultiBody library.

Since the current version of Modiator already (a) is useable on any device, (b) can be utilized just with the Modiator URL within a few seconds without installation, and (c) can translate and simulate smaller Modelica models locally in the browser nearly instantaneously, Modiator is well suited for *tutorials* and *university courses* on Modelica and for dedicated *web apps with a special user-oriented Web GUI* where the Modiator engine is running in the background.

13 Conclusions

Modiator is the next phase of experimentation and evolution of object-oriented modelling conducted by the authors after the Modia project. New web technologies provide the means to enable quick and easy access to object-oriented modeling and cloud simulation by Modelica Instant Simulation.

Furthermore, Modiator provides a platform for further investigations of new modeling capabilities to meet more and more demanding modelling needs.

Acknowledgements

The authors want to thank Johan Furuhjelm (Lund Institute of Technology) for the implementation of the infinite canvas user interface, Andreas Pfeiffer (DLR-FK) for valuable help regarding WebAssembly and Sundials and Dirk Zimmer (DLR-RM) for useful discussions regarding LIED and dialectic mechanics.

Appendix
Example for Separate Translation

This appendix shows an example of separate translation of models as sketched in section 8. Consider the second order low pass filter[34] in **Figure 15**

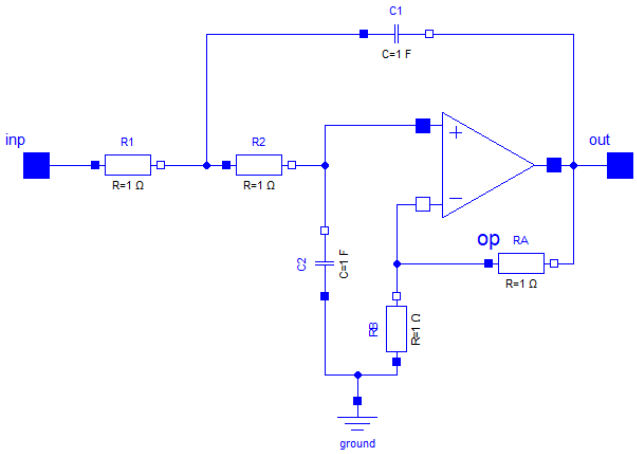

Figure 15. Second order low pass filter.

A corresponding Modelica model is shown below.

Listing 6. Modelica model of **Figure 15**.

```
model LowPass2nd
  Modelica.Electrical.Analog.Basic.Resistor R1(R=1);
  Modelica.Electrical.Analog.Basic.Resistor R2(R=1);
  Modelica.Electrical.Analog.Ideal.IdealOpAmp3Pin op;
  Modelica.Electrical.Analog.Basic.Ground ground;
  Modelica.Electrical.Analog.Basic.Capacitor C1(C=1);
  Modelica.Electrical.Analog.Basic.Capacitor C2(C=1);
  Modelica.Electrical.Analog.Basic.Resistor RA(R=1);
  Modelica.Electrical.Analog.Basic.Resistor RB(R=1);
  Modelica.Electrical.Analog.Interfaces.Pin inp;
  Modelica.Electrical.Analog.Interfaces.Pin out;
equation
  connect(R1.n, R2.p);
  connect(R2.n, C2.n);
  connect(ground.p, C2.p);
  connect(op.out, RA.n);
  connect(ground.p, RB.p);
  connect(R1.n, C1.p);
  connect(C1.n, op.out);
  connect(R2.n, op.in_p);
  connect(RB.n, op.in_n);
  connect(RA.p, RB.n);
  connect(R1.p, inp);
  connect(op.out, out);
end LowPass2nd;
```

If a voltage source is connected between ground and connector inp, the translated model with alias elimination applied will consist of a sequence of 10 solved equations.

If the filter is separately translated according to the algorithm outlined in section 8, an equivalent Modelica model is created (parameter handling simplified):

Listing 7. Modelica model of **Listing 6** transformed into a mix of acausal equations and causal functions.

```
model LowPass2nd
  Modelica.Electrical.Analog.Interfaces.Pin inp;
  Modelica.Electrical.Analog.Interfaces.Pin out;
equation
  LowPass2nd_init = ast.newFunction("C1_v, C2_v",
   "return {
     RA: {R: 1, p:{}, n:{}},
     RB: {R: 1, p:{}, n:{}},
     R1: {R: 1, p:{}, n:{}},
     R2: {R: 1, p:{}, n:{}},
     C1: {C: 1, v: C1_v, p:{}, n:{}},
     C2: {C: 1, v: C2_v, p:{}, n:{}},
     op: {in_p: {}, in_n: {}, out: {}},
     ground:{p:{}},
     out: {}}");

  LowPass2nd_pre = ast.newFunction("M", "
     M.RB.i = M.C2.v / M.RB.R;
     M.RA.v = M.RA.R * (-M.RB.i);
     M.RA.n.v = -((M.RA.v - M.C2.v));
     M.C1.p.v = M.C1.v - (-M.RA.n.v);
     return [M.RA.n.v, M.C1.p.v];");

  LowPass2nd_post = ast.newFunction("M, R1_p_i", "
     M.R2.v = M.C1.p.v - M.C2.v;
     M.R2.i = M.R2.v / M.R2.R;
     M.C1.p.i = -((-R1_p_i + M.R2.i));
     M.C1.der_v = M.C1.p.i / M.C1.C;
     M.C2.der_v = M.R2.i / M.C2.C;
     return [M.C1.der_v, M.C2.der_v];");

     M = LowPass2nd_init(C1_v, C2_v);
     (out.v, R1_n_v) = LowPass2nd_pre(M);

     R1_R = 1;
     R1_R * inp.i = R1_v;
     R1_v = inp.v - R1_n_v;

     (der(C1_v), der(C2_v)) = LowPass2nd_post(M, inp.i);
end LowPass2nd;
```

The equations are then partitioned into

- function LowPass2nd_pre with 4 assignments,
- function LowPass2nd_post with 5 assignments,
- and 2 remaining model equations.

If many instances of LowPass2nd are created, the 9 equations of the functions LowPass2nd_pre and LowPass2nd_post need to be compiled one time.

The functions LowPass2nd_... were defined using a built-in function ast.newFunction with the same semantics as the Javascript constructor Function().

OpenIWPI: Open-Instance Wave-Phasor Interface Library for Power System Simulation Studies in Modelica

Marcelo de Castro[1] Luigi Vanfretti[2]

[1]Mitsubishi Electric Power Products, Inc., USA marcelo.decastro@meppi.com
[2]Rensselaer Polytechnic Institute, USA vanfrl@rpi.edu

Abstract

In the past decades, a large number of power electronic converter-based energy resources have been connected to grids around the world. The increasing number of such devices is pushing for both electromechanical and electromagnetic dynamic simulations to be part of routine stability studies for transmission planning studies. Hybrid wave-phasor simulations have been proposed in the literature to address this challenge. This paper describes Open-Instance Wave-Phasor Interface (OpenIWPI), a Modelica library used to couple phasor-based and electromagnetic power system models, allowing simulation and linearization of such hybrid models to be performed altogether. Examples are presented to describe how the library can be useful in power system studies.

Keywords: power grid, power systems, electromagnetic transients, phasor-based simulation, RMS simulation

1 Introduction

1.1 Background and Motivation

The planning of the grid and its safe operation requires many different simulation-based studies to be performed. The dynamic stability analysis of electric grids is one of these studies, and it is usually assessed using two different approaches, depending on the time scale of the phenomena that need to be assessed. In electromechanical transient stability (usually named just Transient Stability, or TS) simulations, the power system is represented in its positive sequence component equivalent to the fundamental frequency (Kundur, Balu, and Lauby 1994). In essence, a phasor-based representation of the power system is used to create a system of differential and algebraic equations (DAEs). The time scale of electromechanical system dynamics is in the order of milliseconds to tens of seconds and, with appropriate time step selection, a large number of DAEs can be solved via low-order integration methods with high computational efficiency (Kundur, Balu, and Lauby 1994; Chow and Sanchez-Gasca 2020). Electromagnetic transient stability (EMT) simulations have more detailed models of the components of the power system, capturing ultra-fast switching dynamics due to power line tripping or those of the power electronic converter (Dommel 1986; Watson and Arrillaga 2003; Mahseredjian, Venkata Dinavahi, and Martinez 2009). Once again, with an appropriate time step selection, the differential equations describing the EMT simulation are solved for a large frequency spectrum using trapezoidal integration methods. However, the time scale of electromagnetic phenomena is very small, and solving these large systems of differential equations with very small time steps is cumbersome for computers, limiting the study of EMT simulations in extremely large systems (Watson and Arrillaga 2003). Moreover, the information required for the parameterization of EMT models is substantially larger than that used for phasor-based models, and some of this information may not be available, making it challenging to develop large-scale grid models, with some exceptions (Mahseredjian, Venkata Dinavahi, and Martinez 2009; Dennetiere et al. 2019; Thapa et al. 2023).

Traditionally, TS and EMT studies were carried out separately, in different tools. However, there have already been efforts, since the 1980s, for hybrid EMT-TS simulations motivated by the need to understand the interaction between high voltage direct current (HVdc) transmission lines and the power grid (Heffernan et al. 1981; Adapa and Reeve 1988). In recent decades, the electric power system has grown not only in size but also in complexity. Currently, many converter-based resources are operating in modern power systems, and many more will be in service in the next years. These ubiquitous devices deal with large amounts of power and are crucial for the operation of the current power grid. Therefore, it is important for studies to consider how the electromagnetic response of such devices can affect the electromechanical transient stability of the entire system and vice versa.

Many power system libraries have already been developed in Modelica for both TS and EMT studies (Winkler 2017; de Castro, Winkler, et al. 2023; Masoom, Ould-Bachir, et al. 2020; Masoom, Mahseredjian, et al. 2021). Engineers have created these libraries to explore the rich features of Modelica (Modelica Association 2025) while performing EMT or TS studies. Therefore, it is attractive to explore how these can be combined and exploited for hybrid EMT-TS simulations without the typical drawbacks of co-simulation (Schweiger et al. 2019). To this end, hybrid wave-phasor interfaces using Modelica would enable one to adequately model and simulate modern power systems that are rich in converter-based re-

sources (Chang and Vanfretti 2024; Fachini et al. 2025).

Furthermore, in recent years hybrid EMT-TS studies have become more common (Watson and Arrillaga 2003). However, they are usually conducted mainly as co-simulation, with the different parts being simulated as if they were standing alone (Heffernan et al. 1981; Adapa and Reeve 1988; Theodoro, Tomim, Lima, et al. 2017; Theodoro, Tomim, Barbosa, Lima, and Santiago 2018; Theodoro, Tomim, Barbosa, Lima, and Barros 2019). While the EMT part is discretized to be solved using trapezoidal integration method, the TS part uses modified Euler algorithms. This is not done explicitly; instead, the dominant approach used by the power systems community over the last 15 years (V. Dinavahi et al. 2009) is to interface two separate environments that exchange data at specific time instants, i.e., *ad-hoc* co-simulation. However, using Modelica, hybrid EMT-TS simulation is possible without the need of two different tools — one can create a single hybrid EMT-TS model that will be solved using variable step-size algorithms (Gibert et al. 2018; de Castro and Vanfretti 2022), such as DASSL for example (Petzold 1982). Meanwhile, if needed, co-simulation can also be achieved if desired, by exporting portions of the proposed interface and models as a Functional Mock-up Unit (FMU) and interfacing them with FMI-compliant tools (Ramirez-Gonzalez et al. 2024).

It is also worth noting that the ability to create a single hybrid EMT-TS model in Modelica provides a unique added value: it allows the user to perform a small signal stability analysis using linearized models, e.g., by using the `Modelica_LinearSystems2` (Baur, Otter, and Thiele 2009). This is simply not possible with existing power system EMT simulators and certainly not feasible with EMT-TS co-simulation frameworks. Observe that even most TS simulators require additional tools for this analysis task (Martins et al. 2000; Nikolaev et al. 2020).

1.2 Objectives

In this paper, the focus will be in presenting a Modelica library that contains an interface that can be used for hybrid EMT-TS simulations. This wave phasor interface is designed to be coupled with the Open Instance Power Systems Library (OpenIPSL) (de Castro, Winkler, et al. 2023) and the Modelica Standard Library (MSL). While the phasor-based portion of a system can be represented by OpenIPSL, the electromagnetic behavior is represented by the appropriate Electrical sub-package within the MSL. The wave-phasor interface present in this library is based on a positive-sequence component filtering approach (Theodoro, Tomim, Lima, et al. 2017; Theodoro, Tomim, Barbosa, Lima, and Santiago 2018; Theodoro, Tomim, Barbosa, Lima, and Barros 2019) originally developed for co-simulation.

1.3 Paper Structure

The remainder of this paper is structured as follows: Section 2 presents the structure of the library and its organization; Section 3 shows the auxiliary models that are used in the library; Section 4 describes the mathematical description of the wave-phasor interface and its implementation in Modelica; Section 5 brings two simulation examples and their results; Final discussion and conclusions are presented in Section 6.

2 Library Overview and Organization

The Open-Instance Phasor-Wave Interface (OpenIWPI) library was developed to help engineers simulate hybrid power system models composed of phasor-based circuits and detailed components represented in the electromagnetic-transient fashion. The main idea is to be able to interface detailed components, using EMT-like representations, with power system grids, which are usually modeled in their phasor-domain positive sequence equivalents. In other words, this library should help engineers in creating hybrid EMT-TS models and simulation using a wave phasor interface (Theodoro, Tomim, Lima, et al. 2017; Theodoro, Tomim, Barbosa, Lima, and Santiago 2018; Theodoro, Tomim, Barbosa, Lima, and Barros 2019) implemented in Modelica (de Castro and Vanfretti 2022).

The interface uses electrical connectors from the OpenIPSL (de Castro, Winkler, et al. 2023) and from the Modelica Standard Library - MSL. Therefore, the library is ideal for interconnecting phasor-based representations built using the OpenIPSL, for TS studies, with EMT-like models that are built using the Electrical library within the MSL. As an outcome, the user will need to have both libraries loaded (OpenIPSL and MSL) before loading the OpenIWPI library. The OpenIWPI library has six sub-packages as shown in Figure 1.

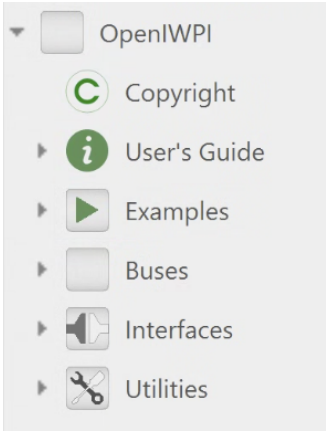

Figure 1. Library sub-packages overview.

The sub-packages are briefly described below:

- **Copyright:** the library's copyright notice informing users that the library is subject to a 3-clause BSD license.
- **User's Guide:** package containing informative items for the users, such as a starting guide and a list of

DOI 10.3384/ecp218223

reference papers used by the library.

- **Examples:** package to demonstrate the application of the interface using simple examples of the power system for simulation.
- **Buses:** contains the electrical bus that uses the hybrid wave-phasor interface to connect phasor-based models with EMT-like models.
- **Interfaces:** contains the filter-based wave-phasor interface that allows the simulation of hybrid wave-phasor (EMT-TS) circuits.
- **Utilities:** contains auxiliary models that are used in the library, such as a Phase-Locked Loop (PLL) model, reference frame transformations, as well as resettable and second-order generalized integrators.

The OpenIWPI has two important sub-packages imported from its dependencies. They are listed in the library's main `package.mo` file as shown below. The first import is related to OpenIPSL's `Types`, which allows OpenIWPI to maintain dimension consistency in calculations made in the library. The second import is related to the mathematical constants listed in MSL and that are used in the calculations performed within the OpenIWPI.

Listing 1. Importing OpenIPSL Types and Modelica Constants.

```
import OpenIPSL.Types;
import C = Modelica.Constants;
```

3 Auxiliary Models and Blocks

The `Utilities` sub-package of the OpenIWPI library is composed of many auxiliary blocks and models that are essential for assembling the wave-phasor interface. The following subsections describe each auxiliary block/-model in detail, highlighting its contribution to the proper operation of the interface.

3.1 Reference Frame Transformations

In the library, two reference frame transformations are needed: Clarke and Park transformations. Both transformations are implemented as models in the OpenIWPI library. The Clarke transformation model uses three real inputs (v_A, v_B, and v_C) and outputs two real variables (v_α and v_β) (Yazdani and Iravani 2010). In Modelica, this transformation is implemented as shown in Listing 2.

Listing 2. Clarke transformation implementation.

```
equation
    v_alpha = (2/3)*(v_A - (1/2)*v_B -
        (1/2)*v_C);
    v_beta = (2/3)*(sqrt(3)/2)*(v_B - v_C);
```

Similarly, the Park transformation model uses three real inputs (v_α, v_β and δ) and outputs two real variables (v_d and v_q) (Yazdani and Iravani 2010). The Park transformation transforms a reference frame composed of two waves in quadrature ($\alpha\beta$) into a set of two stationary values (dq) using a reference frame that rotates with the grid's frequency. Its Modelica implementation is as depicted in Listing 3.

Listing 3. Park transformation implementation.

```
equation
    v_d = v_alpha*Modelica.Math.cos(delta)
        + v_beta*Modelica.Math.sin(delta);
    v_q = -v_alpha*Modelica.Math.sin(delta)
         + v_beta*Modelica.Math.cos(delta);
```

3.2 Resettable Integrator

The integrator with a reset option was created in order to be used in the PLL present in the library. This integrator is a re-implementation of the regular integrator used in the MSL. The only difference is that it resets its output every time it reaches the value of 2π. The reason behind this reset is that it allows the output to always be within one angular revolution, avoiding an unnecessary large-angle variable to be used in calculations. This reset integrator is common in hardware implementations of PLLs based on the Synchronous Reference Frame (SRF) to avoid an integer overflow issue in the digital signal processor. In Modelica, the resettable integrator equations are implemented as shown in Listing 4. Note that this integrator uses the same parameters as the basic integrator found in MSL. Also note that Listing 4 is built under the assumption that `y_start` is 0, and that `k*u` is greater than 0.

Listing 4. Resettable integrator's equations in Modelica.

```
initial equation
    y = y_start;
equation
    der(y) = k*u;
    when y > 2*C.pi then
        reinit(y,y_start);
    end when;
```

3.3 Second-Order Generalized Integrator

The Second-Order Generalized Integrator (SOGI) (Rodriguez et al. 2006) is a filter with the purpose of generating two signals in quadrature with each other. The input of the filter, v_{in}, is filtered, and its fundamental component is output as v. The second output is a signal in quadrature with the first output and is named qv. If the transfer function between v_{in} and v is called $D(s)$ and the transfer function between v_{in} and qv is $Q(s)$, then it can be described as Equation (1) (Rodriguez et al. 2006; de Castro and Vanfretti 2022).

$$\begin{cases} D(s) &= \dfrac{v}{v_{in}} = \dfrac{k\omega_s s}{s^2 + k\omega_s s + \omega_s^2}, \\ Q(s) &= \dfrac{qv}{v_{in}} = \dfrac{k\omega_s^2}{s^2 + k\omega_s s + \omega_s^2}, \end{cases} \tag{1}$$

where the gain $\omega_s = 2\pi f_s$ is the angular frequency of the wave that must be filtered and k is a gain that can be adjusted to change the characteristics of the filter. These

two parameters can be set by the user. In this application, $f_s = 60$ hertz, while the gain is set to $k = \sqrt{2}$ because it provides a dynamic response with a good compromise between the settling time and the overshoot of the filtering process under disturbances (Rodriguez et al. 2006; de Castro and Vanfretti 2022). Note that $D(s)$ describes a band-pass filter, while $Q(s)$ describes a low-pass filter. In OpenIWPI, the SOGI has been implemented as a block diagram. It is shown in Figure 2.

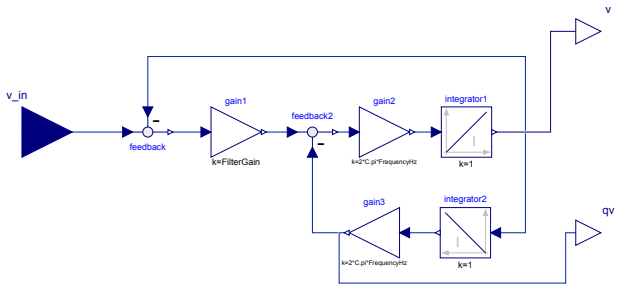

Figure 2. Sencond-order generalized integrator implementation.

3.4 Phase-Locked Loop

The PLL modeled in the library is based on a Synchronous Reference Frame (SRF) loop with double SOGI filters, described below (Rodriguez et al. 2006). The PLL can be divided into two main parts. The first part acts as a positive sequence filter, having three-phase quantities as input (voltage or current), and having as output the positive sequence equivalent for the corresponding $\alpha\beta$ components of the input quantities (Rodriguez et al. 2006; de Castro and Vanfretti 2022).

Suppose the three-phase quantities v_A, v_B, and v_C. They are used as inputs for a Clarke block. Each output, say $v_{\alpha,in}$ and $v_{\beta,in}$, is used as the input of a SOGI filter. The SOGI filter that receives the α component, there will be two outputs: v_α and qv_α. Similarly, in the case of the SOGI that filters the β component, the outputs are v_β and qv_β. The four variables can be used to calculate the positive sequence component in the $\alpha\beta$ reference frame as shown in Equation (2) (Rodriguez et al. 2006; de Castro and Vanfretti 2022). The output of this positive sequence calculation can then be used in a SRF loop designed to track one of the rotating axes. The DSOGI-based SRF-PLL (DSOGI-PLL) block diagram is shown in Figure 3.

$$\begin{cases} v_\alpha^+ = \frac{1}{2}\left(v_\alpha - qv_\beta\right) \\ v_\beta^+ = \frac{1}{2}\left(v_\beta + qv_\alpha\right) \end{cases} \tag{2}$$

The SRF-PLL (Kaura and Blasco 1997) uses a Park model and PI control to synchronize the rotating frame's and the $\alpha\beta$ positive sequence component's frequencies, such that the Park model's outputs are stationary. The SRF-PLL is described in Figure 4.

The compensator $C(s)$ is usually a PI controller with Kp and Ki that can be defined as

$$\begin{cases} K_p = & \frac{2\omega_n\xi}{\hat{X}} \\ K_i = & \frac{\omega_n^2}{\hat{X}}, \end{cases} \tag{3}$$

where $\hat{X}$ is the nominal peak value of the filtered wave, while ξ is the damping factor and ω_n is the cut-off frequency. These parameters can be tuned by the user and, for 60 hertz waves, $\xi = 0.7$ and $\omega_n = 100$ rad/s result in good dynamic performance (Rodriguez et al. 2006).

The implementation of DSOGI-PLL is carried out using block diagrams in Modelica, as shown in Figure 5. Note that the integrator located at the bottom right in the block diagram is the resettable integrator described in previous sections. This means that the output `delta` is always in the interval between 0 and 2π.

4 Wave-Phasor Interface Model

The integration between models created under different paradigms, that is, EMT and TS-like models, requires a component capable of adequately interfacing both representations. In this approach (Theodoro, Tomim, Lima, et al. 2017; Theodoro, Tomim, Barbosa, Lima, and Santiago 2018; Theodoro, Tomim, Barbosa, Lima, and Barros 2019), the TS-type power system with phasor-based models acts similarly to a variable voltage source on the interface bus. Transformation of a voltage phasor into a wave-like voltage source requires a phasor-to-wave transformation. In contrast, the EMT-type power system model will act as a variable current injection on the interface bus. This phasor-type current injection must be calculated from the waveforms obtained from the detailed EMT-type model, and thus a wave-to-phasor transformation is needed.

4.1 Voltage Phasor-to-Wave

This interface takes all necessary information from a phasor and translates it into waveform equations. The phasor information is carried out through OpenIPSL's `connector` with a Cartesian representation. The phasor $\tilde{V}$ is represented in OpenIPSL as

$$\tilde{V} = v_{re} + jv_{im}. \tag{4}$$

Hence, given the nominal voltage of the bus V_b and the base frequency of the system f_s, it is possible to calculate the wave information (amplitude A, frequency ω_s, and angle ϕ_v) as

$$\begin{cases} A = \frac{V_b\sqrt{2}}{\sqrt{3}}\left(\sqrt{v_{re}^2 + v_{im}^2}\right), \\ \omega_s = \omega_0 + \dfrac{d\phi_v}{dt}, \\ \phi_v = tg^{-1}\left(\dfrac{v_{im}}{v_{re}}\right), \end{cases} \tag{5}$$

where $\omega_0 = 2\pi f_s$. The calculated angle ϕ_v is assumed to be the phase from phase A's voltage, and the angles for

DOI 10.3384/ecp218223

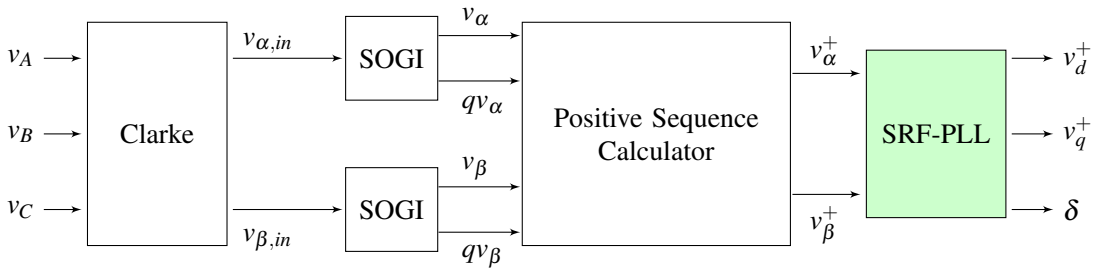

Figure 3. Diagram for the DSOGI-PLL.

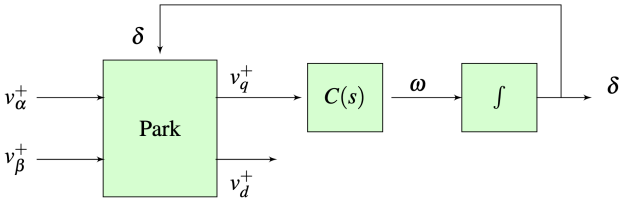

Figure 4. Diagram representing a PLL based on Synchronous Reference Frame (SRF).

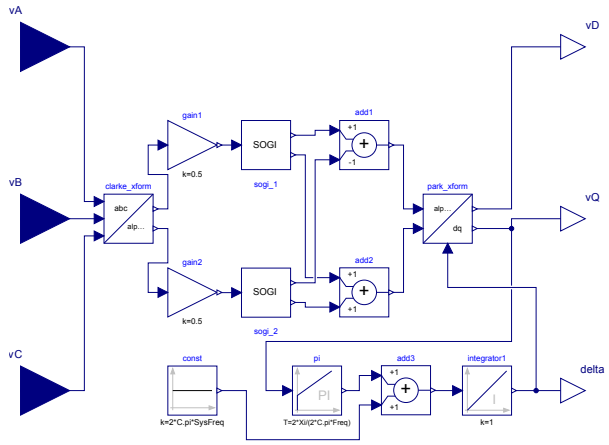

Figure 5. Modelica implementation of the DSOGI-PLL.

the other phase voltages are calculated displacing phase B and C of $\frac{2\pi}{3}$ radians. Hence, the three-phase waves that will be apparent for the EMT portion of the interface can be described as

$$\begin{cases} v_A = A\cos\left(\omega_s t + \phi_v\right), \\ v_B = A\cos\left(\omega_s t + \phi_v - \dfrac{2\pi}{3}\right), \\ v_C = A\cos\left(\omega_s t + \phi_v + \dfrac{2\pi}{3}\right). \end{cases} \tag{6}$$

4.2 Current Wave-to-Phasor

This part of the interface uses a filter to find the current phasor that will be shown at the phasor-domain portion of the interface. This can be done by using two PLLs: one DSOGI-PLL to be coupled with voltage waves described in Equation (6), and one modified PLL coupled with the currents that flow in the EMT portion of the interface. The DSOGI-PLL, coupled with voltage waves, is used to find the δ that varies with the appropriate speed ω_s. The second PLL can be considered as a modified DSOGI-PLL and it uses the current waves as inputs. The first modification is that the PLL can use a DSOGI filter as it is shown in Figure 3, but it could also use other filters to obtain i_α^+ and i_β^+. The second modification comes from the fact that the SRF-PLL part, as depicted in Figure 4 is reduced to a simple Park block that has inputs i_α^+ and i_β^+ as well as δ which is the output from the DSOGI-PLL coupled to the voltage waves. This procedure yields a current phasor

$$\tilde{I} = i_d^+ + j i_q^+. \tag{7}$$

where i_d^+ and i_q^+ are the outputs of the Park block of the modified PLL coupled to current waves. However, the angle δ is such that

$$\left(v_{re} + j v_{im}\right) e^{-j\delta} = v_d + j v_q = v_d. \tag{8}$$

Therefore, the current phasor $i_d^+ + j i_q^+$ produces an angle difference between the voltage and the current phasors. Consequently, to calculate the appropriate positive sequence current phasor value, it must be displaced from the voltage angle ϕ_v (see Equation (6)).

4.3 Modelica Implementation

In Modelica, the model contains one `connector` from the OpenIPSL and four from the MSL (three connectors for the voltage phases and one connector for the ground).

Listing 5. Connector instantiation.

```
// pins for wave signal:
Modelica.Electrical.Analog.Interfaces.
    PositivePin PinA;
Modelica.Electrical.Analog.Interfaces.
    PositivePin PinB;
Modelica.Electrical.Analog.Interfaces.
    PositivePin PinC;
```

```
Modelica.Electrical.Analog.Interfaces.
    NegativePin PinGrd;
// pin for phasor signal
OpenIPSL.Interfaces.PwPin PSPin;
```

Three system parameters are necessary for the calculations and they are entered as parameters for the interface as shown below.

Listing 6. System parameter declaration.

```
parameter Types.ApparentPower S_b = 100e6 "
    System base power";
parameter Types.Voltage V_b = 230e3 "Bus
    base voltage";
parameter Types.Frequency fn = 60 "System
    frequency";
```

The DSOGI-PLL from Figure 3 as well as a derivative block from MSL are instantiated in the model as presented below.

Listing 7. Instantiation of PLL and Derivative block.

```
OpenIWPI.Utilities.PhaseLockedLoop.Dsogi
    pll (SysFreq = fn, VLine = V_b);
Modelica.Blocks.Continuous.Derivative derA(
    T=0.1, y_start=0);
```

In addition, variables that are used in internal calculations are declared as protected. Note that the variables `type` are assigned attributes from those in `OpenIPSL.Types`.

Listing 8. Protected variables.

```
protected
    Types.AngularVelocity w
    // voltage variables
    Types.Voltage MagV;
    Types.Angle AngV;
    // current variables
    Types.PerUnit ir;
    Types.PerUnit ii;
    Types.PerUnit MagI;
    Types.Angle AngI
```

In the **`equation`** environment, the voltage phasor-to-wave transformation can be implemented in Modelica as

Listing 9. Voltage phasor-to-wave implementation

```
equation
    // voltage information from phasors
    MagV = V_b*sqrt(2/3)*sqrt(PSPin.vr^2+
        PSPin.vi^2);
    AngV = Modelica.Math.atan2(PSPin.vi,
        PSPin.vr);
    derA.u = AngV;
    w = 2*C.pi*fn + derA.y;
    // voltage waves
    PinA.v-PinGrd.v = MagV*Modelica.Math.
        sin(w*time+AngV);
    PinB.v-PinGrd.v = MagV*Modelica.Math.
        sin(w*time+AngV-2*C.pi/3);
    PinC.v-PinGrd.v = MagV*Modelica.Math.
        sin(w*time+AngV+2*C.pi/3);
```

The implementation of the current equations is described using Listing 10. The Clarke transformation result, `ialpha` and `ibeta`, is instantiated as `RealOutput`, while the inputs for the Park transformation, `iapos` and `ibpos`, are instantiated as `RealInput`. This allows the user to create other hybrid buses by using other filters and methods to extract the positive sequence of the $\alpha\beta$ frame.

Listing 10. Current wave-to-phasor implementation

```
equation
    // voltage PLL synchronization
    pll.vA = PinA.v-PinGrd.v;
    pll.vB = PinB.v-PinGrd.v;
    pll.vC = PinC.v-PinGrd.v;
    // clarke transformation
    ialpha = (2/3)*(PinA.i - (1/2)*PinB.i -
        (1/2)*PinC.i);
    ibeta = (2/3)*((sqrt(3)/2)*PinB.i - (
        sqrt(3)/2)*PinC.i);
    // Real and imaginary parts of the
        current phasor using Park transf.
    ir = -sqrt(3/2)*(V_b/S_b)*(iapos*cos(
        pll.delta)+ibpos*sin(pll.delta));
    ii = sqrt(3/2)*(V_b/S_b)*(iapos*sin(pll
        .delta)-ibpos*cos(pll.delta));
    // current magnitude and angle
    MagI = sqrt(ii^2+ir^2);
    AngIV = Modelica.Math.atan2(ii,ir);
    // grounding
    PinGrd.i = - (PinA.i+PinB.i+PinC.i);
    // current phasor waves
    PSPin.ir = MagI*Modelica.Math.cos(AngIV
        +AngV);
    PSPin.ii = MagI*Modelica.Math.sin(AngIV
        +AngV);
```

4.4 Hybrid Bus

Finally, the hybrid bus model is assembled using the double SOGI strategy, followed by the use of Equation (2), similar to what is used in the DSOGI-PLL (Theodoro, Tomim, Lima, et al. 2017; Theodoro, Tomim, Barbosa, Lima, and Santiago 2018; Theodoro, Tomim, Barbosa, Lima, and Barros 2019). The hybrid bus model is implemented in the library as shown in Figure 6. Note that the `pwPin` on the left hand side is that of OpenIPSL; while those on the right hand side (`pin_A, pin_B, pin_C`) and the bottom (`pin_grd`) are those from the MSL.

5 Simulation Examples

The OpenIWPI library has two simple examples that are used to show the appropriate behavior of the wave-phasor interface.

5.1 Simple Circuit

This first example shows a comparison between a power system completely represented in phasor-domain models and a circuit that is partially represented in phasor-domain and partially in EMT models. Figure 7 shows the two circuits that are present in the example: the upper circuit is

DOI
10.3384/ecp218223

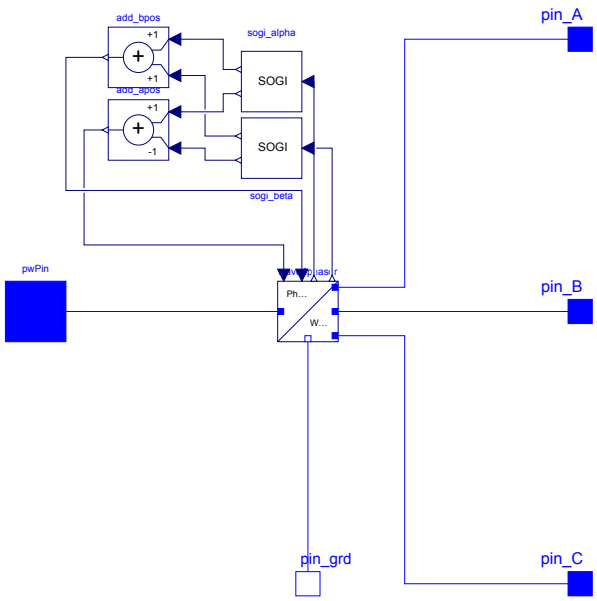

Figure 6. Modelica implementation of the hybrid bus.

the positive sequence (phasor-based model), while the bottom circuit is the hybrid TS-EMT model.

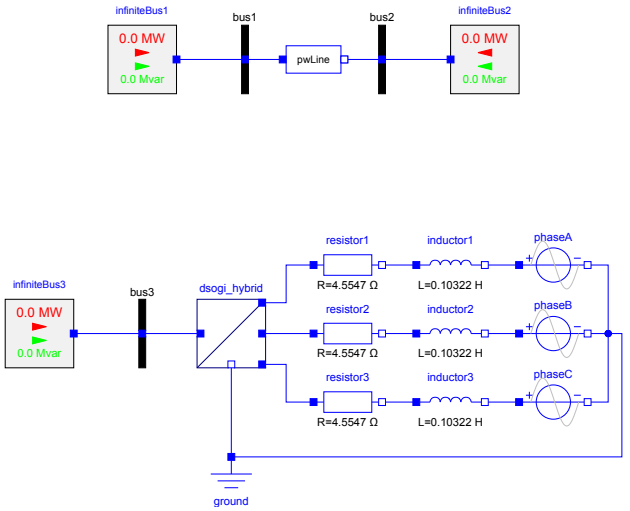

Figure 7. Simple circuit example in Modelica.

The goal of this example is to demonstrate the filtering of the three-phase current wave, showing that both circuits will yield the same result. The example is set to start with zero current on all inductors, which challenges the filter to reach the steady-state response and allows one to observe its behavior. The results presented in Figure 8 show that even under that condition, the filter is able to track the correct real and imaginary values of the current phasor.

5.2 Converter Circuit

The second example describes an application of the hybrid interface, in which a power-electronics-based device

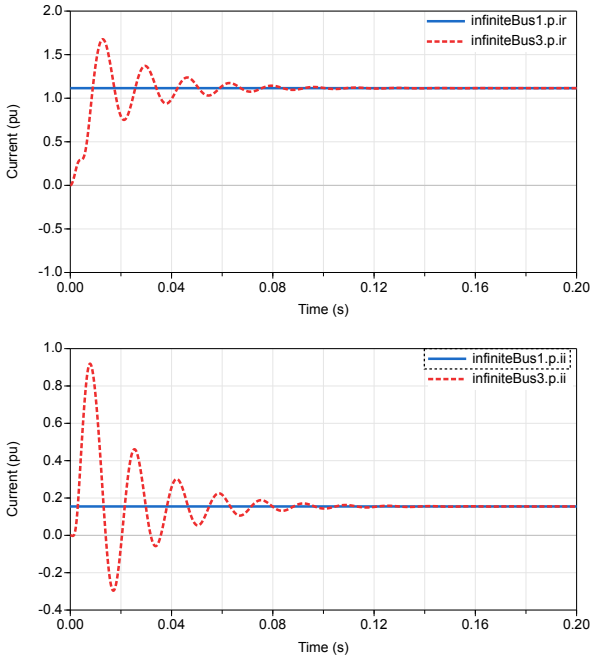

Figure 8. Current filtering simulation result for real (upper plot) and imaginary (bottom plot) components of the positive sequence current phasor.

is represented in detail using its EMT model, while the rest of the grid is built using the phasor-domain (TS) models. The Static Compensator (STATCOM) is an inverter-based resource that can be used to provide reactive power support to the power grid (Hingorani and Gyugyi 1999). The example circuit is presented in Figure 9 showing the interconnection of STATCOM to bus `B2`.

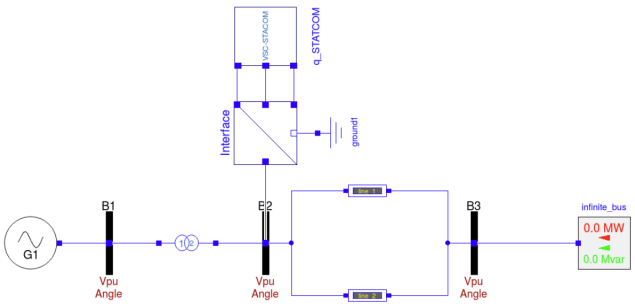

Figure 9. Diagram for converter circuit example.

This test system was developed to show the operation of a STATCOM and its controllers modeled in detail using the EMT approach, while the rest of the system is modeled in phasor-domain for a TS study. The STATCOM controllers used in this example are explained in more detail in (de Castro and Vanfretti 2022). To assess this behavior, the reference to the STATCOM's reactive power injection changes from 0 to 90 Mvar at $t = 1$ second, as shown in Figure 10. The three-phase modulation indices for each phase are shown in Figure 11. Note that the modulation indices change almost instantaneously at $t = 1.0$

sec., showing the appropriate control action for the desired reactive power injection.

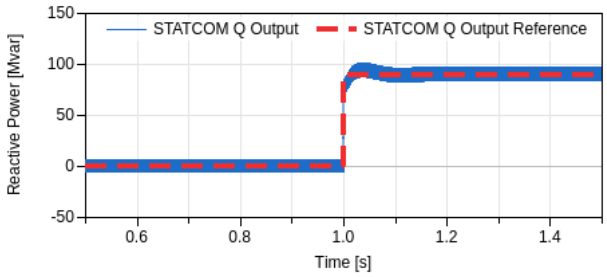

Figure 10. Reference value and reactive power injection by STATCOM.

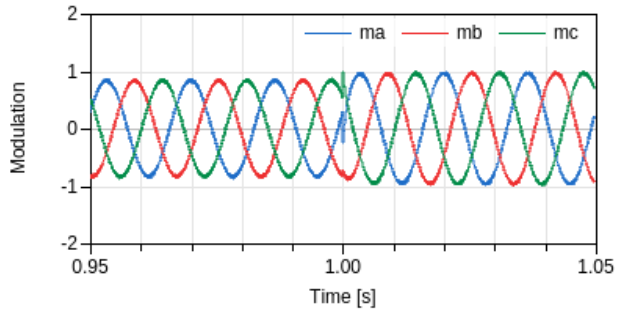

Figure 11. Three-phase modulation indices for the STATCOM's controller.

The voltage behavior on the STATCOM's DC bus is presented in Figure 12. The DC voltage is controlled throughout the simulation at its reference value of 60 kV. Note how the voltage suffers a disturbance exactly at $t = 1$ sec. Another disturbance in the voltage occurs at $t = 0.05$ sec., which is the time instant when the STATCOM connects to the grid. The bus `B2` voltage is depicted in Figure 13. Note that the bus voltage increases its magnitude as the reactive support offered by the STATCOM increases.

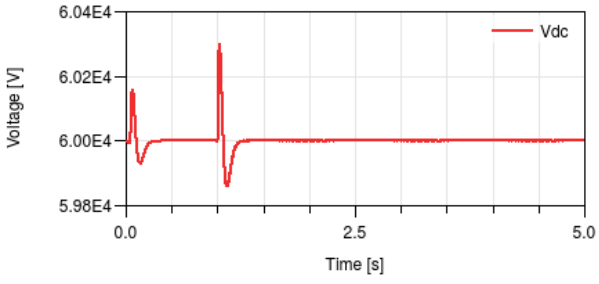

Figure 12. STATCOM DC bus voltage during simulation.

6 Conclusion

This work presented the Open-Instance Wave-Phasor Interface, or OpenIWPI, a Modelica library designed to allow coalesced simulation of hybrid EMT-TS models, using a wave-phasor interface. The interface is built using SOGI-based filters originally proposed in (Theodoro, Tomim, Barbosa, Lima, and Barros 2019). Although the library is small, it provides all the essential components to successfully link EMT and TS models, providing auxiliary models and reference frame transformations that are used by the interface. The interface bus presented in this paper uses connectors from the OpenIPSL, which has power system models for phasor-domain simulations, and it also uses connectors from the Electrical package within the MSL, which allows part of the power system to be modeled for EMT.

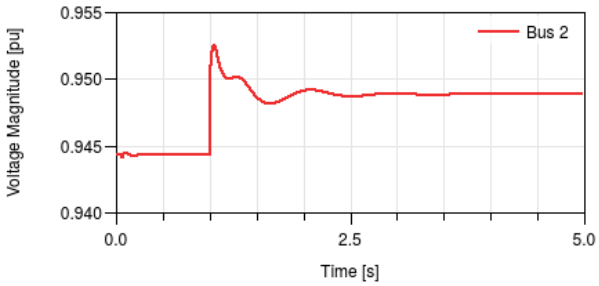

Figure 13. Bus `B2` voltage level during simulation.

Furthermore, this paper describes two example models that are part of the OpenIWPI library and presents their simulation results. The results should provide the user with details on how the library is expected to work and how to assemble larger models using the interface. The wave-phasor interface could be used as a magnifying glass for parts of the system to be modeled in detail (EMT), while other parts of the power grid can continue to have their phasor-based positive-sequence equivalent model (TS). This can be particularly useful when there is not enough information to model the whole power grid in EMT, or when one is interested in a particular plant's response when faced with system-wide dynamics (Boersma et al. 2021) that can only be captured with large-scale simulation models that are typically only represented for TS.

The OpenIWPI library has been tested with Dymola 2025x and requires OpenIPSL release v.3.1.0, which can be found online at: `http://openipsl.org/`. The OpenIWPI library is released as open source, and is available here: `https://github.com/ALSETLab/OpenIWPI`.

Abstract

Power systems undergoing large-scale renewable deployment require accurate dynamic models of inverter-based technologies such as solar photovoltaic plants, wind turbine generators, and battery energy storage systems to perform the require studies that would allow to assess and maintain power grid stability. The second generation of the Western Electricity Coordinating Council (WECC) generic renewable energy system (RES) models provides a general framework for modeling inverter-based resources in power system dynamics and stability studies. In this paper, we expand the existing Modelica-compliant open-source `OpenIPSL.Electrical.Renewables` package by implementing the Renewable Energy Generator/Converter B (`REGC_B`) model along with the Renewable Energy Electrical Controller (`REEC_D`) model, according to the second-generation WECC RES framework. Using Modelica's object-oriented features, the implementation emphasizes modularity and reusability in building scalable power system models using the OpenIPSL library. This work highlights the potential of using Modelica and OpenIPSL to support a standardized, scalable development of inverter-based RES models within the WECC framework, and extends the only fully Modelica-compliant open-source package that implements these models.

Keywords: Modelica, OpenIPSL, WECC RES models, inverter-based resources, power systems

1 Introduction

1.1 Motivation

The modeling of inverter-based resources (IBRs) is critical to ensuring reliable and realistic power system simulations, particularly with the growth of renewable energy integration. The development and validation of WECC generic RES models have played a key role in enabling dynamic studies of IBRs by different domain-specific platforms. Meanwhile, recent implementation of these models in OpenIPSL (Vanfretti et al. 2016; Baudette et al. 2018; Castro et al. 2023) using the Modelica language has demonstrated the benefits of modular object-oriented modeling for renewable energy systems (Fachini, Vanfretti, et al. 2021). Complementing this, power-hardware-in-the-loop (PHIL) testing has shown the practical relevance of the WECC framework in representing typical inverter responses under real-world operating conditions(Fachini, Chang, et al. 2025) and the value of implementing WECC models in Modelica to facilitate customization and extensibility.

However, as inverter-based systems continue to be increasingly deployed in weak grid environments, characterized by low short-circuit ratios and limited system strength, modeling accuracy becomes more critical. This is of particular importance to capture negative control interactions and potential stability issues (Adib et al. 2018; Wang et al. 2022; Mishra, Vanfretti, Delaree, and Jones 2024; Pudasaini et al. 2025). To support a more accurate representation of the inverter dynamics under such conditions, a voltage source interface model was proposed in (Ramasubramanian et al. 2016). Based on this foundation, the updated `REGC_B` and `REEC_D` models were developed to enhance the accuracy of the WECC modeling framework in dynamic performance and stability analysis of the grid. Naturally, extending our previous implementation of the WECC models in Modelica (Fachini, Vanfretti, et al. 2021) with these advancements is attractive and can provide additional benefits; including providing accurate IBR models in large-scale grid modeling that favor tools that support the Functional Mock-up Interface (FMI) standard and do not have these models in their internal libraries (Ramirez-Gonzalez et al. 2024) or provide simulation performance benefits through FMI-based parallelization (Ouafi et al. 2023).

1.2 Background and Related Works

The transformation of traditional power systems, driven by the global shift toward decarbonization and decentralization, has accelerated the integration of inverter-based resources such as solar photovoltaic (PV) plants, wind turbines (WT) and battery energy storage systems (BESS). Although crucial for enabling cleaner and flexible power systems, these sources exhibit dynamic responses that depart significantly from those of traditional generation tech-

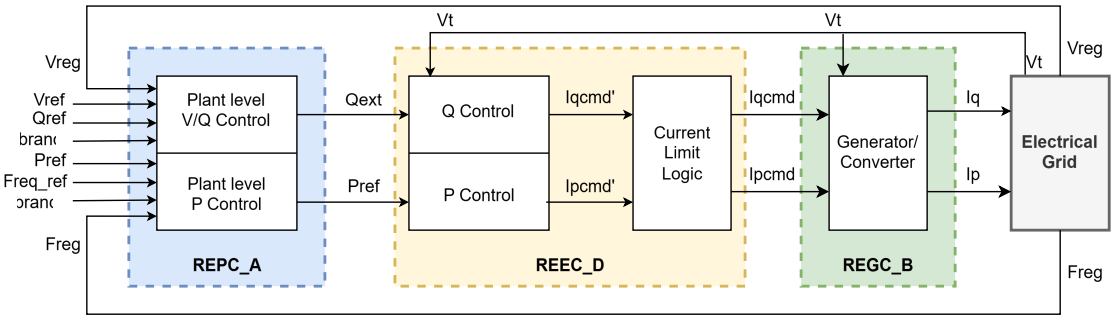

Figure 1. WECC RES Model Framework (Fachini, Vanfretti, et al. 2021)

nologies, posing new challenges to system stability and control. To address these challenges, the Western Electricity Coordinating Council (WECC), through its Renewable Energy Modeling Task Force (REMTF) (Sanchez-Gasca 2015), developed a standardized framework of second generation generic renewable energy system (RES) models for dynamic studies of inverter-based resources. Building on earlier first-generation modeling efforts, this framework aligns with broader international initiatives such as those of the International Electrotechnical Commission (IEC) (Fortmann et al. 2015), to improve modularity, broaden control representation, and support a wider range of technologies, including both wind and photovoltaic systems. Although these modeling efforts offer a consistent framework for representing inverter-based resources, their implementation in Modelica (Fritzson and Engelson 1998; Fritzson 2014) provides the added advantages of open access, modularity, and cross-platform compatibility that are not easily achieved in traditional domain-specific tools (Chang and Vanfretti 2024). When combined with the Open Instance Power System Library (OpenIPSL) (Baudette et al. 2018; Castro et al. 2023), Modelica offers a versatile and open-source language to develop standardized power system models suitable for dynamic simulation and analysis (Winkler 2017; Bhattacharjee, Vanfretti, and Fachini 2024).

The WECC RES models including the renewable energy generator / converter `(REGC_A)`, renewable energy electrical controller `(REEC_A/B/C)`, and renewable energy plant controller `(REPC_A)` were developed and validated against the commercial tool PSS®E in (Fachini, Vanfretti, et al. 2021), setting a viable proof of concept for open-source development of generic inverter-based models in Modelica using OpenIPSL. This effort led to the development of the `OpenIPSL.Electrical.Renewables` (here-forth referred as to the `*.Renewables`) package, which provides the only Modelica language-compliant and Modelica-tool–compatible implementation of the WECC Generic Renewable Energy Models — the models have been validated and tested in multiple Modelica-based simulation environments. Our implementation fully leverages templates with replaceable classes and other object-oriented features of the Modelica language, while also adopting the latest version of the Modelica Standard Library (MSL). Furthermore, the models in `*.Renewables` are compatible with multiple simulation tools such as Dymola, Wolfram System Modeler, Modelon Impact and OpenModelica, and can the models can be translated and simulated directly within these platforms. This is in contrast to other Modelica-based implementations that rely on MSL 3.2.3 and can only be viewed but not simulated in Modelica tools, requiring a domain-specific tool chain for simulation (Nuschke et al. 2021; Franke, Guironnet, and Cardozo 2024). In addition to these advantages, our present work expands the capabilities of the `*Renewables` package by incorporating the latest variants of WECC components, establishing it as the most up-to-date open-source collection of generic models of renewable energy sources available.

To support this expansion, updated versions of the WECC RES models have been introduced to better represent inverter-based resources under challenging grid conditions. The `REGC_B` model improves on `REGC_A` by introducing a voltage-source interface and enhanced current-limiting logic, offering better performance and numerical stability in weak grid scenarios. Likewise, the `REEC_D` improves upon the `REEC_A/B/C` with refined voltage-dependent limits, improved blocking, and more flexible control freeze logic (Pourbeik 2018).

This paper builds on our previous implementations of the WECC generic RES models in (Fachini, Vanfretti, et al. 2021) by extending the framework to include the `REGC_B` and `REEC_D` using the Modelica language and the OpenIPSL library. It presents a modular and reusable approach that uses Modelica's object-oriented feature to build standardized dynamic models of inverter-based resources. This work aims to extend the existing Modelica-based WECC framework and highlights how OpenIPSL can be used to support model development by leveraging open access standardization (i.e., the Modelica language), re-usability, and extensibility for power system studies.

1.3 Contributions

This paper focuses on demonstrating how key features of the Modelica language and the OpenIPSL library can be used to implement and extend standardized WECC RES models for power system studies. Thus, the contributions of this paper are as follows:

DOI
10.3384/ecp218233

- To implement next generation WECC RES models using the OpenIPSL Modelica Library.
- To exploit the replaceable template in Modelica to build the integrated models.
- To demonstrate the simulation setup and verify the features implemented in the new models.

1.4 Paper Structure

This paper is structured as follows. Section 2 describes the development of the new WECC generic models. In Section 3, we explain how Modelica is leveraged to integrate the new models within the WECC framework implemented in OpenIPSL. Section 4 illustrates the experimental setup and the simulation result. Finally, Section 5 concludes the work.

2 Development of the new WECC Generic Renewable Energy Models

Accurate representation of renewable energy sources based on inverters in dynamic power system studies requires standardized and adaptable modeling frameworks. The WECC generic RES models fulfill this need through a modular architecture that separates system-level coordination, electrical control, and grid interfacing into distinct components, as shown in Figure 1. At the plant level, the `REPC_A` module manages voltage and frequency regulation by generating real and reactive power references in response to system conditions. These references are passed to the electrical control module, historically modeled by `REEC_A/B/C`, which translates them into active and reactive current commands. Finally, the `REGC_A` generator/converter model interfaces with the grid, injecting current based on these commands. Although effective under normal operating conditions, this model structure lacks certain capabilities required to accurately simulate inverter behavior during certain types of faults, grid disturbances, or in weak-grid environments. To address these limitations in simulating realistic inverter behavior under faults and weak-grid conditions, the WECC framework has introduced more advanced controller and converter models —`REEC_D` and `REGC_B`. Figure 1 illustrates the updated RES modeling framework, which retains the original modular structure while replacing `REEC_A/B/C` and `REGC_A` with their improved counterparts.

This section discusses the development of the new models - `REEC_D` and `REGC_B` implemented in the Modelica language and integrated into the OpenIPSL library, following WECC specifications and ensuring compatibility with existing plant-level controllers such as `REPC_A`.

2.1 `REGC_B` Generator/Converter Model

The `REGC_B` model serves as the generator/converter component within the second-generation WECC generic RES framework. It replaces the earlier `REGC_A` model and introduces functional enhancements that improve the accuracy and numerical stability of inverter-based resource

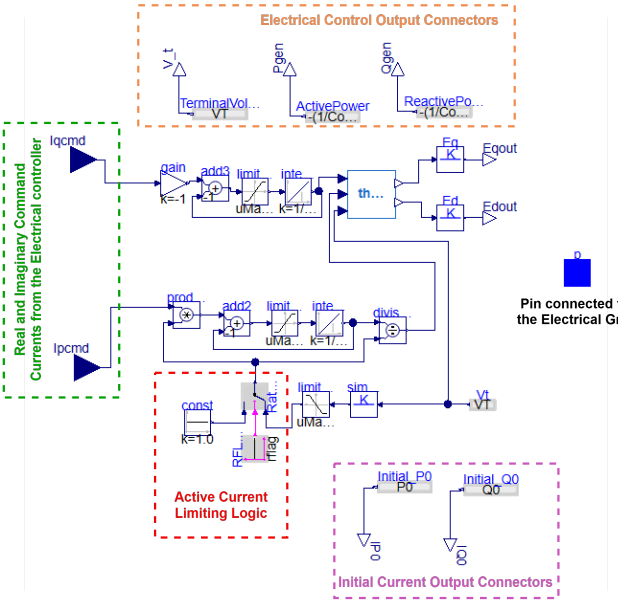

Figure 2. REGC_B model in Modelica and OpenIPSL

(IBR) simulations, particularly under conditions involving grid disturbances and low short-circuit strength.

The original `REGC_A` model is based on a current-source representation, wherein the model directly injects active (I_p) and reactive current (I_q) into the network. While effective under strong grid conditions, it has two key limitations. These include ignoring the voltage and impedance at the connection point; which leads to poor performance in weak grids with low short-circuit ratios (SCR), often causing numerical instability in domain-specific tools that are limited to fixed time-step solvers such as the trapezoidal integration method. According to the WECC REMTF, `REGC_A` becomes unreliable when the SCR drops below 2–3, frequently requiring artificial numerical stabilization measures.

To address these limitations, `REGC_B`, as shown in Figure 2, models the converter as a voltage source. The transition from `REGC_A` to `REGC_B` introduces several key enhancements aimed at improving numerical stability, dynamic performance, and modeling flexibility under weak grid conditions. The essential ones are as follows:

- **Voltage-Source Interface:** `REGC_B` replaces the current-source representation of `REGC_A` with a voltage source interface, improving behavior in low short-circuit ratio (SCR) scenarios. The injected current is computed using:

$$\vec{I}_{dq} = \frac{\vec{E}_{dq} - \vec{V}_t}{R_e + jX_e}$$

- **Active Current/Power Rate Limiting:** REGC_B introduces a `RateFlag` to select between active current or power ramping, using a rate limit parameter

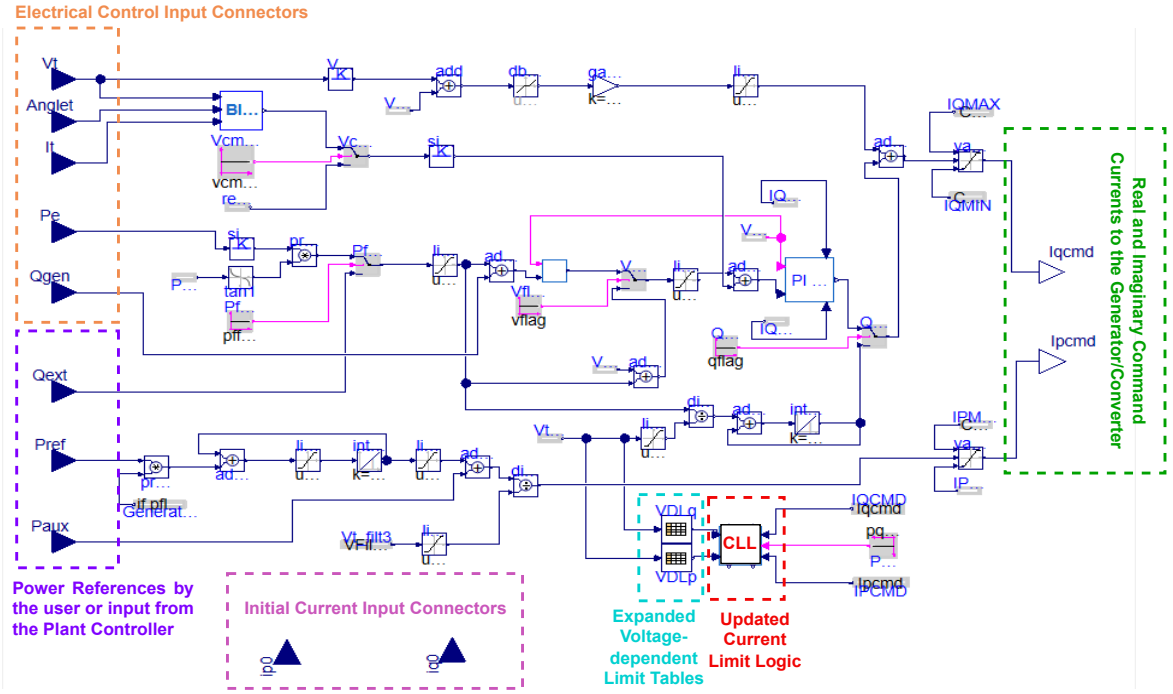

Figure 3. REEC_D model in Modelica and OpenIPSL

`rrpwr`. For current ramping:

$$\frac{dI_p}{dt} = \begin{cases} +rrpwr & \text{if } \frac{dI_p}{dt} > rrpwr \\ -rrpwr & \text{if } \frac{dI_p}{dt} < -rrpwr \\ \frac{dI_p}{dt} & \text{otherwise} \end{cases}$$

- **Removal of LVPL Block:** The LVPL block present in `REGC_A` is removed, as its behavior is now handled more effectively in upstream control logic (e.g., `REEC_D`).
- **Reactive Current Rate Limiting:** Ramp rate limits are also applied to the reactive current path, using bounds defined by `Iqrmax` and `Iqrmin`.
- **Current Magnitude Limiting:** The total current output is constrained by a maximum limit `Imax`. Priority between active and reactive current is set using `pqflag`, with:

$$I^2 = I_p^2 + I_q^2 \leq I_{\max}^2$$

when this limit is exceeded, the model applies prioritization logic (via the `pqflag`) to limit either I_p or I_q, depending on the configuration. This algebraic approach avoids the need for dynamic differential limiters and improves the simulation performance.

Together, the voltage-source interface and current-limiting logic enable `REGC_B` to operate reliably in low SCR environments (SCR $\approx$ 1), respond more accurately to fault conditions, and avoid numerical convergence issues common to current-source models. These enhancements make `REGC_B` a more robust and practical choice for dynamic simulation of inverter-based resources.

2.2 `REEC_D` Electrical Controller Model

The `REEC_D` model builds on the structure of the earlier electrical controller model `REEC_A`, introducing a more flexible framework for handling voltage-dependent behavior. `REEC_D` integrates a flexible set of control mechanisms, including an improved current limiting logic that allows a more realistic representation of inverter behavior under abnormal or low-voltage grid conditions. Figure 3 illustrates the entire model in Modelica using OpenIPSL. It shows key input signals such as *Pref*, *Qext*, *Pe*, and *Qgen* and the resulting current commands *Ipcmd* and *Iqcmd* that are fed to the generator/converter model. Internal blocks such as the updated current limit logic and expanded voltage-dependent limit tables are highlighted to show their roles. These advancements are discussed below.

- **Expanded Voltage-Dependent Limit (VDL) Tables:** `REEC_D` defines both reactive and active current limits using 10-point VDL tables:

$$\texttt{VDLq} = \{(V_{q,i}, I_{q,i})\}, \quad i = 1, \ldots, 10$$

$$\texttt{VDLp} = \{(V_{p,i}, I_{p,i})\}, \quad i = 1, \ldots, 10$$

Expanding the tables allow detailed shaping of the inverter's current response to different voltage levels.

DOI 10.3384/ecp218233

- **Enhanced Current Limit Logic:** The new limit equations are defined as:

$$I_{q\max} = \min(\mathrm{VDL}_q, I_{\max})$$

$$I_{q\min} = \begin{cases} I_{q\max}, & I_{q\max} < 0 \\ -I_{q\max}, & \text{otherwise} \end{cases}$$

$$I_{p\max} = \min(\mathrm{VDL}_p, \sqrt{I_{\max}^2 - I_{q\mathrm{cmd}}^2})$$

$$I_{p\min} = -K_e \cdot I_{p\max}$$

To implement these limit equations, a new logic as shown in Listing 1 was developed. It enables the model to distinguish between the generator and storage behavior by adjusting the lower active current limit based on the parameter K_e, allowing absorption of active power when $K_e > 0$. Furthermore, it ensures consistent handling of reactive power limits during high-voltage events by forcing $I_{q\min}$ to match a negative $I_{q\max}$, improving the model response under extreme conditions.

Listing 1. Enhanced Current Limit Logic in the `REEC_D` Model

```
model CLL_REECD "Current limit logic
    for REECD"

equation

Iqmax = if pqflag == false then min(
    VDLq_out, Imax) else min(VDLq_out,
    sqrt(Imax^2 - Ipcmd^2));
Iqmin = if Iqmax < 0 then Iqmax else -
    Iqmax;
Ipmax = if pqflag == false then min(
    VDLp_out, sqrt(Imax^2 - Iqcmd^2))
    else min(VDLp_out, Imax);
Ipmin = -Ke*Ipmax;
```

- **Local Current Compensation Block :** In this new electrical controller model there is a dedicated block to compensate for current measurement delays using the expression

$$|V_t - (R_c + jX_c)I_t|\,.$$

This helps stabilize the inverter response by correcting for dynamic errors due to measurement lags or system impedance, which is especially important for grid-tied converters.

- **The Baseload Flag :** The baseload flag feature allows control over how the power output of the inverter behaves. With the flag set to 0, the model operates normally. When set to 1, the output is capped at the initial power level P_{gen0}, allowing only reductions. If set to 2, the output is fixed to P_{gen0}.

3 Leveraging Modelica's Object Oriented Features for Open-Source Generic RES Models

This section discusses the benefits of using Modelica to implement the generic RES models in OpenIPSL, particularly through its support for the development of model architectures that provide modularity and object-oriented design. One of the key features leveraged in this work is the use of `replaceable` classes, which enable the substitution of flexible components and system reconfiguration. Figure 4 shows the structure of the `OpenIPSL.Electrical.Renewables` package, where control components such as the plant controller, electrical controller, and generator/converter are organized into distinct subpackages, supporting a clean and extensible modeling architecture for renewable plant systems.

3.1 Replaceable Template-Based Modeling of the WECC Modules

A key advantage of using Modelica in this work is the use of `replaceable` classes. This feature enhances flexibility and modularity in system design. Figure 4 illustrates the PV plant, enclosed in the red dotted box, where the modules `REPC_A`, `REEC_D`, and `REGC_B` are visually represented as gray highlighted blocks, indicating their implementation as `replaceable` classes in Modelica. The `RenewableElectricalController` block is highlighted in a green box to emphasize this concept, although the replaceable structure applies equally to the other modules. This approach is further illustrated in the Listing 2, where the `RenewableElectricalController` is declared as `replaceable` in the text layer, allowing flexible reconfiguration of renewable plant components in accordance with WECC modeling guidelines. This flexibility is especially valuable when evaluating multiple converter configurations or when integrating new control strategies. It allows for rapid model customization, making it well suited for system-level studies where converter behavior may vary based on application or test conditions. The modeling approach adopted here builds on principles demonstrated in our previous work on generation units using OpenIPSL and Modelica's object-oriented architecture (Fachini, Bhattacharjee, et al. 2023). While that work focused on synchronous generation units, the current model extends the concept to detailed representation of power converter units, further validating the usefulness of `replaceable` templates for scalable and reusable component modeling.

3.2 Utilizing the Switch Component in Modelica for Current Limit Logic

The implementation of the `RateFlag` in the `REGC_B` model marks a key improvement over the `REGC_A` by introducing logic that allows the rate limit to apply either to active-current (*Ip*) or to active-power (*P*), depending on the value of the flag. When `RateFlag = 0`, the logic enforces a rate limit on the current ramp (*Ip*), and when `RateFlag = 1`, it enforces it on active power. This distinction reflects practical considerations, as some vendors implement rate limits in terms of power rather than current. The flexibility of Modelica enables this logic to be cleanly embedded using graphical components such as the `Logical.Switch` block, which conditionally routes the signal based on the Boolean value of the `RateFlag`. As shown in Figure 2, the section marked with red dotted lines labeled "Active Current Limiting Logic" implements the `RateFlag` functionality. The use of a `Switch` block in Modelica enables seamless routing between control paths based on the flag value, without repeating the code in the text layer.

4 Results

4.1 Simulation Model Configuration

The components built in Sections 2 and 3 are arranged and connected as shown in Figure 4, forming the internal

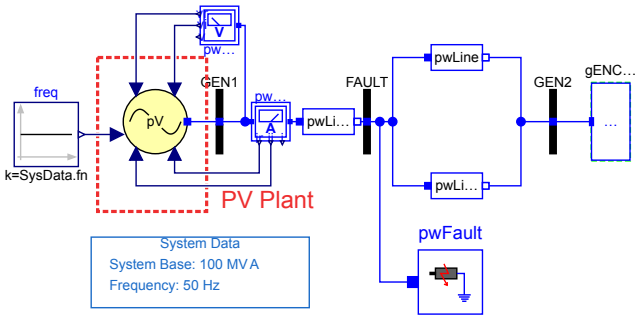

Figure 5. PV Plant in an SMIB Test Setup in OpenIPSL

structure of the PV plant. Then this PV plant model as highlighted within the red dotted block in Figure 5 is tested by integrating it into a single machine infinite bus (SMIB) test system. A similar model can be set for other models, such as BESS or Wind Plant, simply by making changes to existing templates in OpenIPSL, `*.Renewables.BESS` or `*.Renewables.Wind`, and setting control flags according to the WECC guidelines.

The setup in Figure 4 introduces a three-phase fault from ground to ground through the `pwFault` component of OpenIPSL allowing for evaluation of their dynamic response under grid disturbances. The system includes three transmission lines (`pwLine`, `pwLine1`, and `pwLine2`) with defined impedances. The bus `GEN2` is connected to an infinite bus model from OpenIPSL that represents the connection to the grid.

4.2 Comparing `REEC_B` vs `REEC_D`

Next, the voltage response and fault dynamics are analyzed to validate the behavior of the model under grid disturbances when using the existing `REEC_B` vs. the newly implemented `REEC_D`. The results are verified through

DOI
10.3384/ecp218233

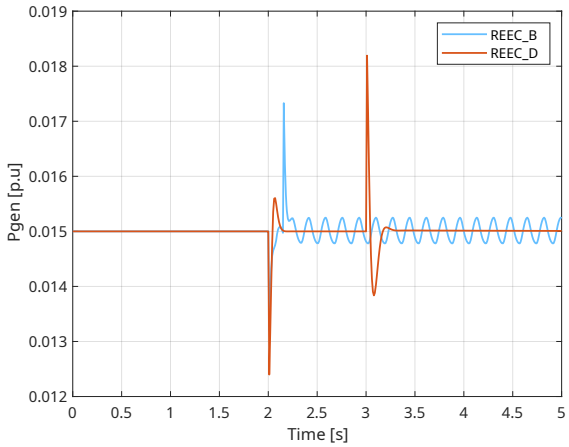

Figure 6. Active Power generated by the PV Plant in OpenIPSL, comparing the response of the new `REEC_D` model vs the previous `REEC_B` model.

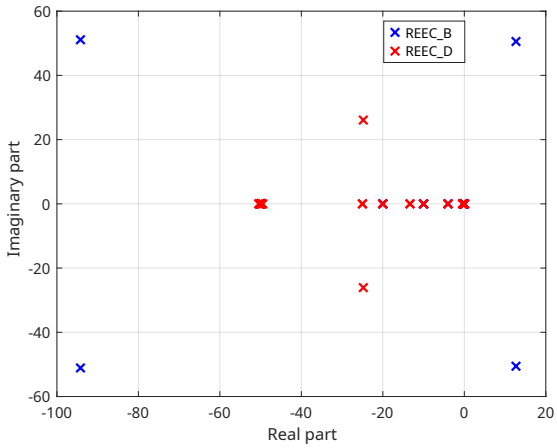

Figure 7. Poles of the PV plant comparing the REEC_B and REEC_D controllers

linear analysis of the two model variants.

Figure 6 shows the active power output P_{gen} of the `REGC_A` converter model along with the newly implemented controller `REEC_D` (in red), along with the response of the `REGC_A` with the previous controller `REEC_B` (in blue). The simulation scenario subjects the power system to a fault at the `FAULT` bus (see Figure 5), which occurred around 2 seconds and lasted for 1 second. Observing the red trace, which corresponds to the use of the new controller model `REEC_D`, during the application of the fault, there is a sharp deviation in P_{gen}followed by a transient response as the system stabilizes. After the event, the power gradually returns to its steady state, indicating the system's ability to recover from the fault. It should be noted that the blue line that corresponds to the response when simulating the use of the `REEC_B` controller results in a growing oscillatory response during the fault, along with a critically stable response after the fault. This shows one of the main benefits for simulation accuracy that the new model offers.

Figure 7 illustrates the linear analysis of the PV plant test model as shown in Figure 4. The poles of the model with both the electrical controllers, `REEC_D` and the previous version `REEC_B`, are compared. It can be observed that the `REEC_B` model, exhibits an unstable pole, which is not present in the newly implemented `REEC_D` model. This is also reflected in the Table 1 where the `REEC_D` model shows poles with lower frequency (5.73 Hz) and moderate damping (0.6889), indicating slower, well-damped oscillations. In contrast, the `REEC_B` model has a pair of poles with a higher frequency (8.3 Hz) and negative damping (-0.2433), which explains the oscillations as seen in Figure 6. Observe that although this is an unstable pole, the states that affect are internal to the plant, that is, the plant controller and the renewable energy controller, as indicated in the contribution to states column in Table 1. Consequently, this results in the oscillatory response in Figure 6, and because in the test model it does not interact with other

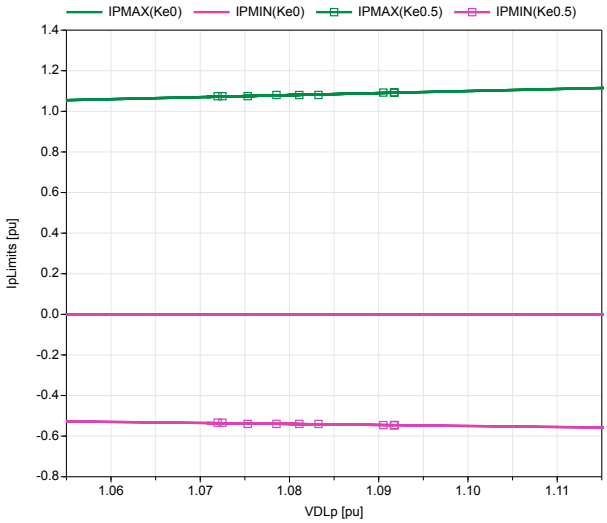

Figure 8. Active Current Limits for $K_e = 0$ and 0.5 based on the expanded VDL_p table.

dynamic components, the power system will not become unstable. This is the effect of modeling the "infinite bus", which absorbs the oscillations injected by the PV and does not interact with it. This bounded response when interfacing a power electronic device with a strong network has recently been observed for the case of PV plants (Wang et al. 2022) and data centers (Mishra, Vanfretti, Delaree, Purcell, et al. 2025), and therefore care should be taken when choosing when to use `REEC_B` or `REEC_D`, and/or, how they are parameterized in order to capture this behavior if appearing in a particular plant.

4.3 Illustrating New Model Features of `REEC_D`

Figure 8 illustrates the verification of the enhanced current limit logic based on the expanded voltage-dependent limit table implemented in the `REEC_D` model, as defined in Listing 1. The plot shows the active current limits (`Ipmax` and `Ipmin`) for two configurations: $K_e = 0$ and $K_e = 0.5$, plotted against the voltage-dependent limit out-

Conjugate Pair number	Eigen Value	Freq. [Hz]	ζ	Contribution to States
Model: REEC_D				
19/20	$-24.795 \pm j26.09$	5.7284	0.6889	z[19/20] → `PlantController.leadLag.TF.x_scaled[1]` (73 %) z[19/20] → `PlantController.simpleLag2.state` (8.7%)
Model: REEC_B				
18/19 & 16/17	$12.68 \pm j50.55$	8.2959	-0.2433	z[18/19] → `PlantController.leadLag.TF.x_scaled[1]` (41%) z[16/17] → `RenewableController.integrator2.y` (25.5%)

Table 1. Complex conjugate pairs of eigenvalues and their contributions for REEC_D and REEC_B models.

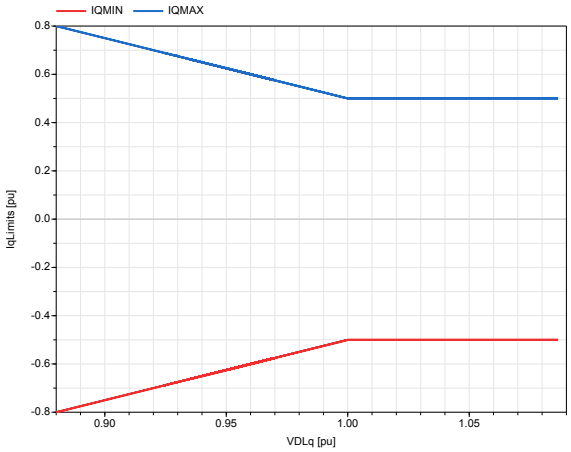

Figure 9. Reactive Current Limits for $K_e = 0$ based on the expanded VDL_q table.

put, VDL_p. The results are consistent with the expected behavior presented in the WECC report introducing the model (Pourbeik 2018), where the maximum current (`Ipmax`) remains unchanged in both cases, reflecting its independence from the K_e parameter.But the minimum active current (`Ipmin`) varies with K_e, remaining at zero for $K_e = 0$, which corresponds to a generator that allows discharging only, with no charging capability. In contrast, for $K_e = 0.5$, `Ipmin` is around -0.5 while `Ipmax` remains around 1.0, reflecting a storage device and indicating that the it can charge at half the maximum discharging rate. This is clearly reflected in the plot, where the `Ipmin` curve for $K_e = 0.5$ reaches half the magnitude of the corresponding `Ipmax`.

Similarly, Figure 9 compares the implemented reactive current limits (`Iqmax` and `Iqmin`) in the model against the expected behavior defined by the VDL_q table. The simulated curves closely follow the voltage-dependent shape of the reference table which confirms that the model correctly applies the VDL_q logic to constrain the reactive current based on terminal voltage. The observation made on both Figures 8 and 9 is verified by the results reported in the WECC documentation (Pourbeik 2018).

5 Conclusions

This work demonstrates the effective use of Modelica and the OpenIPSL library to implement the second-generation WECC generic renewable energy system models, specifically the generator/converter `REGC_B` and the electrical controller `REEC_D` components. Leveraging replaceable template-based modeling in Modelica allowed us to build flexible and modular models that can adapt to different simulation needs without changing the base structure. This approach supports faster testing and better customization, especially when working with different converter setups. The use of the `RateFlag` in the `REGC_B` model added a practical and important improvement by allowing the model to switch between limiting based on current or power. This logic was built using Modelica's `Switch` component, which simplifies the design by clearly separating control paths and makes the model easier to trace and modify through its visual interface. Overall, the combination of Modelica and OpenIPSL offers a strong and reusable way to model inverter-based resources and supports more accurate and scalable studies of power system dynamics.

In future work, we will develop new power grid models that would allow us to better illustrate the behavior of the generator/converter `REGC_B`, with a particular focus on presenting its results, as it is specifically designed to handle weak grid conditions. We will also examine the electrical controller `REEC_D` under different SCRs and compare them against the previous models in order to illustrate the benefits mentioned in the `WECC` reports (Pourbeik 2018).

To access the models in this paper before they are integrated into OpenIPSL, the reader can find them in the following GitHub repository: `https://github.com/ALSETLab/OpenIPSL_IMC2025WECC`

Analytical Treatment of Hollow Toroid Flux Tubes

Herbert Schmidt

Department of Electrical Engineering, Bochum University of Applied Sciences, Germany
herbert.schmidt@hs-bochum.de

Abstract

Stray flux tubes around cylindrical poles are commonly modelled starting from the results for planar flux tubes using the circumference of the cylinder as depth. While this is a tried and tested approach, we here discuss analytical expressions using the actual axisymmetric geometry of a fraction of a hollow torus and compare their results to those of the accepted approach.
Keywords: magnetics, stray flux, reluctance force

1 Introduction

In analytically calculating the permeance G_m (or equivalently the reluctance R_m) of a given stray flux tube, we start from Hopkinson's law for a prismatic element:

$$\frac{1}{R_m} = G_m = \frac{\Phi}{V_m} = \mu_0 \frac{A}{l} \tag{1}$$

where Φ is the flux perpendicular to a surface area A and V_m is the magnetic tension along its length l. This simple equation explicitely requires a prismatic flux tube, i.e., constant cross-section and constant length of flux lines within this element (cf. Fig. 1a).

If one of these prerequisites is not met, the flux tube may be subdivided indefinitely and the effective permeance then is computed as an integral over these elements.[1] This works well, e.g., for a hollow cylinder (or any fraction thereof) with radial or circumferential flux. A typical teaching problem might be a half hollow cylinder with circumferential flux (cf. Fig. 1b), resulting in (Roters 1941, P. 132, Eq. 8b):

$$G_m = \frac{\mu_0 l}{\pi} \ln \frac{r_o}{r_i} = \frac{\mu_0 l}{\pi} \ln \left(1 + \frac{2t}{g}\right) \tag{2}$$

where r_o is the outer radius, $r_i = g/2$ is the inner radius, $t = r_o - r_i$ their difference, and l is the length (depth) of the hollow cylinder. Here, the cross section $A = tl$ is constant, but the length of the flux lines varies from πr_i to πr_o.

The same method that yields this analytical result becomes slightly more cumbersome, if both the cross section and the length vary within the flux tube. It still is valid, though, and in this paper we will show the analytical result for the flux in similar flux tubes wrapped within or without cylindrical poles, i.e., for half or quarter hollow torus geometries, where both the cross section per flux line and the length of each flux line are variable. We will cover five qualitatively different situations (cf. Fig. 2):

(a) inner half hollow torus

(b) lower (or upper) half hollow torus

(c) outer half hollow torus

(d) inner quarter hollow torus

(e) outer quarter hollow torus

[1] Note, that this is allowable only for stray flux tubes, i.e., $\mu_r = 1$ (or at least constant), since variable cross section means variable operating point and hence variable permeability within the element.

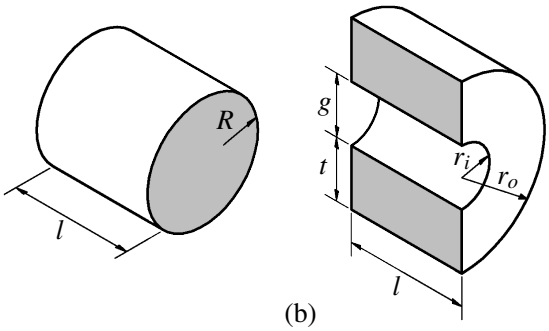

Figure 1. Flux tube geometries. (a) generic prismatic flux tube with $A = \pi R^2$. (b) Half hollow cylinder with circumferential flux. In both figures, flux enters and exits the flux tube through areas marked in gray.

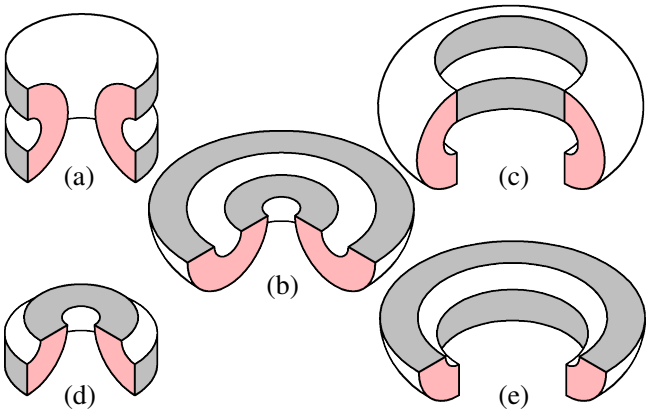

Figure 2. Flux tube geometries. (a) inner half hollow torus. (b) lower half hollow torus. (c) outer half hollow torus. (d) inner quarter hollow torus. (e) outer quarter hollow torus. In all figures, flux enters and exits the flux tube through areas marked in gray. Red are areas opened by 3/4 cut-aways. The actual flux tubes extend over a full rotation.

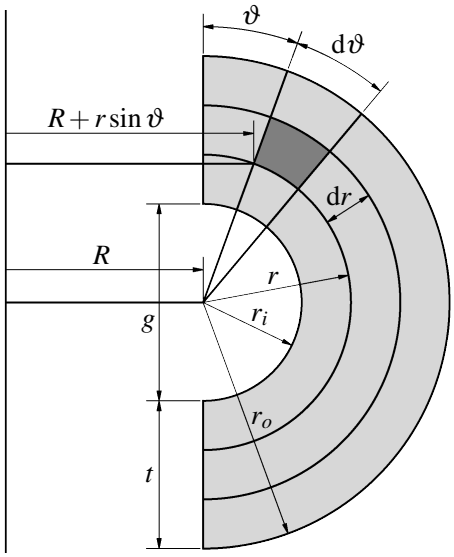

Figure 3. Geometry used in integration.

All these may be addressed by first focusing on the outer and inner half hollow torus. The quarter variants have half the reluctance of the half variants, while the lower (or upper) half hollow torus is the sum of an inner and an outer quarter hollow torus.

Mind that these flux tubes look like half hollow cylinders in their cross section, but they are none, because they are wrapped around cylindrical poles. It is therefore not permissible to simply scale the result to arbitrary polar angles. Scaling from half to quarter hollow torus is the only acceptable fraction, since the flux tube is perfectly mirror symmetrical with respect to this cutting plane.

2 Analytical Treatment

We use a subdivision as depicted in Figure 3 and start by calculating the permeance of an infinitesimal flux tube at radius r and polar angle ϑ:

$$G_m(r,\vartheta) = \mu_0 \frac{2\pi(R \pm r\sin\vartheta)\,\mathrm{d}r}{r\,\mathrm{d}\vartheta} \tag{3}$$

The positive sign refers to the outer half hollow torus geometry shown in Figure 3, the negative sign refers to the corresponding inner half hollow torus.

We first derive the total permeance of a slice of polar width $\mathrm{d}\vartheta$:

$$G_m(\vartheta)\,\mathrm{d}\vartheta = \int_{r_i}^{r_o} 2\pi\mu_0 \left(\frac{R}{r} \pm \sin\vartheta\right) \mathrm{d}r \tag{4}$$

$$= 2\pi\mu_0 \left(R\ln\frac{r_o}{r_i} \pm (r_o - r_i)\sin\vartheta\right) \tag{5}$$

We then calculate the total reluctance of the full flux tube:

$$R_m = \frac{1}{2\pi\mu_0 t} \int_0^{\pi} \frac{\mathrm{d}\vartheta}{\frac{R}{t}\ln\frac{r_o}{r_i} \pm \sin\vartheta} \tag{6}$$

With $\eta = \frac{R}{t}\ln\frac{r_o}{r_i}$ we find two cases for the primitive (Bronštein et al. 1993, P. 763, Eq. 306):

$$\int \frac{\mathrm{d}\vartheta}{\eta \pm \sin\vartheta} = \begin{cases} \frac{2}{\sqrt{\eta^2-1}} \arctan\frac{\eta\tan\frac{\vartheta}{2}\pm 1}{\sqrt{\eta^2-1}} & \text{for: } \eta > 1 \\ \frac{1}{\sqrt{1-\eta^2}} \ln\frac{\eta\tan\frac{\vartheta}{2}\pm 1-\sqrt{1-\eta^2}}{\eta\tan\frac{\vartheta}{2}\pm 1+\sqrt{1-\eta^2}} & \text{for: } \eta < 1 \end{cases} \tag{7}$$

We deviate from Bronštein et al. (1993) by stating the cases without the use of squares. Comparing η to 1 is equivalent to comparing η^2 to 1 since all radii are positive and $r_o > r_i$, so η is always positive.

2.1 Inner Half Hollow Torus (Negative Sign)

We first observe that only the case $\eta > 1$ exists for the inner half hollow torus. To see this, we consider the case $\eta = 1$:

$$\frac{R}{t}\ln\frac{r_o}{r_i} = 1 \tag{8}$$

$$\ln\frac{r_o/R}{r_i/R} = \frac{r_o}{R} - \frac{r_i}{R} \tag{9}$$

$$\ln\frac{r_o}{R} - \frac{r_o}{R} = \ln\frac{r_i}{R} - \frac{r_i}{R} \tag{10}$$

$\ln x - x$ is always negative, yet has a single high point at $x = 1$. For the inner half hollow torus we know the argument to be smaller than one, otherwise the flux tube could not exist without intersecting itself. Thus this function is strictly monotonic increasing for relevant arguments, and the only solution of Equation 10 hence is $r_i = r_o$. In this case, the flux tube ceases to exist and $R_m \to \infty$. This means, the only relevant case is $\eta > 1$.

Looking at the upper integration limit first, $\vartheta = \pi$. Then $\tan\frac{\vartheta}{2} \to +\infty$, while everything else in the argument of the arctan is finite, so the arctan returns $\frac{\pi}{2}$. Looking at the lower integration limit now, $\vartheta = 0$. Then $\tan\frac{\vartheta}{2} = 0$ and the argument of the arctan is negative, so we end up with:

$$R_m = \frac{1}{\pi\mu_0 t}\frac{1}{\sqrt{\eta^2-1}}\left(\frac{\pi}{2} + \arctan\frac{1}{\sqrt{\eta^2-1}}\right) \tag{11}$$

using the point symmetry of the arctan. With $G_{m0} = \pi\mu_0 t$ and using that the argument of the arctan is always positive, so we can use $\alpha_+ = \frac{\pi}{2} + \operatorname{arccot}\sqrt{\eta^2-1}$, we can write the permeance as:

$$G_m = G_{m0}\frac{\sqrt{\eta^2-1}}{\alpha_+} \tag{12}$$

All major results, like this permeance, are collected in Table 1 towards the end of the paper for quick reference.

We can finally verify the expected behaviour of the reluctance for $\eta^2 \to 1$ by considering $\eta^2 = 1 + \varepsilon^2$:

$$\lim_{\varepsilon\to 0}\frac{1}{G_{m0}}\frac{1}{\varepsilon}\left(\frac{\pi}{2} + \arctan\frac{1}{\varepsilon}\right) \to \infty \tag{13}$$

DOI 10.3384/ecp218243

2.2 Outer Half Hollow Torus (Positive Sign)

In turning to the outer half hollow torus now, we first note that in this case both $\eta > 1$ and $\eta < 1$ are physical. Consider first, $r_o = 2r_i = R$, i.e., $t = r_i = R/2$ and $\eta = 2\ln 2 > 1$. Consider next $r_o = 2r_i = 2R$, i.e., $t = r_i = R$ and $\eta = \ln 2 < 1$. The restriction for the inner half hollow torus exclusively came from the limited radial space towards the center – outwards there is unlimited space.

Looking at the case $\eta > 1$ first, the reasoning is much the same as before (here, $\alpha_- = \frac{\pi}{2} - \operatorname{arccot}\sqrt{\eta^2-1}$, allowing for the sign), leaving:

$$G_m = G_{m0}\frac{\sqrt{\eta^2-1}}{\alpha_-} \tag{14}$$

Looking at the case $\eta < 1$ now, we find at $\vartheta = \pi$ that both the tangens in the numerator and the denominator of the logarithm's argument diverge, i.e. the argument approaches unity and the logarithm vanishes. At $\vartheta = 0$, both tangens vanish, and we are left with:

$$R_m = -\frac{1}{2G_{m0}}\frac{1}{\sqrt{1-\eta^2}}\ln\frac{1-\sqrt{1-\eta^2}}{1+\sqrt{1-\eta^2}} \tag{15}$$

We use $\lambda = \ln\frac{1+\sqrt{1-\eta^2}}{1-\sqrt{1-\eta^2}}$ to write the permeance concisely:

$$G_m = G_{m0}\frac{2\sqrt{1-\eta^2}}{\lambda} \tag{16}$$

Note that the reciprocal in the logarithm's argument cancels the sign in Equation 15. Both terms may not be evaluated at $\eta = 1$, yet other than before they do not diverge but match up continuously. To see this, we start from the equation for $\eta > 1$, and use $1 = \eta^2 - \varepsilon^2$, arriving at:

$$\lim_{\varepsilon\to 0}\frac{1}{G_{m0}}\frac{1}{\varepsilon}\left(\frac{\pi}{2} - \operatorname{arccot}\varepsilon\right) = \frac{1}{G_{m0}} \tag{17}$$

Similarly, using $\eta^2 = 1 - \varepsilon^2$ for the equation for $\eta > 1$ yields:

$$\lim_{\varepsilon\to 0}\frac{-1}{2G_{m0}}\frac{1}{\varepsilon}\ln\frac{1-\varepsilon}{1+\varepsilon} = \frac{1}{G_{m0}} \tag{18}$$

as above. So all these cases give physical solutions, and they match continuously.

2.3 Inner and Outer Quarter Hollow Torus

The equations for the inner and outer quarter hollow torus immediately follow from the observation, that their reluctance will be half that of the corresponding half hollow torus, their permeance will be twice that of the corresponding half hollow torus.

2.4 Lower Half Hollow Torus

The lower half hollow torus then follows from these:

$$R_m = \frac{\alpha_-}{2G_{m0}\sqrt{\eta^2-1}} + \frac{\alpha_+}{2G_{m0}\sqrt{\eta^2-1}} \tag{19}$$

$$G_m = G_{m0}\frac{2\sqrt{\eta^2-1}}{\frac{\pi}{2} - \operatorname{arccot}\sqrt{\eta^2-1} + \frac{\pi}{2} + \operatorname{arccot}\sqrt{\eta^2-1}} \tag{20}$$

$$= G_{m0}\frac{\sqrt{\eta^2-1}}{\pi/2} \qquad \text{for: } \eta > 1 \tag{21}$$

We do not need to consider other cases, as the inner quarter torus only exists for $\eta > 1$.

3 Check with Finite Element Method

In order to evaluate the applicability of these formulae, we want to compare them with finite element method (FEM) calculations (Meeker 2025). This is necessary since on our way here we made two separate steps: we firstly *assumed* a flux pattern and we then secondly did the appropriate calculations to solve for this assumption. We did so far, however, not verify that the assumed flux patterns are correct in the first place. *Are* the flux lines exactly shaped like half circles? The prior results are only valid insofar as this is a reasonable approximation of reality.

To verify the flux pattern, we compare with FEM. The way the simulation is set up, only three areas are actually modelled (cf. Fig. 4): First, the flux tube in question, modelled as air ($\mu_r = 1$). Second, the area inside r_i, modelled as an insulator ($\mu_r = 10^{-6}$) containing a current linkage of, in this case, $\Theta = 1$ A. Third, a yoke serving as a magnetic short ($\mu_r = 10^{12}$). All outside areas are cut off by Dirichlet boundary conditions ($A = 0$). We then evaluate the integral over B_n in the center of the yoke, thus making sure that the flux lines at the point of integration have minimal curvature and are expected to yield a reliable value of Φ. The permeance is finally computed from:

$$G_m = \frac{\Phi}{\Theta} \tag{22}$$

Since all flux patterns scale, we effectively have to consider only two variables instead of three (R, r_i and r_o). For FEM we fix $R = 1$ mm for all calculations and use r_i/R as independent variable for our plots. We show different values of r_o/R as a family of curves, taking care to keep $r_i < r_o$ and $r_o < R$ where appropriate. Note that the quarter hollow torus elements (d) and (e) were not separately studied, as they are exactly half of (a) and (c).

Three exemplary results of such analysis are shown in Figure 4. Apart from the permeance, these pictures give us valuable clues with respect to the previously raised question: *are* the flux lines half-circle shaped? Even though we dictate the outer limit to be a half-circle, this is not exactly the case. In Figure 4a, e.g., it is quite evident that the distance of the outer-most flux line from the white surrounding area is *not* constant. Similarly, it is obvious, that

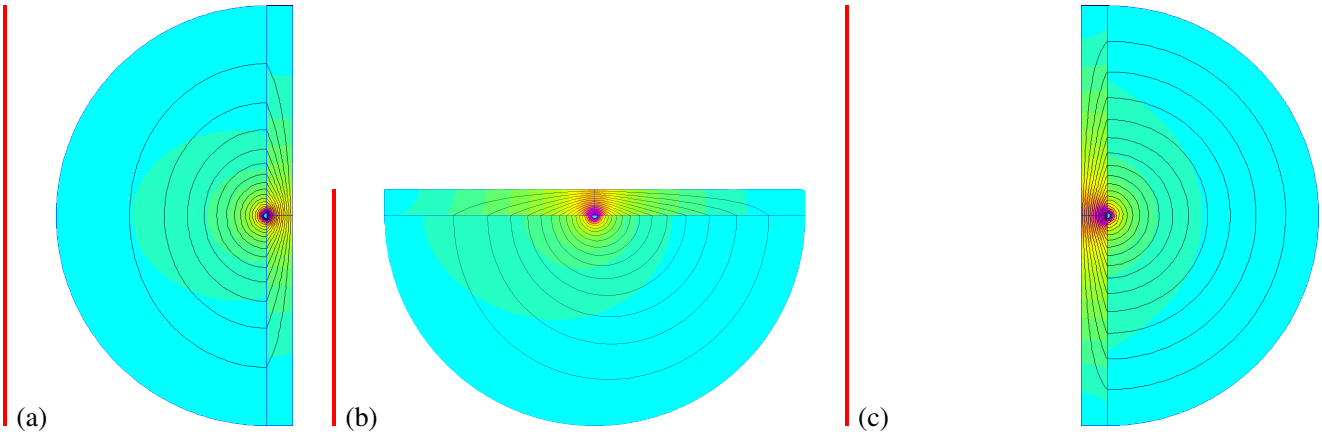

Figure 4. FEM results for $r_o/R = 0.8$ and $r_i/R = 0.01$. (a) inner half hollow torus. (b) lower half hollow torus. (c) outer half hollow torus. The left vertical red lines indicate the rotational axes.

the false colour map (showing the absolute of the flux density) does not exactly mimic the circular symmetry of the flux tube. The teal area is horizontally elongated in Figure 4a, while it is vertically elongated in Figure 4c. So we do well to remain cautious.

Next we study the values for G_m from FEM, from our formulae and from the formulae presently implemented in Modelica. The results are shown in Figure 5.

Let us consider the inner and outer half hollow torus first. Both these are compared to `Modelica.Magnetic.Fluxtube.Shapes.Leakage.HalfHollowCylinder`, which essentially assumes that the half hollow torus is a half hollow cylinder wrapped around a cylinder:

$$G_m = 2\mu_0 R \ln\left(1 + \frac{t}{r_i}\right) = G_{m0}\frac{\eta}{\pi/2} \tag{23}$$

The latter is written using the abbreviations introduced above. Comparing this to our expression for G_m ($\eta > 1$) requires $\sqrt{\eta^2 - 1} \to \eta$ in the numerator and $\operatorname{arccot}\sqrt{\eta^2 - 1} \to 0$ in the denominator. Both are true for $\eta \to \infty$, i.e., the presently used Equation 23 holds up for:

$$\frac{R}{t}\ln\frac{r_o}{r_i} \to \infty \tag{24}$$

In this limit, it similarly approaches our expressions for either half hollow torus (the sign of the arccot in the denominator is inconsequential, as in the considered limit the entire arccot is neglected). So our analytical result is not at odds with the present practice, but is a consistent extension to arbitrary parameter choices.

We intuitively expect Equation 23 to be fine for $R \gg r_i$ and $R \gg r_o$ (the former is noted in `Modelica.Magnetic.Fluxtube.Shapes.Leakage.HalfHollowCylinder` as a condition for cylindrical poles). What we find here is, that the actual condition is $R \gg (r_o - r_i)$ while at the same time r_o markedly larger than r_i (if the latter is not the case, the logarithm will be small). So the former condition cannot be fulfilled by making both r_o and r_i large while keeping their difference small.

In Figure 5a and 5c we find a reasonable fit for $r_o/R = 0.1$, however, for larger r_o/R we find considerable deviations even for $r_i/R = 0.01$. So if stating the above condition using a single simple equation, $R \gg r_o$ might be more useful than $R \gg r_i$ (since $r_i < r_o$, the former includes the latter anyway).

Considering the lower half hollow torus now, we find a quite reasonable fit with the equation presently used in Modelica (Roters 1941, P. 139, Eq. 22a),[2] which after substituting the appropriate symbols actually is identical to Equation 23.

This actually gives quite reasonable results with the exception of r_o/R close to unity, since the systematic errors of the inner and outer bit mostly cancel each other out. Note however, that in this case, our exact result is not much more complex, yet gives consistently good results for all parameter combinations.

For all three cases, our analytical result shows excellent fit over the studied parameter range. There actually are deviations from exactly circular flux lines, however, these do not result in notable differences in permeance. In order to quantify this statement, we in Figure 6 show the relative deviations at $r_o/R = 0.1$. For high r_o/R the shortcomings of the presently implemented approach are obvious. What we want to do here is to make sure that our analytical approach is at least as good as the presently used approach where there are no obvious problems with the latter.

From this comparison we find that even for $r_o/R = 0.1$ our approach is systematically better than the presently used formula. In the case of the inner and outer half hollow torus, it is better in terms of the relative deviation from the FEM results by at least one order of magnitude. In the

[2] There are two cases given in (Roters 1941) which actually are used to decide which bit of open pole surface does not count towards the useful radius sector, depending on whether the inner or outer useful radius difference is larger. We do not note these cases here as we explicity only use the appropriate radius sectors here, by starting from R and drawing two half circles with radii r_i and r_o centered there.

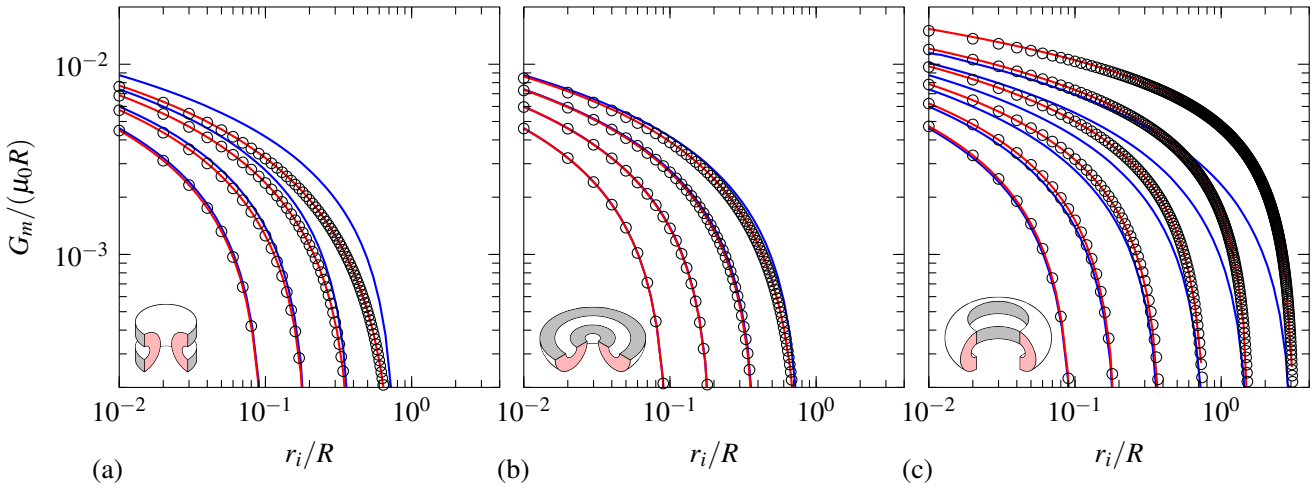

Figure 5. Results for the permeance. (a) inner half hollow torus. (b) lower half hollow torus. (c) outer half hollow torus. Each left to right (bottom to top): $r_o/R = 0.1, 0.2, 0.4, 0.8, 1.6, 3.2$ (the latter two only in (c)). Circles mark individual FEM results, red lines are analytical formulae presented here, blue lines are formulae presently used in Modelica.

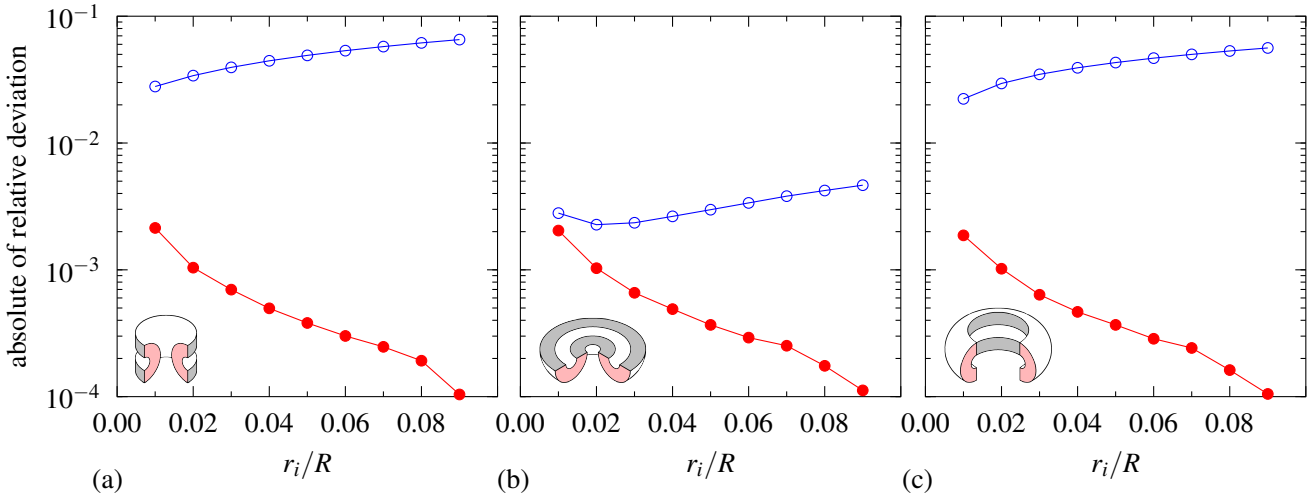

Figure 6. Relative deviations from FEM results for $r_o/R = 0.1$. (a) inner hollow hollow torus. (b) lower half hollow torus. (c) outer half hollow torus. Red filled symbols are analytical formulae presented here, blue open symbols are formulae presently used in Modelica.

case of the lower half hollow torus, the deviations partly cancel, especially for $r_i/R = 0.1$ the result is almost as good as the one presented here. Still, we can conclude that over the studied parameter range the formulae presented here give consistently better results than the status quo.

4 Equations for Force

Having analytical expressions for the permeance of flux tube geometries (a) through (e) (cf. Fig. 2) puts us in a position to also provide analytical expressions for forces generated by their deformation, e.g., by a moving armature. We use (Roters 1941, P. 197, Eq. 2a):

$$F = \frac{1}{2} V_m^2 \frac{\mathrm{d}G_m}{\mathrm{d}g} \tag{25}$$

which in Modelica is implemented in `Modelica.Magnetic.FluxTube.BaseClasses.Force`. To utilize this, we only need to supply an equation for the latter derivative, `dGmBydx`. We will, however, have to address a number of different cases, as for computing the derivatives it is quintessential to specify, which quantities are allowed to change with the air gap, g. We will walk through the relevant cases to illustrate what is meant by this.

The first relevant case is $r_o = \text{const}$. This case is appropriate if there is a natural limit to the radial extent of the flux tube. For an inner hollow torus this might simply be $r_o = R$. For an outer hollow torus this might be due to another part of the magnetic circuit, which would attract flux lines outwards from a given radius. A typical example might be the red flux tube in Figure 7a. At a point, where $\frac{\pi}{2} r_o$ equals the radius difference of the shown yoke parts, flux lines would short out to the outer part of the yoke

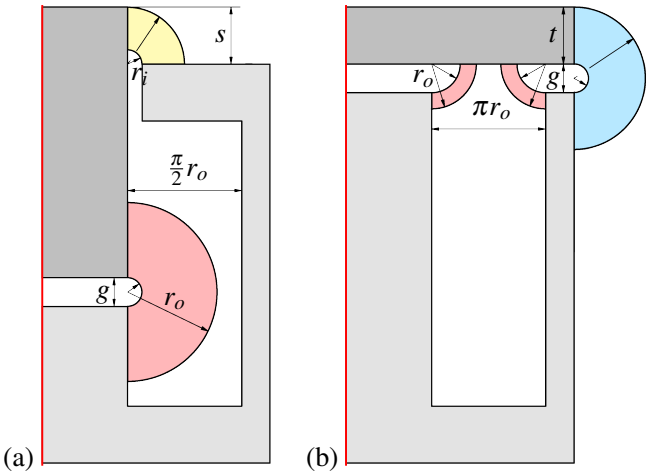

Figure 7. Application cases for force calculation. (a) plunger type solenoid. (b) flat face type solenoid. Light gray is the yoke, dark gray the armature. The left vertical red lines indicate the rotational axes. Red flux tubes are of type $r_o = \text{const.}$, blue of type $t = \text{const.}$, yellow of type $r_i = \text{const.}$

rather than arcing over this outer half hollow torus. Analogous cases will occur for inner half hollow tori, if there are equivalent hollow cylinder parts facing each other. A similar example for an inner and outer quarter hollow torus might be seen in the red flux tubes in Figure 7b, where again the radius difference within the yoke gives an upper limit to what outer radius such a toroid flux tube could have.

The second relevant case is $t = \text{const.}$ This is the case presently implemented in `Modelica.Magnetic.FluxTubes.Shapes.Force.LeakageAroundPoles`. This case is appropriate, if the stray flux tube is limited by a given axial width t of either one or both of the facing elements. As an example, consider the blue flux tube in Figure 7b. While the armature moves, $r_i = g/2$ will change, t will stay constant and $r_o = r_i + t$ will change accordingly.

Flux tubes of this type again may occur in the shape of inner or outer, half or quarter hollow tori. In discussing the relevant derivatives below, though, we will not consider the quarter hollow tori separately, as nothing qualitatively new happens when doing that. The force will simply be quadruple what we find in a half hollow torus, since for the quarter hollow torus twice the magnetic tension per length is applied (i.e., twice the magnetic field strength), while twice the distortion is effected on a quarter hollow torus for given stroke, s, as compared to a half hollow torus. Since for the derivatives, we only need the change of stroke, ds, it is allowable to identify $r_i = s$ for $t = \text{const.}$ and $r_o = \text{const.}$, and $r_o = s$ for $r_i = \text{const.}$

The latter is the third relevant case, and this case will mostly occur for inner or outer quarter hollow tori.[3] The technical situation might be a cylindrical plunger in a cylindrical hole, so an outer quarter hollow toroid flux tube is restricted in r_o and t, while at the same time r_i (being the fixed radius difference between plunger and hole) is constant. This situation is visualized by the yellow flux tube in Figure 7a. The same type of flux tube may occur on the inside, e.g., if the face of the plunger is lowerd into a hole in the yoke.

Note, that since in axisymmetric geometries motion is expected along the rotational axis, lower half hollow toroid flux tubes will generally not generate force (while maintaining this general geometry). Looking at the case of two coaxial hollow cylinders moving relative to each other, e.g., the relevant flux tube would be expected to be significantly distorted away from the half hollow torus geometry considered here. We will therefore not give equations for these.

We will now proceed to look at the required derivatives. All the relevant results are collected in Table 1 for quick reference (formulae for quarter tori are only shown for $r_i = \text{const.}$ to keep the table concise; the equations for $r_o = \text{const.}$ and $t = \text{const.}$ may easily be derived from those shown, as pointed out above).

4.1 Inner Half Hollow Torus ($r_o = \text{const.}$)

Starting from Equation 12, the required derivative is of the structure:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = \left(\frac{G_m}{G_{m0}} \frac{\mathrm{d}G_{m0}}{\mathrm{d}r_i} + G_{m0} \frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}} \frac{\mathrm{d}\sqrt{\eta^2-1}}{\mathrm{d}\eta} \frac{\mathrm{d}\eta}{\mathrm{d}r_i} \right) \frac{\mathrm{d}r_i}{\mathrm{d}g} \tag{26}$$

wherein we need the following derivatives:

$$\frac{\mathrm{d}G_{m0}}{\mathrm{d}r_i} = -\frac{G_{m0}}{t} \tag{27}$$

$$\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}} = \frac{\left(\frac{\pi}{2} + \operatorname{arccot}\sqrt{\eta^2-1}\right) + \frac{\sqrt{\eta^2-1}}{\eta^2}}{\left(\frac{\pi}{2} + \operatorname{arccot}\sqrt{\eta^2-1}\right)^2} \tag{28}$$

$$\frac{\mathrm{d}\sqrt{\eta^2-1}}{\mathrm{d}\eta} = \frac{\eta}{\sqrt{\eta^2-1}} \tag{29}$$

$$\frac{\mathrm{d}\eta}{\mathrm{d}r_i} = \frac{1}{t}\left(\eta - \frac{R}{r_i}\right) \tag{30}$$

$$\frac{\mathrm{d}r_i}{\mathrm{d}g} = \frac{1}{2} \tag{31}$$

This might look somewhat intimidating, however, there are a lot of recurring terms that are needed to calculate the permeance, anyway, so this can actually be coded quite efficiently. In doing that, it becomes necessary to ascertain $r_o > r_i$. Once this is no longer valid, this flux tube ceases to exist, resulting in $G_m = 0$ and $\frac{\mathrm{d}G_m}{\mathrm{d}g} = 0$. The same is true for the outer half hollow torus. This check is unnecessary if $t = \text{const.}$ is used, as this way $r_o - r_i = t$ for $t > 0$ always results in an existing flux tube.

[3] It is possible to invent scenarios, where this might occur for half hollow tori. These scenarios, however, appear to be rather artificial. For this reason, we do not present them here. If needed, the required formulae may easily be produced starting from what is presented here.

DOI 10.3384/ecp218243

4.2 Inner Half Hollow Torus ($t = \text{const.}$)

The general procedure is much the same as above:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = G_{m0}\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}}\frac{\mathrm{d}\sqrt{\eta^2-1}}{\mathrm{d}\eta}\frac{\mathrm{d}\eta}{\mathrm{d}r_i}\frac{\mathrm{d}r_i}{\mathrm{d}g} \tag{32}$$

The first term in Equation 26 may be omitted, as $G_{m0} = \pi\mu_0 t$ is constant in this case. η we can therefore rewrite as:

$$\eta = \frac{R}{t}\ln\left(1+\frac{t}{r_i}\right) \tag{33}$$

As far as the derivatives themselves are concerned, only Equation 30 needs to be adjusted accordingly:

$$\frac{\mathrm{d}\eta}{\mathrm{d}r_i} = -\frac{R}{r_i(r_i+t)} \tag{34}$$

4.3 Outer Half Hollow Torus ($r_o = \text{const.}$)

In this case, we need to keep in mind to separate the cases $\eta > 1$, $\eta = 1$ and $\eta < 1$ (this was not necessary for the inner half hollow torus). Starting with $\eta > 1$ and using Equation 14 this time, the equations look much the same as before for the inner half hollow torus and we can keep using Equation 26. We only need to adjust Equation 28 to:

$$\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}} = \frac{\left(\frac{\pi}{2}-\operatorname{arccot}\sqrt{\eta^2-1}\right)-\frac{\sqrt{\eta^2-1}}{\eta^2}}{\left(\frac{\pi}{2}-\operatorname{arccot}\sqrt{\eta^2-1}\right)^2} \tag{35}$$

Since the permeance is defined using cases, we will have to check for continuity between these. In order to facilitate this, we will give the full relevant equation:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = \left(\frac{G_m}{G_{m0}}\frac{\mathrm{d}G_{m0}}{\mathrm{d}r_i} + G_{m0}\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}}\frac{\mathrm{d}\sqrt{\eta^2-1}}{\mathrm{d}\eta}\frac{\mathrm{d}\eta}{\mathrm{d}r_i}\right)\frac{\mathrm{d}r_i}{\mathrm{d}g} \tag{36}$$

$$= \frac{G_{m0}}{2t\alpha_-}\left(\left(\frac{\eta}{\sqrt{\eta^2-1}}-\frac{1}{\eta^2\alpha_-}\right)\left(\eta-\frac{R}{r_i}\right)-\sqrt{\eta^2-1}\right) \tag{37}$$

For $\eta < 1$ the following derivatives need to be added to our pool:

$$\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{1-\eta^2}} = -2\frac{\frac{2\sqrt{1-\eta^2}}{\eta^2}-\ln\frac{1+\sqrt{1-\eta^2}}{1-\sqrt{1-\eta^2}}}{\ln^2\frac{1+\sqrt{1-\eta^2}}{1-\sqrt{1-\eta^2}}} \tag{38}$$

$$\frac{\mathrm{d}\sqrt{1-\eta^2}}{\mathrm{d}\eta} = -\frac{\eta}{\sqrt{1-\eta^2}} \tag{39}$$

Again, we give the full relevant equation:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = \left(\frac{G_m}{G_{m0}}\frac{\mathrm{d}G_{m0}}{\mathrm{d}r_i} + G_{m0}\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{1-\eta^2}}\frac{\mathrm{d}\sqrt{1-\eta^2}}{\mathrm{d}\eta}\frac{\mathrm{d}\eta}{\mathrm{d}r_i}\right)\frac{\mathrm{d}r_i}{\mathrm{d}g} \tag{40}$$

$$= \frac{G_{m0}2}{2t\lambda}\left(\left(\frac{2}{\eta\lambda}-\frac{\eta}{\sqrt{1-\eta^2}}\right)\left(\eta-\frac{R}{r_i}\right)-\sqrt{1-\eta^2}\right) \tag{41}$$

We now turn to consider the limit $\eta \to 1$, $\eta > 1$, by Taylor expansion using $\eta^2 = 1+\varepsilon^2 \Rightarrow \sqrt{\eta^2-1} = \varepsilon$ or $\eta = 1+\frac{\varepsilon^2}{2}$. First, we consider:

$$\alpha = \frac{\pi}{2} - \operatorname{arccot}\varepsilon \approx \varepsilon - \frac{\varepsilon^3}{3} = \varepsilon\left(1-\frac{\varepsilon^2}{3}\right) \tag{42}$$

Since the factor in front of the brackets is the same for $\eta > 1$ and $\eta < 1$, we only consider the term in the brackets and find for $\varepsilon \to 0$:

$$-\frac{1}{3}\left(1+2\frac{R}{r_i}\right) \tag{43}$$

We now turn to consider the limit $\eta \to 1$, $\eta < 1$, again by Taylor expansion using $\eta^2 = 1-\varepsilon^2 \Rightarrow \sqrt{1-\eta^2} = \varepsilon$ or $\eta = 1-\frac{\varepsilon^2}{2}$. First we consider:

$$\lambda = \ln\frac{1+\varepsilon}{1-\varepsilon} = \ln(1+\varepsilon)-\ln(1-\varepsilon) \tag{44}$$

$$\approx 2\varepsilon + 2\frac{\varepsilon^3}{3} = 2\varepsilon\left(1+\frac{\varepsilon^2}{3}\right) \tag{45}$$

We now again only consider the term in the brackets of Equation 41 and finally arrive at the same expression:

$$-\frac{1}{3}\left(1+2\frac{R}{r_i}\right) \tag{46}$$

The limits therefore coincide at $\eta = 1$ and we can note in this case:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = -\frac{G_{m0}}{2t}\frac{1}{3}\left(1+2\frac{R}{r_i}\right) \tag{47}$$

This flux tube (like all others) only exists, if $r_o > r_i$. Since in this case, we keep r_o constant while changing $g = 2r_i$, it becomes important to handle the case $r_o \leq r_i$ separately, resulting in $G_m = 0$ and $\frac{\mathrm{d}G_m}{\mathrm{d}g} = 0$.

4.4 Outer Half Hollow Torus ($t = \text{const.}$)

For the general structure of the solution we again use Equation 32. Starting with $\eta > 1$ and using Equation 14 we actually did compute all relevant derivatives before. Since we need to consider the limit $\eta = 1$ in a minute, we note the full expression of this term:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = -\frac{G_{m0}R}{r_i r_o}\frac{\eta}{2\sqrt{\eta^2-1}}\frac{\left(\frac{\pi}{2}-\operatorname{arccot}\sqrt{\eta^2-1}\right)-\frac{\sqrt{\eta^2-1}}{\eta^2}}{\left(\frac{\pi}{2}-\operatorname{arccot}\sqrt{\eta^2-1}\right)^2} \tag{48}$$

For $\eta < 1$ we start from 16, do not need any additional derivatives either, and we again note the full expression:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = -\frac{G_{m0}R}{r_i r_o}\frac{\frac{2}{\eta}-\frac{\eta}{\sqrt{1-\eta^2}}\ln\frac{1+\sqrt{1-\eta^2}}{1-\sqrt{1-\eta^2}}}{\ln^2\frac{1+\sqrt{1-\eta^2}}{1-\sqrt{1-\eta^2}}} \tag{49}$$

In both cases, the first term is identical. In order to check for continuity, we check the remaining terms. First, $\eta^2 = 1+\varepsilon^2 \Rightarrow \sqrt{\eta^2-1} = \varepsilon$ or $\eta = 1+\frac{\varepsilon^2}{2}$ as above:

$$\lim_{\varepsilon\to 0} \frac{\left(1+\frac{\varepsilon^2}{2}\right)}{2\varepsilon} \frac{\frac{\pi}{2} - \operatorname{arccot}\varepsilon - \frac{\varepsilon}{1+\varepsilon^2}}{\left(\frac{\pi}{2} - \operatorname{arccot}\varepsilon\right)^2} = \frac{1}{3} \tag{50}$$

Now for $\eta^2 = 1-\varepsilon^2 \Rightarrow \sqrt{1-\eta^2} = \varepsilon$ or $\eta = 1-\frac{\varepsilon^2}{2}$, again using the limit for λ stated earlier we find:

$$\lim_{\varepsilon\to 0} \frac{\frac{2}{1-\frac{\varepsilon^2}{2}} - \frac{1-\frac{\varepsilon^2}{2}}{\varepsilon} \ln\frac{1+\varepsilon}{1-\varepsilon}}{\ln^2\frac{1+\varepsilon}{1-\varepsilon}} = \frac{1}{3} \tag{51}$$

As expected, the curve is continuous and for $\eta = 1$ we can note:

$$\frac{\mathrm{d}G_m}{\mathrm{d}g} = -\frac{G_{m0}R}{3r_i r_o} \tag{52}$$

4.5 Inner Quarter Hollow Torus (r_i = const.)

Since the gap, g, is not meaningful for quarter hollow tori, we instead use the stroke, s, as discussed above (cf. Fig. 7a). A constant offset will not change the result, and we may simply use $r_o = s$ and $t = s - r_i$. We need to consider:

$$\frac{\mathrm{d}G_m}{\mathrm{d}s} = \frac{G_m}{G_{m0}}\frac{\mathrm{d}G_{m0}}{\mathrm{d}s} + G_{m0}\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}}\frac{\mathrm{d}\sqrt{\eta^2-1}}{\mathrm{d}\eta}\frac{\mathrm{d}\eta}{\mathrm{d}s} \tag{53}$$

with:

$$\eta = \frac{R}{s-r_i}\ln\frac{s}{r_i} \tag{54}$$

Most of the derivatives we have noted before. We only need:

$$\frac{\mathrm{d}G_{m0}}{\mathrm{d}s} = \frac{G_{m0}}{t} \tag{55}$$

$$\frac{\mathrm{d}\eta}{\mathrm{d}s} = \frac{1}{t}\left(\frac{R}{r_o} - \eta\right) \tag{56}$$

We thus arrive at:

$$\frac{\mathrm{d}G_m}{\mathrm{d}s} = \frac{2G_{m0}}{t\alpha_+}\left(\sqrt{\eta^2-1} + \left(\frac{\eta}{\sqrt{\eta^2-1}} + \frac{1}{\eta\alpha_+}\right)\left(\frac{R}{r_o} - \eta\right)\right) \tag{57}$$

Note that this term is positive, other than the terms considered before. This is due to the fact that by moving the plunger into the hole, the permeance in this case increases, so this flux tube (by itself) actually acts to push the plunger out of the yoke (it of course is more than compensated by the radial flux contribution pulling the plunger into the yoke - the latter term is well-described already, though, and therefore not included here).

This term only exists for $r_o < R$. Since we use $r_o = s$ while changing s, it becomes important to handle the case $s > R$ separately (the permeance remains that of $r_o = R$, the force, however vanishes, since the permeance does not change anymore). Furthermore, this term only exists for $s > r_i$ (resulting in $G_m = 0$ and $\frac{\mathrm{d}G_m}{\mathrm{d}s} = 0$).

4.6 Outer Quarter Hollow Torus (r_i = const.)

In this case we again need to consider cases depending on η. We start with $\eta > 1$, can keep using Equation 53 and do not need any new derivatives. The desired result is:

$$\frac{\mathrm{d}G_m}{\mathrm{d}s} = \frac{G_m}{G_{m0}}\frac{\mathrm{d}G_{m0}}{\mathrm{d}s} + G_{m0}\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{\eta^2-1}}\frac{\mathrm{d}\sqrt{\eta^2-1}}{\mathrm{d}\eta}\frac{\mathrm{d}\eta}{\mathrm{d}s} \tag{58}$$

$$= \frac{2G_{m0}}{t\alpha_-}\left(\sqrt{\eta^2-1} + \left(\frac{\eta}{\sqrt{\eta^2-1}} - \frac{1}{\eta\alpha_-}\right)\left(\frac{R}{r_o} - \eta\right)\right) \tag{59}$$

For $\eta < 1$, no new derivatives are needed for arriving at:

$$\frac{\mathrm{d}G_m}{\mathrm{d}s} = \frac{G_m}{G_{m0}}\frac{\mathrm{d}G_{m0}}{\mathrm{d}s} + G_{m0}\frac{\mathrm{d}G_m/G_{m0}}{\mathrm{d}\sqrt{1-\eta^2}}\frac{\mathrm{d}\sqrt{1-\eta^2}}{\mathrm{d}\eta}\frac{\mathrm{d}\eta}{\mathrm{d}s} \tag{60}$$

$$= \frac{2G_{m0}}{t}\frac{2}{\lambda}\left(\sqrt{1-\eta^2} + \left(\frac{2}{\eta\lambda} - \frac{\eta}{\sqrt{1-\eta^2}}\right)\left(\frac{R}{r_o} - \eta\right)\right) \tag{61}$$

As before we need to consider the case $\eta = 1$ by testing limits for both cases and coincidingly find:

$$\frac{\mathrm{d}G_m}{\mathrm{d}s} = \frac{2G_{m0}}{t}\left(1 + \frac{2}{3}\left(\frac{R}{r_o} - 1\right)\right) \tag{62}$$

5 Numerical Implementation

All of these formulae have been implemented in Modelica (Schmidt 2025). This process is mostly straightforward, only a few remarks might be in place.

Firstly, some flux tubes allow only for certain parameter combinations, and while the variable geometry changes, they may essentially cease to exist. This might be fixed by setting $G_m = 0$ and $\frac{\mathrm{d}G_m}{\mathrm{d}x} = 0$ in those cases, however, since in the base class `Force` a reluctance is produced by calculating the inverse of G_m, the latter needs to be set to an arbitrary small number rather than zero (we chose $G_m = 10^{-15}$ H). It is in the nature of absolute values, that none will be small as compared to every other value, thus there is an inherent (if practically small) risk in doing that.

Secondly, while mathematically the three given cases $\eta \lessgtr 1$ cover all eventualities, numerically one needs to keep some distance from $\eta = 1$. Otherwise, Modelica is needlessly forced to evaluate terms that analytically safely converge, yet numerically might introduce significant errors. Experimentally it is found that by reserving $\eta \in [0.999999, 1.000001]$ to the solution strictly correct for $\eta = 1$ only, such problems can be avoided. Since all three solutions merge continuosly, no harm is done by this.

Thirdly, what does the added accuracy and versatility cost in terms of computational time? We put this to the test using our `OuterHalfHollowTorusConstantt` and the presently implemented `LeakageAroundPoles`.

We will start by looking at the accuracy of the force calculation. While our class is exact within the assumption of circular flux lines, the presently implemented class

DOI
10.3384/ecp218243

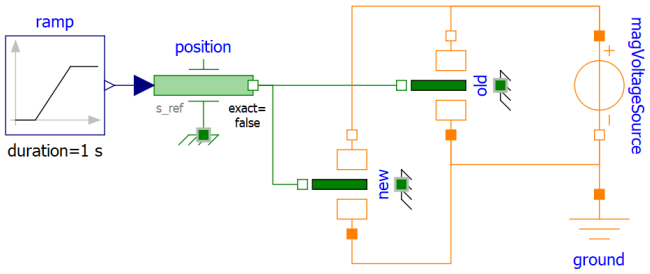

Figure 8. OMEdit test model used to compare the "new" model to the established "old" model of an outer half hollow torus.

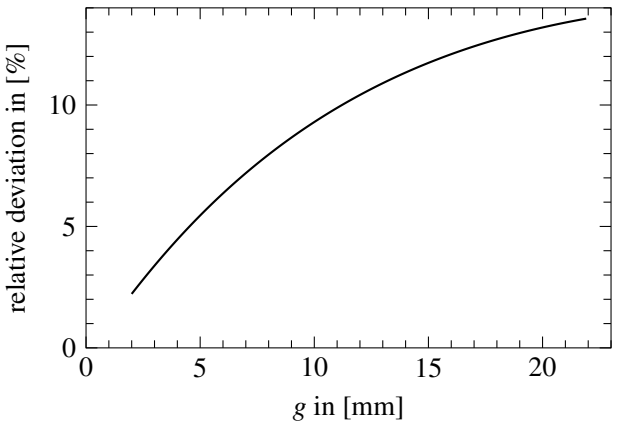

Figure 9. Relative deviation of force calculated from "old" compared to "new" model.

assumes bending a straight quarter hollow cylinder into a quarter hollow torus. This restricts the meaningful parameter choices. An additional, practical problem with `LeakageAroundPoles` is, which circumference to use? The class calls for the mean circumference to use as width, w, however, even if one accepts the arithmetic mean to be applicable, this mean changes as $r_o = r_i + t$ increases with increasing gap, $g = 2r_i$. Most likely, users will either put $2\pi R$, i.e., an obviously constant, yet systematically low value, or $2\pi(R + t/2)$, which might be expected to fit best for low values of the gap. Actually, the former gives quantitatively better results in our case, and we therefore went with $w = 2\pi R$. Other parameters were $t = R = 10$ mm.

We set up a model (cf. Fig. 8) using a prescribed positional ramp (20 mm stroke, 2 mm offset over 1 s) and a minimal magnetic loop including 1 A of magnetic tension to produce force vs. stroke curves. Figure 9 shows the relative deviation of these two curves. Note that the torus model went through all three cases $\eta \lessgtr 1$ within this ramp, without any trace of it in the result (as it should be).

`LeakageAroundPoles` systematically neglects that the width of the flux tube is a function of the gap. Including that would reflect into the derivative needed to calculate force and thereby change the class itself. This existing class deviates noticably from the more exact result. However, the significant relative deviation for large gaps is to be taken with a grain of salt, as absolute values of force in this region of stroke are very small.

Finally looking at the computational times listed in the transformational debugger (in OMEdit), we find the following break down of major contributions:

- 25.6 % for the position
- 13.3 % for the old force calculation
- 61.1 % for the new force calculation

At first glance, we find that our more elaborate model needs more than quadruple the computational time of the existing, simpler model. To put that into perspective: 12.2 % of the computational time is used up in calculating $\ln \frac{r_o}{r_i}$ alone. This illustrates that the absolute increase in computational time is not quite as significant as it may appear from looking at the relative increase. In absolute terms one may put it like this: the new force calculation is comparable in computational time to two position presets.

Whether this is acceptable may obviously be decided on a case-to-case basis. In most geometries considered in this paper, there is no "presently used model" anyway, so mostly such flux tubes would have previously been neglected or falsly been modelled using the one existing class, even though that would not really have been applicable (e.g., if r_o was constant rather than t).

6 Conclusion

In this paper we have derived exact expressions for the permeance of half or quarter hollow toroid flux tubes (cf. Tab. 1). These expressions are an extension of the much simpler expression extensively used previously, lifting the limitation to a certain range of allowable parameters. Our derivation started from the assumption that the flux lines follow a general circular pattern. We verified our result by studying the actual flux patterns using FEM analysis. Quantitatively we find our expressions for the permeance to be in agreement with the FEM results within the expected limitations of the numerical method. We furthermore derived expressions necessary for calculating force, taking into account three relevant use cases (constant outer radius, constant radius difference, and constant inner radius of the torus, respectively). Corresponding Modelica models have been made available electronically.

Master controller concept for power flexible energy systems

Thomas Egsgaard Kallesen[1] Søren Waagø Christiansen[1] Rene Just Nielsen[1]

[1]Added Values P/S, Denmark, {tep, swc, rjn}@AddedValues.eu

Abstract

A generic model of a master controller concept is presented to demonstrate the advantages of aggregating multiple flexible electrical power units. The master controller consists of various submodels with different features. A Power Balancing Controller ensures that the operation does not cause any imbalance with the traded power. A waterfall method that ensures that any ancillary service activations are handled using the appropriate units to obtain cheapest operation. Simulations of the concept include examples of step responses on automatic Frequency Restoration Reserve (aFRR) activations, as well as actual aFRR data from the Danish TSO. The results suggest that if the system consists of slow units, the aggregation of units can increase the capacity offered to faster types of ancillary services. Additionally, by allowing certain units to shut down automatically more capacity can be offered as the units are no longer bound by minimum loads.

Keywords: master controller, district heating, energy systems, ancillary services

1 Introduction

The expected continued expansion of and reliance on non-dispatchable renewable energy sources in the production of electricity has led to greater volatility in the power markets (International Energy Agency 2020). That is, production does not necessarily follow consumption as fewer dispatchable energy sources are available in electricity grids. In order to mitigate this increased volatility, weather forecasting has become an important tool used to predict the production capacity, which is used to set the prices on the day-ahead market.
However, uncertainties in weather forecasts will always cause deviations between planned production and consumption. Here, the importance of ancillary services comes in. They are standardized across the connected grids to ensure that enough capacity is connected to compensate for the uncertainties with the increasing share of renewable energy. The forecast deviation from actual production will only increase in the future. Hence, there is a need for more flexible grid-connected capacity that can participate in ancillary services (Energinet 2024b).

Multiple ancillary services are available on the Danish DK1 grid, which is part of the European Network of Transmission System Operators for Electricity – ENTSO-E (ENTSO-E 2018). DK1 is chosen as the reference in this paper, as it is the market of the authors' workplace. The ancillary services (AS) are distinguished by their response time requirements and the energy delivery that are inversely correlated (Energinet 2025b):

- **Frequency Containment Reserve (FCR)** requires response time from zero to activated load in 30 seconds, but is typically quickly returned to baseline load again resulting in average activations as ratio of capacity of 0.05 %. The load is proportional to grid frequency deviation.
- **Automatic Frequency Restoration Reserve (aFRR)** requires a response time from zero to activated load in 5 minutes. It has an average activation ratio below 12 % compared to the reserved capacity. The transmission system operator (TSO) uses a closed-loop controller to suppress the power imbalance, which makes it automatic, as the name implies.
- **Manual Frequency Restoration Reserve (mFRR)** requires a response time from zero to activated load in 12.5 minutes—typically through the balance responsible party (BRP).

These ancillary services can be performed both by electricity *consuming* or *producing* units as long as they can adjust the power at the required rate. There is even an economic incentive to participate, but this is not covered in this paper. However, often enough, electric units do not comply with any of the above requirements, and certainly not all of them (Danish Energy Agency 2025). Besides, many units have some minimum power limit they can operate at. Thus, some unexploited capacity is available in many power or power-to-heat (PtH) district heating plants that could be optimized with respect to utilization and speed. This can be done by combining the attributes of different units in the plant. For example, a fast but expensive unit can temporarily help a slower but cheaper unit increase its speed so that it can participate in faster ancillary services, such as aFRR. Furthermore, the power consumption or production in a plant can be distributed, so it allows units to shut down and start up dynamically. This gives additional regulation capacity to the plant while maintaining a continuous trajectory of the power.

Most of the literature on the aggregation of grid-connected units focusses on coordinating large populations of small household devices to provide ancillary

services. Within this field, (Iria, Soares, and Matos 2019) addresses the optimisation of day-ahead market bidding for aggregated resources. In terms of real-time control approaches, (Meyn et al. 2015) investigates the aggregation of large load populations using optimal control techniques, while (Bella et al. 2021) applies mixed-integer linear programming to the problem of load distribution. Similarly, (Iria and Soares 2019) introduces a fast model predictive control method, though it is still computationally heavy. A common feature of these studies is their focus on aggregating large numbers of small devices or prosumers to provide ancillary services. In contrast, (Tan and Zhang 2017) proposes a state machine approach for the combined control of a battery and wind power plant; however, this method is highly specific to that particular application.

The present work instead targets industrial-scale plants and aims to develop a general-purpose algorithm suitable for real-time control systems. The proposed approach emphasizes low computational requirements and operational transparency, ensuring that it remains accessible and comprehensible to plant operators, thus facilitating troubleshooting. By aggregating several power producing or consuming units with different technical characteristics, the strategy coordinates their setpoints to gain larger overall regulation capacity and faster response times. This is enabled by utilizing the fast response times of the more expensive units to aid the cheaper but slower units.
The final result is a structured Modelica implementation of the control concept, exemplified on a test system combining a heat pump, an electric boiler, and a battery. This implementation demonstrates both the internal architecture of the controller and the methodology applied to develop and validate it.

2 Master controller — working principle

The so-called *master controller* (MC) connects the electrical consumption or production units in the plant portfolio with the power grid, as illustrated in Figure 1.

The balance responsible party (BRP) is a third-party company responsible for power bidding and trading on behalf of the plant owner and for handling ancillary service requests from the transmission system operator (TSO). The BRP distributes AS activation signals from the transmission system operator directly to the master controller of its customers. A load scheduling system generates optimized base load setpoints for the individual plants, based on day-ahead prices, operating characteristics, plant availability, weather forecasts, and heat demand forecasts, among other factors.

Figure 2 illustrates the internal control concept of the master controller which can be divided into several parts introduced below. The parts are explained in the same order in which the setpoints are processed throughout the

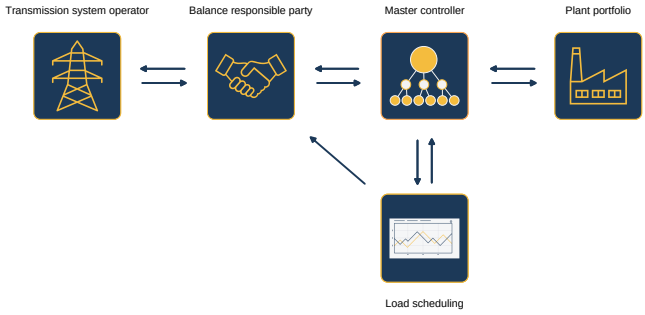

Figure 1. Simple overview of the master controller principles.

MC:

- **Load Schedule (LS)** handles the setpoints to each unit received from the load scheduling system. The setpoints are ramped according to the mFRR requirements and provide the operating point (baseline) of the system.
- **Balance Responsible Party (BRP)** handles ancillary service activations to the plant. The BRP setpoints are not individual for each production or consumption unit as the strategy requires the system to be considered as one aggregated unit. Each of the AS — FCR, aFRR and mFRR — are ramped according to their respective requirements, added together, and forwarded to the power balance controller.
- **Power Balance Controller (PBC)** ensures that the power consumption is equal to the traded power including AS. This is necessary since non-dispatchable consumption from pumps, lights, or similar ("house load") can be hard to predict. The PBC uses a closed-loop controller to steadily reach a zero deviation between the actual and traded power.
- **Waterfall method** distributes the AS and balance controller output to the units in a prioritized order. Higher-priority units respond to activations before lower-priority units.
- **Output signal handling** Each unit receives their load plan and the respective power correction from the waterfall method. Additional unit-related control such as output magnitude and ramp limitation, and unit start/stop is also handled here.

3 Model

The model is built of components from the Modelica Standard Library (MSL) (Modelica Association 2020) and blocks from an in-house developed library. It is divided into sub-models that correspond to each of the

DOI
10.3384/ecp218253

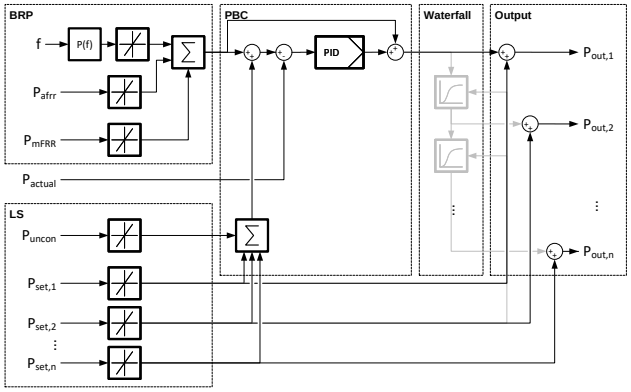

Figure 2. Overview of the master controller principles.

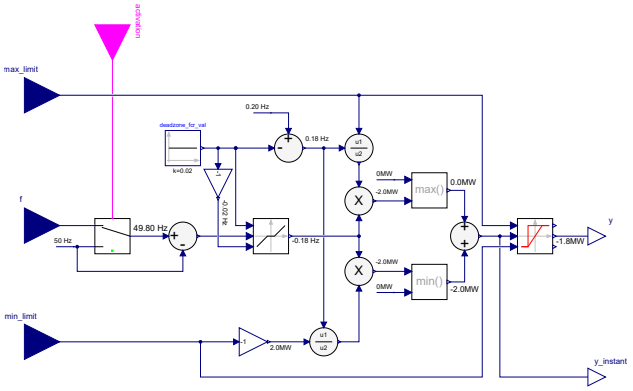

Figure 3. Diagram of FCR input handling

framed sections in Figure 2.

3.1 Input handling

Input handling comprises the BRP and LS functionality and the master controller inputs consist of load schedules and ancillary services signals. The load schedules are ramped to comply with the mFRR response times, and the resulting signal is routed to each corresponding unit to define their operating points. The ancillary services, which are later distributed to the units by the waterfall method, are ramped to meet their individual timing requirements. Thus, the aFRR input signal is ramped so that it can reach reserved capacity in less than 5 minutes. FCR is ramped so that the reserved capacity can be reached in 30 seconds. This differentiation in ramping, depending on the source of the activation, ensures that the reacting units and their components do not react faster than necessary.

Most setpoint sources are simply treated with a ramp. The exception is FCR, which is derived from the grid frequency deviation. Figure 3 shows the FCR calculation model. It converts the frequency measurement deviation from 50 Hz, into a proportional power response based on reserved capacity in the system. A rate limiter placed at the output performs the final setpoint shaping.

The input of the load schedule and the mFRR setpoint is ramped differently than the other ancillary services. The ramp times are set to 10 minutes to ensure compliance with the formal 12.5 minute requirements. mFRR responses that deviate from the 10 minute ramping are expressed as bills to the participant, depending on the current imbalance price. Therefore, these inputs are handled with the model shown in Figure 4, which is a modified rate limiter that adjusts the slope to ensure that the input value is reached after a prescribed time. It works by continuously calculating the slope required to reach the input from the current output and then inserting it into the rate limiter model. An *analogue memory* model in the

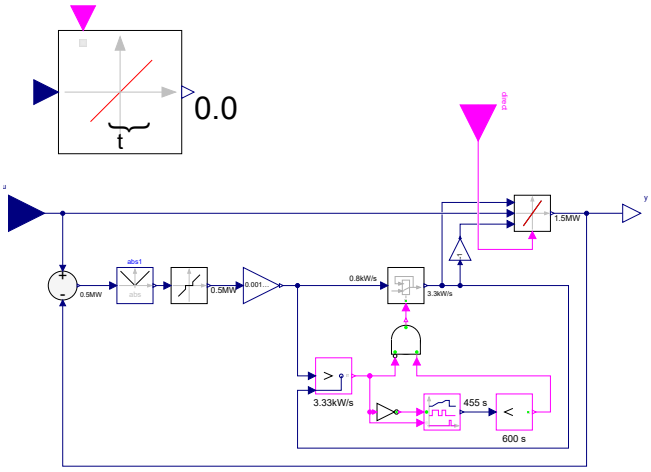

Figure 4. Modelica icon and diagram view of the constant timed ramp model including its icon.

centre of the figure saves the slope until a larger slope is derived from the calculation, at which point the updated maximum slope is replaced. With this method, the model works with any arbitrary input.

3.2 Power balance controller

The Power Balance Controller (PBC) compares the actual (measured) total power consumption with the combined setpoint of AS and the sum of LS setpoints. It uses an integrator followed by a PID controller to adjust the combined setpoint, so that the electric energy deviation becomes zero within a 15 minute horizon when the integrator is reset. See Figure 5. The 15 minutes cycle is introduced in the model because the BRP issues the electric power bill to the plant owners on the basis of 15 minutes energy accumulation.

Typically, it is difficult to predict the intermittent house load and, therefore, the PBC can help to precisely reach the setpoint, removing any possible economic consequences when deviating from the traded power. Some units have to actually change their consumption, but that is

distributed by the waterfall method (subsection 3.3). The controller output is added to the AS feed-forward setpoint as shown in Figure 2.

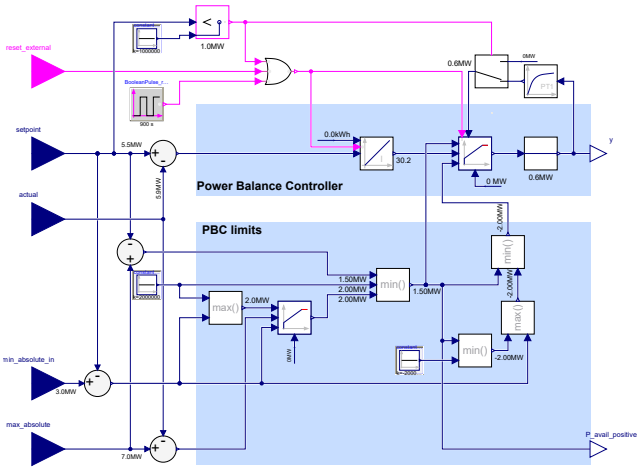

Figure 5. Modelica graphical model of the power balance controller.

In Figure 6, the system used later on in Section 4 is subjected to a step change in the ancillary services input. This is done both with and without the power balancing controller to compare the responses. Looking at the response without PBC, it is clear that there is a non-zero steady-state error. This is simply because, in this case, the system is essentially an open-loop system that does not correct the (non-dispatchable) house load of the system.

The steady-state error is cancelled when the PBC is activated. However, it introduces a relatively large overshoot that settles at the setpoint after 5–10 minutes. The overshoot is intentional and ensures that the accumulated energy deviation from the day-ahead energy purchase is zero over a 15 minute horizon. This means that steady state must be reached in 15 minutes, and that the overshoot actually compensates for energy that was not covered in the beginning of the response. This is illustrated by the two equally sized hatched areas. Normally, the overshoot is not going to be this large. It is purely due to the step input, which is not a realistic input and is chosen here to show the concept.

3.2.1 Power limitation

The power balance controller is also used to limit total power consumption or production. This is useful if faults occur on a transformer or at the electricity provider. When the power limit is reduced (input "max_absolute" in Figure 5) or the power consumption exceeds its limit, the power limitation proactively reduces the PBC output (via its upper limit input signal), potentially driving it to a negative value. This ensures that the sum of all

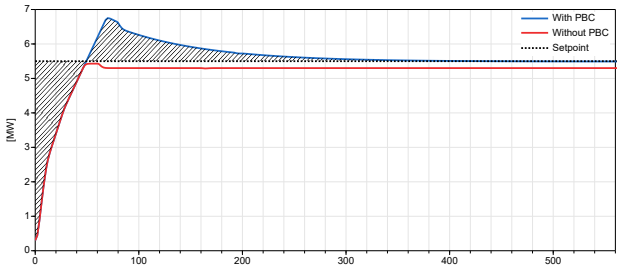

Figure 6. Demonstration of the power balance controller.

setpoints for the units is immediately reduced to comply with the transformer power limits. The power reduction is distributed to the units in the same way as the output from PBC.

If the setpoint is inaccurate compared to the actual power consumed or produced, then the above proactive (feed-forward) power limitation may be insufficient. Thus, an additional feedback controller is used to ensure that the actual power does not exceed the power limit. The minimum of the proactive power limitation and the controller limiter is the final maximum power used in the PBC.

3.3 Waterfall method

The *waterfall method* distributes one setpoint correction among several units according to a denoted priority associated with each unit. Generally, it means that one (total) setpoint is delivered to the unit with priority 1. The deviation between the setpoint and the *expected* dynamic response from the first unit is sent to the unit with priority 2. Similarly, the expected control deviation from unit 2 is forwarded to the unit with priority 3. This pattern is repeated until the setpoint is zero or the system runs out of available units.

The waterfall method is demonstrated with a system of three units: a slow heat pump as the first priority. A faster electric boiler as second priority, and a fast, but low-energy battery as third priority. The step responses from the output of the PBC sub-model to the individual units are shown in Figure 7. This corresponds to a 1 MW step change in ancillary services.

The heat pump receives the entire correction but has a large deviation at the beginning of the transition. The estimated deviation is passed on to the electric boiler which covers more of the transients. Lastly, the expected deviation of the electric boiler (shown as a short pulse) is passed as a setpoint to the battery The combined responses of all three units cover most of the delivery as shown with the output P_{total}.

This waterfall method consists of mainly two parts to

DOI 10.3384/ecp218253

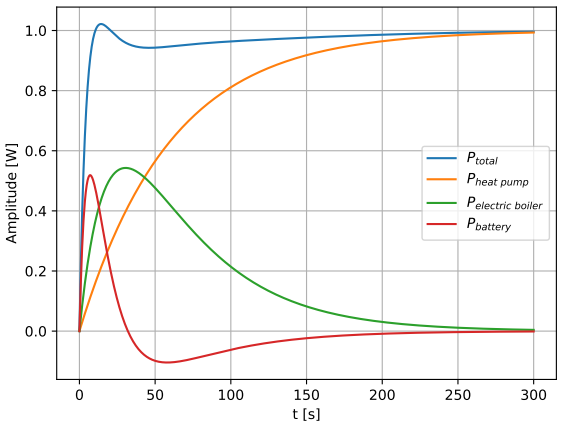

Figure 7. Step response of linear system with three units and two first order unit estimations.

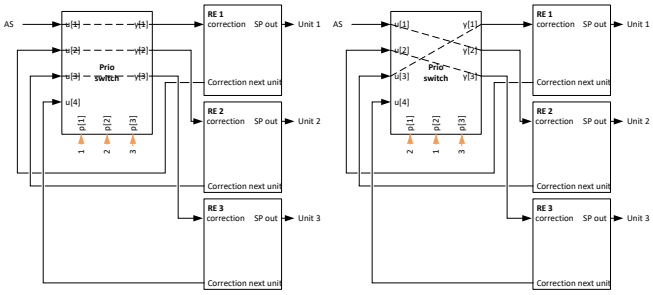

Figure 8. Different configurations of the priority switch

operate:

- **Priority switch** routes setpoints from the unit with first priority to the unit with the next priority and so on. It allows dynamic switching of priorities between units.
- **Response estimation** is the function that is repeated for each unit to estimate the power residual that *cannot* be covered by the unit. This residual is forwarded to the next unit in the order.

3.3.1 Priority switch

The priority switch is a function that connects each output to one of the inputs, such that the setpoint is handled by each unit in the order specified by the list of priorities. The priority switch is required in the case that different priorities are needed. otherwise, simple routing between each Response Estimation is sufficient. Figure 8 illustrates the layout of the waterfall method comprising the three mentioned units and shows the functionality with two different prioritization lists. In the figure to the left, the priority list is $\{heat\,pump = 1, boiler = 2, battery = 3\}$. This is the simplest configuration as it connects the outputs with the corresponding indexed input, indicated by the dashed lines inside the "prio switch" block. The priority list can be any incremented list of integers starting from 1 $(1 : n_{units})$. Thus, another valid case is $\{heat\,pump = 2, boiler = 1, battery = 3\}$ which is the case shown in the figure to the right.

Reversing The priority switch features a Boolean input that enables automatic reversal of the priority order during operation. This is useful because a participant may not want the highest priority unit to react as the first unit in both up- and downward directions. Using heat pump and electric boiler as an example, the heat pump produces much cheaper heat. Therefore, it is desirable to use the heat pump as priority 1 when increasing its load. But when the combined load is decreased, it is beneficial to reduce the load of the electric boiler before the heat pump. Therefore, when ancillary services move from a positive setpoint to a negative one, the priority order can be reversed to ensure the cheapest unit is always running. Additionally, the model gives the option to include only the first n units in the reversing. This is again useful if a system uses a battery to only adjust for the last corrections as the last priority. Then it is undesired if it suddenly acts as the first priority due to the reversing action.

3.3.2 Response estimation

It is commonly known that real measured responses introduce delays and more complex higher-order dynamics. While implementing a feedback control scheme for the priority switch inputs using real measured responses would be quite simple, introducing these delays in the control of the units would result in unnecessary activation of all prioritized units, which is undesirable. This is the case, because the delays in the measurements of the first priority unit will cause a small amount of the signal to be forwarded to the subsequent unit and so on, even if that unit is not necessary to meet the response requirements.

This phenomenon is also shown in the top graph of Figure 9. The figure shows a comparison between using real measured responses as feedback instead of estimations (top graph) and using an approach based on a rate limit block (bottom graph). The figure uses the example featuring a heat pump, an electrode boiler, and a battery energy storage system. In this test, the electric boiler is parametrized to meet the FCR requirements, eliminating the need for a faster battery in this specific case. However, it is clear that on the top graph, which uses real measurements, the battery still contributes, even though it is unnecessary.

For that reason, the dynamic response of the units is estimated with rate limit blocks as they react without any delay. Although the implementation is not as simple as using measured responses, using rate limit blocks prevents the lowest priority unit from being activated every time. This is shown in the bottom graph of Figure 9.

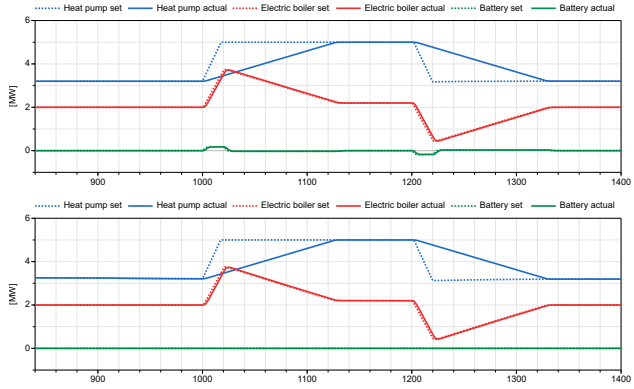

Figure 9. Comparison of waterfall method using real feedback (top figure) or estimated feedback (bottom figure).

The response estimation (RE) model utilizes information on ramping and limiting capabilities of the corresponding unit to estimate the response of the unit. The setpoint that is fed back to the priority switch to be routed to the next unit is the input setpoint subtracted by the estimated response of the unit. This can be formulated with Equation 1:

$$r_{corr,i+1} = (r_i + r_{corr,i})(1 - \hat{G}_{p,i}) \quad (1)$$

Where r_i is reference (load schedule) for unit i. $r_{corr,i}$ is the correction setpoint from the priority switch and $\hat{G}_{p,i}$ represents the estimation model of the unit. The combined setpoint that is sent to the unit is $u_i = r_i + r_{corr,i}$. A block diagram of the example with three units (without the priority switch) is shown in Figure 10.

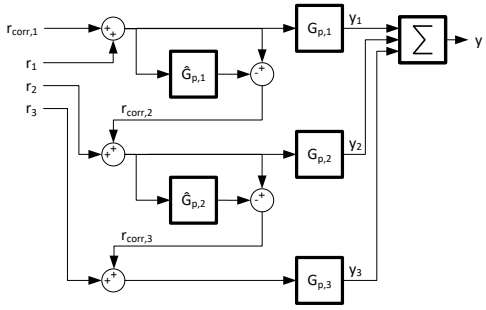

Figure 10. Block diagram of the waterfall principle

In the simulation, $\hat{G}_{p,i}$ is simply modelled with a power rate limiter and absolute limits of the unit. The rate limiter is sufficient to model the unit, as the master controller ramps the setpoint before it is sent to the unit. However, the unit typically also ramps the input itself if the input ramp is faster than the capability of the unit. Therefore, it is also important for this strategy to receive up-to-date information on the ramping capability of each unit as it is used as input in the response estimation.

If the actual ramping slopes differ from that used in the unit response estimations, the responses can become less accurate.

3.4 Automatic shutdown

A function can be implemented to automatically shutdown a unit in the output signal handling module mentioned in Section 2. This function can cause the unit to shut down when ancillary services combined with the planned setpoint reach the minimum limit of the unit. When this occurs, the waterfall method ensures that other units with lower priority temporarily replace the lost power during the ramp, resulting in almost continuous control.

3.5 Ancillary service validation

A validation function is modelled to ensure that activated ancillary services are within the response envelope required by the transmission system operator (TSO). The model calculates the upper and lower bounds required in the response and uses the constant-timed ramp model in Figure 4.

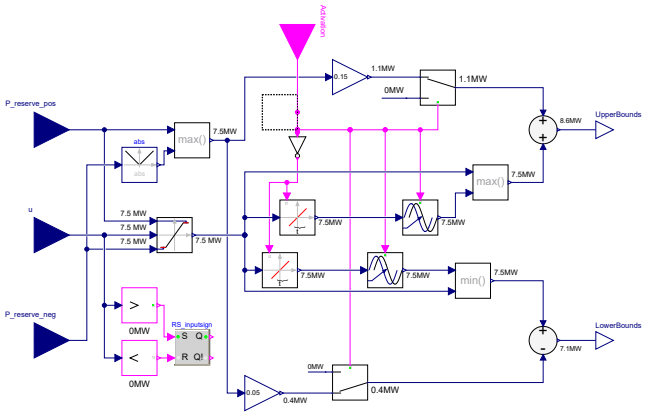

Figure 11. Modelica graphical model of the ancillary services validation.

This validation model (Figure 11) is based on the pre-qualification requirements in DK1, described in (Energinet 2025c). The model is applied to the setpoint components (load schedule, aFRR, mFRR) that cover the relevant ancillary services, after which the upper and lower bounds of each setpoint component are added together and plotted with the actual total response of the system for comparison. An example of bounds applied on a square-wave input setpoint is shown in Figure 12.

The envelope shows that the *increasing* source signal (the square wave) is allowed to rise immediately and must increase at least as fast as the blue ascending slope of the lower boundary. In the opposite direction, the source signal can decrease immediately and must decrease at

DOI 10.3384/ecp218253

least as fast as the blue descending slope. Similarly, the envelope allows for a certain steady-state deviation from the setpoint, indicated by the vertical margins. The validation model is especially useful when using realistic aFRR data that are updated continuously.

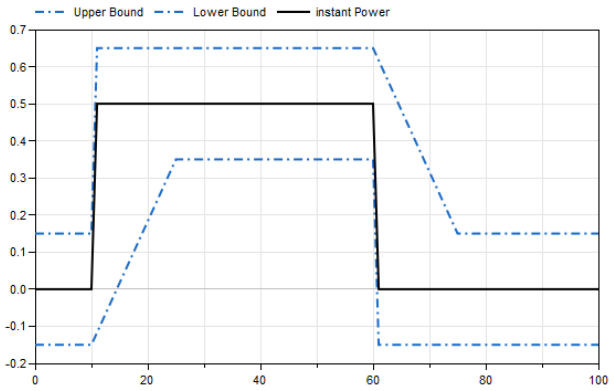

Figure 12. Modelica graphical model of the ancillary services validation envelope.

4 Simulation results

To demonstrate the functionality of the master controller, the concept is exemplified with three aggregated units in a PtH district heating system: a slow but inexpensive heat pump, a faster, but more expensive electric boiler and a battery with limited energy capacity. Participating in the AS markets requires some flexibility, so the example here assumes that a sufficient large heat storage tank can adjust for heat production variations.

The characteristics of the three units are shown in Table 1.

Table 1. Key model parameters.

Quantity	*Value*	*Unit*
Heat pump rate limit	$\pm$ 0.0125	MW/s
Electric boiler rate limit	$\pm$ 0.05	MW/s
Battery rate limit	$\pm$ 0.1	MW/s
Heat pump max limit	5	MW
Electric boiler max limit	5	MW
Battery max limit	1	MW
Heat pump min limit	2	MW
Electric boiler min limit	0.4	MW
Battery min limit	-1	MW
Heat pump priority	1	-
Electric boiler priority	2	-
Battery priority	3	-

Heat pump response times vary considerably depending on, e.g., compressor type. (MAN 2024) shows a heat pump that can participate in part in FCR and (Danish Energy Agency 2025) shows that heat pumps can typically ramp with 5 % in 30 seconds. Thus, to show the concept working on slower types of units, the rate limit of the heat pump in the table is selected to correspond to 400 seconds. (PARAT 2020) is an example of a fast ramping electric boiler with full FCR capabilities. Instead of 30 seconds, the selected rate limit in the table corresponds to 100 seconds, to show that the performance of the equipment does not need to be maxed out. Based on the notion that batteries regulate fast, 10 seconds is selected for the battery. Thus, the rates have been selected so that the heat pump is too slow for aFRR activations, whereas the electric boiler is not.

Other notable features in the simulations are

- The heat pump and electric boiler are configured to swap priority when $r_{corr,1} < 0$.
- A simple State-Of-Charge (SOC) proportional controller is added to the battery setpoint to ensure the battery is within capacity limits of 1 MWh.
- The heat pump can automatically shut down as described in Section 3.4.

In the following sections, the system is simulated mainly with aFRR responses, since its requirements are more strict than mFRR. FCR is even more strict, but in DK1 the activated bids are smaller and less profitable than aFRR, and thus from an economic perspective not as interesting.

4.1 Up- and down regulation

This simulation adds an aFRR input to the control scheme. The combined load schedule is around 5 MW, and the aFRR signal contributes first with an additional 5 MW in upward direction followed by 4 MW in downward direction. This is close to the maximum capacity possible with the chosen set-up given the minimum limits of the units. See Figure 13.

The combined electric power consumption is shown on the top and stays within the allowed envelope during the simulation. The second plot shows how the response is distributed between units. The heat pump reacts first, followed by the electric boiler when the heat pump reaches its limit. The battery reacts when the electric boiler reaches its limit. During the load reduction, starting after 24 minutes, the heat pump and electric boiler swap priority, causing the electric boiler to back down first, followed by the heat pump and then the battery. The responses from different units are delivered without any notable bumps in the combined response.

Note that the battery only contributes when the other units reach the limits and not every time there is a correction to the overall setpoint. This shows the advantage of

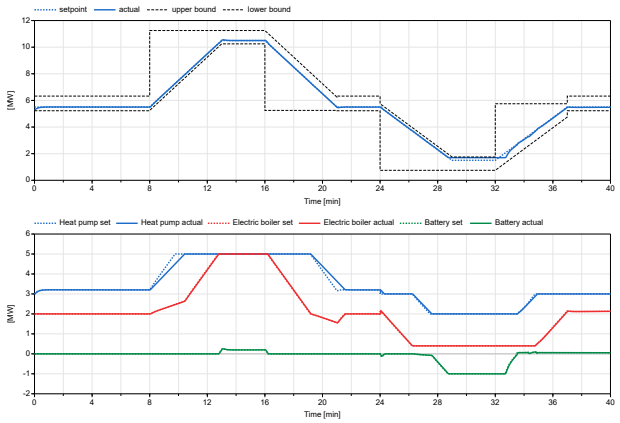

Figure 13. Simulation of an aFRR response on the example system.

using rate limiters to model expected responses.

4.2 Automatic startup and shut-down

The simulation test in Figure 14 shows the option of letting the heat pump automatically stop when the setpoint is below minimum. Similarly, it starts when the setpoint is above the minimum again. Thus, allowing the system to regulate in the downward direction with 5.5 MW, contrary to the 4 MW in Figure 13. In addition, the shutdown dynamics have been modelled to be faster than normal rates, whereas the startup rate is assumed to be equal to the continuous rate limit.

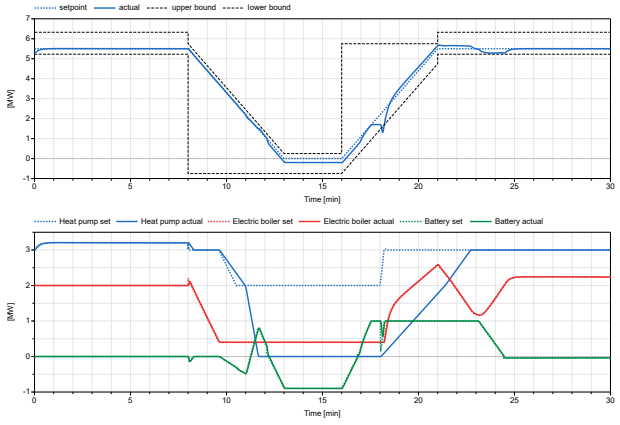

Figure 14. Simulation of auto-stop response on the example system.

Only minor bumps in power consumption are seen in combined consumption. However, after approximately 18 minutes, the total consumption decreases as the battery reaches its maximum power limit. With the current concept, the electric boiler cannot contribute from the waterfall method, since at this moment the priority is 1 for the electric boiler and 2 for the heat pump, due to the reversing. In this case, the PBC is utilized to increase the setpoint of the electric boiler before the total consumption deviates for a prolonged period of time.

4.3 Realistic aFRR activations

The entire system is tested with actual DK1 aFRR activations gathered from the Danish TSO data base (Energinet 2025a). The data covers ranges between ± 150 MW, but is then scaled with 0.035 to match the showcased capability (around 5 MW in each direction).

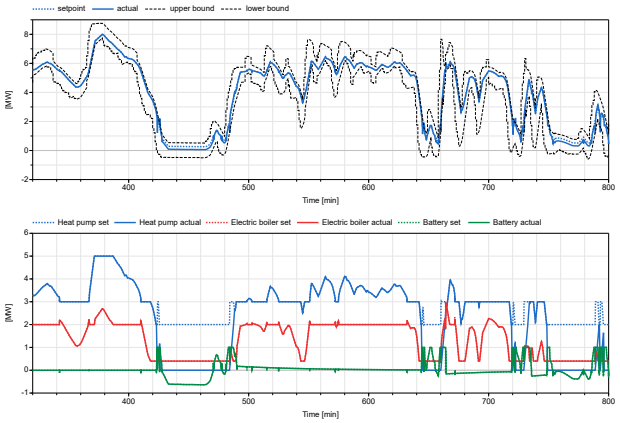

Figure 15. Simulation of an realistic aFRR response on the example system.

The simulation is shown in Figure 15 which shows several elements introduced in the paper. The waterfall method coordinates the units as expected even when using this continuous setpoint. Evaluation and visualization of the upper and lower boundaries of aFRR activations show that the response is, in fact, within the requirements. Occasionally stopping and starting the heat pump is not handled perfectly as there are some quick spikes in the consumption, but they stay within the boundaries. During the large load reductions, the automatic stopping of the heat pump happens fairly often. This could indicate potential issues with real heat pumps if they are not built for frequent on and off cycles. Lastly, the SOC controller for the battery is seen to apply small and slowly changing setpoints. This is compensated by some of the other units by the PBC.

5 Discussion

This work presents the concept of aggregating the electric power units of a PtH district heating plant. It shows that the master controller concept offers several advantages in terms of providing flexible operation to the grid through ancillary services. Since participation in ancillary service can be economically beneficial, it should be taken advantage of as much as possible. This work shows that the master controller concept provides the following potential advantages.

DOI
10.3384/ecp218253

- **Faster responses:** The power capacity in dynamically slow units can now participate in fast ancillary services.
- **Automatic shutdown:** Units with a relatively high minimum power level are no longer a limiting factor when aggregating, as long as there are other units that can replace its power level when it is off. If some units have a minimum power level of 50% (which is not uncommon (Danish Energy Agency 2025)), then the capacity in ancillary services can be practically doubled.
- **Power balancing:** Uncertainties in actual power consumption can be adjusted with the power balance controller to produce or consume the exact amount of power that has been traded, reducing the imbalancing bill.

It is important to note that this work is still quite theoretical, with multiple tests performed on estimated data instead of real-world data. However, the work presents a general structure of the master controller concept from which it is possible to create more tailored solutions based on the setup and needs of individual PtH plants.

The work highlights a potential economic benefit to be gained from implementing the different parts of the master controller. If a slow unit, such as a heat pump, cannot ramp fully within the 5-minute aFRR window, adding a 1 MW battery to help with transients increases the system's regulation capacity by 1 MW. The battery alone cannot be pre-qualified to deliver 1 MW due to its limited energy content (Energinet 2025c), so both units benefit from aggregation. The prices vary and evolve a lot, but at the time of writing, the price of the aFRR up-regulation capacity averaged around 70 €/MW/h throughout the year (Energinet 2024a). This can be directly translated into additional income when the battery is added to the portfolio. If it is assumed that the battery can only help half the time during 6 months of cold weather, then it is still possible to earn 151,000 € throughout the year. Additional income can be earned in the energy activation market, but it requires a more extensive analysis. An interesting next step would be to further explore this potential economic benefit with specific real-world PtH district heating plant setups and also adding actual imbalance costs, AS prices, etc.

The theoretical nature of the work means that some real-world complications are not taken into account. As mentioned, this work emphasises that some units can help other units decrease response time, but this is exclusively relevant if the response time is slower than the AS requirements to begin with. If all units are technically able to meet all requirements on their own, this concept could become less beneficial.

Another point made in this work is that it is possible to utilize a larger capacity by automatically shutting down units instead of being restricted by a minimum load on all units. Here, it has already been mentioned that this requires other units to help in meeting all requirements. However, the work does not account for any complications related to possible shutdown/startup restrictions. Such restrictions could potentially be due to, i.e., wear and tear, minimum downtimes during shutdown, or other unit obligations tied to shutdown/startup of the unit. As an example, it is quite common for some of the units used in the simulations (e.g., heat pumps) to have minimal downtime between operational cycles. In addition, there could be a limit on the number of shutdowns allowed within a day or other period of time. Any such restrictions are not taken into account in this work, but could cause the automatic shutdown function to be less useful.

6 Conclusion

This paper presents a master controller concept that aggregates electricity producing and consuming units of a power-to-heat district heating plant. The concept has shown potential to offer improved participation in ancillary services. Aggregating the units enhances the ability of some units to meet certain AS delivery time requirements. Using the described Waterfall Method, the faster units can assist the slower ones, ensuring that the overall response complies with the requirements. Thus, it is possible to increase the total capacity that can be offered to AS. Additionally, by utilizing the ability to completely shut down units, the aggregated system can also increase the total capacity offered to AS.

Along with these improvements associated with AS, the master controller concept can also increase performance on other parameters. The power balance controller component assists the system in maintaining zero deviation between purchased and used electricity. This can help prevent the undesirable costs associated with imbalances. The Waterfall Method in conjunction with the priority switch also enables the system to use the correct units for different AS activations. This entails that the cheapest units are utilized the most and the more expensive units are used last.

The potential benefits provided by the concept are shown using a simple example with a heat pump, an electric boiler, and a battery energy storage system. This example indicates that the concept offers a framework in connection with operating a power-to-heat district heating plant.

Abstract

This publication presents models for dynamic, 3-dimensional simulation of the thermal runaway, thermal propagation and the thermo-electric behavior of battery cells. An optional and replaceable electrical equivalent circuit diagram describes the electrical behavior of the battery cell. Coupled with the 3-dimensional, thermal equivalent circuit diagram, consisting of a resistance-capacitance network, the thermo-electric behavior is represented. A special feature of the battery cell model is the optional, replaceable and physical model of the thermal runaway based on Arrhenius equations and the associated mass loss. This means that either the thermo-electric or the thermal runaway behavior or both can be simulated in combination if required. The anisotropic thermal conductivity of the battery cell and the modelling of relevant heat conduction paths, such as the path across the housing of the battery cell, is made possible by 3D discretization of the battery cell.

Keywords: Lithium-Ion-Battery, thermo-electric Battery model, Arrhenius, Thermal Runway, Dymola, Modelica

1 Introduction

Lithium-ion batteries are used in electrochemical energy storage systems due to properties such as high cycle stability, energy density and capacity at comparatively low costs. However, thermal runaway (TR) can occur in lithium-ion batteries (Lenz et al. 2023; Walker et al. 2022; Groß und Golubkov 2021). This is a chain reaction in which exothermic decomposition reactions lead to exponential self-heating of the battery cell. This fault results in the destruction of the battery cell and, in worst case, can lead to the spread of the fault in the entire system, known as thermal propagation (TP). In addition to the release of heat, there is also a significant release of gas and particles during TR, which leads to a loss of mass in the battery cell. Suitably designed battery systems, particularly their thermal management, can limit the occurrence of faults and thus prevent a TR or at least a TP. The design can be carried out either by means of expensive and time-consuming experiments or by using suitable models (Walker et al. 2022; Groß und Golubkov 2021).

Two modelling approaches for TR are widely used in literature. The first approach is based on empirical heat release models, which can be further subdivided into time-dependent and temperature-dependent models (Hoelle et al. 2023). The advantage of empirical heat releases is the low parameterization and calculation effort (Groß und Golubkov 2021). An overview of other empirical models can be found in Hoelle et al..

The second modelling approach is Arrhenius equation-based models. These models are based on the publication by Hatchard et al. 2001. This model, originally based on two Arrhenius equations, has been extended by various authors for different cell formats and compositions (Kriston et al. 2019; Ren et al. 2018; Wang et al. 2022; MacNeil und Dahn 2001; Lenz 2024). Both modelling approaches (empirical, Arrhenius-based) have advantages and disadvantages. According to Groß und Golubkov the chosen empirical approach has the advantage that no fitting of the Differential Scanning Calorimetry (DSC) curves is necessary and the calculation effort is relatively low even for large battery packs. A decisive disadvantage of empirical modelling is the neglect of the chemical reactions and thus the lack of insight into the reaction cascade. In addition, the TR heat is only released above a certain temperature T_{TR} (Hoelle et al. 2023). As a result, the heat released in the battery cell before the temperature T_{TR} is not considered in the design of thermal management systems.

In addition to the heat release during TR, the modelling of normal operating states is necessary for the design of battery systems and in particular for thermal management (Epp et al. 2022; Epp et al. 2023). Therefore, models for the thermo-electric simulation of pouch and prismatic battery cells are also present. Modelica was chosen as modelling language due to its physical, object-oriented and equation-based characteristics. Several models and libraries are already available for modelling the electrical behavior of a battery cell in Modelica. Einhorn et al. 2013 compared three electrical equivalent circuit models in terms of parameterization effort and accuracy. However, no thermal effects were considered. Gerl et al. 2014 and Uddin und Picarelli 2014 focus on the thermo-electric

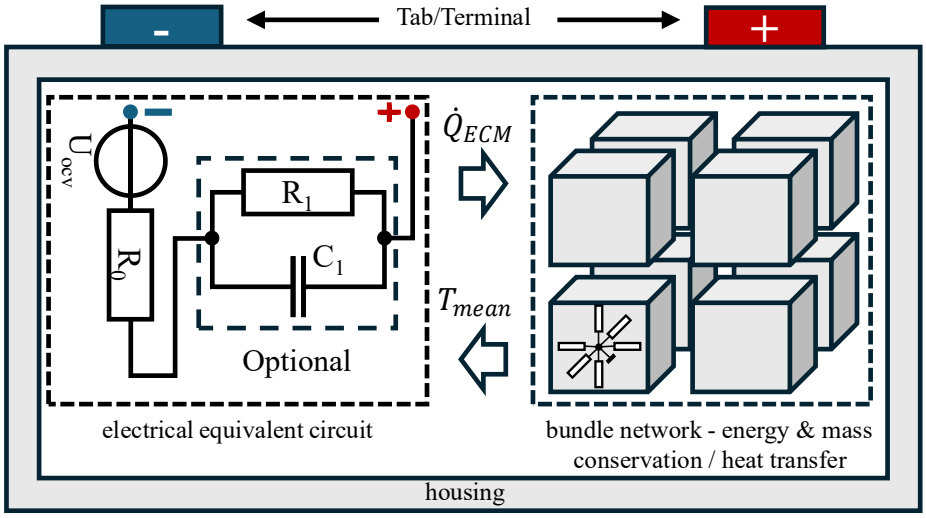

Figure 1. Schematic representation of a prismatic battery cell with the sub models ECM, bundle network, terminal/tab and the coupling of ECM and bundle network

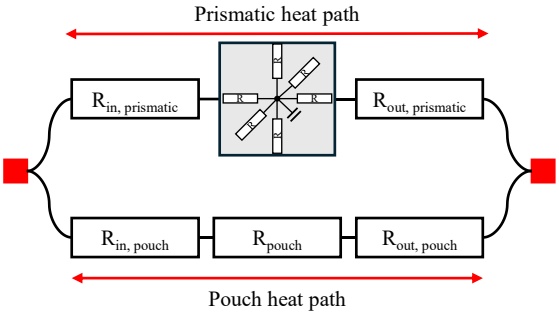
behavior in the respective Modelica library, but do not consider the anisotropic thermal conductivity or the TR. Wendland et al. 2018 address the anisotropic thermal conductivity but does not offer the possibility to consider the TR for individual battery cells. In addition, a point mass can comprise more than one battery cell. The Modelica library by Groß und Golubkov 2021 enables an empirical simulation of the TR, but does not take into account either the anisotropic thermal conductivity or a possible temperature distribution in the battery cell. The library presented by Groß und Golubkov is, to the authors' knowledge, currently the only available library for simulating TR in Modelica.

The models presented in this publication are used for thermo-electric simulation including a TR based on the Arrhenius equation with optional 3D discretization of the battery cell. This allows the anisotropic thermal conductivity and other relevant thermal conduction paths of the battery cell to be considered. In addition, this discretization combines many advantages of high-dimensional flow simulations (CFD) and simplified point mass models.

2 Modelling

The models are combined in the Modelica package named *TIL3_AddOn_Battery*. The package is partly based on the *TIL Suite* and *TILMedia Suite* libraries from TLK-Thermo. In the following, elementary models are presented. Not all models of the package are covered in this publication.

2.1 The Battery Cell



The battery cell model consists of various components (see Figure 1), which are described with sub models. The core of the battery cell is the so-called bundle network, which describes the active material, separators and current collectors in discretized form. No distinction is made between the individual active material layers, separators and current collector foils, so that the bundle network is only parameterized as one material. The bundle network is a replaceable model with 6 heat port matrices consisting of heat ports to enable thermal connection to the housing. The basic 3D control volumes, so-called bundles, are located within the bundle network (see section 2.2). These bundles are instantiated as a 3D matrix. The control volumes are thermally coupled in 3 dimensions in order to address the anisotropic thermal conductivity in the battery cell (Coman et al. 2017; Kim et al. 2021). The discretization is freely selectable.

The bundle network is surrounded by a housing (cf. Figure 1). Apart from the thickness, its discretization is based on the discretization of the bundle network. The housing is not discretized in thickness. A special feature of the housing is the non-structural change of the cell type (pouch-shaped, prismatic). As well as the consideration of the internal heat conduction paths for prismatic housing. For pouch-shaped battery cells, the housing consists of pouch foil. Due to the low foil thickness and to avoid the resulting small-time constants, the foil is modelled as a discretized thermal resistor. For the prismatic battery cell, the heat capacity is considered due to the significantly thicker housing (see Figure 2). By adjusting the internal and external thermal resistance, the heat conduction path can be virtually eliminated depending on the housing. In addition, these resistances are used to model inner/outer foils and to consider reduced thermal conductivity due to the safety valve and/or the terminals for the prismatic battery cell.

The electrical equivalent circuit model (ECM) (see section 2.4 and Figure 1) is globally (not discrete, one ECM per battery cell) integrated in the battery cell and electrically contacted via the two pins. The ECM was not implemented locally due to additional states. For the thermo-electric coupling, the volumetric mean value of the temperatures in the bundle state is used as input. The

DOI 10.3384/ecp218263

heat from the ECM is distributed volumetrically to all bundles. The heat distribution is a simplification; in the event of a thermal runaway, local effects such as short circuits can occur due to a breakdown of the separator (Kim et al. 2021); these effects cannot be modelled by the ECM.

Prismatic heat path
R
R
R

(see section 2.3), the ECM heat $\dot{Q}_{ECM}$ (see section 2.4) and the heat across the balance boundaries. For the enthalpy flow, it is assumed that the ejected mass carries the same specific enthalpy as the solid has at the time ($h_{s,out} = h_s$).

$$\begin{aligned}\frac{dU_s}{dt} = &\sum_{i=1}^{6} \dot{Q}_i + \dot{Q}_{ECM} \\ &+ m_s \dot{q}_{TR} + m_{s,initial} \dot{Y}_{rel,out} h_{s,out} \\ &- p \frac{dV_s}{dt}\end{aligned} \tag{6}$$

Equation 6 represents the energy balance according to the first law of thermodynamics, neglecting potential and kinetic energy. The relationship between the solid enthalpy H_s and the internal energy $U_s = H_s - pV_s$ leads to the following total differential.

$$\frac{dU_s}{dt} = \frac{dH_s}{dt} - p\frac{dV_s}{dt} - V_s\frac{dp}{dt} \tag{7}$$

Where p describes the pressure. Due to the pressure-independent properties of the solid, only $dU_s = dH_s - pdV_s$ remains. By inserting the relationship (cf. equation 7) into equation 6, the work of volume change pdV_s is reduced and the following total differential of the solid enthalpy remains on the left-hand side.

$$\frac{dH_s}{dt} = m_s\frac{dh_s}{dt} + h_s\frac{dm_s}{dt} \tag{8}$$

With the mass balance and the assumption for the enthalpy flow carried along, equation 6 can be simplified to the following implemented equation.

$$m_s\frac{dh_s}{dt} = \sum_{i=1}^{6} \dot{Q}_i + \dot{Q}_{ECM} + m_s\dot{q}_{TR} \tag{9}$$

2.3 The Thermal Runaway Model

Another central element of the battery cell is the calculation of the TR. For this purpose, a base class has been implemented to enable the replacement of different TR models. This means that new TR models can be easily integrated. The base class implementation targets Arrhenius equation based TR models, but can be easily adapted to empirical models, such as the one by Groß und Golubkov.

One of the most important inputs in the TR model is temperature. The decisive output is the mass-specific heat flow. This is determined by the change in the degree of conversion of the reactions. In literature, the degree of conversion is often referred to as dimensionless concentrations. The output and the implementation are illustrated below using the publication by Ren et al..

In the mentioned publication, DSC measurements are carried out for various battery cell components (cathode, anode, electrolyte). Using these measurements at different heating rates and the Kissinger or Flynn-Wall-Ozawa method, the kinetic triplet for specific DSC-peaks is derived (Ren et al. 2018). The decisive kinetic triplet (equation 10) consists of frequency parameter A_x, activation energy $E_{A,x}$ and reaction model f.

$$\begin{aligned}\kappa_x &= A_x \exp\left(-\frac{E_{A,x}}{RT(t)}\right) \\ \frac{d\alpha_x}{dt} &= -\kappa_x f \\ f &= \alpha_x^{n_x} \\ &\quad \cdot (1-\alpha_x)^{m_x} \\ &\quad \cdot (-\ln(1-\alpha_x))^{p_x} \\ \alpha_x(t=0) &= 1, \qquad \alpha_x \in [0,1]\end{aligned} \tag{10}$$

κ_x represents the respective conversion rate described by the Arrhenius equation. α_x is the degree of conversion of the approximated x-th DSC peak. f represents the kinetics-dependent reaction model, which describes the thermal decomposition of the solid. The exponents are used to represent different reaction models, such as the autocatalytic reaction ($n_x = 1, m_x = 1$) (Al-Khamis et al. 2010; MacNeil und Dahn 2001).

For the TR model of Ren et al., a power law reaction model with variable reaction order n_x is assumed for the reaction model ($p_x = 0, m_x = 0$). Six dominant DSC peaks are found in the publication and an ordinary differential equation (ODE) is implemented accordingly. The correct implementation can be verified by specifying a heating rate (via the temperature input) and then comparing the modelled with the measured DSC peak. The superposition of the modelled DSC peaks enables the determination of the resulting, mass-specific total heat flow $\dot{q}_{TR}$ (see equation 11). Figure 3 shows the simulated mass-specific total heat flow of the using equation 11 (for the DSC-simulation the reactive mass is set to one) compared to the DSC-measurement of the anode-electrolyte sample by Ren et al.

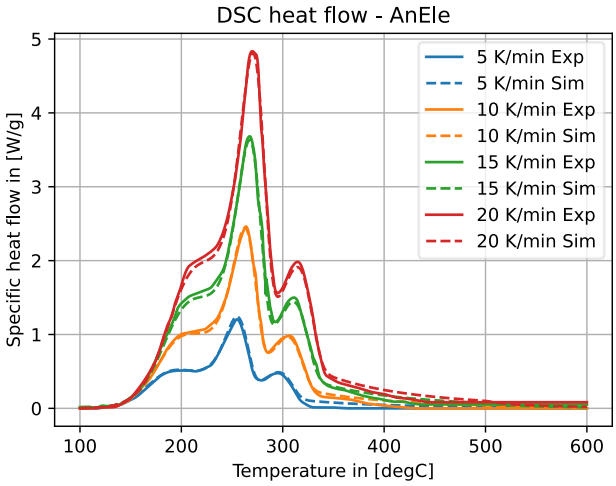


Figure 3. Comparison between modelled and measured specific heat flows for different heating rates

DOI 10.3384/ecp218263

The reaction enthalpy $\Delta h_{R,x}$ in equation 11 is the integral under the specific DSC-peak and n describes the number of peaks considered. $\varphi_{reactive}$ describes the reactive mass in the battery cell and is 55.3 % according to Ren et al..

$$\dot{q}_{TR} = \varphi_{reactive} \sum_{x=1}^{n} \Delta h_{R,x} \frac{d\alpha_x}{dt} \tag{11}$$

The relative change $\dot{\gamma}_{rel,out}$ must be defined for the ejected mass (see section 2.2). Therefore, the change of a specific degree of conversion or an average value from several degree of conversions can be used. A relative, dynamic mass loss is thus determined using the equation 12. φ_{loss} represents the relative mass loss of the battery cell.

$$\dot{\gamma}_{rel,out} = \frac{\varphi_{loss}}{n} \sum_{x=1}^{n} \frac{d\alpha_x}{dt} \tag{12}$$

By inserting the conversion degrees into equation 12, not the derivative, the already relative, ejected mass is described, so that equation 5 can be simplified to the following equation. This avoids the porosity state for each Li-Ion-bundle.

$$\rho_s V \phi = m_{s,initial} \cdot \left(1 - \frac{\varphi_{loss}}{n} \sum_{x=1}^{n} \alpha_x\right) \tag{13}$$

From a numerical perspective, it is useful to limit the conversion rate κ_x. The influence on the heat release should be as low as possible. The limitation via a time constant is not expedient in this case, as this is dependent on the temperature (see equation 14). For this reason, the numerical limitation is carried out using the characteristic time τ. For equation 14 a linear DGL was assumed for simplifications. The characteristic time is limited to $\tau_{min} = 10\,ms$. This time has proven to be a good compromise between numerical solvability and influence on the heat release.

$$\begin{gathered} \frac{d\alpha_x}{dt} = -\kappa_x \alpha_x \\ a_x = a_{x,t=0} e^{-\frac{t}{\tau}} = a_{x,t=0} e^{-\kappa_x t} \\ \tau = \frac{1}{\kappa_x} \\ \frac{d\alpha_x}{dt} = \begin{cases} -\kappa_x \alpha_x, & \kappa_x < \frac{1}{\tau_{min}} \\ -\frac{1}{\tau_{min}} \alpha_x, & \kappa_x \geq \frac{1}{\tau_{min}} \end{cases} \end{gathered} \tag{14}$$

2.4 The Electrical Equivalent Circuit Model

A replaceable ECM was chosen for the battery cell. The reasons for choosing an ECM are accurate description of the electrical behaviour and the released heat with low computational effort (Auch et al. 2023; Einhorn et al. 2013) as well as the direct possibility of parameter identification in Modelica (Einhorn et al. 2013; Uddin und Picarelli 2014). The currently implemented ECM are based on the publications by Einhorn et al. and Gerl et al.. They include the Rint (Ri), Thevenin (Th) and Dual Polarization Model (DP) (cf. Figure 4). These models have advantages and disadvantages depending on the accuracy and performance requirements (Einhorn et al. 2013). All ECM's use the same base class, which consists of several components such as a voltage source, resistors and current interrupt devices (CID). The CID decouples the ECM from the electrical pins at high temperatures, e.g. triggered by the TR. The voltage source U_{OCV} describes the open circuit voltage (OCV). The resistors describe several effects. R_0 represents the ohmic internal resistance of the battery cell. The terminal voltage U_T must be calculated differently depending on the model selected (see Figure 4).

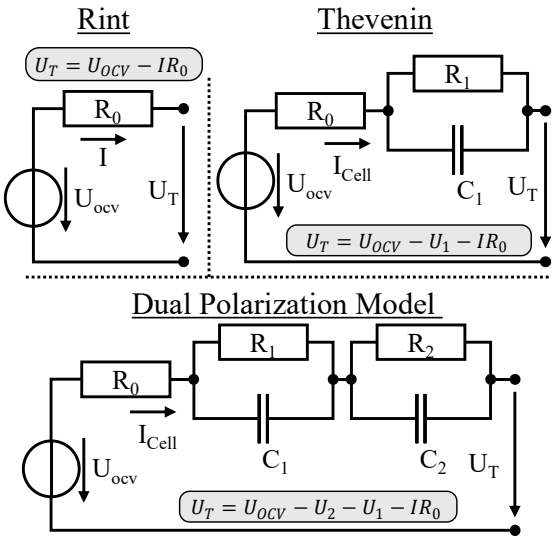

Figure 4. Schematic representation of the ECMs

The electrical data for the OCV, resistances and capacitances can be constant, equation-based or table-based. Whereby the look-up table enables 2D interpolation to consider the SoC and temperature dependence of the data (cf. Einhorn et al. 2013; Uddin und Picarelli 2014). The SoC is determined by Coulomb counting. According to Bernardi et al. 1985 the released heat is described by the irreversible $\dot{Q}_{Loss}$ and reversible $\dot{Q}_{Rev}$ heat. The irreversible part includes ohmic losses, charge transfer, overpotentials and the limitation of mass transfer. The reversible part includes entropy changes and is described by the partial derivative of the OCV with respect to temperature $\frac{\partial U_{OCV}}{\partial T}$ (ϵ small temperature delta) (Auch et al. 2023; Bernardi et al. 1985).

$$\begin{aligned} \dot{Q}_{ECM} &= \dot{Q}_{Loss} + \dot{Q}_{Rev} \\ \dot{Q}_{Loss} &= \mathrm{I}(\mathrm{U_{OCV}} - U_T) \\ \dot{Q}_{Rev} &= IT\frac{\partial \mathrm{U_{OCV}}}{\partial \mathrm{T}} \\ \frac{\partial \mathrm{U_{OCV}}}{\partial \mathrm{T}} &= \frac{\mathrm{U_{OCV}}(T+\epsilon) - \mathrm{U_{OCV}}(T-\epsilon)}{2\epsilon} \end{aligned} \tag{15}$$

2.5 States and Sparse Solvers

The number of differential states changes depending on the discretization. For each thermal and Li-Ion-bundle there is exactly one differential state, the temperature. The porosity can be replaced by an algebraic expression (see section 2.3). Thus, the number of states for the bundle network and housing depends on the discretization. In addition, there is one state each for the tabs/terminals. The Dymola sparse solver (Dassault Systèmes AB 2025) can help speed up the simulation. For example, a TR simulation of a 125-fold discretized battery cell without sparse solver takes ~36 s, with only ~15 s (on a laptop with an 11th Gen Intel Core i7-11800H - 2.30GHz and 16 GB RAM). Thus, the simulation time for this case can be reduced by approx. 42 % by using a sparse solver. A 1000-fold discretization of a battery cell is possible, but the simulation time increases to 2700 s and the DAE system 133408 scalar equations. Higher discretization's were not tested. A comparison with an CFD simulation has not yet been conducted.

By using a global TR model (not discretized one per battery cell) the number of states can be greatly reduced, which can be helpful when simulating entire battery systems. The model shows that Modelica and Modelica tools should continue to improve dealing with high discretization, since the translation time increases exponentially with the number of states, even though the bundles all consist of the same code. This challenge has been recognized and is being addressed in the European OpenSCALING 2023 project.

3 Experiment

The battery cell model described in Section 2.1 can be used to model normal operating behavior with charging and discharging processes as well as dynamic load profiles (Epp et al. 2022; Epp et al. 2023). In addition to simulating the normal operating behavior, it is also possible to carry out safety analyses for the event of damage to TP. These safety considerations can be used for the development of thermally safer battery systems. Furthermore, applications in model-based early detection of the TP are conceivable.

In this section, the *TIL3_AddOn_Battery* is checked for plausibility by comparing it with an experimental propagation test. The test by Schöberl et al. 2024 is used for comparison. This plausibility check concentrates on the thermal propagation. A simulation of the electrical behavior coupled with the thermal behavior is not carried out.

3.1 Propagation Experiment Setup

In the experimental propagation test by Schöberl et al. two battery cell types are examined with regard to their thermal propagation behavior. The battery cells investigated are nickel-manganese-cobalt (NMC)-811 and lithium iron phosphate (LFP). The measurement results for NMC-811 are considered below.

In the experiment, five cells were mounted between two steel plates with two additional thermal insulation layers. The cells are not electrically connected to each other. The battery cells were tensioned with a SoC of 30 %. The battery cells are wrapped in a thin insulating film. Vermiculite plates were used as thermal insulation layers. A heater was placed between one of the insulating layers and the neighboring battery cell to trigger the TR in the first cell. The TR in the first battery cell provided enough heat to trigger the TR in the other cells. By measuring the temperature between the cells, between the first cells it was possible to trace the propagation process

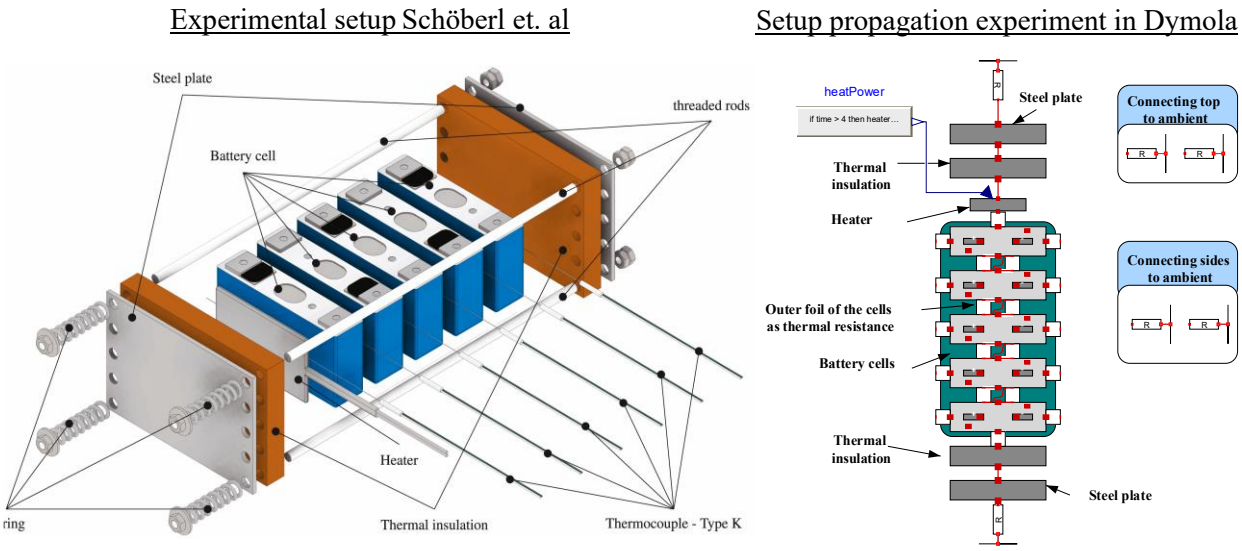

Figure 5. Propagation experiment by Schöberl et al. and the transfer of the setup to Modelica diagram

DOI 10.3384/ecp218263

in the experiment. The structure described is shown in Figure 5.

The steel plates, the thermal insulation layers and the heater are modelled as layers using the thermal bundles (see section 2.2). With the help of the *TILMedia Suite*, a material can be assigned to the layers via the replaceable *SolidType* record. As in the experiment, the dimensions of the layers are adapted to the cell size with an additional allowance, which is estimated using the illustrations from Schöberl et al.. In addition to the thermal insulation layers visible in Figure 5, a further insulation layer is placed on the undersides of the cells. The power for the heater is provided via input. The specified heat flow per area is selected as in the publication. Schöberl et al. specifies that the heater is switched off manually if the TR has occurred in the first cell. In the simulation setup, the heater is switched off at a defined temperature T_{off}.

The model described in section 2.1 is used for battery cells. The foils with which the battery cells are wrapped are modelled in the simulation experiment using thermal resistors.

The TR model (see section 2.3) of the battery cell used for the simulation is parameterized using Ren et al.. The parameters specified in the publication were determined for cell chemistry of NMC-111 and a different battery cell type. The model therefore needs to be adapted. The relative mass loss φ_{loss} and the factor for the relative mass of the cell that can decompose in the TR reaction $\varphi_{reactive}$ are adjusted. The estimation of the reactive mass $\varphi_{reactive}$ was based on the temperature levels available from the measurements. The mass loss is described in Schöberl et al. for all five cells with an average of $\varphi_{loss} =$ 45,8 %. For the individual cells, the relative mass loss is stored in the TR model.

The heat ports of the battery cells and the heater, which are not visibly connected to another heat port in Figure 5 are connected to the environment via a convection resistor. Table 1 shows the details of the individual models with their respective properties for the simulation.

Table 1. Summary of the relevant values for the propagation simulation

Symbol	Description	Value	Literature
General			
T_{Start}	Initialization & ambient temperature	20 °C	Assumption
T_{off}	Heater switch-off temperature	375 °C	Assumption
$\dot{q}_{HT}$	Heat output per heating surface	6.2 $\frac{W}{cm^2}$	Schöberl et al. 2024
α_{Air}	Heat transfer coefficient for convection resistance	12 $\frac{W}{m^2K}$	Assumption
Steel Plate (TILMedia-Stainless Steel)			
$n_{x,St}$,$n_{y,St}$,$n_{z,St}$	Discretization in x-, y- and z-direction	1, 1, 1	-

3.2 Simulation Results

For the plausibility check of the models, the temperatures between the battery cells are examined as in the experiment. The temperatures at the respective heat ports of the cell models can be used for this purpose. The simulation results compared to the measurement data are shown in Figure 6. In the simulation, all five cells enter the TR, and a TP could be shown.

The simulation and the experiment show a good agreement for the initial temperature rise of the TR for the first three battery cells. This shows that heat conduction is well represented for the first three battery cells and that TR heat is released at a temperature comparable to the experiment. However, some deviating temperature curves are recognizable. A comparison between T1 measurements and T1 simulation shows a slower heating phase for the simulation. The reasons for this may lie in the lack of information on the internal cell structure or in

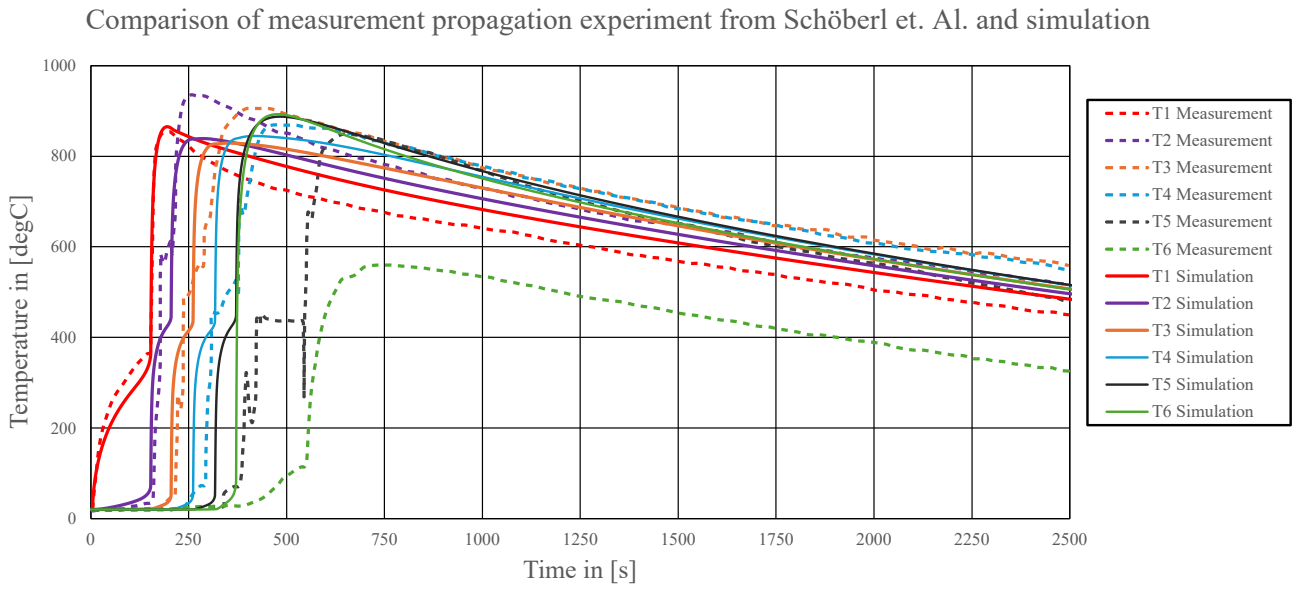

Figure 6. Comparison measurement (Schöberl et al. 2024) and simulation (T1-Heater-Cell 1; T2- Cell 1-Cell 2; T3- Cell 2-Cell 3; T4- Cell 3-Cell 4; T5- Cell 4-Cell 5; T6- Cell 5-Insulation)

deviating thermal properties due to assumptions made during modelling. Furthermore, the temperature for the measurement after the TR in cell 1 drops faster than in the simulation. In Schöberl et al. the mass loss could only be estimated retrospectively for the first cells. The mass loss of the first three cells was averaged due to irreversible fusion. If cell 1 has emitted more mass in the experiment than assumed, this can lead to the recognizable deviating cooling behavior. In the cooling phase of the other cells after the TP, similar temperature curves are observed between simulation and measurement.

The behavior of cell 5 cannot be matched with the simulation. The temperature rise in the TR stagnates here. One reason could be the decomposition reactions which are subject to a certain scatter (Lenz et al. 2023). Another reason could be the loss of mechanical integrity due to the mass loss and a resulting thermal contact resistance between the battery cells where the temperature is measured (Schöberl et al. 2024). This could also be the reason for the different temperature curve between simulation and measurement in cell 6. In addition, the temperature of cell 6 is significantly influenced by cell 5.

The simulation is based on several assumptions (cf. Table 1). The mentioned deviations in temperature curves can arise due to deviating thermal properties of the assumed material parameters. To make the simulation more reliable, the materials used should be thermally characterized in advance for a battery system to be investigated. In conclusion, it can be said that a TP can be simulated with the battery library and that these simulations can be used to carry out safety assessments for battery systems.

4 Conclusion

This publication presents a discretized 3D battery cell model in Modelica. The focus of the modelling is the physical simulation of the TR based on the Arrhenius equations and the modelling of the anisotropic thermal conductivity. This allows to consider relevant heat conduction paths in the battery cell using 3D discretization. The thermo-electric behavior is modelled by a coupled ECM. The model was developed for the user-friendly and fast simulation of battery cells and systems. To the authors' knowledge, the 3-dimensional thermal calculation with a coupled physical TR model is a novel approach in Modelica for the simulation of battery systems. The comparison with an experiment from the literature has shown good agreement with the simulation. The calculation of the TP was possible within approx. 83 s (experimental time approx. 47 min) and thus represents only a fraction of the required simulation time compared to complex 3D CFD simulations.

Future enhancements of battery cell model are gas generation, outgassing and particle ejection, which have a significant influence on the TR. As well as further components and exemplary models for simulation of entire battery systems.

Abstract

This work introduces the first validated, user-friendly, and accurate open-source photovoltaic-thermal (PVT) collector model in Modelica, tailored for system-level simulation and optimization. Current state-of-the-art PVT collector Modelica models are largely limited to oversimplified, steady-state representations that fail to capture the dynamic thermal behavior inherent to real PVT systems. A comprehensive Modelica model is developed based on the ISO 9806 standard (test method for the quasi-dynamic thermal performance of solar thermal collectors), coupled with an electrical system model through an internal heat transfer coefficient. The model calibration relies exclusively on manufacturer datasheet parameters, thereby eliminating the need for parameter estimation from measurement data. The model is validated using experimental results from an unglazed PVT collector, demonstrating strong agreement for various (weather) conditions. The findings highlight that, while steady-state models may suffice for conventional solar thermal collectors (STCs), accurate PVT modeling necessitates a dynamic approach, particularly for the thermal aspects. The electrical output of the PVT collector is less sensitive to transient effects. In addition to the model formulation and validation, this work presents a user-friendly automated calibration method based on manufacturer data, and critically addresses the limitations and potential trade-offs of using exclusively datasheet-derived parameters, thereby providing a transparent tool for PVT system simulation, design, and optimization within the open-source IDEAS library.

Keywords: Photovoltaic-thermal (PVT) solar collector, Modelica, PVT model validation, PVT model calibration, manufacturer datasheets

1 Introduction

Physics-based system models are key for addressing the challenges of climate change and the transition towards decarbonized energy systems. These models play a key role in the effective deployment of renewable energy sources (RES) such as photovoltaic (PV), solar thermal collectors (STC), and photovoltaic-thermal (PVT) systems, enabling optimal system design and control. PVT collectors, also known as hybrid solar collectors, simultaneously convert solar radiation into electricity and heat. A key distinction exists between glazed and unglazed PVT collectors: glazed collectors often prioritize thermal efficiency, while unglazed collectors, due to their lower operating temperatures, can enhance electrical efficiency. This paper focuses on unglazed (so-called WISC[1]) PVT collectors, which consist of a PV module coupled with a heat exchanger and may include rear insulation to reduce heat loss. Variants without insulation perform particularly well under sub-ambient conditions, making them suitable as heat sources for heat pump systems. The unglazed collectors are typically classified according to their rear insulation and heat transfer characteristics (Lämmle et al. 2020). The favorable market conditions for unglazed PVT designs further demonstrate their relevance in various urban and industrial energy contexts (Kramer, Amrizal, et al. 2020). Modeling approaches in the PVT field range from highly accurate, detailed, component-level models to simplified methods designed for integrated system performance assessment within a broader energy context. Although Modelica is a powerful modeling language for developing interdisciplinary simulation models, no validated open-source Modelica PVT model currently exists that captures the full dynamic thermal behavior while accounting for the thermal-electrical coupling. This paper addresses this gap by presenting a novel Modelica PVT collector model, validated using experimental data from unglazed PVT collector. Moreover, the PVT model relies solely on publicly available manufacturer data, avoiding complex calibration procedures for which measurement data are needed.

2 Background

The IEA SHC Task 60 *"Application of PVT Systems"* (2018–2020) has played a central role in evaluating PVT technologies by focusing on system operation, collector testing, system-level simulation, and global performance assessment (IEA SHC 2018). One of its key objectives

[1]Wind and/or infrared sensitive collectors

was to identify scenarios in which PVT systems provide added value compared to separate PV and solar thermal installations. To facilitate the integration of PVT systems into simulation environments and ensure broader adoption, Task 60 stresses the need for standardized input parameters that guarantee the "processability" of technical data for tools like TRNSYS, Polysun, Modelica, and SCenoCalc (Kramer, Amrizal, et al. 2020). This standardization is crucial due to potential variations in testing procedures among manufacturers (market fragmentation), making consistent component-level characterization essential. Therefore, Task 60 recommended the application of international standards, specifically ISO 9806 (ISO 9806 2013) for the thermal aspect and IEC 60904 for the PV component. To incentivize the use of these standards, established certification frameworks such as the Solar Keymark (ESTIF/SKN n.d.) utilize and promote them, with targeted extensions to address the hybrid interactions between electrical and thermal components. This includes specifying the operational mode of electricity generation, such as maximum power point (MPP) tracking or open-circuit (OC), as required by ISO 9806 (2013) which has been identified by Hofmann et al. (2010) as highly influential on the thermal output.

Existing PVT collector models can generally be categorized into (1) those requiring detailed design data and parameter estimation, and/or (2) simplified models based on datasheet parameters. Stegmann et al. (2011) developed a datasheet-based simulation model for unglazed, liquid-cooled PVT collectors, relying solely on standard test procedures and OC-tested datasheet parameters within the TRNSYS environment. In contrast, Lämmle (2018) proposed both a collector-level model in Modelica capable of capturing the detailed optical, electrical, and thermal energy flows using detailed manufacturer data, and a system-level model in TRNSYS that assesses overall performance based on empirical efficiency curves. Other approaches focus on parameter identification of ISO 9806 parameters using measurement data: Jonas et al. (2019) presented a detailed implementation and validation procedure within TRNSYS, while Veynandt, Klanatsky, et al. (2023) extended this work using data-driven grey-box models in MATLAB. Additionally, Kang (2021) developed a Modelica-based PVT model for district heating applications, but they didn't provide any implementation details. These existing models present several limitations: some are not implemented in Modelica, others lack sufficient implementation details, and many rely on parameter estimation of ISO 9806 parameters, requiring extensive measurement data. The work presented here offers an alternative by providing a Modelica-based PVT collector model that combines a high-fidelity physical representation with the simplicity of datasheet-only inputs.

The electrical operation of a PVT collector differs from standard PV IEEE rating schemes due to the influence of heat transfer fluid (HTF) flow and the resulting temperature distribution across the PV cells (Herrando, Markides, and Hellgardt 2014; Lämmle 2018; Brottier 2019; Jonas et al. 2019). Similarly, the electricity generation mode (MPP/OC) impacts the thermal behavior of the PVT collector (Hofmann et al. 2010). The existing equations describing the thermal and electrical performance, used as the starting point in this paper, are presented in Section 2.1 and 2.2, respectively.

2.1 Thermal modeling

The thermal part of a PVT collector is similar to a STC. Similarly, a good efficiency requires both effective solar absorption and efficient heat transfer to the HTF (Zondag 2008). Different mathematical models are used to describe the thermal performance of liquid heating collectors, depending on the collector type (glazed or unglazed) and the test method (steady-state or quasi-dynamic). ISO 9806 defines a steady-state model for glazed liquid-heating solar collectors, widely adopted in both testing and simulation. Its useful thermal power output is calculated by Equation 1

$$\frac{\dot{Q}_{\text{th}}}{A_G} = \eta_{0,\text{hem}}\, G - a_1\,(\theta_m - \theta_a) - a_2\,(\theta_m - \theta_a)^2, \qquad (1)$$

where $\dot{Q}_{\text{th}}$ is the useful thermal power output (W), A_G is the collector area (m^2), $\eta_{0,\text{hem}}$ is the zero-loss (optical) efficiency for hemispherical irradiance (–), G is the global irradiance on the collector plane (W m^{-2}), θ_m and θ_a are the mean HTF and ambient air temperatures (K or °C). a_1 and a_2 are the linear and quadratic heat-loss coefficients ($\text{W m}^{-2}\,\text{K}^{-1}$ and $\text{W m}^{-2}\,\text{K}^{-2}$, respectively).

For unglazed collectors under steady-state conditions, wind-speed and long-wave effects must be included. One convenient formulation replaces G by a net solar irradiance G'', which integrates the long-wave irradiance:

$$\frac{\dot{Q}_{\text{th}}}{A_G} = G''\Big[\,\eta_{0,\text{hem}}\,(1-b_u)\;-\;(b_1 + b_2\,u)\,\frac{\theta_m - \theta_a}{G''}\Big], \qquad (2)$$

$$\text{with}\quad G'' \;=\; G \;+\; \frac{\varepsilon}{\alpha}\left(E_L - \sigma\,\theta_a^4\right) \qquad (3)$$

Here, b_u is the collector efficiency coefficient (wind dependence) (s m^{-1}), b_1 is the linear heat-loss coefficient ($\text{W m}^{-2}\,\text{K}^{-1}$), b_2 is the wind-speed dependence of the heat-loss coefficient ($\text{W s m}^{-3}\,\text{K}^{-1}$), u is the wind speed, E_L is the long-wave irradiance (W m^{-2}) , and σ is the Stefan–Boltzmann constant.

To capture both unglazed/glazed types and transient effects, the quasi-dynamic model adds a thermal capacitance, dependence of direct (G_b) and diffuse (G_d) radiation via incidence-angle modifiers (K_b, K_d), and explicit wind/infrared terms:

$$\begin{aligned}\frac{\dot{Q}_{th}}{A_G} &= \eta_{0,b} K_b(\theta_L,\theta_T)\,G_b + \eta_{0,b} K_d\,G_d - c_1\,(\theta_m - \theta_a)\\ &\quad - c_2\,(\theta_m - \theta_a)^2 - c_3\,u\,(\theta_m - \theta_a)\\ &\quad + c_4\left(E_L - \sigma\,\theta_a^4\right) - c_5\,\frac{d\theta_m}{dt} - c_6\,u\,G. \end{aligned} \qquad (4)$$

The quasi-dynamic model extends the steady-state form by including coefficients c_1 and c_2, linear and quadratic

DOI 10.3384/ecp218273

heat-loss terms analogous to a_1, a_2 in Equation 1, with units $\mathrm{W\,m^{-2}\,K^{-1}}$ and $\mathrm{W\,m^{-2}\,K^{-2}}$; c_3 and c_6, representing wind-speed dependence of heat losses and zero-loss efficiency, with units $\mathrm{J\,m^{-3}\,K^{-1}}$ and $\mathrm{s\,m^{-1}}$; c_4, the sky temperature dependence of the heat-loss coefficient (-); and c_5, the effective thermal capacitance, with unit $\mathrm{J\,m^{-2}\,K^{-1}}$.

Equations 1–4 were originally developed for STCs, but are commonly applied to describe the thermal behavior of PVT systems, as no dedicated PVT testing standard currently exists. Depending on the test method (unglazed) steady-state or quasi-dynamic, manufacturer datasheets list all coefficients needed to solve the corresponding equation that gives the collector's thermal output under specific operational and ambient conditions. Due to the strong coupling between thermal and electrical performance in PVT systems, the thermal coefficients should ideally be determined under MPP conditions. If testing is performed under OC conditions, the solar irradiance must be corrected to account for the electrical power that would be extracted under MPP operation, as outlined by Lämmle (2018).

2.2 Electrical modeling

In PVT collectors, the electrical performance is highly sensitive to the temperature of the PV cells, which is influenced by the thermal coupling between the PV layer and the HTF in the STC. A low thermal resistance between the PV cells and the HTF is essential to avoid excessive PV cell temperatures, which degrade both electrical and thermal efficiency (Zondag 2008). This section focuses on two key aspects: the calculation of electrical yield using performance ratios, and the modeling of the PV(T) cell temperature, which plays a central role in determining the electrical output.

2.2.1 Electrical yield

The general form of the electrical power output from a PVT collector is given by Equation 5

$$\frac{P_{\mathrm{el}}}{A_G} = \eta_{\mathrm{PV}} \cdot PR_{\mathrm{tot}} \cdot G, \tag{5}$$

where η_{PV} is the electrical efficiency at nominal conditions (–), PR_{tot} is the overall instantaneous performance ratio (–), and G is the global solar radiation on the PVT plane (W).

The typical loss mechanisms affecting the electrical performance of PV and PVT systems are detailed and summarized in Kramer, Amrizal, et al. (2020), with their corresponding performance ratios PR_{IAM}, PR_G, PR_T, PR_C and PR_I denoting incidence-angle modifier losses, irradiance-related losses, PV cell temperature losses, ohmic (cable) losses and inverter efficiency losses, respectively. In this work, only the temperature-related performance ratio PR_T is explicitly modeled. All other losses are grouped into a single lumped loss factor, as discussed in Section 3.1.3.

The temperature dependence of the electrical efficiency is calculated following the approach by Skoplaki and Palyvos (2009) as formulated in Equation 6

$$PR_T = 1 - \beta \cdot (T_{\mathrm{cell}} - T_{\mathrm{nom}}), \tag{6}$$

where β is the temperature coefficient of power for the PV cells ($\%\,\mathrm{K^{-1}}$), T_{cell} is the PV cell temperature, and T_{nom} is the nominal cell temperature under standard test conditions.

2.2.2 PV cell temperature

An essential step in assessing PV efficiency and electrical yield is determining the PV cell temperature, since higher temperatures reduce performance (see Equation 6). In PV modules, cell temperature follows the module's steady-state temperature (Lämmle 2018), whereas in PVT collectors it is governed by the HTF temperature.

Solar radiation absorbed by a PV cell is partly converted to electricity; the remainder is dissipated to the ambient, influenced by wind speed, ambient temperature, and irradiance. Mounting-type-dependent cell-temperature models are reviewed in Maier et al. (2023).

A simple PVT estimate equates T_{PV} to the fluid outlet temperature $T_{\mathrm{fluid,out}}$ (Brottier 2019), as implemented in tools such as Polysun. A more accurate method extends the Hottel–Whillier–Bliss equation with a PV–fluid heat-transfer coefficient U_{AbsFluid} (Florschuetz 1976; Zondag 2008; Jonas et al. 2019).

Based on Lämmle (2018) and Jonas et al. (2019), the model couples the ISO 9806 quasi-dynamic thermal collector (Equation 4) with a two-node PV performance formulation (see Section 3.1.1), linking the PV cell and the HTF via U_{AbsFluid} ($\mathrm{W\,m^{-2}\,K^{-1}}$) to yield the cell-temperature relation in Equation 7

$$T_{\mathrm{cell}} = T_m + \frac{\dot{q}_{\mathrm{th}}}{U_{\mathrm{AbsFluid}}}, \tag{7}$$

where $\dot{q}_{\mathrm{th}}$ is the specific thermal power output of the collector ($\mathrm{W\,m^{-2}}$), and T_m is the mean HTF temperature (K), calculated as the average of the HTF inlet and outlet temperatures, T_{in} and T_{out} respectively.

In principle, U_{AbsFluid} can be calculated from the series combination of the absorber-to-pipe conductive resistance, characterized by the conductive heat transfer coefficient U_{AbsPipe}, and the pipe-to-fluid convective resistance, characterized by the convective heat transfer coefficient $U_{\mathrm{PipeFluid}}$, based on the collector geometry, material properties, and operational conditions (e.g., fluid flow rate) using analytical models or finite-element (FEM) simulations (Kramer, Amrizal, et al. 2020). However, for most commercial PVT collectors, the absorber-specific parameters required for such detailed modeling are not readily available, as only standardized test reports or manufacturer data are typically accessible. In such cases, an approximate approach needs to be applied. Stegmann et al. (2011) developed an approach for unglazed PVT collectors, using thermal parameters extracted from OC tests. Lämmle (2018) similarly proposed a procedure for glazed PVT collectors that derives U_{AbsFluid} from standard MPP

test data using a makeshift procedure. In this work, the glazed and unglazed parameter estimation methods are integrated in the Modelica model, such that U_{AbsFluid} can be derived solely from manufacturer datasheet parameters for MPP tested collectors, including wind-speed dependence. Details of this method are given in Section 3.1.2.

2.3 Novelty of the work

Existing PVT modeling approaches (Lämmle 2018; Jonas et al. 2019) provide robust frameworks for simulating PVT systems. However, these models typically rely on detailed parameter identification procedures or proprietary datasets, often requiring experimental calibration, finite element modeling, or surface temperature measurements. While such methods can yield high accuracy, they limit accessibility and replicability for broader research and system simulations, hinder transparent product comparisons, and ultimately restrict the market uptake of PVT technology. Furthermore, existing simplified (non-validated) Modelica models often fail to capture the full dynamic thermal behavior of PVT systems and do not adequately integrate the coupling between thermal and electrical components. For instance, Stegmann et al. (2011) proposed a simplified model based on datasheet parameters, but this model is not implemented in Modelica and is strictly limited to unglazed PVT collectors, as it relies on the steady-state ISO 9806 formulation for unglazed collectors (see Equation 2) rather than the more general quasi-dynamic approach.

In summary, the current literature regarding PVT modeling has two main research gaps: (1) the absence of a PVT model that leverages only publicly available datasheet parameters thereby eliminating the need for unavailable or proprietary measurement data, and (2) the absence of a comprehensive Modelica model that accurately represents the full dynamic thermal behavior of PVT systems while incorporating thermal-electrical coupling.

In this work, a novel Modelica-based PVT collector model is introduced and validated with experimental data from unglazed PVT collectors. Unlike previous approaches, the proposed model relies solely on datasheet parameters, thereby eliminating the need for complex calibration procedures. Moreover, the model's performance is critically assessed, highlighting its limitations and comparing its accuracy against methods based on detailed parameter estimation.

3 Model development

In this section, the methodology used to develop, implement, and validate the novel PVT collector model is presented. In Section 3.1, the underlying modeling framework is detailed while in Section 3.2, the metrics employed to assess model accuracy are discussed.

3.1 PVT collector model

The PVT collector model consists of two coupled submodels—thermal and electrical—which are detailed in Sections 3.1.1–3.1.3. To account for the changing HTF temperature along the lenght of the collector, the model is discretized into n_{Seg} segments along the flow path. Each segment is solved in a coupled thermal–electrical loop. For clarity, the core segment index is omitted in the equations presented in the following subsections.

3.1.1 Thermal performance

To model the thermal behavior of PVT collectors, a two-node, one-capacitance network is adopted (schematically presented in Figure 1), extending the ISO 9806 solar-thermal formulation. An internal heat transfer coefficient U_{AbsFluid} couples the mean HTF temperature node T_m and the absorber (PV cell) temperature T_{cell}. All physical heat capacities (fluid, absorber, frame, insulation) are lumped into an effective thermal capacity c_{eff}, which is assigned to the mean HTF temperature T_m (Fischer and Müller-Steinhagen 2009). Physically, this means that the thermal inertia of the entire collector system is at one uniform temperature T_m.

The T_m-node energy balance is formulated by Equation 8

$$c_{\text{eff}} \frac{dT_m}{dt} = \dot{q}_{\text{rad}} - \dot{q}_{\text{loss}} - \dot{q}_{\text{th}}, \tag{8}$$

where $\dot{q}_{\text{rad}}$ are radiative gains ($\mathrm{W\,m^{-2}}$), $\dot{q}_{\text{loss}}$ conduction/-convection losses ($\mathrm{W\,m^{-2}}$), and $\dot{q}_{\text{th}}$ the useful thermal output per area ($\mathrm{W\,m^{-2}}$). Rearranging Equation 8 and substituting the radiative gain and loss terms from Figure 1 yields: (1) the steady-state ISO 9806 model (Equation 1), by setting $c_{\text{eff}} = 0$ and including only the blue terms. (2) the quasi-dynamic ISO 9806 model (Equation 4), by retaining c_{eff} and adding the red wind-speed and sky-temperature terms.

The ISO 9806 thermal network model (dashed lines in Figure 1) is available in the open-source IBPSA Modelica library for simulating STC behavior (Wetter et al. 2019), where it is based on a simplified version of the quasi-dynamic ISO 9806 model (Equation 4) with $c_3 = c_4 = c_6 = 0$, thus neglecting wind and sky-temperature dependencies. This existing implementation serves as the starting point for the PVT collector model developed in this work. To extend its validity to unglazed collectors, wind-speed and long-wave loss terms are in-

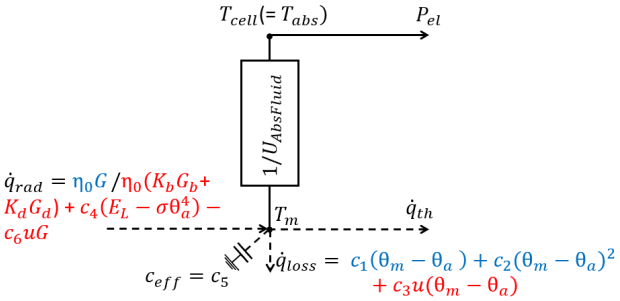

Figure 1. Two-node, one-capacitance thermal network for PVT collectors (ISO 9806: dashed lines; extension: solid lines).

DOI 10.3384/ecp218273

corporated, resulting in the quasi-dynamic formulation (Equation 4), which captures the effects relevant for unglazed PVT thermal operation (Stegmann et al. 2011; Fischer and Müller-Steinhagen 2009). Compared to a two-node, two-capacitance network[2], this two-node, single-capacitance approach is ISO-compliant, simpler, and directly uses standardized parameters—and has been demonstrated as the preferred method for the PVT collectors investigated by Jonas et al. (2019).

The specific thermal output is calculated as:

$$\dot{q}_{\text{th}} = \frac{\dot{m}\, c_p\, (T_{\text{out}} - T_{\text{in}})}{A_G}, \tag{9}$$

where $\dot{m}$ is the mass flow rate ($\mathrm{kg\,s^{-1}}$) and c_p the HTF specific heat capacity ($\mathrm{kJ\,kg^{-1}\,K^{-1}}$).

3.1.2 Thermal–electrical coupling

Both numerical and experimental approaches can be used to determine U_{AbsFluid} for a specific absorber design. However, the absorber-specific parameters required by these methods are rarely available for commercial PVT collectors, where test reports and datasheets are usually the only information source. PVT models that rely on parameter estimation typically fit U_{AbsFluid} alongside other thermal and electrical parameters. Since this work aims to develop an accurate PVT model based solely on datasheet inputs, a datasheet-based derivation of U_{AbsFluid} is proposed by merging two established approaches. Stegmann et al. (2011) derived U_{AbsFluid} from OC-mode thermal tests (including wind-speed dependence) making it valid for unglazed collectors. Lämmle (2018) generalized this to MPP-mode glazed collectors but they omitted wind effects. The MPP-mode approach is preferred because the electrical operating point significantly influences thermal performance; if only OC-mode parameters are available, the corresponding MPP coefficients can be obtained via the conversion procedure of Lämmle (2018), which properly accounts for the coupling between electrical and thermal losses and avoids physically incorrect simplifications (Kramer and Helmers 2013).

Combining these two methods yields a unified, wind-dependent formulation using MPP datasheet coefficients:

$$U_{\text{AbsFluid}} = \frac{\left[(\tau\alpha)_{\text{eff}} - \eta_{0,\text{el}}\right]\left(c_1 + c_3\, u + b_{1,\text{el}}\right)}{\left[(\tau\alpha)_{\text{eff}} - \eta_{0,\text{el}}\right] - \left(1 - \frac{c_6}{\eta_{0,\text{th}}}\, u\right)\eta_{0,\text{th}}}. \tag{10}$$

Here $(\tau\alpha)_{\text{eff}} = 0.901$ for unglazed PVT collectors as reported in Lämmle (2018), and the electrical temperature-dependence coefficient is given by $b_{1,\text{el}} = |\beta|\, G_{\text{nom}}$, where β is the temperature coefficient in $\%\,\mathrm{K^{-1}}$ and $G_{\text{nom}} = 1000\,\mathrm{W\,m^{-2}}$. When computed across varying wind speeds u, the resulting U_{AbsFluid} values should remain approximately constant, serving as a consistency check on the datasheet parameters (Stegmann et al. 2011).

[2]Some PVT models introduce a second capacitance linked to T_{cell} to represent the thermal inertia of the PV panel, but this additional capacity cannot be determined using typically available manufacturer data.

3.1.3 Electrical performance

The electrical output power P_{el} is calculated using the PVWatts V5 formulation (Dobos 2014) as presented by Equation 11

$$P_{\text{el}} = P_{\text{nom}}\, \frac{G}{G_{\text{nom}}}\left[1 + \gamma(T_{\text{cell}} - T_{\text{nom}})\right](1 - P_{\text{loss}}), \tag{11}$$

where P_{nom} is the module's rated DC power under standard test conditions ($G_{\text{nom}} = 1000\,\mathrm{W\,m^{-2}}$, $T_{\text{nom}} = 25\,^{\circ}\mathrm{C}$), T_{cell} is the PV cell temperature from the two-node thermal model (Equation 7), and P_{loss} is a constant system loss factor covering soiling, shading, mismatch, wiring and connection losses, inverter inefficiency, light-induced degradation (LID), and availability (Dobos 2014).

The term $\left[1 + \gamma(T_{\text{cell}} - T_{\text{STC}})\right]$ in Equation 11 explicitly accounts for the temperature-dependence of the electrical efficiency, similar to the performance ratio formulation in Equation 6. All remaining losses are merged into a system loss factor (P_{loss}). In this study, panels are assumed unshaded with negligible soiling, yielding a P_{loss} of 9 % per Dobos (2014). Given PVT 2's higher positive electrical output tolerance (up to +5 % vs. +3 % for PVT 1; see Table 1), its loss factor is reduced to 7 %.

3.2 Error analysis

Model validation is performed against the measurement data (Section 4) by comparing both instantaneous power and cumulative energy for the thermal and electrical outputs. Instantaneous errors are quantified using the mean absolute error (MAE) and root mean square error (RMSE), while cumulative deviations are evaluated over the full dataset. For a scale-independent assessment, normalized MAE (nMAE) and normalized RMSE (nRMSE) are also computed.

The MAE and nMAE between simulated and measured outputs are defined by Equation 12 and Equation 13 respectively.

$$\text{MAE}_Y = \frac{1}{n}\sum_{i=1}^{n} |Y_{\text{sim}}(t_i) - Y_{\text{meas}}(t_i)|, \tag{12}$$

$$\text{nMAE}_Y = \frac{\text{MAE}}{\frac{1}{n}\sum_{i=1}^{n} |Y_{\text{meas}}(t_i)|}. \tag{13}$$

The RMSE and nRMSE are defined by Equation 14 and Equation 15 respectively.

$$\text{RMSE}_Y = \sqrt{\frac{1}{n}\sum_{i=1}^{n} (Y_{\text{sim}}(t_i) - Y_{\text{meas}}(t_i))^2}, \tag{14}$$

$$\text{nRMSE}_Y = \frac{\text{RMSE}}{\frac{1}{n}\sum_{i=1}^{n} |Y_{\text{meas}}(t_i)|}. \tag{15}$$

Where, Y represents either the thermal power output $\dot{Q}_{\text{th}}$ or the electrical power output P_{el}, depending on the context.

Table 1. Datasheet parameters for the two PVT collectors.

Parameters	PVT 1	PVT 2
Electrical		
A_{gross} (m^2)	1.66	1.64
β ($\%\,K^{-1}$)	-0.41	-0.375

c_6 ($\text{s}\,\text{m}^{-1}$)	0.003	0.036
$\eta_{0,\text{th}}$ (%)	0.475	0.535

4 Collector data and test sequences

Experimental data from two different unglazed PVT collecors, provided directly by the authors of the respective studies, are used for validation and are briefly summarized below.

The first dataset (PVT 1) was obtained from experimental measurements on an outdoor test bench at the Laboratory for Solar Energy Systems of the University of Applied Sciences (HTW Saar) in Saarbrücken, Germany. In this case, the PVT collector is an uncovered collector that features a rear cover and thermal insulation on the back of the absorber. A detailed description of this dataset and the corresponding test setup is provided in Jonas et al. (2019). The experimental measurements cover the typical days[3]as defined in ISO 9806 and include both standard thermal performance measurements and continuous recordings of the relevant electrical values.

The second dataset (PVT 2) was obtained from the real operation of a flat-plate, uncovered, and uninsulated PVT collector on a test bench in Austria. This dataset spans 58 summer days (from July 11 til September 6) with a 5-second sampling interval. The data, which is publicly available, is described in detail in Veynandt, Inschlag, et al. (2023). A selection of the measured variables from this dataset has previously been used in the development of a grey-box PVT model (Veynandt, Klanatsky, et al. 2023).

Table 1 lists the datasheet parameters describing the thermal and electrical behavior of both collectors. The thermal coefficients follow the quasi-dynamic (general) test method, following Equation 4. For PVT 2, the thermal coefficients were originally obtained under the unglazed steady-state method (Equation 2) and then converted to quasi-dynamic form (Equation 4) following the approach detailed in Solar Keymark Network (2019).

[3]Day type 1: η_0-conditions, mostly clear sky conditions.Day type 2: Elevated operating temperature or η_0-conditions, partly cloudy conditions including broken cloud and clear sky conditions.Day type 3: Mean operating temperature conditions including clear sky conditions.Day type 4: High operating temperature conditions including clear sky conditions.

As both datasets did not contain all data required to do a (one-to-one) validation of the model presented in Section 3.1, some assumptions had to be made. First, for PVT 1, the measured long-wave irradiance on the tilted plane was found to be unreliable, necessitating the estimation of long-wave radiation losses from the effective sky temperature. Only the solar irradiance components on the tilted plane were measured. Estimating cloud cover (and thus sky temperature) requires horizontal-plane irradiance data to determine the diffuse fraction. In the absence of such data, the diffuse fraction is assumed identical across all orientations. This assumption affects the sky temperature estimate and, consequently, the modeled long-wave radiation losses. Second, for PVT 2 the total irradiance on the tilted collector plane is used directly in the simulation following Equation 2; accordingly, no conversion of the datasheet value for $\eta_{0,\text{hem}}$ is necessary.

5 Results and analysis

This section is organized as follows: Section 5.1 validates the thermal and electrical performance against the measurement data introduced in Section 4, both in terms of instantaneous power and cumulative energy. Sections 5.2 and 5.3 examine how thermal and electrical parameters affect the model's accuracy.

5.1 Model validation

The accuracy of the PVT collector model is assessed against the two datasets introduced in Section 4, using only the datasheet coefficients from Table 1 to set up the PVT collector model. The evaluation of PVT 1 is based on Table 2 and Figure 3, while PVT 2 is assessed using Figure 2. The sole model parameter not directly provided in the datasheet, namely the overall absorber-fluid heat transfer coefficient U_{AbsFluid}, is computed for each PVT collector using Equation 10. As discussed in Section 3.1.2, Stegmann et al. (2011) argue that similar U_{AbsFluid} values across different wind speeds is indicative of robust datasheet parameters. In our case, both datasets exhibit a pronounced variation of U_{AbsFluid} with wind speed, suggesting a possible inconsistency in the wind-dependent coefficients c_3 and c_6. For the reference scenario, the wind-independent U_{AbsFluid} values for PVT 1 and PVT 2 are 32.76 $\text{W}\,\text{m}^{-2}\,\text{K}^{-1}$ and 56.85 $\text{W}\,\text{m}^{-2}\,\text{K}^{-1}$, respectively. Section 5.3 will further explore how the choice of U_{AbsFluid} affects the accuracy of the predicted electrical power output.

Table 2 reports the error metrics (introduced in Section 3.2) for PVT 1. For day types 1 to 3, thermal performance shows acceptable agreement between model and measurements, with energy deviation (ΔE) remaining below 5 %. In contrast, day type 4 shows a significantly higher deviation of 36.7 %, indicating model limitations under high temperature difference and low irradiance conditions (see Figure 3(d)). These discrepancies likely stem from underestimated wind-dependent losses (coefficients c_3 and c_6) and increased radiative losses due to the larger

DOI 10.3384/ecp218273

HTF-to-ambient temperature difference. As the absolute thermal output is low in this case, model limitations have a stronger effect, leading to disproportionately large relative deviations. While the MAE and RMSE are lowest under clear-sky conditions, larger errors during variable-sky periods (type 2 and type 4) point to a mismatch in the dynamic response of the thermal model, involving the c_5 coefficient. Additionally, the use of a sky temperature approximation introduces uncertainty in the long-wave loss term c_4, as noted in Section 4, and warrants closer examination. Electrical performance validation of PVT 1 yields normalized MAE and RMSE values below 3.1 % (Table 2), confirming the accuracy of the electrical component of the PVT collector model.

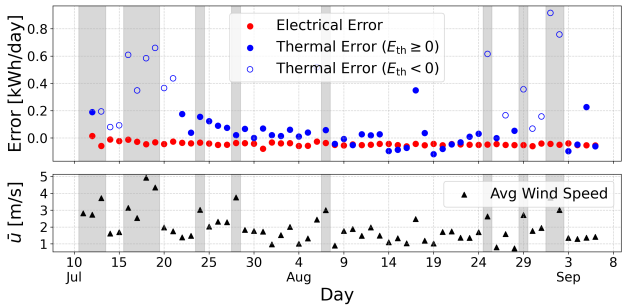

Figure 2. Top: Error between the measured and simulated daily thermal and electrical energy production of the PVT 2 collector, expressed in $\mathrm{kWh\,d^{-1}}$, over the entire dataset. Bottom: Corresponding average wind speed during operation for each day, with high wind speed periods ($\bar{u} > 2.5\,\mathrm{m/s}$) indicated by the grey sections.

For PVT 2, Figure 2 compares measured and simulated daily thermal and electrical energy alongside average wind speed, and Table 2 summarizes the key error metrics. Figure 2 indicates a clear correlation between thermal energy mismatch and higher wind speeds, suggesting further investigation of the wind-dependent coefficients c_3 and c_6. Over the full validation period at 5-s resolution the thermal model predicts 20.4 kWh vs. 13.4 kWh measured ($\Delta E = +53.1\%$), but this large error is driven by many periods of negative thermal output that would not occur in real operation. Filtering to $Q_{\mathrm{th,sim}}(Q_{\mathrm{th,meas}}) > 0$ yields a more realistic energy error of $\Delta E = +6.85\%$ (-4.7%). Electrical predictions remain robust (MAE: 3.2 W, ME: –1.8 W, $\Delta E = -2.9\%$, 83.8 kWh predicted vs. 86.3 kWh measured) and are essentially unaffected by wind speed.

5.2 Thermal parameters

Thermal performance is first examined for PVT 1 under controlled conditions, followed by an assessment of deviations for PVT 2 including high wind speed operation.

PVT 1: standard test conditions

Analysis is based on four representative day types (Figure 3), spanning clear to overcast skies with mean HTF–ambient temperature differences of 0 K (types 1–2), 10 K (type 3) and 20 K (type 4). An artificial blower maintained a constant wind speed of $3\,\mathrm{m\,s^{-1}}$ to $4\,\mathrm{m\,s^{-1}}$, such that wind effects remain uniform across cases. The stacked loss distributions represent the individual heat loss contributions within the quasi-dynamic thermal model (Equation 4), each defined by a specific datasheet coefficient. The impact of these loss terms on thermal performance is examined in the remainder of this section. The heat-loss coefficients c_1 and c_2 are excluded from further discussion due to their negligible influence on model accuracy under the given operating conditions.

Wind-speed dependence (c_3, c_6). In this study, wind speeds during all day type measurements (Figure 3) remained within $3\,\mathrm{m\,s^{-1}}$ to $4\,\mathrm{m\,s^{-1}}$, placing them at the upper edge of the ISO calibration range (0–3.5 m/s) and calling the accuracy of the wind-dependent coefficients into question. The persistent steady-state error across all day types indicates an underestimation of c_6, which is significant even for day types 1–2 where c_3 has limited impact due to small $\theta_m - \theta_a$, while c_3 becomes more influential at larger temperature differences. These findings suggest that convective losses do not scale linearly beyond the calibration range.

Sky-temperature dependence (c_4). The c_4 term accounts for radiative heat losses based on the difference between ambient air and sky temperature, expressed as $\left(E_L - \sigma\,\theta_a^4\right)$. This term is typically negative, with values around $-100\,\mathrm{W\,m^{-2}}$ for clear skies, $-50\,\mathrm{W\,m^{-2}}$ under hazy conditions, and approximately zero for overcast skies (ISO 9806 2013). In this work, the sky temperature for PVT 1 is approximated according to the assumptions in Section 4, which may introduce steady-state errors in the long-wave loss term and affect the accuracy of the thermal simulation.

Thermal capacity (c_5). ISO 9806 limits uncertainty in HTF heat capacity to ±10 %, yet quasi-dynamic identification often yields larger deviations (Weißmüller, Frenz, and Krämer 2012), attributable to limited variation in HTF temperature during standard tests. Calculations based on material properties and ISO weighting factors can reduce this uncertainty (Lämmle 2018). However, identified values may still fail to capture rapid irradiance transients (Stegmann et al. 2011). In this study, the datasheet c_5 is too large, slowing the model's thermal response (Figure 3) and causing notable errors during fast-changing conditions. Reducing c_5 would sharpen transients but exacerbate steady-state bias, indicating that adjustment of c_5 alone cannot resolve the dynamic mismatch.

Comparison with quasi-dynamic identification. For day types 1–2, underestimation of steady-state losses leads to overestimated thermal output, implicating the sky-temperature term c_4 and/or the wind-dependent term c_6. A similar bias occurs in types 3–4, but larger $\theta_m - \theta_a$ elevates the influence of c_3, while the model's slower transient response points to an overestimated thermal capacity c_5. Compared to the parameter set identified by Jonas et al. (2019), the datasheet coefficients differ by

Table 2. Model validation results for PVT 1 and PVT 2. Computations use a 3-segment discretization, datasheet parameters, a loss factor of 9 % for PVT 1, and 7 % for PVT 2. For PVT 1, $U_{\text{AbsFluid}} = 32.76\,\text{W}\,\text{m}^{-2}\,\text{K}^{-1}$; for PVT 2, $U_{\text{AbsFluid}} = 56.85\,\text{W}\,\text{m}^{-2}\,\text{K}^{-1}$.

$\Delta c_3 = -1.4\,\%$, $\Delta c_4 = 63.1\,\%$, $\Delta c_5 = 11.5\,\%$, and $\Delta c_6 = -90.3\,\%$. The strong negative bias in c_6, partly offset by a positive bias in c_4, highlights that model limitations peak under high wind speeds, as further illustrated by the thermal behavior of PVT 2.

PVT 2: high wind conditions

As shown in Figure 2 and discussed in Section 5.1, the model systematically overestimates the thermal output of PVT 2, particularly under higher wind speeds. The collector frequently operates near its upper temperature limit, with a mean HTF-to-ambient temperature difference of 19.52 K, which is suboptimal for unglazed PVT collectors. This condition, resulting from the test setup described in Veynandt, Inschlag, et al. (2023), leads to phases of low or even negative thermal output. While not representative of typical operation, this validation is valuable for exposing model limitations.

The pronounced overestimation under high wind conditions (occasionally exceeding 10 $\mathrm{m\,s^{-1}}$) suggests that the wind-dependent coefficients c_3 and c_6 do not scale linearly beyond the calibrated range. This effect is exacerbated by the uninsulated rear side of the collector, increasing its sensitivity to convective losses. Additionally, the use of a varying mass flow rate, differing from the (nominal) one used for datasheet coefficient determination, may contribute to discrepancies. Because these effects primarily affects convective heat transfer and potentially electrical performance, they will be addressed in Section 5.3.

5.3 Electrical parameters

As discussed in Section 2.2.2, the PV cell temperature strongly affects the electrical efficiency of a PVT collector (see Equation 6). To account for the influence of thermal operation on the PV cell temperature, a thermal coupling between the PV cell and the HTF is introduced via the coefficient U_{AbsFluid}, which is formulated in Equation 7. In this work, U_{AbsFluid} is estimated using a simplified, datasheet-based method (Section 3.1.2). This section examines the impact of variations in the estimated U_{AbsFluid} on the accuracy of the modeled electrical power output.

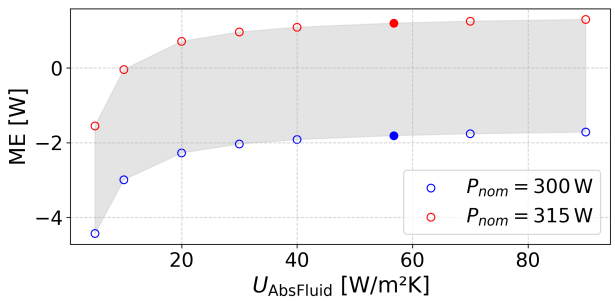

Figure 4. Mean electrical error versus U_{AbsFluid} for $P_{\mathrm{nom}} =$ 300 W and 315 W. Filled markers denote the estimated (datasheet-based) value of U_{AbsFluid}.

Figure 4 shows the normalized mean error in electrical output versus variations in U_{AbsFluid} for two nominal powers: $P_{\mathrm{nom}} = 300\,\mathrm{W}$ and 315 W (reflecting a +5 % tolerance; see Table 1). A constant system loss factor of 9 % is applied throughout (Equation 11). As shown, a shift in U_{AbsFluid} has minimal effect under good thermal coupling, while the grey band, representing uncertainty from rated power tolerance and assumed P_{loss}, causes greater deviation. The trend observed in Figure 4 aligns with Lämmle (2018), who found that values above $60\,\mathrm{W\,m^{-2}\,K^{-1}}$ indicate good coupling, with little gain beyond. Hence, a simplified datasheet-based U_{AbsFluid} suffices for accurate output predictions. Making it mass-flow dependent adds complexity without meaningful accuracy gains, as constant values already yield reliable results.

5.4 Model limitations

The following limitations apply primarily to unglazed PVT collectors: (1) High wind speeds: convective losses (coefficients c_3, c_6) are increasingly underestimated above the ISO calibration range ($\approx 3.5\,\mathrm{m\,s^{-1}}$); (2) Dynamic response: thermal capacity (c_5) may be misestimated, impacting the model's transient behavior under rapidly varying irradiance. Glazed PVT collectors are not affected by (1) but remain subject to (2); this hypothesis should be investigated in future work.

6 Conclusion and future work

By offering an open-source, modular, and transparent modeling framework, this work sets a significant step toward democratizing high-fidelity PVT system simulations, thereby empowering researchers, engineers, and policymakers to optimize PVT systems without relying on proprietary tools or inaccessible data.

Validation against two experimental datasets demonstrated that the electrical sub-model achieves very good accuracy, with the nMAE and nRMSE both below 3.1 % for PVT 1 (day types 1–4) and 5.2 % / 9.9 % for PVT 2. The thermal model reproduces daily energy within 3.3 %, 2.2 %, 4.2 % and 36.7 % for PVT 1 day types 1–4, respectively, and 6.85 % for PVT 2 (excluding negative thermal output periods).

These results confirm that, except under extreme conditions, the simplified datasheet-based approach yields reliable predictions. Limitations arise primarily for unglazed collectors for high wind speeds, where convective and radiative losses are not fully captured.

Future work should validate glazed PVT collectors, whose insulation and higher operating temperatures may mitigate the limitations identified for unglazed systems. For unglazed collectors, investigations into non-linear convective formulations could better characterize the wind-dependent loss coefficients c_3 and c_6. Refining the sky-temperature approximation is also needed to reduce steady-state radiative errors. Finally, embedding this PVT model within full energy-system simulations (e.g., district heating networks or building HVAC models) would enable end-to-end optimization of hybrid solar technologies across diverse climates and applications.

7 Data availability

The PVT model and its validation are available in the IDEAS Library: `https://github.com/open-ideas/IDEAS/pull/1446`. The measurement data is available in the IDEAS resources folder.

Modelling Aquifer Thermal Energy Storage (ATES) System with Buoyancy Flow

Markus Gillner[1] Arne Speerforck[1]

[1]Hamburg University of Technology, am Schwarzenberg-Campus 1, Hamburg, Germany, Institute of Engineering Thermodynamics, {markus.gillner,arne.speerforck}@tuhh.de

Abstract

Aquifer Thermal Energy Storages (ATES) as long-term storages have a strong potential to address the seasonal discrepancy of supply and demand of thermal energy. The operation of high-temperature ATES (HT-ATES) and their integration into district heating systems are the subject of current research projects. Buoyancy plays an important role in determining how HT-ATES performs. The target of this paper is to present a system model in Modelica that takes these buoyancy effects into account. The validation with experimental data and numerical simulations shows that the system model represents the buoyancy effects well. A sensitivity analysis underlines the importance of optimizing the grid structure and shows that a high resolution in the aquifer is necessary, especially in the vertical direction. Finally, a 10-year simulation shows the deviation of the heat recovery factor, i.e. the ratio of the amount of heat extracted to the amount of heat injected, between a model with and without buoyancy effects.

Keywords: High Temperature Aquifer Thermal Energy Storage, ATES, Buoyancy, System Model, TransiEnt Library

1 Introduction

In 2023, only 17 % of Germany's final energy consumption in the heating sector was produced from renewable sources (Umweltbundesamt 2024). One of the major challenges transforming the heating transition is the seasonal offset between the supply of sustainable heat and demand. Aquifer thermal energy storage (ATES) is one of the most promising seasonal storage systems due to its high storage capacity, efficiency and small above-ground footprint (Guelpa and Verda 2019). The principle of ATES is based on two wells (doublets) drilled into water-bearing soil layers, called aquifer. Thermal water is extracted from one well (cold or compensation well), heated and injected into the second well (hot well). During the heating period, the heated thermal water is pumped up from the hot well, the heat is extracted via heat exchangers and returned to the second well.

A distinction is made between low-temperature ($< 50\,^{\circ}\mathrm{C}$) and high-temperature ($\geq 50\,^{\circ}\mathrm{C}$) aquifer storage, depending on the temperature of the thermal water to be stored. Due to the low temperature level, LT-ATES also serve as cold storage for the summer. While LT-ATES are widely used, only 5 HT-ATES are in operation worldwide (Fleuchaus 2020). Some have been closed after years of operation (e.g. Utrecht University, Hooge Burch in Zwammerdam and Neubrandenburg). In Neubrandenburg and Hooge Burch, Zwammerdam this was due to uneconomic operation due to fluctuating heat demand and supply (Fleuchaus et al. 2021; Drijver, Bakema, and Oerlemans 2019). The ATES at the University of Utrecht closed due to problems in the well and a discrepancy between the required temperature level and the temperature supplied from the aquifer storage (Drijver, Bakema, and Oerlemans 2019). This means that the interaction between the aquifer storage and its surroundings, be it individual buildings or district heating systems with their fluctuating heat demand and supply, requires further research.

New HT-ATES projects such as the Living Lab "GeoSpeicher Berlin" (Federal Ministry for Economic Affairs and Climate Action 2024) and "PUSH-IT" (Push it 2024) are building HT-ATES systems for integration into district heating systems, and projects such as "ATES Vienna" (Forschungsinitiative Green Energy Lab 2022) and "OptInAquiFer" (Hamburg Insitut 2022) are investigating the integration of HT-ATES into district heating systems. Köhler et al. (2025) from the OptInAquiFer project have identified a great potential for seasonal thermal energy storage in district heating systems, for which detailed models for the realisation of efficient storage systems are needed in order to be able to investigate the grid-side challenges in advance.

The most commonly used computer codes for the simulation of underground aquifers are complex CFD-based codes such as FEFLOW (DHI-WASY GmbH 2012), OpenGeoSys (Kolditz et al. 2012), MODFLOW (Langevin et al. 2017), HSTWin-2D (Kipp 1987) etc. These programs can represent complex geometries and take into account physical effects such as chemical reactions and groundwater flow in addition to heat and mass transport, but are only marginally suitable for system analysis. The simulation of aquifer storage in systems can only be represented with these programs using complex co-simulations. System level modelling platforms such as TRNSYS and Modelica are suitable for modelling the interaction of aquifer storage systems with buildings and district heating. For both modelling platforms, ATES

models already exist. The TRNAST (Schmidt 2005) model for TRNSYS allows the simulation of an aquifer storage system whose wells are thermally and hydraulically separated from each other. Heat transport is radial and vertical, while mass transport is radial only. The model of Maccarini et al. (2023) in the Modelica library IBPSA is a low-order model that is designed for fast numerical calculation and therefore only transports heat and mass radially. Both models neglect buoyancy flow due to larger temperature differences in the aquifer.

Various literature and studies have shown that buoyancy flow can have a significant impact on the efficiency of ATES systems (Buscheck, Doughty, and Tsang 1983; Gao et al. 2024; Beernink et al. 2024; Heldt, Beyer, and Bauer 2024). Gao et al. (2024) have shown with a non-dimensional approach that the design of the temperature profile in the aquifer can be classified into three different regimes: Conduction dominated, buoyancy dominated and a transition regime. Nield and Bejan (2013) gives the critical Rayleigh-Darcy number above which buoyancy can no longer be neglected as

$$\mathrm{Ra}_{\mathrm{critical}} = \frac{g\rho_{\mathrm{f}}^2 c_{p,\mathrm{a}} \beta \Delta T K L}{\mu \lambda} = 4\pi^2, \tag{1}$$

with β as the thermal expansion coefficient, g as the gravitational acceleration, ρ_{f} as the density, $c_{p,\mathrm{a}}$ as the specific heat capacity of the aquifer, K as the permeability, L as the characteristic length (here: height of aquifer), μ as the dynamic viscosity and λ as the thermal diffusivity. This means that even at low permeabilities (e.g. 0.1 Darcy) the temperature difference between injected and existing thermal water must not exceed 40 °C. This is almost always exceeded for high-temperature storage tanks. In addition to 2D heat transport, the ATES model presented here also takes buoyancy flow into account. In section 2 the mathematical and numerical model is described and validated against experimental and numerical data in section 3. section 4 presents an example for a 10 Years simulation of an ATES and in section 5 the main results are summarized. The entire model is to be added to the TransiEnt library (Gillner et al. 2025).

2 Method

The purpose of the model is to simulate the thermohydraulic behaviour of an ATES system for high and low temperature injection. The model should then be suitable for integration into larger system levels.

2.1 Modeling approach

The following assumptions are made in the model:

- The aquifer is homogenous and isotropic, so a 2D cylindrical representation is sufficient.
- A local thermal equilibrium between the fluid and the solid phase is assumed.
- Regional groundwater flow is neglected.
- Thermal interference between hot and cold well is neglected.
- The fluid in the aquifer is assumed to be pure water.
- The porosity, the permeability, the height of the layers and the material properties of the solid phase are constant.
- Radiative effects, viscous dissipation and work done by pressure changes are neglected in the energy equation.
- The well screen fully penetrates the aquifer.
- The aquifer is confined by impermeable layers above and below.

The last two assumptions depend on the modeling. They can be adjusted with little effort.

To describe convection and conduction in the aquifer, the model is based on the three governing equations for mass, momentum and energy conservation. The mass conservation equation is given by

$$\phi \cdot \frac{\partial \rho_{\mathrm{f}}}{\partial t} + \nabla \cdot (\rho_{\mathrm{f}} \cdot \mathbf{v}) = 0, \tag{2}$$

where ϕ is the porosity, ρ_f is the fluid density and $\mathbf{v}$ is the seepage velocity or also called Darcy flux given as $\mathrm{m}^3\,\mathrm{m}^{-2}$. The subscript f refers to fluid. The momentum conservation equation for porous medium considering laminar flow is given by

$$\mathbf{v} = -\frac{\mathbf{K}}{\mu}(\nabla p - \rho_f \mathbf{g}), \tag{3}$$

where $\mathbf{K}$ is the permeability tensor, μ is the dynamic viscosity, p is the pressure, and $\mathbf{g}$ is the gravitational acceleration vector. The energy conservation equation in the aquifer is given by

$$\left(\rho c_{\mathrm{p}}\right)_{\mathrm{a}} \frac{\partial T}{\partial t} + \left(\rho c_{\mathrm{p}}\right)_{\mathrm{f}} \mathbf{v} \cdot \nabla T = k_{\mathrm{a}} \cdot \nabla \cdot (\nabla T), \tag{4}$$

where c is the heat capacity, T is the temperature, k is the thermal conductivity, and the subscript a represents the coupled material values of the liquid and solid phase. As the model is assumed to be in thermal equilibrium, heat conduction is parallel in both phases. For an effective thermal conductivity, density and heat capacity, the weighted arithmetic mean is used as follows:

$$k_{\mathrm{a}} = (1-\phi)\, k_{\mathrm{s}} + \phi k_{\mathrm{f}}, \tag{5}$$

$$\rho_{\mathrm{a}} = (1-\phi)\, \rho_{\mathrm{s}} + \phi \rho_{\mathrm{f}}, \tag{6}$$

$$\rho_{\mathrm{a}} c_{\mathrm{p,a}} = (1-\phi)\, \rho_{\mathrm{s}} c_{\mathrm{s}} + \phi \rho_{\mathrm{f}} c_{\mathrm{p,f}}. \tag{7}$$

DOI 10.3384/ecp218283

Since the adjacent layers are assumed to be impermeable, the energy equation of Equation 4 is reduced by the advection term to

$$\left(\rho c_{\mathrm{p}}\right)_{\mathrm{a}} \frac{\partial T}{\partial t} = k_{\mathrm{a}} \cdot \nabla \cdot (\nabla T). \tag{8}$$

Density, heat capacity and dynamic viscosity of water in the aquifer are calculated as a function of temperature and pressure. The material parameter of the solid phase and the adjacent layers are assumed to be constant.

The boundary conditions for pressure and temperature at the outer edge of the aquifer are defined as the initial values for pressure and temperature. This corresponds to the hydrostatic pressure distribution for the pressure and the undisturbed groundwater temperature for the temperature. The same applies to the temperature boundary conditions at the lower and upper surfaces of the adjacent layers, respectively. For accurate simulation of ATES, it is therefore important to ensure that the ATES is modeled to a sufficient size to minimize boundary effects. In the radial direction, this can be estimated by the thermal radius, which is defined as follows:

$$R_{\mathrm{th}} = \sqrt{\frac{c_f \cdot V}{c_{\mathrm{a}} \cdot \pi \cdot H}}, \tag{9}$$

where c_f is the volumetric heat capacity of the fluid, V is the total volume of thermal water injected, c_{a} is the effective volumetric heat capacity of the aquifer and H is the thickness of the aquifer. The thermal radius indicates how far the thermal plume spreads in a radial direction. However, it should be noted that this estimate does not take into account natural convection, convection due to regional groundwater flow and heat conduction in the vertical direction. Nordell, Snijders, and Stiles (2021) recommends three times the thermal radius as the distance between the hot and cold well to prevent thermal interference. At least one and a half times the thermal radius should be selected for the mapping of a single well.

The adiabatic boundary condition at the inner edge of the neighbouring layers results from the cylindrical implementation of the ATES.

To solve the partial differential equations, the Finite Volume Method (FV) is used for local discretization. The nodes are placed in the center of the control volume. The upwind difference scheme is used as an approximation for the conservation variable. The advantage of this approximation lies in its robustness; it is the only approximation that does not lead to oscillating solutions (Ferziger, Perić, and Street 2020). However, the approximation has a leading truncation error term that is diffusive, i.e. it smoothes the solution. To keep this error term small, the grid must be chosen very finely.

2.2 Model implementation

The model is implemented in Modelica and uses components from the TransiEnt library (Senkel et al. 2021) and the Clara library (Vojacek et al. 2023). The TILMedia library available in Clara is used to calculate the temperature- and pressure-dependent properties of pure water. The model can roughly be divided into three levels. The top level represents the overall model of the underground well and can be used for instantiation in larger system levels. In this model, the models of aquifer, adjacent clay layers, well are instantiated and connected. Also the boundaries are set. One level lower the well, the aquifer and the stone layers are described. The energy equation, the continuity equation and the pressure loss model are located in the lowest level.

In Figure 1 the top layer with the models, boundary conditions and connections is shown schematically. The diagram is intended to illustrate that the discretization of the adjacent layers (clay layers) takes place on this level. However, the discretization of the aquifer and the well filter is implemented in the lower levels in order to reduce the number of fluid ports and fluid models. Furthermore, the Figure 1 shows that the *Aquifer* model also has fluid ports in the vertical direction. Thus, modeling of heterogeneous layered aquifers is also possible, as shown in section 3.

The material properties, the geometry of the aquifer and the adjacent layers, the initial conditions are set in a record and can be easily changed in the top level. The mesh for discretization is also set in the record. It is possible to design the discretization in vertical and radial direction very individually. The only restrictions are the same number and size of control volumes in the radial direction for the aquifer and the adjacent layers, as well as the axially symmetrical arrangement of the control volumes of the adjacent layers.

3 Validation

To validate the model, the results are compared with measured values from field experiments at Auburn University in 1981 and their simulation results. The experiment is described in Molz et al. (1983) and the simulation in Buscheck, Doughty, and Tsang (1983).

3.1 Experiment and simulation at Auburn University

In the 1970s, Auburn University began a series of field experiments on water storage at temperatures above 35 °C. In the third experiment, injection temperatures were increased on average to 58.5 °C in the first loop and to 81 °C in the second loop to study the effect of buoyancy flow on efficiency (Molz et al. 1983). The geometric, operational and material-related data on the aquifer and the experiment are taken from Buscheck, Doughty, and Tsang (1983). The aquifer under consideration lies at a depth of between 40 and 61 m and is bounded above by a 9 m thick clay layer. Above this is another aquifer. Below the aquifer is a layer consisting of clay, sand and sandstone. The undisturbed groundwater temperature is 20 °C. The

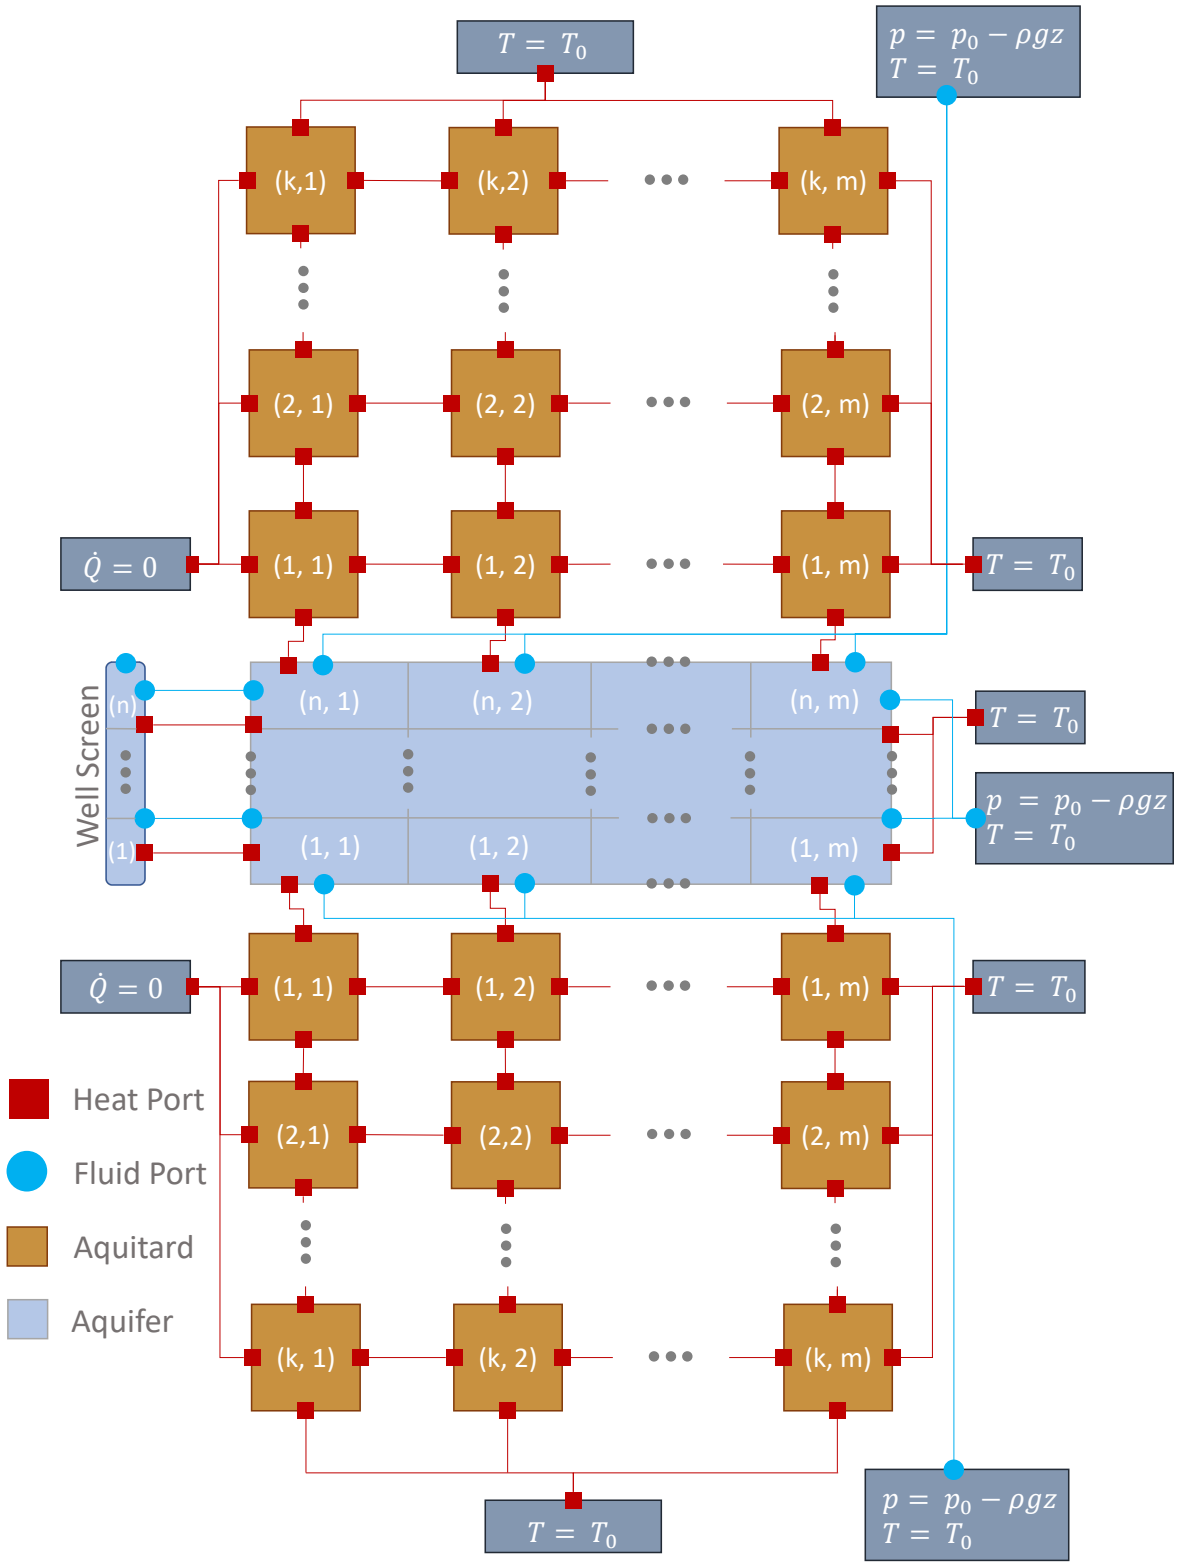

Figure 1. Schematic drawing of connecting the main layers at the top level.

DOI
10.3384/ecp218283

well screen extends across the full thickness of the aquifer and has a radius of 0.1 m. A compilation of the values used in this simulation can be found in Table 1. Although the second cycle is run at significantly higher temperatures, the calculation of the Rayleigh number according to Equation 1 with $\mathrm{Ra} = 403 > 4\pi^2 = \mathrm{Ra}_{critical}$ shows that buoyancy effects must be taken into account already in the first cycle. Therefore, the validation in this paper focuses on the first cycle.

The operating parameters of the first cycle are listed in the table Table 3. The first period of injection, storage and production lasts just under 87 days. The flow rate and temperature of the water in the injection phase are variable over time in the experiment. For the simulation, Buscheck, Doughty, and Tsang (1983) calculated mean values for injection temperature and volume flow. However, since these values can only be read from a graph, the values were compared to Lopik, Hartog, and Zaadnoordijk (2016).

Table 1. material parameters

Properties	*Parameter values*
Aquifer properties	
Porosity[1]	0.25

[1] Parameters taken from Buscheck, Doughty, and Tsang (1983).

In Buscheck, Doughty, and Tsang (1983) the field experiment is represented by two models. In the first model the aquifer is assumed to be a homogeneous layer. The second model takes more account of the actual heterogeneity of the aquifer by modelling a three-layer aquifer

Table 2. Horizontal permeability and height values for the three layers in heterogeneous model taken from Buscheck, Doughty, and Tsang (1983)

	Thickness in m	*Permeability in* $\mathrm{m^2}$
Upper Layer	9.6	4.6×10^{-10}
Middle Layer	5	1.16×10^{-10}
Lower Layer	6.6	4.6×10^{-10}

The vertical to horizontal permeability ratio in each layer is 1:6.

Table 3. Operational parameters for the first cycle taken from Buscheck, Doughty, and Tsang (1983).

Phase	*Duration in days*	*Flow rate in* $\mathrm{m^3\,d^{-1}}$	*Inj. temperature in* °C
Injection	20	760	60
	7	1100	58

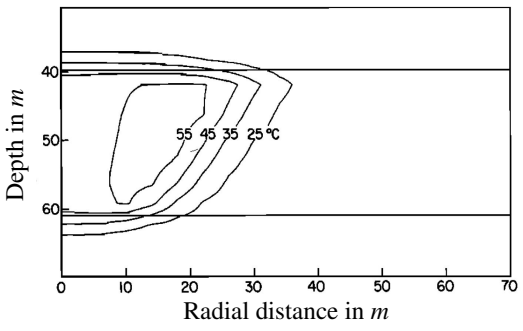
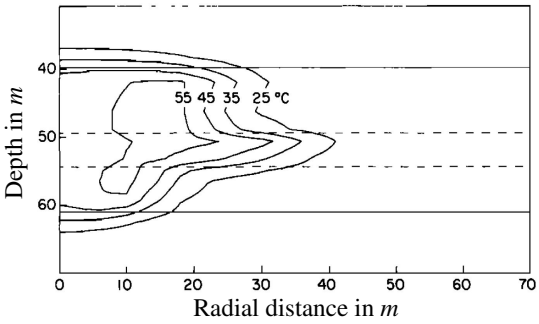
Production	2	-1684.4	-
	21	-1054.08	-
Rest	26	-	-



where the middle layer has a permeability 2.5 times higher than the two adjacent aquifer layers. The permeabilities and thicknesses of the aquifer layers are given in Table 2. A thickness of 9 m is assumed for the adjacent lower and upper layers and a permeability of $1 \times 10^{-15}\,\mathrm{m^2}$ is assumed for Buscheck, Doughty, and Tsang (1983). For the Modelica simulation, the upper and lower confined layers are assumed to be impermeable to water (aquitard). The temperature distribution in the aquifer and adjacent layers at the end of injection for the homogenous and heterogenous model can be seen in Figure 2.

3.2 Comparison of simulation results



Both models with the homogeneous and heterogenous aquifer are rebuilt in Modelica and the results are compared with the results of the experiment and the two models of Buscheck, Doughty, and Tsang (1983). The comparison is made for the temperature distribution in the aquifer and its adjacent layers at the end of the injection phase and the temperature profile of the water in the well during production phase. The aquifer and its adjacent layers are discretized in volumes with 1 m edge length in vertical direction (except two smaller ones in heterogenous model to rebuild the height of the layers) and 1 m in radial direction until the end of the thermal plume at 40 m and then 10 volumes with 3 m. The temperature distribution in the aquifer and its adjacent layers for the homogeneous and heterogenous model at the end of the injection phase is shown in Figure 3a and 3b, respectively. The tilting of the thermal plume due to natural convection can be seen in both figures. In addition, the three layers in the aquifer are clearly visible in the path of the thermal plume in the het-

erogeneous model. Due to the higher permeability of the middle layer, the largest mass flow is expected there. The temperature distribution in the aquifer and the adjacent layers show a high degree of agreement with the simulations in Figure 2 and the experiment (Buscheck, Doughty, and Tsang 1983, p. 1130). Figure 4 shows the temperature curves of the water during the production phase in the wells for the experiment and all numeric models. The black line shows the measured values of the experiment, the red and green line shows the homogenous and heterogenous model, respectively. The dashed lines are the simulation results of Buscheck, Doughty, and Tsang (1983), the solid lines are the simulation results of this work. The temperature curves of the homogenous model is almost identical to the simulation results of Buscheck, Doughty, and Tsang (1983). The temperature curves of the heterogenous model show a slightly higher temperature in the production well than the simulation results of Buscheck, Doughty, and Tsang (1983). Both Modelica models initially show an increase in well temperature after the start of production. This is due to the different loading temperature of the thermal water during the injection phase and can also be seen in the temperature distribution. This first increase in the well temperature is neither recognizable in the simulation results of Buscheck, Doughty, and Tsang (1983) nor in the measured values from the experiment.

These results show that the Modelica model can not only predict the production well temperature affected by buoyancy, but also model more complex aquifer structures.

4 Grid Analysis and 10 Years Simulation

This chapter presents the results of a 10-year simulation of a single well model. It shows that the model can be used as a system component in larger systems and compares the results with and without buoyancy.

For the simulation, the material properties and the geometry of the aquifer are taken from the section 3. A medium sized aquifer with a discharge of $50\,\mathrm{m^3\,h^{-1}}$ (Fleuchaus 2020) and a temperature of $60\,^{\circ}\mathrm{C}$ is assumed. The calculation of the thermal radius according to Equation 9 results in $R_{\mathrm{th}} = 66\,\mathrm{m}$. After first impressions of the simulation results, the modeled radius is set to 130 m. To keep the model structure simple, the adjacent layers are represented as 30 m thick aquitards, although there is a wide aquifer above the 9 m thick clay layer. The aquifer is also assumed to be homogeneous. The loading and unloading schedule is kept constant, and the individual phases - injection, storage, production, and resting - each last 91.25 days.

4.1 Grid study

In order to keep the accuracy of the results high and the computational speed as low as possible, a grid study is

DOI
10.3384/ecp218283

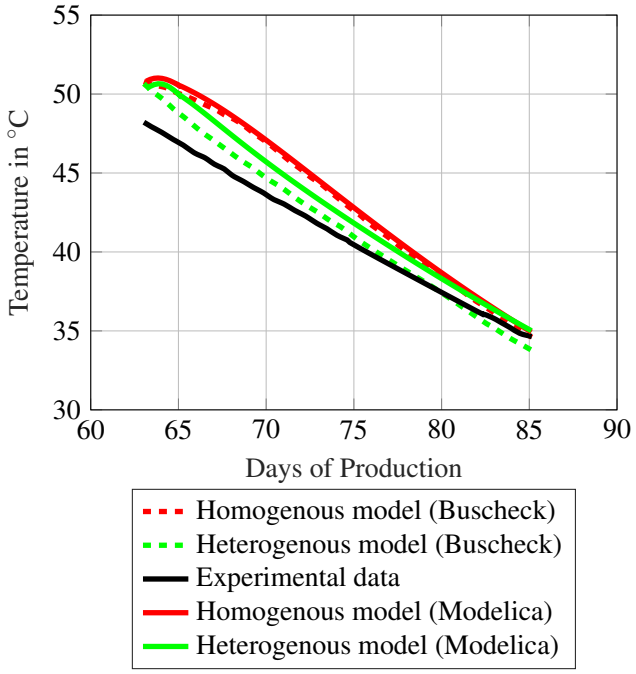

Figure 4. Temperature curves of the water during the production phase in the well for the experiment and all numeric models.

essential. For this purpose, a sensitivity analysis is performed in which the grid is changed individually and together in the radial and vertical directions. In addition, the grid structure is changed so that a finer grid structure is chosen in the radius of the thermal plume than outside of it. Inside the plume, the temperature gradients are steeper than outside, depending on the time. This is due to the numerical diffusion by the upwind difference scheme approach in FVM (Ferziger, Perić, and Street 2020).

Table 4 lists the structure of the grids in the sensitivity analysis. A total of nine different grid structures are tested. The first column assigns a number to the individual simulations. The second column lists the number of volumes in the radial direction, vertical direction of the aquifer and vertical direction of the aquitards, in that order. The third column contains the extent of the volumes in meters. If there are vectors in the second and third columns, the columns are assigned to each other. Radially, the discretization is performed from the well; vertically, the discretization is performed from bottom to top for the aquifer and from aquifer to outside for the adjacent layers. The fourth column shows the total number of volume elements. An example for the grid structure is shown in Figure 5.

The first simulation has the finest grid with an edge length of one meter. The subsequent simulations increase the edge length in the radial direction (S2 and S3) and in the vertical direction (S4 and S5). Simulations 6 and 7 combine the changes from simulations 2 and 4 as well as simulations 3 and 5. Simulations 8, 9, 10 and 11 increase the edge lengths outside the thermal plume and in radial direction.

Table 4. Grid Structure Variation

Number of Simulation	*Number of Volumes*	*Size of Volumes in* m	*Overall number of volumes*

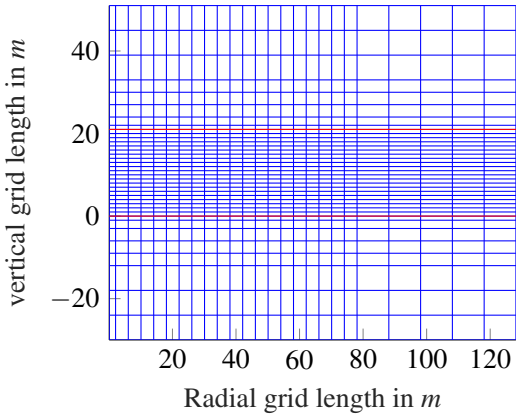

Figure 5. Visualisation of grid structure of simulation S11.

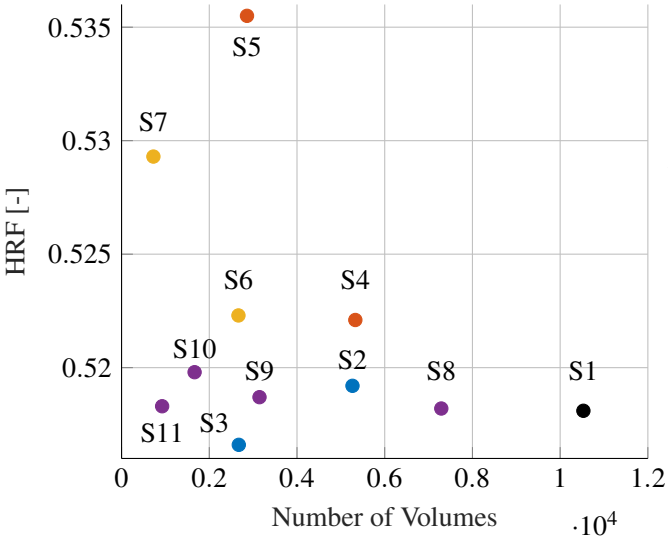

Figure 6. Heat Recovery Factor of the individual simulations of grid study after one year operation against the total number of volumes.

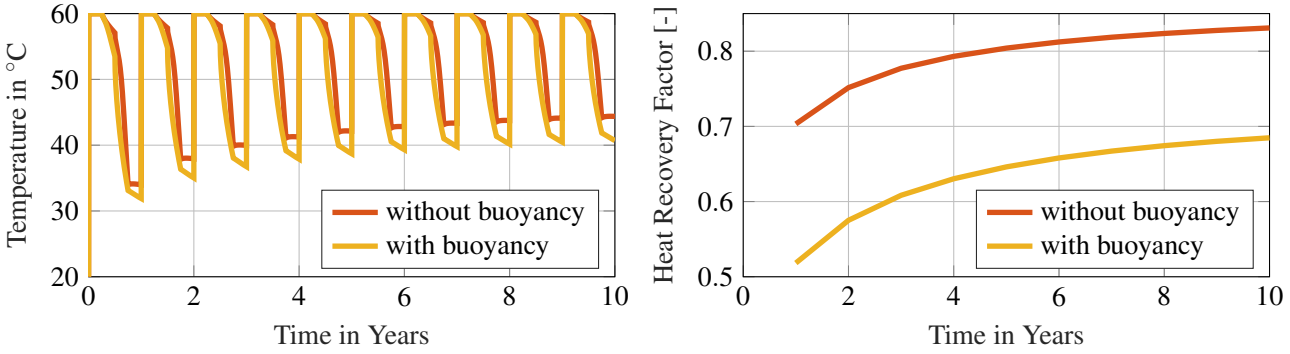
The simulations are compared using the Heat Recovery Factor (HRF), which is used as a measure of the efficiency of the ATES after a complete cycle. The HRF is calculated from the ratio of the amount of heat extracted to the amount of heat injected from the thermal water in a cycle:

$$\mathrm{HRF} = \frac{\int \dot{Q}_{\mathrm{out}} \mathrm{d}t}{\int \dot{Q}_{\mathrm{in}} \mathrm{d}t} = \frac{\int \dot{m}_{\mathrm{out}} \cdot c_{\mathrm{p}} \cdot (T_{\mathrm{out}} - T_{\mathrm{initial}})\, \mathrm{d}t}{\int \dot{m}_{\mathrm{in}} \cdot c_{\mathrm{p}} \cdot (T_{\mathrm{in}} - T_{\mathrm{initial}})\, \mathrm{d}t}, \quad (10)$$

where $\dot{Q}$ is the heat flow, $\dot{m}$ is the mass flow, c_p is the specific heat capacity, T is the temperature, and T_{initial} is the temperature of the undisturbed aquifer.

In Figure 6 the HRF of each simulation is plotted against the total number of volumes. The colors of the dots indicate the similarity of the variation. As expected, the coarser the grid structure, the greater the deviation of the HRF from the reference simulation. A coarser grid in the vertical direction in the aquifer has a significantly greater effect on the HRF than in the radial direction. Adjusting the grid outside the thermal plume has the least effect on the deviation. The number of volumes have a linear impact on the calculation time. By reducing the number of volumes by more than 11 times in simulation S11 compared to the reference simulation, the computation time is also reduced by almost 14 times to 10.2 s (Dymola2025x, Advanced.Translation.SparseActivate = true, Solver: DASSL, 1000 intervals, tolerance 0.0001 %). Simulation 11 is therefore used for the 10-year simulation.



4.2 10 Years Simulation

The well temperature curve and the HRF of the ATES system are shown in Figure 7a and 7b respectively. In both figures the simulation without buoyancy is compared to the simulation with buoyancy. Comparing the well temperature of the two simulations shows significant differences in the three phases - storage, production and rest. In the storage and rest phases, the well fluid cools significantly faster. This is due to buoyancy and the resulting influx of colder fluid from the lower part of the aquifer. In addition, the lower adjacent layer is less heated than the upper adjacent layer. The production phase is characterized by a steeper decline in well temperature, resulting in a lower temperature at the beginning of the rest phase. This is caused by mixing processes in the well of cold thermal water from the lower part of the aquifer with warmer thermal water from the upper part of the aquifer. This results in a significantly lower heat recovery factor. The evolution of the HRF in Figure 7b of both simulations is similar. After 10 years the ATES has a HRF of more than 83 % without buoyancy. With buoyancy, the heat recovery drops below 70 %. Although the gap to the simulation without buoyancy decreases from over 18 % pt. in the first year to just under 15 % pt. in the tenth year, this clearly shows the relevance of considering the buoyancy forces. It can be seen from the two figures that the HRF will increase slightly in the following years.

5 Conclusion

The expansion of thermal energy storage is essential for the implementation of the heat transition, and in particular seasonal storage solutions are needed. ATES are a promising technology for seasonal heat storage. With their integration into district heating systems, HT-ATES in particular have become the focus of current research. However, buoyancy effects have to be taken into account in HT-ATES. The author is not aware of any system models that take this effect into account. This paper presents a model for the simulation of HT-ATES systems in Modelica. The model is capable of simulating the thermohydraulic properties of an ATES system with high and low temperature injection. The model has been validated with the results of field tests at Auburn University. The results show that the model is able to predict the temperature distribution in the aquifer and the temperature profiles in the production well with good accuracy. In addition, the model is capable of modeling more complex aquifer models.
A sensitivity analysis of the grid structure has been imple-

mented to reduce computation time in case of acceptable deviations of the heat recovery factors from the reference simulation. The grid analysis shows that outside the thermal plume, the grid structure has less influence on the results. However, the vertical grid structure has a greater influence on the results than the radial grid structure. By adjusting the grid structure, the computation time can be reduced by more than 6 times with an acceptable deviation of the heat recovery factor from the reference simulation. In future work, the optimization of the grid structure in radial and vertical direction could be investigated to achieve further savings in computation time. The relevance of buoyancy effects for the simulation of ATES systems is emphasized by comparing the simulation results with and without buoyancy effects.

Abstract

TAeZoSysPro is a Modelica library developed for thermal and fluid dynamics simulations in industrial applications. The library provides components and models for heat transfer, fluid flow, and mass-energy release calculations. It includes modules for heat transfer modeling, fluid dynamics phenomena, specialized media, and partial differential equations. This paper presents the motivations behind developing this specific library and demonstrates its capabilities through industrial use cases, particularly for applications involving ventilation systems, equipment thermal behavior, and accident scenarios.

Keywords: fluid dynamics, heat transfer, Modelica, simulation, buildings thermodynamics

1 Introduction

The development of industrial systems relies increasingly on automated electrical equipment. In modern facility design, particular attention is paid to installation constraints, which has led to a higher concentration of thermal dissipation. This has highlighted new challenges related to thermal transients, especially in the event of ventilation loss.

Beyond these concerns, the TAeZoSysPro MODELICA library addresses another critical aspect: the impact of transients such as water/steam circuit breaches and boiling transients. These phenomena require detailed evaporation-condensation calculations and flexible modeling tools to effectively simulate installations, analyze transient behaviors, and perform sensitivity studies. For instance, (R. Moulouel et al. 2023) performed a sensitivity analysis on a nodal model to better understand how certain parameters influence the air temperature in an electrical room.

In the field of thermal modeling of buildings and industrial facilities, several Modelica libraries already exist, notably Buildings (Lawrence Berkeley National Laboratory 2025) and BuildSysPro (EDF R&D 2022). These libraries are primarily primarily designed for commercial building thermal systems. TAeZoSysPro positions itself as complementary by focusing on industrial thermal aspects and fine modeling of fluid dynamics phenomena. The library is compatible with the MODELICA Standard Library (Modelica Association 2021) interfaces and existing solutions while providing specific functionalities for industrial applications.

Recent studies (R. Moulouel et al. 2023) (Beiza et al. 2014) have emphasized the importance of accurately modeling thermal phenomena in industrial installations, particularly for predicting the behavior of temperature-sensitive equipment. However, existing libraries often lack specialized components that can address the complex thermal and fluid interactions typical of such environments.

The development of TAeZoSysPro was guided by several key requirements: accurate thermal modeling of industrial equipment such as electrical cabinets and transformers; implementation of the CARROLL method for improved separation of convective and radiative heat transfers; support for bi-species fluids, including handling of null species fractions and condensation phenomena; the capability to simulate transient thermal scenarios, such as ventilation loss; and full compatibility with existing Modelica libraries and the MODELICA Standard Library interfaces.

The present paper aims to provide a general overview of the TAeZoSyPro Modelica library which is available within the `OpenMODELICA` library manager or at https://gitlab.pam-retd.fr/TAeZoSysPro with detailed `html` description for each components. It first presents the theoretical foundations of the library, organized into two main subpackages: thermal heat transfer and fluid dynamics. For each subpackage, the main modeling assumptions are described and discussed in terms of their implications and limitations. Key components are illustrated to convey the overall modeling philosophy. Finally, typical application examples are presented, including comparisons with experimental results when available.

2 Library Overview

TAeZoSysPro is organized into four main modules as illustrated on Figure 1 and detailed further in the following subsections.

2.1 Heat Transfer

This module provides components for modeling heat transfer through conduction, convection, and radiation. It includes models for walls, equipment, and thermal exchanges with the environment. Built on a nodal approach, the module enables a detailed and flexible representation

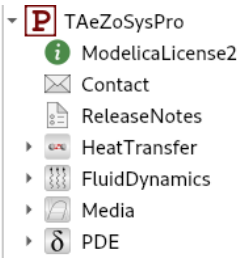

Figure 1. TAeZoSysPro library general architecture

of thermal phenomena.

2.2 Fluid Dynamics

This module handles air flows and mass-energy transfers, enabling the simulation of evaporation-condensation phenomena and multi-species flows. A key feature is the ability to model phase changes, which are essential for capturing a wide range of industrial thermal processes.

2.3 Media

The Media module defines the thermodynamic properties of fluids used in the library, with particular attention to bi-species mixtures and condensation phenomena. The module implements specialized materials whose properties vary with temperature, pressure, and composition. Unlike the standard Modelica Media library, TAeZoSysPro media can handle null species fractions, which is crucial for certain industrial scenarios such as pool boiling, where non-condensable species (e.g., air) are initially present and gradually replaced by steam during the boiling transient.

2.4 PDE

This module provides tools for solving partial differential equations (PDEs), enabling detailed modeling of physical phenomena. It supports spatial discretization schemes tailored to specific types of transport processes and is designed to be used as a subcomponent within more complex systems. The module includes a first-order upwind 1D spatial discretization scheme for purely advective transport, and a second-order centered 1D spatial discretization scheme for diffusive transport. Temporal discretization is handled directly by the Modelica solver used in the simulation environment. Temporal discretization scheme is directly handled by used Modelica solver. The module solves advection-dominated transport equations of the form:

$$\alpha \partial_t Y + \beta \partial_x Y = \dot{\omega} \tag{1}$$

Here, α and β are constants across the spatial domain, specified by the modeler. $\dot{\omega}$ is a source term that can vary from node to node, and Y represents the transported quantity (e.g., enthalpy). Typically, $\alpha = \rho$ and $\beta = \rho U_b$ for a dynamic pipe where U_b stands for the bulk velocity within the pipe. The module also supports diffusion-dominated transport described by:

$$\alpha \partial_t Y = \gamma \partial_{x^2} Y + \dot{\omega} \tag{2}$$

In this case, γ is the diffusion coefficient. The same conventions apply for α, $\dot{\omega}$, and Y as in the advection case.

3 General framework

All physics model embedded in the library are based on the three fundamentals balance equations of the Navier-Stokes equations which are conservation of mass, conservation of motion and conservation of energy. The first rely on mass conservation, the second is establish using the Newton second law while the latter is established with the first principle of thermodynamics:

$$\partial_t \rho + \underline{\nabla} \cdot (\rho \underline{u}) = 0 \tag{3}$$

$$\partial_t (\rho \underline{u}) + \underline{\nabla} \cdot (\rho \underline{u} \otimes \underline{u}) = -\underline{\nabla} p + \underline{\nabla} \cdot \underline{\underline{\tau}} + \rho \underline{g} \tag{4}$$

$$\partial_t (\rho e_t) + \underline{\nabla} \cdot (\rho \underline{u} e_t) = \underline{\nabla} \cdot \left(\underline{u} \cdot \underline{\underline{\sigma}} \right) + \rho \underline{u} \cdot \underline{g} - \underline{\nabla} \cdot \underline{q} + \dot{\omega} \tag{5}$$

where ρ is the density, $\underline{u}$ the velocity, μ the kinematic viscosity, p the pressure, $\underline{g}$ the gravity, $\underline{\underline{\sigma}}$ the stress tensor, e_t the total energy, q the heat flux, $\dot{\omega}$ the volumetric heat gain. The stress tensor can be decomposed as follow:

$$\underline{\underline{\sigma}} = \underline{\underline{\tau}} - p \underline{\underline{1}} \tag{6}$$

where $\underline{\underline{\tau}}$ is the viscous stress tensor. The total energy e_t can be decomposed as the sum of the internal energy and the kinetic energy.

$$e_t = e + \frac{1}{2} u^2 \tag{7}$$

In zonal approaches, local equations previously defined are generally integrated over a large volume of control defined by physical boundary such as a whole pipe, a room or a vessel. Effects of unresolved small scales needs then to be adequately accounted at the resolved scales level, usually relying on relevant correlations. The following subsection presents how local balances are integrated and solved within the TAeZoSysPro modelica library.

3.1 Heta transfer sub-package approach

Objective of this sub-package is to solve the energy equation 5 integrated over the whole volume of components used to model the studied system. A balance of kinetic energy is performed by multiplying Equation 4 on both side by $\underline{u}$ and substitute to Equation 5 leading to:

$$\partial_t (\rho e) + \underline{\nabla} \cdot (\rho \underline{u} e) = -\underline{\nabla} \cdot \underline{q} + \dot{\omega} + \mu S^2 - p \underline{\nabla} \cdot \underline{u} \tag{8}$$

where $S^2 = \underline{\underline{\tau}} : \underline{\underline{\tau}}$ is dissipated kinetic energy power due to fluid viscosity which is generally neglected. The enthalpy $h = e + p/\rho$ is introduced in Equation 8. Assuming constant pressure transformation, incompressible flows and constant specific heat c_p, enthalpy can be expressed as $h = c_p T$ and Equation 8 reads:

$$c_p \partial_t \rho T + c_p \underline{\nabla} (\rho \underline{u} T) = -\underline{\nabla} \cdot q + \dot{\omega} \tag{9}$$

DOI
10.3384/ecp218293

Integration of this latter equation over a volume of control, denoted c, whose mean temperature is defined as:

$$T_c = \frac{1}{m_c} \iiint_V \rho T dV \tag{10}$$

leads to:

$$V_c \rho_c \partial_t T_c - \dot{W} = \sum_i \dot{m}_i c_p (T_i - T_c) + \sum_j \Phi_j \tag{11}$$

where Φ_j is the thermal flux at the boundary j of the control volume, $\dot{m}_i$ the mass flux at the boudary i and $\dot{W}$ the total heat gain at the component level volume which can eventually account for thermal radiant transfers absorption. For each boundary with inlet mass flux, flow being assumed incompressible, a boundary with exactly the mass flux exists assuming leaving temperature is the mean component temperature. Within the thermal sub-package, mass fluxes are considered as model parameters that needs to be provided by the modeler, the only state variable of models only constructed with this sub-package is thus the temperature T.

Elementary components assembly rely on a staggered scheme, as illustrated on Figure 2, where state variables are computed within capicity components, the nodes, with time derivative ∂_t and fluxes between inertial components are computed within fluxes components based on connected state variables values. Typically, left hand side of Equation 11 is handled in capacity components while right hand side is handled within flux components.

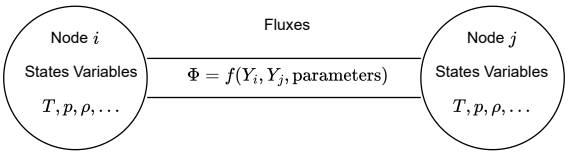

Figure 2. Staggered scheme between nodes

Thermal fluxes at component boundaries can involve radiant, convective, or conductive transfers. Convective heat transfers at a solid-fluid boundary refer to the conductive heat fluxes at the wall, which are then carried away by the fluid motion within the boundary layer. Conductive heat fluxes are accounted using Fourrier's law:

$$\phi_{cond} = -\lambda \underline{\nabla} T \tag{12}$$

where λ is the thermal conductivity. Convective fluxes are estimated using Newton's cooling law:

$$\phi_{cv} = h_{cv}(T_w - T_c) \tag{13}$$

where T_w is the wall surface temperature and h_{cv} is the heat transfer coefficient which have to either provided by the modeler or estimated using correlation in the typical form $Nu = f(Ra, Pr)$ with Nu being the Nusselt number, Ra the Rayleigh number and Pr the Prandtl number.

Radiant heat fluxes between surfaces can be either modeled with radiant heat exchange coefficient h_r to be added to h_{cv} or with a fictive mean radiant node, denoted the Carroll node, as exposed by (Carroll 1980). In this context, the radiosity of the Carroll node is:

$$J_{MRT} = \frac{\sum_k F_k J_k S_k}{\sum_k F_k S_k} \tag{14}$$

where k relates to the k^{th} opaque surface involved with S_k surface, J is the radiosity and F_k is the Carroll surface viewing factor. This latter factor is computed using the following heuristic equation:

$$F_i = \frac{1}{1 - \frac{S_i F_i}{\sum_k F_k S_k}} \tag{15}$$

The net radiant fluxes for each involved opaque surface is then estimated as follow:

$$\phi_{rad} = F_i' \left(J_{MRT} - \sigma T_i^4 \right) \tag{16}$$

where σ is the Stefan-Boltzmann constant and F' the viewing factor modified to account emissivity of surface.

$$\frac{1}{F_i'} = \left(\frac{1 - \varepsilon_i}{\varepsilon_i} + \frac{1}{F_i} \right) \tag{17}$$

This approach is applied to each components, such air volume control, slice of walls or isothermal mass, for each them boundary fluxes needs to be modeled with relevant approaches to account thermal conductive fluxes within the unresolved boundary layer.

3.2 Fluid dynamics sub-package approach

Fluid dynamics aims to solve the three fundamental balance equations—mass conservation (3), momentum conservation (4), and energy conservation (5)—at an integral scale level by integrating them at the level of macroscopic components with physical boundaries.

A staggered approach, depicted in Figure 2, is also applied within this module. The node modeled within this package can handle mixtures of species, including possible condensation.

Mass conservation is solved for each species, while global equations for the conservation of momentum and energy are solved. Equations of state for each species enable the system to be closed. In defining the number of equations solved, the equations of state are usually not counted. Therefore, the Fluid Dynamics Package is commonly referred to as a model with four equations in the case of humid air, which is the primary focus of this module.

Integration of mass conservation for each species leads to:

$$\partial_t m_i = \sum_j \dot{m}_i + \Gamma_i \tag{18}$$

where $\dot{m}_i$ are the mass fluxes for the species $_i$, Γ_i is the mass generation (can be negative) of a given species which

can be due to phase change leading to drain vapor from humid air because of condensation for instance. Within each node, mean temperature T_c is assumed to be the same for each species while pressure and density is computed as follow:

$$p = \sum_i p_i \quad \rho = \sum_i \rho_i \quad e = \sum_i X_i e_i \quad X_i = \rho_i / \sum_i \rho_i \tag{19}$$

where X_i is the mass fraction of species i.

Mass fluxes at fluid interfaces are estimated by assuming a ratio between the Nusselt number and the Sherwood number close to one ($Nu/Sh \approx 1$). Additionally, the Lewis number ($Le = \alpha/D$), where α is the thermal diffusivity and D is the mass diffusivity, is also assumed to be close to one. This allows for the definition of the mass transfer coefficient and the associated mass flux as follows:

$$h_m = \frac{h_{cv}}{c_p} \tag{20}$$

$$\phi_m = h_m (X_w - X_c) \tag{21}$$

where X_w is the mass fraction of the species at the wall, which is assumed to be equal to the saturated mass fraction as a maximum.

Conservation of momentum energy is integrated between node, within equivalent pipes or duct of section S using Bernouilli's theorem which can be derived from Equation 4 for incompressible and irrotational flow. The fluid head is then defined as:

$$H = p + \frac{1}{2}\rho u^2 + \rho g \tag{22}$$

Within an equivalent pipe the integral solve equation is:

$$\underbrace{S_p L_p \rho_m \partial_t u_b}_{\text{unsteady term}} + \underbrace{S_p \left[(p_o + \rho_m g z_o) - (p_i + \rho_m g z_i) \right]}_{\text{head flux integral balance}} = \underbrace{S_p \Delta H}_{\text{singular and regular head losses}} \tag{23}$$

where u_b is the bulk velocity, ρ_m is the mean fluid density within pipe, z the altimetry, L_p its length and S_p its cross section surface. $_i$ stands for pipe inlet and $_o$ for pipe outlet. S_p is assumed to be the same at pipe inlet and outlet, implying and equal dynamic pressure at the inlet and the oulet, however singular head losses due to singularities such as pipe diameter change can be accounted in the singular head losses term. The flow within pipes is assumed to be quasi static regarding mass balance equation, the mass flux within pipe is thus:

$$\dot{m}_p = u_b \rho_m S_p \tag{24}$$

Within each node, only the total pressure defined as $p_t = p + 1/2\rho u^2$ and the total energy are used within balance equation.

The energy conservation equation 5 is integrated at the node level neglecting the work of the viscous forces at the boundaries $\underline{\nabla} \cdot \underline{\underline{\tau}}$ and the work of the volumes forces $\rho \underline{u} \cdot \underline{g}$. One can notice that work of the pressure force can be combined with the advection of internal energy:

$$\underline{\nabla} \cdot (\rho \underline{u} e) + \underline{\nabla} \cdot \left(\underline{u} \cdot p \underline{\underline{1}} \right) = \underline{\nabla} \cdot (\rho \underline{u} h) \tag{25}$$

where $h = e + p/\rho$ is the enthalpy. At the node level, the resulting balance is:

$$V_c \partial (\rho_c e_{c,t}) - \dot{W} = \underbrace{\sum_i \dot{m}_i h_i}_{\text{enthalpy fluxes}} + \underbrace{\sum_j \Phi_j}_{\text{heat fluxes}} \tag{26}$$

3.3 Moist air media

Theory presented in §3.1 and §3.2 is valid for any media within the volume control. Thermodynamics properties are computed separately within the TAeZoSysPro library to enable the use of the `Media` packages of the `Modelica Standard Library` if needed. The library has a specific media dedicated to moist air, with a formulation based on temperature and density (ρ, T) as explicit variables to handles potential total disappearance of one species while still being numerically stable. The enthalpy of the fluid is estimated as the ratio of the different mass fraction X:

$$\begin{aligned} h = & X_a \underbrace{c_{p,a}(T - T_{ref})}_{\text{dry air enthalpy}} \\ & + X_v \underbrace{\left[c_{p,wv}(T - T_{ref}) + h_{vl}(T_{ref}) \right]}_{\text{vapour enthalpy}} \\ & + X_l \underbrace{c_{p,wl}(T - T_{ref})}_{\text{liquid water enthalpy}} \end{aligned} \tag{27}$$

where $h_{vl}(T_{ref})$ is the latent heat of water at the reference temperature. The mass fraction of liquid water within a node is computed as a function of the saturation density $\rho_{sat} = f(T)$ ensuring ρ_{wv} is below the saturation density. The fraction of liquid water within a gas node is expected to be small but possible, for instance, in the case of fog. Specific nodes for this medium are available in the library to manage the drainage of liquid from the node. This is based on the fall speed of water droplets and the a priori number of droplets per unit of volume.

4 Heat Transfer Details

4.1 Bases classes subpackage

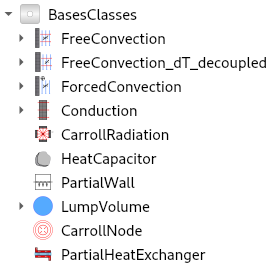

Figure 3. BasesClasses TAeZoSysPro subpackage overview

DOI 10.3384/ecp218293

The BasesClasses, illustrated in Figure 3, subpackage includes elementary functions that can be used directly within a model or serve as building blocks for more complex macro components.

Ports used by components within this package involve only on one state variable declared as follow:

Listing 1. Thermal port for heat transfer appoach

```
within TAeZoSysPro.HeatTransfer.Interfaces;

partial connector HeatPort "Thermal port
    for 1-dim. heat transfer"
  Modelica.SIunits.Temperature T "Port
      temperature";
  flow Modelica.SIunits.HeatFlowRate Q_flow
```

These ports are fully compatible with the thermal port defined in the Modelica Standard Library as well as in BuildSysPro (EDF R&D 2022)

4.1.1 Convection

Several correlations are available to handle various free and forced convection scenarios encountered in industrial installations, including vertical walls, ceilings, ground surfaces, and cylinders. These correlations are used to compute the Nusselt number (Nu), from which the convection coefficient is determined using the relation $h_{cv} = Nu\lambda/L_c$. Alternatively, this coefficient can also be directly specified by the user. The heat convection flux is then computed using Equation 13.

4.1.2 Conduction

For conduction through a homogeneous material, the heat conduction flux modeled using Fourier's law (Equation 12). In practice, the PDE module is typically used to solve the heat equation for a wall with a given thermal conductivity by discretizing the wall into multiple layers or nodes.

4.1.3 Carroll Radiation

This component implements the Carroll radiation method, as detailed in subsection 3.1. It is associated with each radiative surface, for which the area and emissivity are specified, and is connected to the CarrollNode. Additionally, it interfaces with the FviewCalculator, which computes and supplies the Carroll view factor, accounting for the configuration of all radiative surfaces.

4.1.4 Elementary components

In addition to the previously introduced functions for handling various modes of heat transfer, the BasesClasses subpackage includes elementary components such as the HeatCapacitor, which is characterized by a given mass and thermal capacitance and allows for the supply of a heat flux. The LumpVolume component models the thermal inertia of an open lumped volume by linking variations in potential enthalpy (or temperature for an ideal gas) to the heat flow balance. It operates under the assumption of constant pressure and accounts for isobaric expansion, as the volume boundaries are not sealed.

4.2 Main Components

The library provides several basic components for thermal and basic HVAC modeling:

- Wall: models walls with consideration of thermal inertia and homogeneous material (an special multilayer wall model is also available). The wall model solves the heat equation with appropriate boundary conditions using the PDE module assuming 1-D thermal conduction:
- InertMass: represents equipment thermal masses with a lumped thermal capacity:

$$C \cdot \frac{dT}{dt} = \sum \dot{Q}_{in} - \sum \dot{Q}_{out} \tag{28}$$

  where C is the thermal capacity, T is the temperature, and $\dot{Q}_{in}$ and $\dot{Q}_{out}$ are the incoming and outgoing heat flows.
- HeatExchanger: models heat exchangers using an effectiveness approach:

$$\dot{Q} = \varepsilon \cdot C_{min} \cdot (T_{h,in} - T_{c,in}) \tag{29}$$

  where ε is the effectiveness, C_{min} is the minimum heat capacity rate, and $T_{h,in}$ and $T_{c,in}$ are the inlet temperatures of the hot and cold fluids.
- Ventilation and FanVentilation: simulate ventilation systems with variable flow rates and temperature influences.
- FviewCalculator: implements the CARROLL method to calculate radiative temperatures and view factors for radiative exchanges. This component is a key element in the library's approach to radiation modeling. It computes view factors between surfaces without requiring detailed geometric information, using only the surface areas as inputs.
  The CARROLL method creates a virtual node (represented by the CarrollNode component) that acts as a fictitious blackbody enclosure exchanging radiation with all surfaces. This node's temperature corresponds to the Mean Radiant Temperature (MRT).
- CabinetPower: a significant example of a macro component is the model, which represents an electrical cabinet with its thermal dissipations. Having a RealInput port connection for the heat power allows for a fine control of the thermal power dissipated by the cabinet, including transient behaviors.
  The model solves a system of equations for each thermal node representing the emitter inside the cabinet and the casing of the cabinet. The heatload are dissipated within the emitter. The emitter exchanges by convection with the fluid between the emitter and the casing. Regarding the convection, the emitter is supposed flat and horizontal or vertical depending on the value of correlation_internal. The convective surface of the emitter ($A_conv_emitter$) has thus

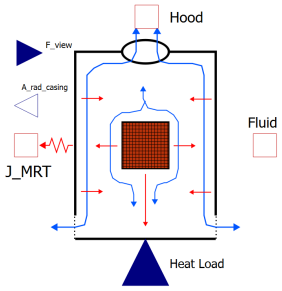

Figure 4. Icon view of the CabinetPower model

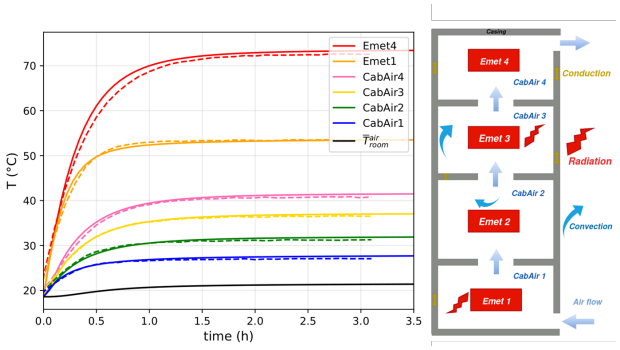

Figure 5. Comparison of the Zephyr electrical cabinet model with experimental data

to be an equivalent surface is both vertical and horizontal surfaces are present. For the casing for the inner and outer convection, the correlation is always a correlation for a vertical plate.

Based on the `CabinetPower` model, a more detailed representation can be developed to investigate various physical phenomena. For instance, the model of the electrical cabinet room (cf. Figure 6) reproduces the actual experimental setup: a simple parallelepiped cabinet with four vertically stacked drawers. Each drawer is represented as an enclosing structure containing a mass-based heat emitter. These emitters exchange heat via radiation with the cabinet's enclosure and through natural convection with the air inside the drawers. The enclosure, in turn, exchanges heat by convection with the ambient room air and by radiation with Carroll's radiosity node (MRT). Additionally, the cabinet features openings that enable air circulation between the drawers and with the room's aeraulic node. This detailed electrical cabinet model was calibrated and validated using experimental data shown in Figure 5.

4.3 Application Example: Room with Electrical Cabinet

In order to study thermo-aeraulic phenomena in industrial spaces containing thermosensitive electrical equipment, EDF-R&D has developed a dedicated experimental facility within the ZEPHYR laboratory (Rafik Moulouel et al. 2024). This full-scale, instrumented facility, shown in Figure 6 is representative of the electrical or control-

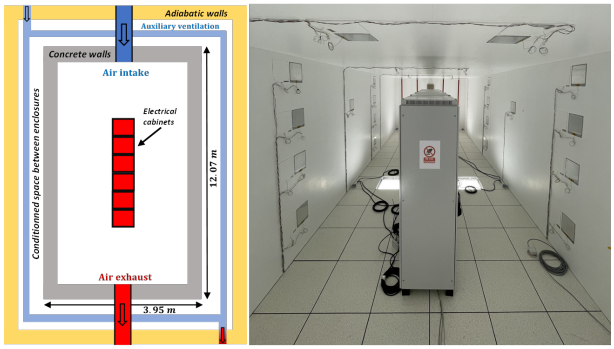

Figure 6. Picture of the electrical cabinets room facility

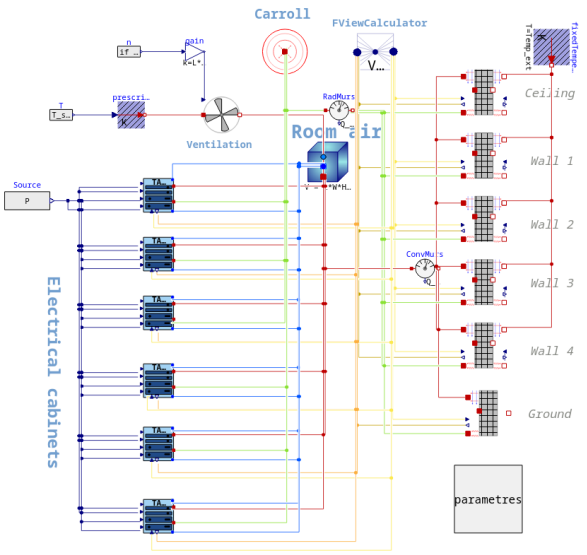

Figure 7. TAeZoSysPro model of the Zephyr electrical room cabinet facility

command rooms found in nuclear power plants. It allows detailed temperature fields measurements to be taken in the air and in the surrounding walls under controlled and repeatable conditions, making it suitable for validating numerical simulation models.

This experimental cell was modeled using the TAeZoSysPro library, as illustrated in Figure 7, to investigate its behavior and perform sensitivity analysis (R. Moulouel et al. 2023). The thermal interactions between the cabinets and their surrounding environment were simulated, along with the air circulation within the various compartments of the cabinets. The influence of the ventilation and the external conditions were studied. Multiple experiments, varying several thermo-aeraulic parameters, were conducted. The results were then compared to both a CFD model and the TAeZoSysPro model, as shown in Figure 8. The 3-D modeling is implemented using the OpenSource CFD solver Code Saturne((Archambeau, Méchitoua, and Sakiz 2004), (EDF 2021)). This comparison demonstrates the TAeZoSysPro library's capability to predict air temperature, although it tends to overestimate it due to its assumption of a homogeneous temperature across the entire room volume, which does not account for thermal strati-

DOI 10.3384/ecp218293

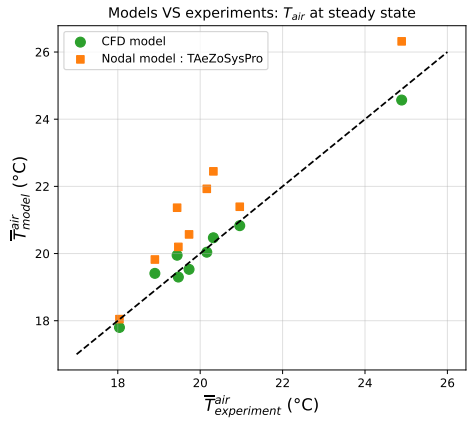

Figure 8. Comparison of TAeZoSysPro thermo-aeraulic model prediction to experimental data

fication. In contrast, the CFD model provides a more accurate prediction of the average air temperature at steady state. These findings will be discussed in further publications.

4.4 Current Limitations

The current approach of separating radiative exchanges presents certain limitations, particularly in the absence of thermal stratification modeling. While the CARROLL method provides advantages for detailed analysis of radiative phenomena, the lack of a stratification model can lead to less accurate results in some scenarios. Developments are ongoing to improve the modeling of these phenomena.

5 Fluid Dynamics Details

The fluid dynamics package is organized in a similar way as the heat transfer package described in §4 and illustrated on Figure 9. Each node is provided

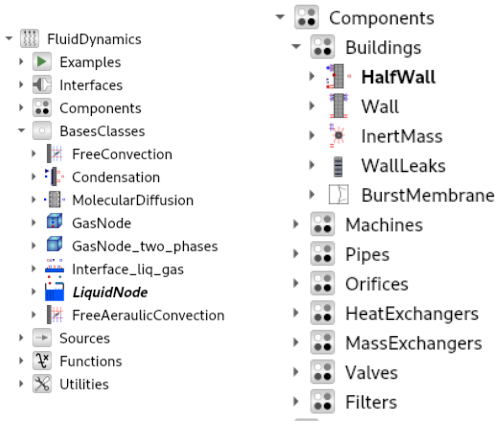

Figure 9. Overview of the fluid dynamics module

with three `Modelica` ports. One Thermal port presented on Listing 1 to handle heat fluxes, a `flowPort` dedicated to moist air media presented in §3.3 and a `Modelica.Fluid.Interfaces.FluidPort` to ensure compatility with the Modelica Standard Library.

5.1 Specialized Media

The library implements two specific media models.

- **Moist Air Media** - For mass-energy release calculations ;
- **Air H2 Media** - As an example media to track a specific species.

The moist `MoistAir` is a specialized model using density and temperature as explicit state variables, which handles the phase transition between vapor and liquid water with superior numerical stability. A Generic bi-species mixtures, providing a framework for modeling various fluid combinations is also proposed.

The `MoistAir` model in TAeZoSysPro is formulated with density and temperature (ρ, T) as primary state variables, unlike other implementations that use pressure and temperature or enthalpy and pressure. This explicit formulation offers several significant advantages:

- **Enhanced numerical stability** - Particularly important during phase transitions where pressure may experience discontinuities, while density varies more continuously
- **Better handling of near-saturation states** - The (ρ, T) formulation facilitates calculations in regions near saturation, where property derivatives with respect to pressure can become very large
- **Direct mass conservation calculations** - Mass conservation equations are directly expressed in terms of density, simplifying the differential equations to be solved
- **Smoother phase transitions** - Special numerical treatments manage state transitions without the discontinuities that can lead to simulation failures

A key difference between TAeZoSysPro media and the standard `Modelica.Media.Air.MoistAir` is the ability to handle null species fractions. In the standard MSL implementation, having zero mass fraction of a species can lead to numerical issues in certain calculations. TAeZoSysPro implements robust handling of these edge cases, ensuring continuous simulation even when a species disappears completely due to phase change which can be typically the case in industrial buildings thermodynamics studies.

Additionally, the condensation model in TAeZoSysPro includes special numerical treatments to handle the transition between states smoothly, avoiding the discontinuities that can cause simulation failures in complex systems.

5.2 Main Components

An overview of some of the main components is presented below, though it is not exhaustive. The required media are declared as `Replaceable Package` within each component and subcomponent to allow the modeller to use any medium compatible with the proposed structure of the Modelica Standard Library.

The component `gas_node_two_phases` implements mass and energy conservation equations while allowing for phase changes of condensable species and drain of condensate based on fall velocity of liquid droplets. This component is specific to the TAeZoSysPro MoistAir Media.

The `condensation` elementary component model the mass flow rate and energy transfer induced by the condensation of a condensable species over a colder surface. The component is used on macro components such as wall dedicated to studies with potential condensation. In case of surface temperature below dew point, it is assumed that water vapour density within the boundary layer is equal to the saturation density estimated with the wall temperature. Mass transfer flowrate is computed using mass coefficient defined in §3.2.

`Interface_liq_gas`: This component models a flat interface between liquid and surrounding gas where evaporation-condensation, boiling, radiation, and convection occur. It is designed to work with the TAeZoSysPro moist air media for the gas media and Standard Water of the `MSL` for the liquid media. *Evaporation-condensation* is modelled with a similar approach than condensation on surface. Evaporation occurs is liquid surface saturation density is higher than water vapor density in the connected gas node. *Convection* and *Radiation* are modelled with the approach presented in §3.1 *Boiling* is modelled as homogeneous formation of equal-diameter bubbles that form in the liquid node and escape through the interface The boiling process is modeled thanks to the estimation of the gas fraction within liquid node from the dew and buble enthalpy when the fluid enthalpy is higher than bubble enthalpy but lower than dew point enthalpy:

$$h = (1 - X_g)h_{bubble} + X_g h_{dew} \tag{30}$$

where X_g is the gas mass fraction within the connected liquid node.

The library propose also flow junctions and separations, allowing for complex network modeling. A set of heat exchangers with phase change, which handle energy transfer between fluids while accounting for condensation or evaporation is available, which is particularly valuable for building thermodynamics or cooling coils studies.

A subpackage containing walls and building orifices is dedicated to components needed for building thermodynamics studies, typically involving vapor breaches.

These components are interconnected to model complex fluid systems with multi-species flows and phase changes. The module implements a connector-based approach, where connectors carry information about pressure, mass flow rate, enthalpy, and species composition.

5.3 Applications

Two application cases illustrate the library's capabilities:

5.3.1 Pressure Cooker Model

This example case validates the modeling of evaporation phenomena under pressure:

- Pressure rise through evaporation, following the relationship between temperature and saturation pressure
- Liquid-vapor thermodynamic equilibrium, ensuring consistency between phases
- Pressure regulation through relief valve, modeling the mechanical behavior of the system

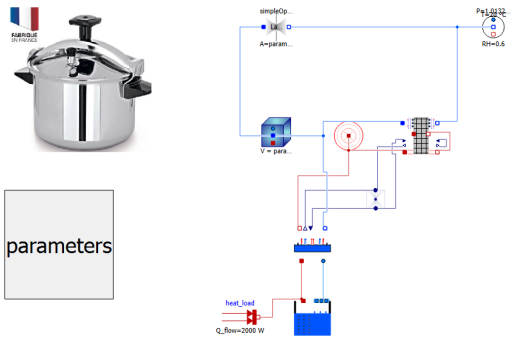

Figure 10. Model of a pressure cooker

The Modelica implementation of this model integrates the following key components:

- A two-phase gas node (`gasNode_two_phases`) representing the steam phase above the liquid
- A liquid node (`liquidNode`) modeling the water volume with thermal inertia
- A liquid-gas interface (`interface_liq_gas`) that handles mass and heat transfer between phases
- A vessel wall (`wall`) with thermal inertia and heat transfer capabilities
- A simple opening component (`simpleOpeningComp`) acting as a pressure relief valve
- A heat source (`heat_load`) providing 2000 W of thermal power to the system
- A Carroll node (`carrollNode`) implementing the CARROLL method for radiative heat transfer calculations

The model uses the `MoistAir` medium from TAeZoSysPro's Media library, which handles the water-vapor mixture with phase change capabilities. Key parameters include the total volume (`V_tot`), gas phase volume

DOI
10.3384/ecp218293

(`V_gas`), wall surface area (`S`), interface area (`A`), and thermal properties such as emissivity (`eps`).

This model demonstrates the library's ability to handle phase changes and pressure dynamics in a closed system. The resulting pressure and temperature curves match experimental data, confirming the accuracy of the phase change calculations.

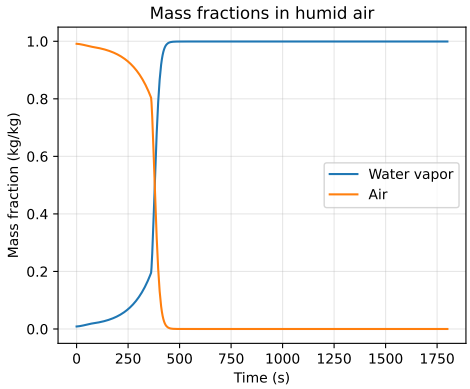

Figure 11. Evolution of mass fractions in the pressure cooker model.

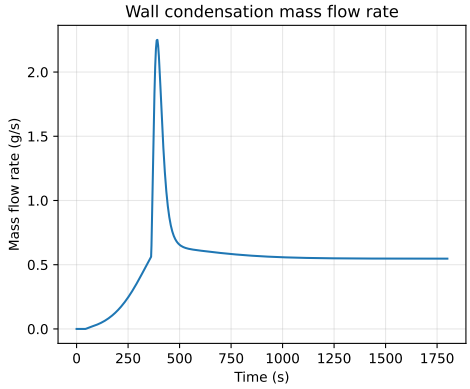

Figure 12. Condensation mass flow rate on the inner wall of the pressure cooker.

The simulation results illustrated in Figures 11 and 12 highlight several key phenomena that occur during the pressure cooker heating process:

- **Phase transition dynamics**: As shown in Figure 11, we observe the gradual evolution of species composition in the gas phase, with a continuous decrease in air mass fraction counterbalanced by an increase in water vapor fraction. This transition demonstrates how the model captures the progressive replacement of incondensable air by water vapor during heating.
- **Condensation phenomena**: Figure 12 illustrates the mass flow rate of condensation occurring at the inner wall of the pressure cooker. The initial peak corresponds to the early heating phase when temperature differences between the vapor and the cooler wall are significant, followed by variations that reflect the complex thermal equilibrium establishment.
- **Multi-phase interactions**: The combined analysis of both figures reveals the interplay between evaporation at the liquid-gas interface and condensation at the cooler walls, showing how the model accurately represents the complete cycle of water phase changes in a confined environment.

These results validate the library's capability to simulate the complex thermodynamic behavior of multi-species fluids undergoing phase changes, a critical feature for industrial applications involving pressurized systems and heat transfer.

5.3.2 Boiling and Steam Line Breaches Transients

A second application case concerns the simulation of transients in nuclear power plant scenarios, including high energy breaks (water/steam line breaches) and pool boiling phenomena (such as in spent fuel pools). These simulations allow for the observation of impacts on pressure and temperature in containment rooms, taking into account various physical phenomena:

- Progressive liquid evaporation and condensation processes, with bidirectional mass transfer between phases
- Thermodynamically-driven phase changes, calculated based on local conditions and interface properties
- Heat transfer through multiple mechanisms (conduction, convection, radiation) affecting phase transition rates and wall temperature
- Pressure increase dynamics resulting from vapor generation and gas compressibility effects
- Spatial distribution of thermal effects and resulting flow patterns

The model Figure 13 captures the complex coupled behavior between thermal, fluid dynamic, and phase change phenomena, providing detailed insights into the evolution of temperature, pressure, humidity, and phase composition during accident scenarios. This capability is particularly valuable for safety analyses where accurate prediction of containment conditions is essential.

This model demonstrates the library's ability to handle phase changes and pressure dynamics in a closed system. The resulting pressure Figure 14 and temperature curves match experimental data, confirming the accuracy of the phase change calculations. Results have been compared against experimental data including the Carolinas-Virginia Tube Reactor (CVTR) containment response tests (Schmitt, Bingham, and Norberg 1970), which provided valuable benchmark data for evaluating steam condensation models under conditions representative of containment structures in nuclear power plants. The initial comparisons are encouraging and show a reasonable level of agreement and a behaviour representative of the experimental data. Some discrepancies are observed in the pressure curve, which is likely due to the complex geometry of the CVTR containment structure and the associated modeling bias.

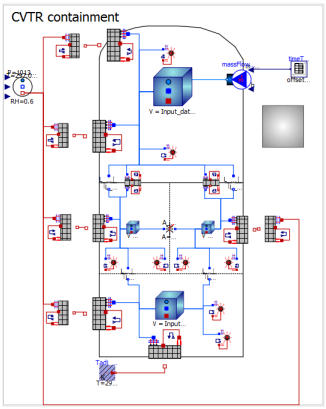

Figure 13. TAeZoSysPro model of the CVTR containment structure.

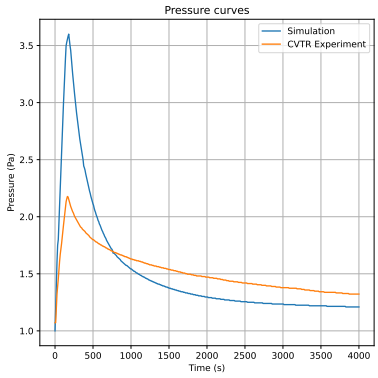

Figure 14. Comparison of pressure evolution between TAeZoSysPro simulation and CVTR experimental data.

6 Conclusion and Perspectives

The TAeZoSysPro library provides an innovative solution for modeling thermal and aeraulic phenomena in industrial installations including buildings thermodynamics. Its strengths include:

- Fine modeling of heat transfers with the CARROLL method and convective heat transfer correlations allowing separating convective and radiative phenomena
- Building Thermodynamics calculations using advanced management of bi-species media with robust handling of null species fractions and condensation
- Experimentally validated components
- Modular architecture, standard interfaces facilitating extensions and coupling with other libraries

Future developments will focus on:

- Improvement of thermal stratification models
- Extension of validation cases
- Qualification of the library according to industrial standards
- Implementation of automatic non-regression tests and MODELICA validation tests allowing the qualification files to be up to date with the latest version of the library
- Extension of multi-scale modeling capabilities

Finally, the modular design of TAeZoSysPro makes it particularly suitable for coupling with uncertainty propagation tools like OpenTURNS (OpenTURNS Team 2023), enhancing its utility for industrial applications where understanding parametric sensitivities is crucial.

Acknowledgments

The authors thank all contributors to the TAeZoSysPro project, as well as the teams who participated in the experimental validation campaigns.

Development of a Refrigerant Mixture Package for Dynamic Simulation of Auto-Cascade Refrigeration: A Case Study with R23/R134a

Rohit Dhumane[1] Dan Gorman[1] Rajkumar K S[2] Dongping Huang[3]

[1]Trane Technologies, USA, {Rohit.Dhumane,Daniel.Gorman}@tranetechnologies.com

[3]Trane Technologies, China, Dongping.Huang@tranetechnologies.com

Abstract

The auto-cascade refrigeration cycle offers higher reliability and lower manufacturing costs compared to the cascade refrigeration cycle, making it particularly attractive for applications involving significant temperature differences between the heat source and sink. However, this advantage comes with increased complexity in its operation. This article aims to develop a media package in Modelica to simulate auto-cascade refrigeration cycles, with the goal of enhancing understanding of their operation and control. The method is demonstrated using an R23/R134a mixture, a commonly used refrigerant combination in such applications. The media package is compatible with the `Modelica Standard Library` and is constructed using curve fits based on the REFPROP dataset. Unlike typical refrigeration systems, the media package for auto-cascade components includes the independent mixture composition (Xi) as an additional variable in function calls. A combination of polynomial and Chebyshev polynomial curve-fits for the refrigerant properties has been shown to provide an optimal balance between accuracy and computational efficiency. The article presents example simulations performed to demonstrate use of the media package with component models from the `Modelica.Fluid` package. A lumped model for the phase separator is developed and simulated with the R23/R134a media to demonstrate ideal phase separation.

Keywords: refrigeration, auto-cascade, two-phase

1 Introduction

Modern and next generation vapor compression systems are increasingly using refrigerant mixtures to address multiple competing design constraints like low global warming potential, improved system performance and costs. Accurate and fast refrigerant property models are essential for model-based design of vapor compression systems, where simulation speed is often bottlenecked by iterative property calculations.

1.1 Auto-Cascade Refrigeration Cycle

The auto-cascade refrigeration cycle (ARC) offers the advantage of achieving a higher temperature difference between the source and sink using a single compressor. This is made possible by employing a zeotropic refrigerant mixture and adjusting its composition to meet operational requirements. However, calculating the thermodynamic properties of zeotropic mixtures is more complex than for pure refrigerants, making the analysis of ARC systems more complicated (He et al. 2022).

1.2 Refrigerant Mixture Properties

Modeling and simulation is an indispensable tool to improve our understanding about complex systems like the ARC. Modelica provides a mature and robust environment for simulating refrigeration systems, while REFPROP (Lemmon et al. 2018) is the industry standard for calculating refrigerant properties. However, the complexity of mixture models in REFPROP can significantly increase the computational cost of simulations. To address this, curve fits derived from REFPROP-generated data are used to reduce computational demands during simulation.

REFPROP is a powerful and widely accepted tool for thermodynamic property calculations, but it presents several limitations when used for dynamic simulations. REFPROP's reliance on nested iterative root-finding algorithms often leads to non-convergence or local numerical anomalies, especially near phase boundaries and critical points. These anomalies manifest as spikes in density derivatives, which can destabilize dynamic simulations or yield inaccurate results (Laughman et al. 2024). Dynamic simulations in Modelica involve frequent property evaluations which can run into millions of calls in a short time window. REFPROP's iterative nature makes these calls computationally expensive. Simulations using REFPROP can be 100–5000 times slower than those using optimized lookup or interpolatory methods (Aute and Radermacher 2014). Additionally, computing thermodynamic properties for these mixtures using first principles is numerically complex and often yields non-physical anomalies, especially in standard tools like REFPROP (Laughman et al. 2024). These anomalies, particularly in the two-phase

region near the critical point can disrupt dynamic simulations by introducing discontinuities in property derivatives, leading to inaccurate or failed predictions. To overcome these limitations, researchers have developed specialized refrigerant property models using spline-based table look-up methods, polynomial fits, and interpolatory techniques (Aute and Radermacher 2014; Laughman et al. 2024; Li et al. 2018).

1.3 Chebyshev Polynomials

Chebyshev polynomials possess several attractive properties when it comes to function approximation. It has been proven that for any continuous function on a given interval, there exists a Chebyshev polynomial that can approximate the said function. These polynomials have been found particularly effective for approximating refrigerant properties, offering a favorable balance between accuracy and computational efficiency (Aute and Radermacher 2014). In this article, we will use Chebyshev polynomials of the first kind T_n which are defined by Equation 1.

$$T_n(cos(\theta)) = cos(n\theta) \tag{1}$$

These are typically calculated with a recurrence equation as shown by Equation 2 - Equation 4.

$$T_0(x) = 1 \tag{2}$$
$$T_1(x) = x \tag{3}$$
$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x) \tag{4}$$

A polynomial in a single variable, referred to as 1D, can now be calculated with a coefficient vector c_i, which can be calculated from a least squares fit over the data.

$$T_{n+1}(x) = \sum_{i=0}^{n} c_i T_i(x) \tag{5}$$

For the case of polynomials with two variables, separate series for each of the input is created. The orthogonality property of the Chebyshev polynomials is then used to create the 2D equation. The methodology and terminology from the Python's numpy package (Harris et al. 2020) is followed in this article. The reader may refer to its documentation for details.

$$T_{n+1,m+1}(x,y) = \sum_{i=0}^{n}\sum_{j=0}^{m} c_{i,j} T_i(x) T_j(y) \tag{6}$$

Similarly for an equation with three variables, the Equation 7 can be used.

$$T_{n+1,m+1,l+1}(x,y,z) = \sum_{i=0}^{n}\sum_{j=0}^{m}\sum_{k=0}^{l} c_{i,j,k} T_i(x) T_j(y) T_k(z) \tag{7}$$

The ability to create polynomial functions with different maximum degree for the inputs helps to reduce computational cost.

The objective of the article is to present a method to develop a two-phase refrigerant mixture package for zeotropic mixture combinations which are applicable for auto-cascade refrigeration systems. Compatibility with `Modelica Standard Library` Media package is to be maintained to enable reuse of components especially from the `Fluids` package. The method is applied to a binary refrigerant mixture and the required property functions are created in Modelica. The applicability of the autocascade media is demonstrated by simulating a few component level simulations involving change in refrigerant mixture concentration.

2 Fitting Property Data

The entire p-h domain of the zeotropic refrigerant properties domain can be divided into four regions: 1. subcooled, 2. two phase, 3. super-heated and 4. super-critical (Aute and Radermacher 2014). These will be referred to as Regions 1 - 4 henceforth. The state of a binary refrigerant mixture can be defined by three independent properties. In this article pressure (p), specific enthalpy (h) and mixture independent composition (Xi) are used as the independent properties. The properties like density, specific heat capacity, thermal conductivity which cover all the four regions are functions of three variables. The properties on the saturation line like bubble enthalpy, dew enthalpy, bubble density, dew density and so on, require only two independent variables. Finally, critical properties like critical pressure and critical temperature will be fitted to a 1D Chebyshev polynomial.

The method will be demonstrated with a mixture combination of R23-R134a which is commonly used in autocascade refrigeration systems as seen in several publications(Du et al. 2009; Bai, Yan, and Yu 2019; He et al. 2022). The mixture combinations for auto-cascade are such that the boiling points of the constituents are significantly different.

Python is used for the purposes of fitting. Numpy library provides fitting functions for 1D Chebyshev. Sampling the points to generate dataset from REFPROP is performed using Python's Scipy library (Virtanen et al. 2020). Finally, metrics like RMSE are obtained from functions in Scikit-learn (Pedregosa et al. 2011).

2.1 Data Generation

The datasets obtained from REFPROP are sanitized by removing anomalies and replacing them with smooth, physically consistent estimates. This approach enables fast, accurate, and robust simulations in Modelica.

2.1.1 Critical Properties

Critical properties of the zeotropic refrigerant mixture are functions of its mixture composition. These are hence a function of a single independent variable and referred to as 1D functions. For generating 1D dataset for critical properties, 1000 points are sampled within the range 0-1 by latin hypercube sampling (LHS). The critical properties

DOI
10.3384/ecp218303

are calculated by taking this 1D LHS as mass composition of R23.

To fit the data using Chebyshev polynomials, it must first be scaled to the range [-1,1]. This scaling is performed using the `MinMaxScaler` from the Scikit-learn library. The optimal degree of the polynomial is not known a priori, so a parametric study is conducted by varying the degree from 1 to 25. A tolerance value of 10^{-8} is selected for the fitting process.

The results of the parametric study for critical pressure are shown in Figure 1, while results for all properties are summarized in Table 1. A single calculation of the critical pressure is not sufficient to represent the computational expense accurately. Therefore, a random set of 1000 values of Xi is used for benchmarking.

The median computation time to calculate the critical pressure using REFPROP is calculated to be 357.335 ms. This is the median of the same calculation repeated 14 times. The mean was 357.799 ms $\pm$ 4.306 ms. For each polynomial degree between 1 and 25 in the Chebyshev fit, the computational expense for the same evaluation is approximately 30 μs. For these cases, 10000 calculations were used. The standard deviation is of the order 30 μs which contributes to the jagged nature of the plot of computational expense. Nevertheless, it is evident that using Chebyshev polynomials yields a speedup of approximately four orders of magnitude. Similar acceleration is observed for the computation of critical temperature and critical density.

Table 1. Polynomial degree to meet tolerance.

Property	*Degree*
Critical Pressure	20
Critical Temperature	12
Critical Density	24

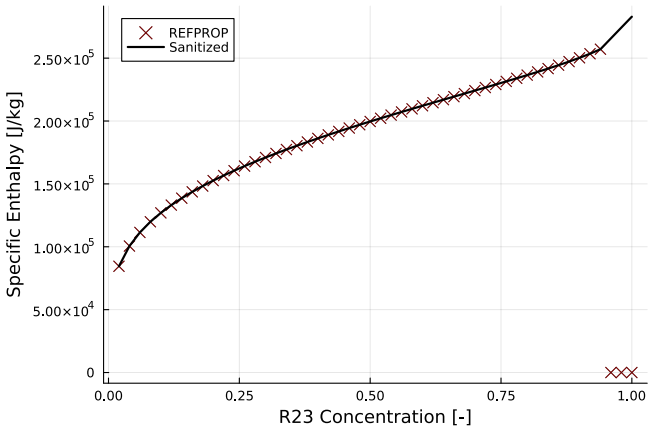

Figure 3. Sanitized values of bubble enthalpy as function of R23 concentration

2.1.2 Saturated Properties

The saturated properties, i.e. the properties which lie on the saturation line, require two independent variables as inputs. These are referred to as 2D properties in this article. Pressure and specific enthalpy are the most commonly used input variables for the properties of this type. To generate the dataset, a Latin Hypercube Sampling (LHS) of two variables of size 100 with values between 0 and 1 is created. Using these two columns of LHS, a total of 10000 is created as a tabular grid. The first variable of the LHS is assigned as the mixture concentration by mass. For pressure, the upper and lower ranges are not constant. This helps with filtering noisy data by observing property trends.

The upper limit is the critical pressure of the refrigerant mixture at that concentration. Lower limit (p_{min}) determination is arbitrary. For the purpose of this article, the bubble pressure corresponding to a temperature of $-80°C$ for the given mixture concentration is taken as the lower limit. The second variable of the LHS is then used to scale the point in between these two limits. This is achieved by applying Equation 8 to each row. x_i is i^{th} sample of the

second variable of the LHS.

$$p_i = p_{min,i} + x_i(p_{crit,i} - p_{min,i}) \tag{8}$$

Now that the pressure and mixture concentration is available, the following refrigerant properties on the vapor dome are calculated: bubble enthalpy, bubble temperature, bubble specific volume, bubble specific heat capacity at constant pressure, bubble thermal conductivity, bubble dynamic viscosity, surface tension, dew enthalpy, dew temperature, dew specific volume, dew specific heat capacity at constant pressure, dew thermal conductivity and dew dynamic viscosity.

As mentioned earlier, data obtained from REFPROP needs to be sanitized. The method used for the current article is described with an example of bubble enthalpy. The bubble enthalpy function depends on two independent variables - reduced pressure and Xi. A latin hypercube design of 100 rows and 2 columns can be used to obtain two vectors varying between 0 and 1. Specific enthalpy of critical points (Hcrit) is a function of Xi. For Xi values starting from 0 to 1 with a step size of 0.001, Hcrit is calculated using REFPROP and shown in Figure 2. It can be observed that there are a few points (22 points out of 1001) which are not following the trend and need to be removed. A simple filter (value > 4e5) is used to eliminate these anomalous values. Linear interpolation is then used to estimate the values for these points to create the sanitized set for critical specific enthalpy.

The linear interpolation of critical specific enthalpy can be used to fill in data by interpolation for some points which fail to compute near the critical point. For the evaluation of 10000 point dataset, a for loop can be constructed which calculates the bubble enthalpy for all the values of reduced pressure at a given value of R23 concentration. For example, for Xi = 0.98 the data is shown in Figure 3. A try-catch block is used and for the failed simulation cases near critical point a value of 0 is provided. These error points can be then easily filtered out (value < 1000). The final point in the interpolation data is for reduced pressure of 1 which corresponds to the critical specific enthalpy for the given Xi. This can be obtained from the interpolation of Figure 2. The removed points can now be added by interpolation since the end point is now available. This is shown in Figure 3. The method is repeated for all the values of Xi to generate the dataset.

Polynomials of degree 16 are used to create curve-fits of the dataset. It is observed that using natural logarithm of the pressure as a feature instead of absolute pressure provides a better fit in some cases. Standard scaling is also used since the two inputs have different orders of magnitude. Several statistics along with visual comparison are used to observe the goodness of the fit. An example plot showing the quality of the fit is shown in Figure 4. In this plot, the values obtained from REFPROP are on the x-axis while curve fits obtained are on the y-axis. Table showing

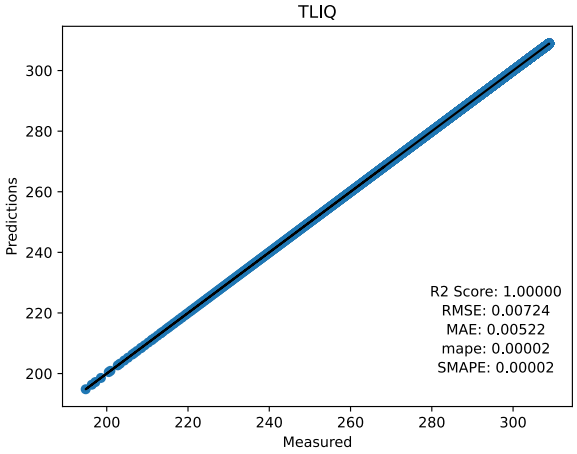

Figure 4. Checking goodness of polynomial fit for bubble temperature

the list of all the 2D properties and their inputs is shown in Table 2.

2.1.3 Regular Properties

The properties of the refrigerant mixture like specific entropy, density, etc. cover all the regions. These properties are referred to as 3D properties in this article. A dataset is created covering 10000 samples in 3 variables in each of the regions.

For the sub-cooled region (Region 1), the mixture composition by mass is obtained directly from one of the three columns of the 3x10000 LHS. Pressure is again obtained using the second variable and the application of Equation 8. To calculate specific enthalpy in the region, the range of enthalpy values and the third variable of the sampling are used. The maximum value of enthalpy possible for the region is the bubble enthalpy h_{bub}. The lower limit for enthalpy h_{min} is the value for which the subcooling is $-50°C$ for the given value of pressure and the mixture concentration. The enthalpy values can now be calculated using an equation similar to Equation 8 for these limits.

For the two phase region (Region 2), the mixture composition and pressure are taken from region 1. The third variable of sampling is used as the refrigerant quality to calculate the enthalpy in the two phase region using the bubble and dew enthalpy.

For the superheated region (Region 3), the mixture composition and pressure are taken from region 1. The minimum value of enthalpy is the dew enthalpy. The maximum value of enthalpy h_{max} is obtained by taking a superheat value of $+50°C$ at the given pressure and mixture composition. An equation of the form Equation 8 for these enthalpy limits is then used to calculate the specific enthalpy in Region 3.

For the supercritical region (Region 4), the mixture composition is obtained from the first variable of LHS. The pressure is obtained by using Equation 9. The maximum pressure is 1.5 times the critical pressure. The en-

DOI
10.3384/ecp218303

thalpy is sampled by calculating temperature in the range of $\pm 50°C$ of the critical temperature. The enthalpy is calculated using the pressure and this sampled temperature.

$$p_i = p_{crit,i} + x_i(p_{max,i} - p_{crit,i}) \tag{9}$$

Now with pressure, specific enthalpy and mixture composition available in each of the regions, temperature, specific entropy, specific volume, specific heat capacity, thermal conductivity, dynamic viscosity and speed of sound are calculated using REFPROP. A regular polynomial of degree 8 is used to create curve-fits for the dataset. Several regions are combined to create a curve-fit if the accuracy is good with combined datasets. However, only specific entropy is observed to have good accuracy (less than 1% mean absolute percentage error) for all four regions with a single 8 degree polynomial. In more typical cases, multiple polynomial fits of degree 8 are created and then a spline interpolation is performed at the border of the regions.

3 Media Class

The `Media` package in `Modelica Standard Library` provides examples for creating media. The refrigerant mixture media is creating by extending the class `Modelica.Media.Interfaces.PartialMedium`. In the extended class the `mediumName` and `substanceName` parameters are defined with string *R23|R134a* and two element string array *"R23","R134a"* respectively.

Since the mixture comprises of multiple components, `singleState` is false. It is preferable to work with only the independent mass fractions of the mixture since they sum to one. For this reason, `reducedX` is set as true. Finally, since mixture composition is expected to change during simulation, `fixedX` is set to false. The `ThermoStates` parameter is set to `phX` to define pressure, specific enthalpy and mixture composition by mass as the three independent variables defining the thermodynamic state of the media. The `BaseProperties` class is defined as shown in Listing 1.

Listing 1. Definition of the base class BaseProperties

```
redeclare replaceable model extends
    BaseProperties(
  h(stateSelect=if preferredMediumStates
      then StateSelect.prefer else
        StateSelect.default),

        StateSelect.default),
  Xi(each stateSelect=if
      preferredMediumStates then
      StateSelect.prefer
        else StateSelect.default),
  final standardOrderComponents=true)
  "Base properties of medium"
equation
  d =density_phX(
      p,
      h,
      X);
  T =temperature_phX(
      p,
      h,
      X);
  u = h - p/d;
  MM = 1/(Xi[R23]/MMX[R23] + (1.0 - Xi[
      R23])/MMX[R134a]);
  R_s = Modelica.Constants.R/MM;
  state = setState_phX(p,h,X);
```

Now that the basic structure of the media is setup, the property functions obtained from curve-fits can be added to it.

3.1 1D Functions

The critical pressure, critical temperature and critical density are not constant for the refrigerant mixture. These properties are functions of the mixture composition. The independent composition of the first component (R23 in this case) is referred to as Xi. The composition array of both the components is referred to by the variable X. The functions are defined as a function of X.

The recurrence relationship to calculate the Chebyshev (Equation 5), is coded as a function. This is used to create a Vandermonde matrix. A dot product of the coefficient vector with the Vandermonde matrix gives the value of the output. The implementation is similar to the numpy library (Harris et al. 2020). The inputs and outputs for Chebyshev functions are scaled to the range [-1,1] and then scaled back to output using `MinMaxScaler` (Pedregosa et al. 2011).

3.2 2D Functions

Recall that the 2D functions represent variables on the vapor dome. These are represented by two independent variables, typically pressure and composition. Standard scaling (Pedregosa et al. 2011) is applied to the inputs and then a dot product between the polynomial terms and the coefficients obtained from curve-fits is done to obtain the desired property. The functions created with this method as listed in Table 2.

The bubble point is the temperature at which a liquid creates the first bubble of vapor and begins the process of boiling. The dew point is the temperature at which the first drop of dew is formed from vapor commencing the condensation of the liquid. The bubble enthalpy is also referred to as liquid point enthalpy and dew enthalpy is also referred to as vapor point enthalpy in literature. The authors have preferred to use bubble and dew points since liquid and vapor enthalpy may also refer to those of subcooled or superheated phases causing confusion to readers.

Table 2. Saturation properties and their inputs.

Property	*Input 1*	*Input 2*

bubbleViscosity	p	X
dewViscosity	p	X
bubblePressure	T	X
dewPressure	T	X
bubbleXi	T	X
dewXi	T	X

3.3 3D Functions

Finally, the property functions which work in all the regions of the refrigerant mixture are added to the media package. The complete list of these functions is seen is Table 3. These are the functions available in the `PartialMedium` class and defined in the media with the 8 order polynomial.

Table 3. Saturation properties and their inputs.

Property	*Input 1*	*Input 2*	*Input 3*
temperature	p	h	X
density	p	h	X

specificEnthalpy	p	s	X
temperature	p	s	X
density-derh-p	p	h	X
density-derp-h	p	h	X
density-derX	p	h	X

Except for specific entropy, it is not possible to obtain a curve-fit with accuracy of 1% mean absolute percentage error with a single polynomial fitting all the regions. In these cases, polynomial fits are performed over single or two or three regions which meet the accuracy target. Then spline interpolation is done at the border of these regions. The spline function used is similar to the `SpliceFunction` in `Modelica.Media.Air.MoistAir.Utilities`. Separation of the transcritical region from the remaining is done with reduced pressure ($p/pcrit$). Then in an inner nested loop, the refrigerant quality is used to separate the remaining regions.

The density calculation is critical because it directly influences the conservation equations and can lead to non-physical scenarios if inaccurate. Additionally, density derivatives are required for time-stepping the state variables. To address this, a 3D lookup table is employed for density computation. The implementation is achieved using the `DataFiles` library by using the functions from `TableND` package. The grid variables for the table are reduced pressure, pseudo vapor quality, and Xi. Pseudo vapor quality is computed using the vapor quality formula but is not constrained between 0 and 1. Consequently, liquid enthalpy values may be negative, and vapor enthalpy values may exceed 1.0. The pseudo vapor quality range used spans from -0.5 to 1.5. Table of size $50 \times 41 \times 21$ is used for the purpose with dimensions for the three independent variables respectively.

The partial derivatives of density are obtained by finite difference method with symmetric difference quotient. Equation 10 shows the implementation for the density derivative with specific enthalpy with pressure and mixture composition constant.

$$\left(\frac{\partial \rho}{\partial h}\right)_{p,Xi} \approx \frac{\rho(h+\delta h) - \rho(h-\delta h)}{2\delta h} \tag{10}$$

4 Model Development

With the media package available it is now possible to run simulation. The `Fluid` subpackage in `Modelica Standard Library` contains several component models which can be used to run simulations.

4.1 Simulating Concentration Change

Figure 6 shows a model to simulate change in concentration of the mixture with time. The `MassFlowSource-h` and `Boundary-ph` blocks are taken from `Modelica.Fluid.Sources`. Inlet enthalpy of 300e3 kJ/kg and mass flow rate of 0.1 kg/s are provided to the mass flow source block. The mass flow source block exposes the concentration as an input. The ramp block sets up the variation of R23 composition in mixture from 0.2 to 0.7 during the simulation. Together with the constant block with input 1 and add block, the composition array X of {Xi, 1-Xi} is provided. A pressure of 10 bar is set in the boundary.

4.2 Simulating Fixed Temperature

An important benefit of Modelica is designing of controllers. For the purpose of demonstration, a simple simulation including a PID controller is created. As in the previous example from 4.1, let us say we want to maintain the temperature to a fixed value. This can be achieved by changing the specific enthalpy.

DOI 10.3384/ecp218303

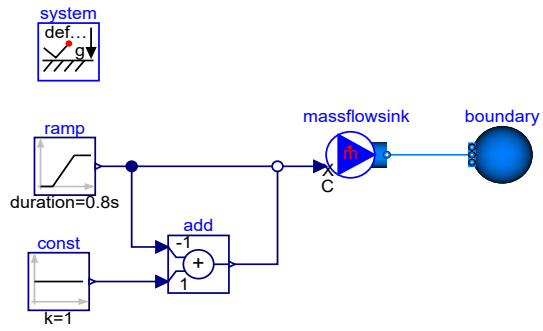

Figure 5. Simulating changing concentration of refrigerant mixture

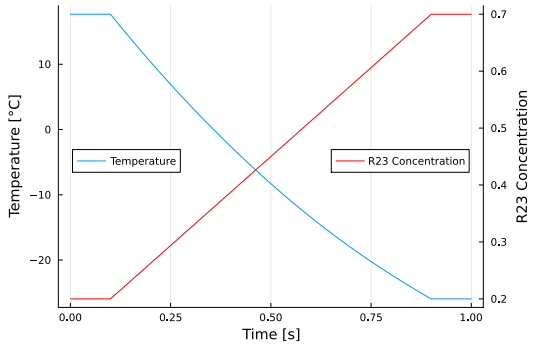

Figure 6. Temperature change of mixture with change of mixture composition

This model is setup as shown in Figure 7. A temperature sensor model is used to obtain the measured value for the PID. Setpoint value for the PID block is provided by a constant block. The value is set to 300 K.

The results can be seen in Figure 8. It can be observed that the PID is changing the enthalpy to obtain the setpoint temperature. As seen in Figure 6, the temperature of refrigerant mixture would have changed with the change in concentration. But by adjusting the specific enthalpy, it is maintained to the setpoint.

4.3 Flow Models

Thermal systems have models which determine refrigerant mass flow rate. A valve is an example of this type of model. There is no change required for these kind of models because the mass conservation, conservation of mixture constituents and energy conservation are trivial in these components. Valve models from the `Modelica.Fluid.Valves` work as is with the new media.

4.4 Lumped Refrigerant Control Volume

The components which model the control volumes with mass and energy conservation need some changes for handling refrigerant mixture. Since the concentration of mixture is also an independent variable, the density is a function of three parameters - p, h, Xi. So the density derivatives used to transform the mass and energy conservation have to include a partial derivative with Xi. For the purpose of this derivation, we will assume that the control volume has one inlet and one outlet. This assumption does not affect the derivation in any way but helps to understand it better.

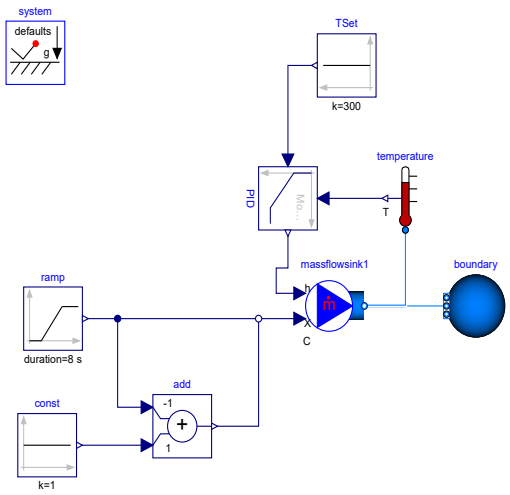

Figure 7. Simulating a simple controller to maintain temperature

4.4.1 Mass Conservation

The conservation of mass for this control volume with a volume V is given by Equation 11.

$$V\frac{d\rho}{dt} = \dot{m}_{in} - \dot{m}_{out} \tag{11}$$

Since density is a function of three independent variables, the derivative of density with time can be written in terms of its partial derivatives.

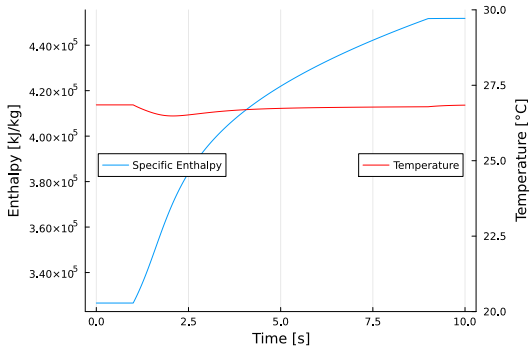

Figure 8. Controller to maintain a fixed temperature with change of mixture composition

$$V\left(\left.\frac{\partial\rho}{\partial p}\right|_{h,X}\frac{dp}{dt}+\left.\frac{\partial\rho}{\partial h}\right|_{p,X}\frac{dh}{dt}+\left.\frac{\partial\rho}{\partial X}\right|_{p,h}\frac{dX}{dt}\right)=\dot{m}_{in}-\dot{m}_{out} \tag{12}$$

This form can be evaluated with the availability of the partial derivatives calculated as shown in Equation 10.

4.4.2 Energy Conservation

Energy equation equation for the control volume can be written as below Equation 13.

$$\frac{d(\bar{m}\bar{u})}{dt}=\dot{m}_{in}h_{in}-\dot{m}_{out}h_{out} \tag{13}$$

Specific internal energy and specific enthalpy are related by:

$$\bar{u}=\bar{h}-\frac{p}{\rho} \tag{14}$$

Substituting for specific internal energy

$$\frac{d\left(\bar{m}\left(\bar{h}-\frac{p}{\bar{\rho}}\right)\right)}{dt}=\dot{m}_{in}h_{in}-\dot{m}_{out}h_{out} \tag{15}$$

For a control volume with a fixed volume.

$$V=\frac{\bar{m}}{\bar{\rho}} \tag{16}$$

Substituting Equation 16 into Equation 15. We obtain

$$\frac{d(\bar{m}\bar{h}-Vp)}{dt}=\dot{m}_{in}h_{in}-\dot{m}_{out}h_{out} \tag{17}$$

Since volume is fixed:

$$\frac{d(\bar{m}\bar{h})}{dt}-V\frac{p}{dt}=\dot{m}_{in}h_{in}-\dot{m}_{out}h_{out} \tag{18}$$

Using Chain rule of Calculus

$$\left(\bar{m}\frac{d\bar{h}}{dt}+\bar{h}\frac{d\bar{m}}{dt}\right)-V\frac{p}{dt}=\dot{m}_{in}h_{in}-\dot{m}_{out}h_{out} \tag{19}$$

We can use conservation of mass to substitute of $\frac{d\bar{m}}{dt}$

$$\bar{m}\frac{d\bar{h}}{dt}+\bar{h}(\dot{m}_{in}-\dot{m}_{out})-V\frac{p}{dt}=\dot{m}_{in}h_{in}-\dot{m}_{out}h_{out} \tag{20}$$

Simplifying

$$\bar{m}\frac{d\bar{h}}{dt}-V\frac{p}{dt}=\dot{m}_{in}(h_{in}-\bar{h})-\dot{m}_{out}(h_{out}-\bar{h}) \tag{21}$$

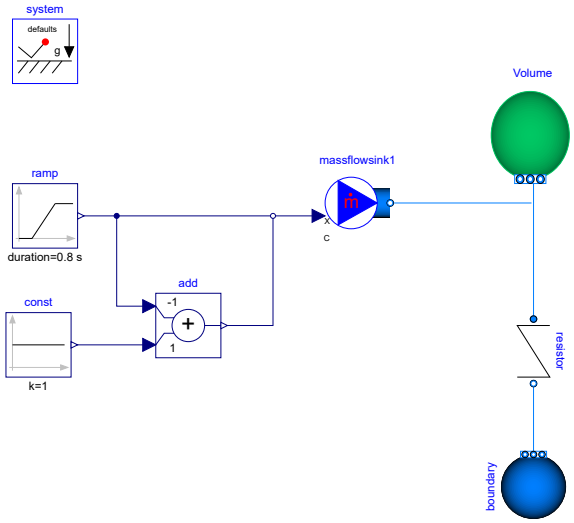

Figure 9. Control volume model simulation

4.4.3 Mixture Conservation

The conservation of the constituents of the mixture can be written as:

$$\frac{d(\bar{m}\bar{X}i)}{dt}=\dot{m}_{in}Xi_{in}-\dot{m}_{out}Xi_{out} \tag{22}$$

Using Chain rule of calculus:

$$\bar{m}\frac{d(\bar{X}i)}{dt}+\bar{X}i\frac{d(\bar{m})}{dt}=\dot{m}_{in}Xi_{in}-\dot{m}_{out}Xi_{out} \tag{23}$$

Using conservation of mass Equation 12

$$\bar{m}\frac{d(\bar{X}i)}{dt}+\bar{X}i(\dot{m}_{in}-\dot{m}_{out})=\dot{m}_{in}Xi_{in}-\dot{m}_{out}Xi_{out} \tag{24}$$

Finally, we obtain

$$\bar{m}\frac{d(\bar{X}i)}{dt}=\dot{m}_{in}(Xi_{in}-\bar{X}i)-\dot{m}_{out}(Xi_{out}-\bar{X}i) \tag{25}$$

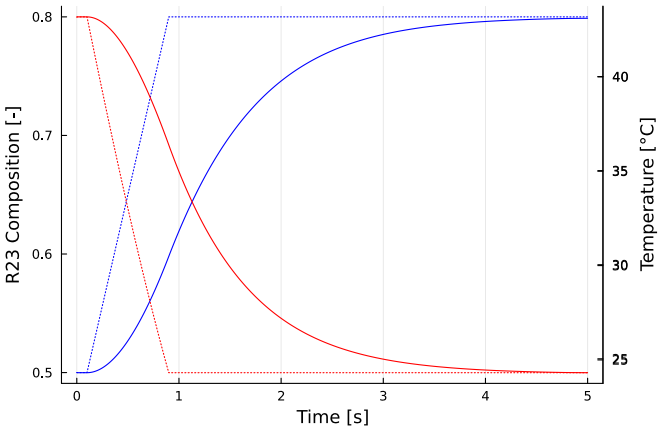

Figure 10. Control volume model simulation

DOI
10.3384/ecp218303

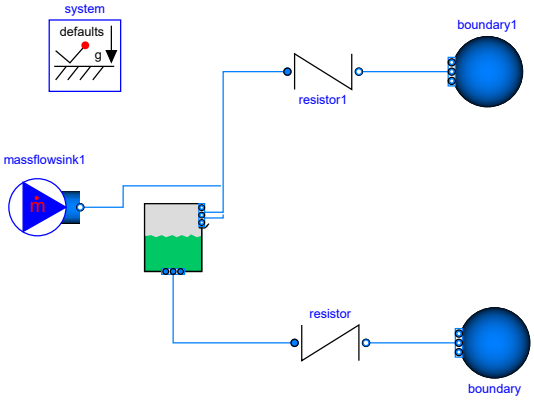

Figure 11. Separator tank model simulation

4.4.4 Model Simulation

The volume model is connected to `MassFlowSource_h` and `Boundary_ph`. The simulation model can be seen in Figure 9. A flow resistor is added between the volume and boundary. The model is simulated with varying refrigerant concentration. The refrigerant state of the lumped control volume is different from the inlet state of the refrigerant entering from `MassFlowSource_h`. The intention is to check that after the initial transients the two states become equal.

The results can be seen in Figure 10. The dotted lines are the refrigerant mixture state values from `MassFlowSource_h` while the solid lines are those from the `Volume`. It can be seen that the values converge after the initial transients.

4.5 Separator Tank

The separator tank is a key component of an auto-cascade refrigeration system. It is a specialized implementation of the lumped refrigerant control volume. A separator tank has an inlet port, a vapor outlet port and a liquid outlet port. When the liquid level is between 5% and 95% the vapor outlet port and liquid outlet port will provide pure vapor and pure liquid respectively. If the liquid level is at 0% or 100%, both outlets will provide vapor or liquid respectively. Between these values a mixed two phase flow is provided depending on a spline interpolation.

The liquid level (L) is calculated by the following equation:

$$L = \frac{1-q}{q \cdot \frac{\rho_{\text{liq}}}{\rho_{\text{vap}}} + (1-q)} \tag{26}$$

The liquid level is compared with the thresholds for dryout and flooded conditions (defaults 5% and 95%). Within the safe operating range, the outlet enthalpy at the vapor port corresponds to the dew enthalpy at the given pressure and mixture composition. For the liquid port, the bubble enthalpy at the same pressure and composition is used. For the mixture concentrations at the vapor port and liquid port, the functions `dew_Xi` and `bubble_Xi` which are functions of pressure and temperature are used. These were obtained from curve-fits of 2D REFPROP data. Since refrigerant vapor and liquid will be at thermodynamic equilibrium, they will have the same temperature and pressure. This will be equal to the temperature and pressure of the lumped control volume refrigerant mixture state.

Figure 11 shows the model with separator tank. The inlet port and vapor port can be connected into the connector array. There are two separate sinks and flow resistors for the vapor and liquid streams. The nominal flow rates in the flow resistors is adjusted to obtain points which do not have dryout or liquid overflow.

The separator tank model is initialized at 30 bar pressure, 250 kJ/kg specific enthalpy and a mixture composition of { 0.3, 0.7 }. The inlet refrigerant flow has 30 bar pressure, 350 kJ/kg specific enthalpy and a mixture composition of { 0.5, 0.5 }.

The results are shown in Figure 12, which displays the liquid level, mass flow rates at different ports, vapor quality, and mixture composition. We can observe that the vapor outlet has output of vapor and liquid outlet has quality close to that of liquid. The R23 composition is higher in the vapor phase than in the liquid phase, indicating effective mixture separation. The R23 composition changes very slowly during the simulation and appears nearly constant in the plot. Note that the separator tank and selected mass flow rates may not be optimally sized for the simulation.

5 Conclusions and Future Work

The article presented a method for simulating thermodynamic systems in Modelica, specifically addressing scenarios where the refrigerant mixture composition changes dynamically during operation. A detailed description of the media package creation was provided, with particular attention to accuracy and computational efficiency. The approach enables the use of component models from the `Modelica Standard Library` to perform simulations with the developed media package. The value of the modeling is demonstrated by the implementation of controllers designed to regulate refrigerant concentration in the mixture to achieve desired performance. A key component of the system, the separator tank used in auto-cascade refrigeration, was modeled in detail. Simulation results showed qualitative agreement with expected qualitative behavior.

The current work is part of an ongoing effort to simulate a complete auto-cascade refrigeration cycle. This will require the development of additional component models like compressor and heat exchangers which can work with the newly created refrigerant mixture media package. There is a lot of scope for enhancing the speed

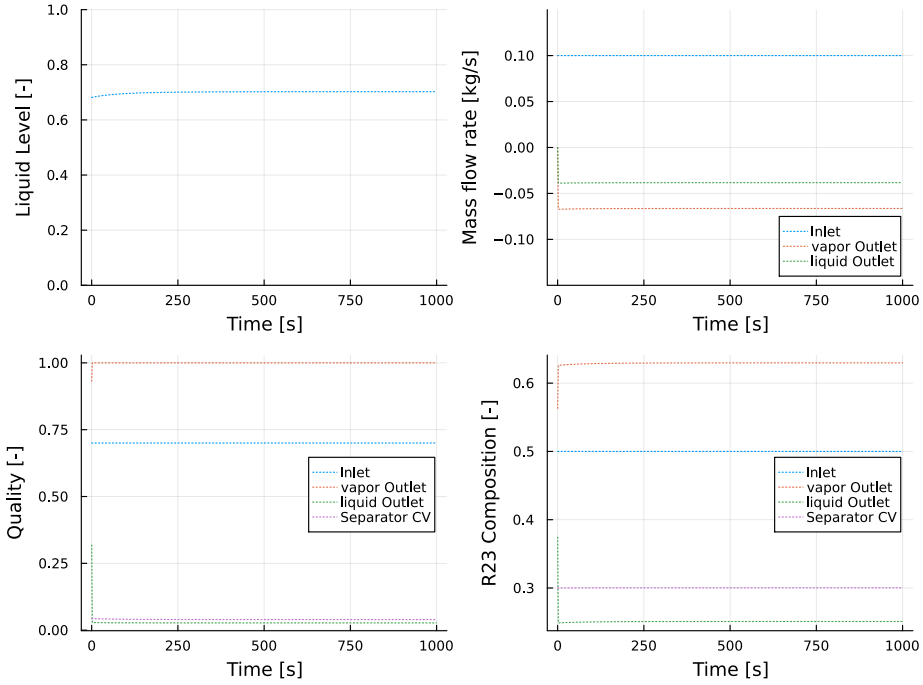

Figure 12. Results of separator tank model (a) Liquid Level (b) Mass Flow Rates (c) Quality (d) R23 Composition.

and accuracy of zeotropic refrigerant property evaluations. One promising direction is the application of multivariable Chebyshev polynomials to improve computational performance. To support applicability to other refrigerant mixture combinations, future developments will also address the automatic removal of erroneous REFPROP data.

A Generic Non-Miscible Liquid-Gas Medium Model in Modelica with Analysis of Incompressibility Assumptions

Hubert Blervaque[1] Félix Marsollier[2]

[1]ModeliConseil, France, hbe@modeliconseil.com
[2]SIL3X, France, felix.marsollier@sil3x.fr

Abstract

Motivated by the representation of draining or leak scenarios in industrial processes, this paper introduces a generic two-phase non-miscible liquid-gas medium model. The model represents two distinct substances with independent thermodynamic states and enables transient simulations involving phase-separated liquid and gas domains. It is designed to remain compatible with the Modelica.Media and Modelica.Fluid interfaces. In developing this model, we analyze how specific assumptions about liquid compressibility — such as the dependency of enthalpy and density on pressure — affect the structure of the resulting balance equations through detailed mathematical analysis. We examine different incompressibility approaches and their implications for the formulation of conservation equations. This article focuses on a comprehensive theoretical analysis of the model formulation, highlighting the trade-offs involved and providing insights into selecting appropriate liquid models for dynamic simulations involving non-miscible flows.

1 Introduction

The Modelica language (Modelica Association 2017) provides a powerful, equation-based environment for the dynamic simulation of complex physical systems, particularly thermal-hydraulic networks (Fritzson 2014). Libraries such as the Modelica Standard Library [MSL] `Modelica.Fluid`, Buildings (Wetter et al. 2014), AixLib (Müller et al. 2016), and ThermoFluidStream (Zimmer, Meißner, and Weber 2022) offer rich sets of components governed by the underlying thermodynamic properties encapsulated in replaceable `Medium` models via the `Modelica.Media` interface.

This framework is well suited for the analysis of advanced concepts, including new generation nuclear reactors: Small Nuclear Reactors (SMRs). Molten Salt Reactors (MSRs), for instance, present demanding simulation requirements due to their unique characteristics and operational scenarios (Serp et al. 2014). Applying Modelica to specific MSR transients, like draining or leak management, has highlighted challenges in modeling systems that transition from a fully liquid (molten salt) state to a fully gaseous (inert gas) state via non-miscible phase interactions.

Most components (pipes, pumps, volumes, etc.) within the `Modelica.Fluid` library — and related libraries based on the same design philosophy — are capable of simulating single-phase liquid or gas flows, as well as equilibrium two-phase flows (e.g., liquid-vapor equilibrium) (Casella and Leva 2024). These components typically rely on media definitions based on a single thermodynamic state and often assume local phase equilibrium when modeling two-phase flows. However, several applications —such as the simulation of draining scenarios or gas ingress— require the ability to model liquid and gas phases as coexisting but strictly non-miscible, without assuming thermodynamic equilibrium. In SMR safety studies, for instance, transient configurations may include the loss or recovery of coolant, resulting in domains where both gas and liquid are present but governed by distinct physical laws. Beyond the nuclear domain, similar configurations are also found in other industrial processes involving large storage tanks, fluid circuit maintenance, or safety-related depressurization events.

To address these needs, we propose a new generic Modelica medium that models two non-miscible substances while maintaining compatibility with the existing ecosystem of components. The proposed `BisubLiqGas` medium allows independent specification of compressibility assumptions for each substance. In particular, it enables the user to represent incompressible or weakly compressible liquids while preserving full thermodynamic modeling of the gas (as perfect gas). The model is designed for seamless integration with `Modelica.Fluid` components, allowing mixed-phase simulations across pipes, tanks, or valves. This allows simulation of systems that transition seamlessly between fully liquid, fully gaseous, or mixed states using standard components.

Creating such a medium, however, necessitates careful consideration of how the individual phases are modeled, particularly the liquid. Molten salts, like many liquids, are often approximated as incompressible for simplicity. Yet, incompressibility ($\rho = f(T)$ only) can lead to different modeling variants regarding the pressure dependency of thermodynamic properties like internal energy u and

enthalpy h. For example, defining enthalpy solely as $h(T)$ versus allowing an implicit pressure dependency leads to different system behavior, as detailed in Section 3. The choice of how to model liquid incompressibility and its thermodynamic consequences therefore becomes a critical aspect, impacting the robustness and efficiency of simulations involving such media.

The main contributions are thus twofold: (1) the presentation of a generic, standard-component-compatible `Medium` model for non-miscible liquid-gas systems, and (2) a detailed mathematical analysis of the trade-offs associated with different representations of liquid incompressibility within this context. Through rigorous derivation of conservation equations, we analyze the structural consequences of these modeling choices and their implications for equation complexity and physical accuracy. Our focus is on the theoretical and structural aspects of the medium formulation, providing a foundation for future implementation and performance studies.

The paper is structured as follows:

- Section 2 introduces a non-miscible two-substance `Medium` model (`BisubLiqGas`), detailing its formulation, assumptions, and general capabilities and limitations, applicable to various liquid-gas pairs.
- Section 3 delves into the core analysis of this paper: the modeling of liquid incompressibility. It discusses different incompressibility approaches and presents a comparative study, focusing on how different incompressibility assumptions impact the structure of the equations generated for a typical test case.

2 Non-miscible liquid-gas medium model

To represent the thermohydraulic behavior of the molten salt/cover gas mixture in scenarios such as draining or leak management, where the liquid and gas phases remain macroscopically separated, a specific medium model has been developed. This model, named `BisubLiqGas`, is designed to capture the essential properties of the mixture while maintaining manageable complexity for dynamic system simulation.

2.1 Medium Components

The `BisubLiqGas` medium is a binary mixture composed of two substances: one is a liquid (indexed L in formulas) and the second a gas (indexed G). While the specific substances used for illustration stem from the original MSR context (Molten Salt and Helium), the model's structure allows for generic application, as detailed in Section 2.5.

- **Liquid substance (Molten Salt)**: The specific model used is from the TRANSFORM library `TRANSFORM.Media.Fluids.NaClKClMgCl2.LinearNaClKClMgCl2_30_20_50_pT` (Greenwood et al. 2023). This choice implies modeling the ternary salt as a fluid whose density is a linear function of temperature T and pressure p, and whose specific heat capacity at constant pressure Cp_L is assumed constant:

$$\rho_L(p,T) = \rho_{L,ref}\left[1 - \beta\cdot(T - T_{ref}) + \kappa\cdot(p - p_{ref})\right] \tag{1}$$

  where $\rho_{L,ref}$, T_{ref}, and p_{ref} are the reference density, temperature, and pressure, respectively, and β and κ are the constant isobaric expansion and isothermal compressibility coefficients. The values for these constants and the transport properties (dynamic viscosity η_L, thermal conductivity λ_L) are derived from correlations or experimental data specific to this molten salt (Greenwood et al. 2023).

- **Gas substance (Helium)**: The standard MSL model `Media.IdealGases.SingleGases.He` is used. This implies that Helium is treated as an ideal gas:

$$p\cdot V = n\cdot R\cdot T \quad \Leftrightarrow \quad p = \rho\cdot R_s\cdot T \tag{2}$$

  where $R_s = R/MM_G$ is the specific gas constant for Helium. Furthermore, its specific heat capacity at constant pressure Cp_G is assumed constant and equal to $\frac{5}{2}R_s$, the theoretical value for a monoatomic ideal gas:

$$Cp_G = \frac{5}{2}\cdot R_s = \text{constant} \tag{3}$$

2.2 Fundamental Assumptions of the Mixture Model

The `BisubLiqGas` model relies on the following key assumptions for the mixture:

- **Non-miscibility**: The liquid (salt) and gas (helium) phases are considered completely immiscible. No dissolution of the gas into the liquid or vice versa is modeled. The interface between the phases is assumed to be sharp within components using this medium.
- **Absence of Phase Change**: No evaporation, condensation, solidification, or fusion is considered. The salt remains liquid, and the Helium remains gaseous throughout the simulated operating range.
- **Local Thermal Equilibrium**: Within an elementary control volume, both phases are assumed to be at the same temperature T.
- **Local Mechanical Equilibrium**: Within an elementary control volume, both phases are assumed to be at the same pressure p. (Note: Hydrostatic pressure differences can exist at the component level).

DOI 10.3384/ecp218313

- **Ideal Thermodynamic Mixing**: The specific enthalpy and internal energy of the mixture are calculated as the mass-fraction weighted average of the respective pure phase properties, implying no heat of mixing.

2.3 Implementation and State Variables

The model is implemented by inheriting from `MSL.Media.Interfaces.PartialMedium`. The chosen independent thermodynamic state variables are pressure p, temperature T, and mass fractions X (`ThermoStates.pTX` option). The liquid substance is considered as X_1 and gas as X_2. The model provides the standard set of functions required by the `PartialMedium` interface to compute thermodynamic and transport properties from various input variable combinations (e.g., `density(setState_phX(...))`, `temperature(setState_psX(...))`). The implementation ensures that calls to component property functions use the appropriate pure substance state derived from the mixture's p and T.

2.4 Mixing Rules

The thermodynamic and transport properties of the mixture are calculated from the properties of the pure components *Liq* and *Gas* (evaluated at the mixture's pressure p and temperature T) using the following mixing rules:

- **Density** (ρ): Derived from the additivity of volumes ($V = V_L + V_G$) and the definition of mass fractions ($m_i = X_i m$), using the linear equation of state for the liquid (1) and the ideal gas law (2) for the gas:

$$\rho(p,T,X) = \frac{m_L + m_G}{V_L + V_G} = \frac{\rho_L(p,T)}{X_L + X_G \frac{\rho_L(p,T) R_s T}{p}} \quad (4)$$

- **Specific Enthalpy** (h): Calculated by mass weighting, consistent with the ideal mixing assumption:

$$h(p,T,X) = X_L \cdot h_L(p,T) + X_G \cdot h_G(p,T) \quad (5)$$

where h_L is given by integrating Cp_L and accounting for the pressure dependency (from the linear model), and h_G is given by $Cp_G(T - T_0)$, with a consistent reference temperature T_0 (here 0 °C).

- **Specific Internal Energy** (u): Derived from enthalpy and density:

$$u(p,T,X) = h(p,T,X) - \frac{p}{\rho(p,T,X)} \quad (6)$$

This is equivalent to the mass-weighted average $u = X_L \cdot u_L + X_G \cdot u_G$.

- **Other Properties (Approximation)**: To simplify the model, other mixture properties Y_{mix} (dynamic viscosity η, thermal conductivity λ, specific entropy s, specific heat capacities Cp and c_v, isentropic exponent γ, speed of sound a) are approximated by a simple mass weighting of the pure phase properties:

$$Y_{mix}(p,T,X) \approx X_L \cdot Y_L(p,T) + X_G \cdot Y_G(p,T) \quad (7)$$

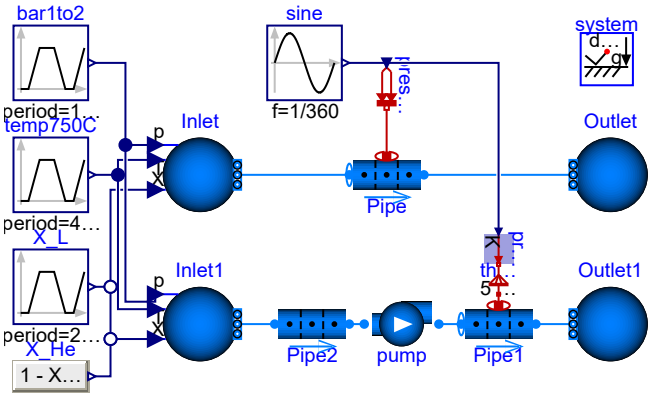

Figure 1. Unit test schematic using the `BisubLiqGas` model with a `DynamicPipe`.

2.5 Model Capabilities and Limitations

The `BisubLiqGas` medium model provides a framework for simulating systems containing non-miscible liquid-gas mixtures using standard Modelica fluid components.

2.5.1 Current Status and Validation

The model demonstrates functionality in several unit tests, such as simulating transient inlet conditions for a `Modelica.Fluid.Pipes.DynamicPipe` component (an example setup is shown in Figure 1). However, achieving robust performance across the full range of standard fluid components and complex scenarios remains an area of ongoing work. Challenges can arise from component-specific assumptions incompatible with a two-substance medium or from the numerical properties of the medium representation itself. Investigating these aspects, particularly the different approaches to modeling liquid incompressibility as discussed in Section 3, is a key objective of this paper.

2.5.2 Compatibility and Genericity

While initially motivated by an MSR application (molten salt/helium), the `BisubLiqGas` model is structured for broader applicability. The choice of liquid and gas substances can be adapted by replacing the specific component models, provided they adhere to the required base interfaces:

- **Liquid Substance**: The medium model for the liquid phase shall extend `Media.Interfaces.PartialLinearFluid`
- **Gas Substance**: The medium model for the gas phase shall extend `Media.`

`IdealGases.Common.SingleGasNasa` (or provide a compatible interface). While the base `SingleGasNasa` models can handle temperature-dependent properties, the enthalpy calculation within the `BisubLiqGas` mixing rules (Eq. (5)) currently assumes a constant specific heat capacity Cp_G (e.g., $5/2R_s$ for Helium) for simplicity in the implementation of inverse functions like `setState_phX`. This simplification should be considered when selecting or adapting the gas model for high-accuracy simulations over wide temperature ranges. The C_p for monatomic ideal gas is $5R/2$ and the value for diatomic ideal gas is $7R/2$.

2.5.3 Inherent Limitations

The use of the `BisubLiqGas` model is subject to the following fundamental limitations stemming from its core assumptions and implementation choices:

- **Component Model Validity**: The overall model validity is restricted to the pressure and temperature ranges where the chosen gas model (e.g., ideal gas behavior for Helium) and the chosen liquid model (e.g., linear approximation for the specific salt) remain acceptable representations of the real substance properties.
- **Non-Miscibility Assumption**: The assumption of perfect non-miscibility must hold. The model does not account for any solubility of the gas in the liquid or vice versa.
- **No Phase Change**: The model cannot simulate scenarios involving phase transitions (boiling, condensation, solidification, melting). Both substances are assumed to remain in their initial liquid or gas state.
- **Mixing Rule Approximations**: The linear mass-weighting rule (Eq. (7)) used for transport properties (dynamic viscosity η, thermal conductivity λ) and several thermodynamic properties (specific entropy s, specific heat capacities c_p, c_v, isentropic exponent γ, speed of sound a) is a significant simplification for non-miscible mixtures. The accuracy impact, especially for η, λ, and a, depends heavily on the specific substances and flow regime, and must be carefully evaluated for the target application.
- **Local Equilibrium Assumption**: The assumptions of local thermal and mechanical equilibrium (uniform T and p for both phases within a control volume) may break down in very rapid transients or highly heterogeneous flows.

Despite these limitations, the `BisubLiqGas` model provides a practical basis for studying dynamic system-level scenarios involving non-miscible liquid-gas mixtures where macroscopic phase separation is dominant, such as draining transients or tank pressurization/depressurization, using standard Modelica components.

3 Liquid state management

In this section, we will focus solely on the liquid substance and more specifically on the treatment of thermodynamic relationships and the handling of incompressibility aspects.

A terminological clarification is necessary because the use of the term incompressible is sometimes ambiguous. In this article, we will use the following terms with precise meanings:

- **Incompressible**: refers to a fluid whose density is constant (invariant with respect to all state variables)
- **Zero compressibility**: refers to a fluid whose isothermal compressibility is zero (or negligible), meaning that the density, which normally depends on temperature and pressure, does not vary with pressure but may vary with temperature

Let us recall that isothermal compressibility is defined by:

$$\chi_T = -\frac{1}{V} \cdot \left(\frac{\partial V}{\partial p}\right)_T = \frac{1}{\rho} \cdot \left(\frac{\partial \rho}{\partial p}\right)_T \tag{8}$$

In a single-species, single-phase fluid, the usual state variables are pressure, density, and temperature. Mass and energy balances provide equations for 2 of the 3 state variables. The closure equation is given by the fluid properties, particularly its equation of state.

The problem with liquids is that the equation of state often results in very small variations of density with pressure (low isothermal compressibility). This can cause numerical issues because pressure is often used as an explicit variable in state functions where density appears more in balance equations. We name an explicit variable one that is used as input to state functions. In this article, the following approaches will be defined and compared:

- Incompressible approach
- Semi-incompressible approach where density remains constant except in the mass conservation equation and in the buoyancy term of momentum conservation, where it is only a function of temperature. This is the counterpart of the Boussinesq approximation for system-scale calculations.
- Zero compressibility approach (density independent of pressure but dependent on temperature)
- Zero compressibility approach combined with the elimination of pressure force work in the internal energy and enthalpy relationships used in the energy balance

DOI 10.3384/ecp218313

The objective is to study the impact of deviations from rigorous thermodynamic relationships in favor of potentially better numerical performance.

3.1 Mathematical descriptions of the liquid state equations

First, let's establish the differentials of thermodynamic relations as functions of pressure and temperature.

3.1.1 Density

$$d\rho = \left(\frac{\partial \rho}{\partial p}\right)_T \cdot dp + \left(\frac{\partial \rho}{\partial T}\right)_p \cdot dT \tag{9}$$

By introducing the definition of isothermal compressibility χ_T (Eq. 8) and the definition of the isobaric thermal expansion coefficient α (Eq. 10), we obtain the differential of density (Eq. 11):

$$\alpha = \frac{1}{V} \cdot \left(\frac{\partial V}{\partial T}\right)_p = -\frac{1}{\rho} \cdot \left(\frac{\partial \rho}{\partial T}\right)_p \tag{10}$$

α can be expressed using the density ρ instead of the volume V by applying the variable change $V = m/\rho$. The mass contained in the volume being constant during the transformation.

$$d\rho = \rho \cdot (\chi_T \cdot dp - \alpha \cdot dT) \tag{11}$$

3.1.2 Internal Energy

Specific internal energy, often used for isochoric transformations and expressed as a function of temperature and density, can also be expressed as a function of pressure and temperature.

The Gibbs identity is given by:

$$dU = T \cdot dS - p \cdot dV \tag{12}$$

We assume that entropy S and volume V are functions of temperature T and pressure p :

$$S = S(T,p), \quad V = V(T,p) \tag{13}$$

By injecting the differentials of the expressions of S and V into the identity of dU (Eq. 12), we obtain:

$$\left(\frac{\partial U}{\partial T}\right)_p = T \cdot \left(\frac{\partial S}{\partial T}\right)_p - p \cdot \left(\frac{\partial V}{\partial T}\right)_p \tag{14}$$

$$\left(\frac{\partial U}{\partial p}\right)_T = T \cdot \left(\frac{\partial S}{\partial p}\right)_T - p \cdot \left(\frac{\partial V}{\partial p}\right)_T \tag{15}$$

Simplifying the partial derivative with respect to temperature by introducing the heat capacity coefficient (at constant pressure (Eq. 16)):

$$C_p = T \cdot \left(\frac{\partial S}{\partial T}\right)_p \tag{16}$$

the partial derivative of the internal energy can be expressed as function of α (Eq. 10) and C_p (Eq. 16):

$$\left(\frac{\partial U}{\partial T}\right)_p = C_p - p \cdot V \cdot \alpha \tag{17}$$

Continuing with the partial derivative with respect to pressure. To simplify the expression, we use one of Maxwell's relations.

$$\left(\frac{\partial S}{\partial p}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_p \tag{18}$$

By injecting this relation into the expression of $\left(\frac{\partial U}{\partial p}\right)_T$, we obtain:

$$\left(\frac{\partial U}{\partial p}\right)_T = -T \cdot \left(\frac{\partial V}{\partial T}\right)_p - p \cdot \left(\frac{\partial V}{\partial p}\right)_T \tag{19}$$

We can now simplify this relation by introducing the isobaric thermal expansion coefficient α (Eq. 10) and the isothermal compressibility coefficient χ_T (Eq. 8).

$$\left(\frac{\partial U}{\partial p}\right)_T = -\alpha \cdot T \cdot V \; + \; p \cdot V \cdot \chi_T \tag{20}$$

Finally, let's express the differential of internal energy using only these coefficients.

$$dU = (C_p - \alpha \cdot p \cdot V) \cdot dT + (-\alpha \cdot T \cdot V + p \cdot V \cdot \chi_T) \cdot dp \tag{21}$$

This expression is general and applies to any real fluid as long as the volume can be expressed as a function of T and p. This equation remains valid when all extensive quantities are expressed per unit mass.

3.1.3 Enthalpy

$$dH = \left(\frac{\partial H}{\partial T}\right)_p \cdot dT + \left(\frac{\partial H}{\partial p}\right)_T \cdot dp \tag{22}$$

To determine the differential, let's combine the internal energy differential (Eq. 21) and a relation between enthalpy and internal energy (Eq. 23) and the differential of volume (Eq. **??**):

$$H = U + p \cdot V \tag{23}$$

$$dH = dU + p \cdot dV + V \cdot dp$$

When replacing dV by its differential (Eq. **??**) and simplifying by the compensating term, the differential of the enthalpy is obtained:

$$dH = C_p \cdot dT + V \cdot (1 - T \cdot \alpha) \cdot dp \tag{24}$$

This expression is the general differential form of specific enthalpy as a function of temperature and pressure, involving calorimetric and thermoelastic coefficients.

3.2 Mathematical descriptions of the studied approaches

3.2.1 Incompressible approach

Recall that in this approach, the density is constant and invariant with respect to all state variables ($\alpha = 0$ and $\chi_T = 0$):

The differentials of internal energy (Eq. 21) and enthalpy (Eq. 24) are then considerably simplified:

$$dU = C_p \cdot dT \tag{25}$$

$$dH = C_p \cdot dT + V \cdot dp \tag{26}$$

The problem with this approach comes from the impossibility of modeling natural circulation, density driven flows, because the driving force of the flow, induced by density variation, is zero. Therefore, we will introduce the semi-incompressible approach to tackle this problem.

3.2.2 Semi-incompressible approach

In this approach, the differentials of internal energy (25) and enthalpy (26) remain unchanged compared to the incompressible approach. Only the differential of density is modified. Actually this density relation is only used in the mass balance equation and in the buoyancy term of the momentum balance equation:

$$d\rho = -\rho \cdot \alpha \cdot dT \tag{27}$$

3.2.3 Zero compressibility approach

In this approach, the isothermal compressibility is zero ($\chi_T = 0$), which means that density is independent of pressure but can vary with temperature. From the differential of density (Eq. 11), we obtain:

$$d\rho = -\rho \cdot \alpha \cdot dT \tag{28}$$

The differentials of internal energy (Eq. 21) and enthalpy (Eq. 24) then become:

$$dU = (C_p - \alpha \cdot p \cdot V) \cdot dT \; - \; \alpha \cdot T \cdot V \cdot dp \tag{29}$$

$$dH = C_p \cdot dT + V \cdot (1 - \alpha \cdot T) \cdot dp \tag{30}$$

By noting that $\alpha \cdot p \cdot V \cdot dT = p \cdot dV$, we can find the classic form:

$$dH = dU \; + \; p \cdot dV \; + \; V \cdot dp \tag{31}$$

The zero compressibility approach is more realistic for liquids, where density variation with temperature is significant (allowing modeling of buoyancy effects), while variation with pressure is often negligible.

3.2.4 Neglected pressure work approach

In this approach, we maintain the zero compressibility assumption ($\chi_T = 0$), but we also assume that pressure work is negligible in the enthalpy equation, which means that enthalpy depends only on temperature:

$$dH = C_p \cdot dT \tag{32}$$

If we now calculate the differential of internal energy from the relationship between internal energy and enthalpy (Eq. 23), we obtain:

$$dU = C_p \cdot dT - p \cdot dV - V \cdot dp \tag{33}$$

With the zero compressibility assumption, we can express the differential of volume directly as a function of the differential of temperature which gives:

$$dU = (C_p - p \cdot V \cdot \alpha) \cdot dT \; - \; V \cdot dp \tag{34}$$

By comparing with the expression of dU obtained with the differential of internal energy assuming zero compressibility (Eq. 29), we can quantify the bias induced by this assumption of negligible pressure work. The bias is therefore:

$$\begin{aligned} \delta dU &= dU_{\delta W=0} - dU_{\chi_T=0} \\ &= -V \cdot dp - (-\alpha \cdot T \cdot V \cdot dp) \\ &= -V \cdot (1 - \alpha \cdot T) \cdot dp \end{aligned} \tag{35}$$

This simplified approach can be useful numerically, but it leads to a thermodynamic inconsistency that can affect the accuracy of the simulation, particularly in cases where pressure variations are significant.

3.3 Conservation equations

Let's establish the mass balance for a fixed volume of a single-species single-phase fluid.

DOI 10.3384/ecp218313

3.3.1 Conservation of mass

$$V \cdot \frac{\mathrm{d}\rho}{\mathrm{d}t} = \sum_{boundaries} \dot{m} \tag{36}$$

Since the mass flow rate is a function of pressure, it is preferable to choose pressure as one of the explicit variables. With the assumption of a single-phase fluid, it is preferable to take temperature as the second explicit variable.

The left term of the continuity equation (Eq. 36) expressed as a function of temperature and pressure derives using the differential of the density (Eq. 11):

The right term is a function of the mass flow rate at the boundaries of the volume. By simplifying the flow as non-inertial, the mass flow rate becomes exclusively a function of the pressure losses at the boundaries. The calculation of the pressure losses requires having the value of the density and temperature to calculate the transport properties.

$$\dot{m} = f(\Delta p, \rho, T) \tag{37}$$

According to the scheme used to compute the flow rate (upstream, centered, order 1, 2 etc), the indices of the density, temperature and pressure differ. However, the general form is preferred to study the non linear behavior. Please note that implicit forms can raised depending on the scheme used. For clarity sake, a simplified centered scheme can be used in this section.

Grouping the left and right terms, we obtain:

$$V \cdot \rho \cdot \left(\chi_T \cdot \frac{\mathrm{d}p}{\mathrm{d}t} - \alpha \cdot \frac{\mathrm{d}T}{\mathrm{d}t} \right) = \sum f(\Delta p, \rho, T) \tag{38}$$

Let's now apply the assumptions of the different approaches to this equation.

Incompressible approach: Since the density is constant, the derivatives of the density with respect to pressure and temperature are zero. The density is always used to calculate the pressure losses but is no longer a function of the explicit variables, so it is removed from the function "f". The equation (Eq. 38) becomes a simple algebraic equation.

$$0 = \sum f(\Delta p, T) \tag{39}$$

Semi-incompressible approach: Since the density is only a function of temperature, it can be removed from the function "f". The equation (Eq. 38) can be simplified to:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{\sum f(\Delta p, T)}{-\rho \cdot V \cdot \alpha} \tag{40}$$

We can clearly see with this approach that:

- The mass conservation equation becomes an equation for the time derivative of temperature
- The equation is linear and the derivative is explicit (does not depend on itself or on another time derivative)

Zero compressibility approach: The expression for density is exactly the same as for the semi-incompressible approach. The conclusions are therefore the same.

Neglected pressure work approach: The expression for density is exactly the same as for the semi-incompressible approach. The conclusions are therefore the same.

3.3.2 Conservation of energy

Let's apply the same process to the energy balance.

$$V \cdot \frac{\mathrm{d}(\rho \cdot u)}{\mathrm{d}t} = \sum_{boundaries} \dot{H} + \sum_{boundaries} \dot{Q} \tag{41}$$

For the energy balance, we will neglect external thermal inputs ($\sum \dot{Q}$). They do not change the conclusions.

The gross enthalpy flow $\dot{H}$ is the product of the mass flow rate and the specific enthalpy. From (Eq. 37), the mass flow rate can be expressed from the explicit variables:

$$\dot{H} = \dot{m} \cdot h = \sum f(\Delta p, \rho, T) \cdot h \tag{42}$$

According to the scheme used to compute the flow rate (upstream, centered, order 1, 2 etc), the indices of the density, temperature, pressure and enthalpy differ. However, the general form is preferred to study the non linear behavior. Please note that implicit forms can raised depending on the scheme used. For clarity sake, a simplified centered scheme can be used in this section.

Using Eq. 41 with the partial derivatives form and the Eq. 37:

$$\frac{\mathrm{d}p}{\mathrm{d}t} \cdot \rho \cdot V \cdot \left[\frac{\partial u}{\partial p} + u \cdot \chi_T \right] + \frac{\mathrm{d}T}{\mathrm{d}t} \cdot \rho \cdot V \cdot \left[\frac{\partial u}{\partial T} - u \cdot \alpha \right] = \sum (f(\Delta p, \rho, T) \cdot h) \tag{43}$$

Incompressible approach: Since density is constant and specific internal energy depends only on temperature, many partial derivatives become zero. Equation (43) becomes:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{\sum (f(\Delta p, T) \cdot h)}{\rho \cdot V \cdot c_p} \tag{44}$$

- The energy conservation equation becomes an equation for the time derivative of temperature

- The equation is linear and the derivative is explicit (does not depend on itself). However, the right-hand term is also a function of pressure via the specific enthalpy formula.

Semi-incompressible approach: Since density and specific internal energy depend only on temperature, many partial derivatives become zero. Equation (43) becomes:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{\sum(f(\Delta p, T)\cdot h)}{\rho \cdot V \cdot (c_p - \alpha \cdot u)} \tag{45}$$

The conclusions are identical to the incompressible approach. The only difference comes from the term in the denominator, which is corrected for the expansion effect.

Zero compressibility approach: The energy conservation equation (43) becomes:

$$\frac{\mathrm{d}p}{\mathrm{d}t}\cdot V\cdot(-\alpha\cdot T) + \frac{\mathrm{d}T}{\mathrm{d}t}\cdot\rho\cdot V\cdot\left[\left(c_p - \frac{p\cdot\alpha}{\rho}\right) - u\cdot\alpha\right] = \sum(f(\Delta p, T)\cdot h) \tag{46}$$

- The equations are linear and the derivative is explicit (does not depend on itself).
- The resolution of pressure is no longer an algebraic system but becomes an ordinary differential equation.

Zero compressibility + neglected pressure work approach: Since density and enthalpy depend only on temperature, the energy conservation equation (43) becomes:

$$\frac{\mathrm{d}p}{\mathrm{d}t}\cdot V\cdot\rho\cdot\left[\frac{\partial u}{\partial p}\right] + \frac{\mathrm{d}T}{\mathrm{d}t}\cdot V\cdot\left[\rho\cdot\frac{\partial u}{\partial T} + u\cdot\frac{\partial \rho}{\partial T}\right] = \sum f_2(\Delta p, T) \tag{47}$$

Note that for the formulation of internal energy, we cannot use equation (21) but (34), which derives from enthalpy without the pressure force work term. Moreover, the function f can be replace by f2 since the specific enthalpy depends only on temperature:

$$\frac{\mathrm{d}p}{\mathrm{d}t}\cdot(-V) + \frac{\mathrm{d}T}{\mathrm{d}t}\cdot\rho\cdot V\cdot\left[c_p - \frac{p\cdot\alpha}{\rho} - u\cdot\alpha\right] = \sum f_2(\Delta p, T) \tag{48}$$

3.4 Applicability of `TableBased` medium on these approaches

In this section, we will explain why the pre-existing generic `TableBased` medium of the MSL are not perfectly suited to our needs. All the four approaches presented in previous section cannot be reproduced with this medium by tuning the following parameters:

- singleState
- enthalpyOfT

For reminder, the definition of the singleState parameter is given in the MSL package `Media.UsersGuide.MediumUsage.Constants` and is as follows:

> singleState = true, if u and d are not a function of pressure, and thus only a function of a single thermal variable (temperature or enthalpy) and of Xi for a multiple substance medium. Usually, this flag is true for incompressible media. It is used in a model to determine whether 1+nXi (singleState=true) or 2+nXi (singleState=false) initial conditions have to be provided for a volume element that contains mass and energy balance.

For a purely incompressible approach, we must therefore have $singleState = true$. However, looking more closely at the system of equations, we find that $singleState = true$ is not always the right condition for the mass density and specific internal energy to depend only on temperature.

If $enthalpyOfT = false$, the function for calculating specific enthalpy (h_pT) becomes:

$$h = h_0 + \int_{T_0}^{T} cp\cdot dT + \frac{p - p_{ref}}{\rho}\cdot(1 - \alpha\cdot T) \tag{49}$$

If the density is constant (incompressible total), this expression simplifies to:

$$h = h_0 + \int_{T_0}^{T} cp\cdot dT + \frac{p - p_{ref}}{\rho} \tag{50}$$

The function for calculating specific internal energy with $singleState = true$ becomes:

$$u = h - \frac{p_{ref}}{\rho} \tag{51}$$

By substituting the expression for specific enthalpy, we obtain:

$$\begin{aligned} u &= h_0 + \int_{T_0}^{T} cp\cdot dT + \frac{p - p_{ref}}{\rho} - \frac{p_{ref}}{\rho} \\ u &= h_0 + \int_{T_0}^{T} cp\cdot dT + \frac{p}{\rho} \end{aligned} \tag{52}$$

We can clearly see that the pressure is always present in the expression for specific internal energy. On the contrary, if $singleState = false$, the function for calculating specific internal energy becomes:

$$\begin{aligned} u &= h_0 + \int_{T_0}^{T} cp\cdot dT + \frac{p - p_{ref}}{\rho} - \frac{p}{\rho} \\ u &= h_0 + \int_{T_0}^{T} cp\cdot dT - \frac{p_{ref}}{\rho} \end{aligned} \tag{53}$$

DOI 10.3384/ecp218313

In this case, specific internal energy and mass density are well independent of pressure. **However, we have the opposite behavior compared to what the user expects**. Moreover, this can cause problems with initialization because with singleState = false, the pressure is initialized in the capacitive components but has no inertial term.

If now $enthalpyOfT = true$ and $singleState = true$, the function to calculate specific enthalpy (h_T) becomes:

$$h = h_0 + \int_{T_0}^{T} cp \cdot dT \tag{54}$$

and the specific internal energy (u_T) becomes:

$$u = h_0 + \int_{T_0}^{T} cp \cdot dT - \frac{p_{ref}}{\rho} \tag{55}$$

Since the mass density is constant, the expression is independent of pressure.

The **semi-incompressible approach** could be modeled with the TableBased medium in the MSL. It would require forcing the constant $DensityOfT = false$ even though the density is a function of temperature. Indeed, the constantis defined as $DensityOfT = size(tableDensity, 1) > 1$. The parameters would then be:

- singleState = false
- enthalpyOfT = false
- densityOfT = false

The approach of **zero compressibility** cannot be modellable with the TableBased medium in the MSL even with the following parameters:

- singleState = false
- enthalpyOfT = false
- densityOfT = true

Introducing the (49) in the expression $u = h - \frac{p}{\rho}$, it can be remarked that there is the missing following term, which is a correction term of the specific heat capacity (check (29)) in the specific internal energy expression:

$$\int_{T_0}^{T} -\alpha \cdot \frac{p}{\rho} \cdot dT$$

Similarly, the approach of **zero compressibility + neglected pressure work** cannot be modeled with the TableBased medium in the MSL for the same reason than for the zero compressibility approach.

Based on the analysis operated in this section, our further developments must concern the modeling of a own liquid medium for the bisubtance model rather than using an existing medium from the Modelica Standard Library (MSL) in order to:

- Build expertise in medium development
- Have total control over the approximations made
- The TableBased medium in the MSL rebuilds polynomials from data points. It does not allow defining arbitrary relationships between variables.

4 Comparison of approaches applied to a flow in a vertical pipe

Let us now attempt to quantify the differences between the approaches by applying them to a simple case: the flow in a vertical adiabatic pipe. In this article, we will focus exclusively on the theoretical study. A further study is ongoing and will contain the practical comparison using an equivalent Modelica model, compiled and executed with OpenModelica.

Suppose a perfectly adiabatic vertical pipe filled with an inert liquid fluid (no heat production). Let's start by assuming that the fluid is static. We can generalize later. The conservation of energy gives us an invariance of the sum of enthalpy and potential energy of gravity.

$$dH + m \cdot g \cdot dz = 0 \tag{56}$$

Replacing dH by its exact expression:

$$C_p \cdot dT + V \cdot (1 - T \cdot \alpha) \cdot dp + m \cdot g \cdot dz = 0 \tag{57}$$

We can express dp in terms of dz using the hydrostatic relation:

$$dp = -\rho \cdot g \cdot dz \tag{58}$$

The conclusions remain valid even when introducing a term for pressure loss: $dp = -\rho\ g\ dz\ -\ dp_{loss}$

$$C_p \cdot dT + V \cdot (1 - T \cdot \alpha) \cdot (-\rho \cdot g \cdot dz) + m \cdot g \cdot dz = 0 \tag{59}$$

By simplifying the terms that cancel out and dividing by the mass ($m = \rho\ V$), we obtain:

$$c_p \cdot dT + T \cdot \alpha \cdot g \cdot dz = 0 \tag{60}$$

We can therefore determine the temperature variation as a function of height variation:

$$\frac{dT}{dz} = \frac{-\alpha \cdot T \cdot g}{c_p} \tag{61}$$

NB: With a mass density that depends on temperature, a temperature change induces a change in mass density. By mass conservation, in steady state, this induces a change in flow rate, hence kinetic energy. The energy balance should therefore be written:

$$H + \frac{1}{2} \cdot m \cdot V^2 + m \cdot g \cdot (z - z_0) = \text{constant} \tag{62}$$

We choose to neglect the effects of kinetic energy for simplicity.

For a real transformation with fluid displacement, we make a change of variable to make the pressure loss term appear in the hydrostatic equation (58). In practice, a pressure loss always has a negative value. However, we assume that an eventual flow would be in the "z" direction. This avoids introducing vectors and allows us to only look at values.

$$\frac{dT}{dz} = \frac{-\alpha \cdot T \cdot g}{c_p} + \frac{(1-\alpha \cdot T) \cdot dp_{loss}}{\rho \cdot c_p} \tag{63}$$

Let's now consider the case where the fluid is incompressible ($\alpha = 0$) :

$$\frac{dT}{dz} = \frac{dp_{loss}}{\rho \cdot c_p} \tag{64}$$

In this case, the temperature can only increase (since $dp_{loss} < 0$) and depends only on the pressure loss. We clearly see here the irreversibility of the conversion of mechanical pressure energy into thermal energy.

The bias on the temperature gradient induced by the assumption of incompressibility is therefore of the order of $\frac{\alpha \cdot T \cdot g}{c_p}$.

Let's now consider the case where the pressure term is negligible in the enthalpy, i.e., $dH(T) = C_p \cdot dT$:

$$C_p \cdot dT + m \cdot g \cdot dz = 0 \tag{65}$$

$$\frac{dT}{dz} = \frac{-g}{c_p} \tag{66}$$

In this case, the temperature no longer depends on the pressure loss. It depends only on height.

The ongoing comparison of the approaches with OpenModelica is using a "DynamicPipe" component from the Modelica Standard library (MSL) coupled with a "pressure" sink at the pipe outlet (top part of the vertical pipe). The inlet conditions studied are of kind source of mass (and the necessary potential variables) flow and source of pressure (and the necessary potential variables).

5 Conclusion

This paper has addressed two key challenges in thermal-hydraulic system modeling: (1) the creation of a generic non-miscible liquid-gas medium that integrates with standard Modelica component libraries, and (2) the investigation of different approaches to model liquid incompressibility through detailed mathematical analysis.

The developed `BisubLiqGas` medium effectively represents systems that transition between fully liquid, fully gaseous, or mixed states, maintaining compatibility with standard components. This allows simulation of important scenarios like draining or leak management in systems such as Molten Salt Reactors. The model's generic structure enables adaptation to various liquid-gas pairs beyond the initial molten salt/helium application.

Our detailed mathematical analysis of different incompressibility approaches revealed significant implications for equation structure and numerical performance:

- The pure incompressible approach, while offering the simplest equation structure (algebraic pressure resolution), cannot model natural convection effects due to its constant density assumption.
- The semi-incompressible approach enables temperature-dependent density variations essential for buoyancy-driven flows, converting mass conservation into an explicit differential equation for temperature.
- The zero compressibility approach provides greater thermodynamic rigor but transform pressure resolution from algebraic to differential equations, increasing system complexity.
- The neglected pressure work variant offers numerical simplification but introduces thermodynamic inconsistencies that may affect accuracy in systems with significant pressure variations.

The theoretical analysis of vertical pipe flow demonstrated quantifiable differences between approaches. For instance, the temperature gradient bias induced by incompressibility assumptions is of the order $\frac{\alpha \cdot T \cdot g}{c_p}$, while neglecting pressure work in enthalpy leads to temperature gradients that depend solely on elevation rather than pressure losses.

This analysis revealed fundamental limitations of existing MSL `TableBased` media for implementing these approaches, particularly the counterintuitive behavior of the `singleState` parameter and the inability to represent zero compressibility formulations correctly. This justifies the development of specialized media rather than relying on generic table-based implementations.

These findings highlight the inherent trade-offs between physical accuracy and numerical efficiency in fluid modeling. The choice of incompressibility approach should be guided by the specific requirements of the application: natural convection modeling necessitates at least the semi-incompressible approach, while systems without significant buoyancy effects may benefit from the numerical advantages of the simpler incompressible model.

Future work will focus on implementing and validating these theoretical approaches in practical Modelica simulations, quantifying their performance differences in large-scale system models, and extending the analysis to more

DOI 10.3384/ecp218313

complex flow configurations. Additionally, exploring more sophisticated mixing rules for transport properties in the non-miscible medium would enhance the model's accuracy for specialized applications.

Acknowledgements

We acknowledge Pierre Lassausset from NAAREA for bringing to their attention the first problem investigated in this paper: the development of a single liquid-gas medium compatible with existing `Fluid` components. We are grateful to BLUE CAPSULE, a start-up developing a natural circulation Sodium-cooled reactor concept, and to NAAREA, a start-up developing a Molten Salt Reactor (MSR) concept, for the opportunities to explore these topics and contribute to MODELICA development within the academic community.

Abstract

Modeling pumps in 1D flows in Modelica is not new. In this paper a new approach is presented that can be used for general centrifugal pumps as well as centrifugal pumps based on measurement data for the DLR Thermofluid Stream (TFS) Library. The presented model uses affinity laws for good scaling. This approach allows to predict the pump behavior also for pumps where no measurement data exist based on data from similar pumps. The models are designed with focus on numerically robustness and focus on normal pump operation. They avoid nonlinear equation systems and can be initialized at zero mass flow rate and/or zero speed. Furthermore care has been taken that extrapolation of the pump data outside the data range is robust without interpolation artifacts. A pump surge example demonstrates that the TFS can handle instationary abnormal pump behavior like surge limit cycles by default without any further modifications needed.

Keywords: Centrifugal Pump; Hydraulic Transients; Thermal Modeling; Thermofluid Stream; TFS

1 Introduction

The pump models available in the Thermofluid Stream (TFS) Library (Zimmer 2020; Zimmer, Meißner, and Weber 2022) have been used for simple modeling tasks. However, in order to create more realistic pumps or pumps based on real measurement data, we have found that current models do not meet all the requirements needed by industry. Therefore, new pump models have been developed that are more realistic. These models are in contrast to the models from Modelica.Fluid, since they avoid division by zero. Furthermore they avoid using polynomials of high degree for interpolation, which can cause oscillation at the edges of the interpolation interval known as *Runge's phenomenon*, see (Trefethen 2019). There exists extensive literature on pump modeling, well known german-language books are e.g. (Gülich 2010) or (Sigloch 2013), and english-language books are e.g. (Stepanoff 1957) or (Karassik et al. 2007). Furthermore it might be worth mentioning (Chaudhry 2014) focusing on hydraulic transients. In Modelica pump models are part of fluid libraries as Modelica.Fluid (Casella et al. 2006), the Buildings Library (Wetter et al. 2014) or TIL Library (Richter 2008). Modelica.Fluid uses polynomial interpolation for head characteristic and either fixed efficiency or quadratic power characteristic. For the Buildings Library one can use spline interpolation of measurement data. The model incorporates several numerical workarounds to avoid singularities and ensure a unique solution (Wetter 2013). Alternatively a method based on the Euler Number can be used that requires only reference values at the point of best efficiency as inputs (Fu, Blum, and Wetter 2023). The TIL Library uses a quadratic head characteristic $h \sim \dot{V}|\dot{V}|$ that has an inflection point at zero flow and uses an empirical relation for the loss power.

First, subsection 2.1 introduces the centrifugal pump model. Subsequently in subsection 2.2 measurements of a sample development pump from the automotive supplier HELLA GmbH & Co. KGaA are used, to validate the pump model, see an example in Figure 1. These pumps, which are developed in several power classes from 80 W to 400 W, are used in battery electric cars to cool and heat several components (e.g. battery, electrical machine, cabin). In most cooling systems the pumps are integrated into a Coolant Control Hub (CCH) together with valves. The fluid used in these systems are mixtures of water and glyocol. In addition, the models have been validated against data from pumps available in the Modelica Buildings library (Wetter et al. 2014). In subsection 2.3 it is shown that centrifugal pump characteristics have great similarities. Hence realistic pump characteristics can be set up with minimum knowledge. Furthermore in section 3, a pump surge example demonstrates that the TFS can handle instationary abnormal pump behavior like surge limit cycles by default without any further modifica-

tions needed and without any numerical modifications of the pump characteristics necessary.

2 Centrifugal pump model

2.1 Basic equations

The centrifugal pump model is based on affinity laws that govern the scaling behavior of head $h \sim \omega^2$, discharge $\dot{V} \sim \omega$, and power $P \sim \rho\omega^3$ with respect to speed ω and fluid density ρ. These relationships, commonly referred to as homologous relationships, are detailed in any textbook on pumps e.g. (Stepanoff 1957; Karassik et al. 2007; Gülich 2010; Sigloch 2013). The model targets normal pump operating conditions characterized by $\dot{V}, \omega, h, P \geq 0$, as measurements for abnormal pump operating conditions are scarce and normal pump operating conditions are of primary interest. The model uses quadratic polynomials for the approximation of homologeous head h/ω^2 and homologeous power $P/(\rho\omega^3)$ as a function of homologeous discharge $\dot{V}/\omega$:

$$\frac{h}{\omega^2} = \tilde{c}_{h,0} + \tilde{c}_{h,1}\frac{\dot{V}}{\omega} + \tilde{c}_{h,2}\left(\frac{\dot{V}}{\omega}\right)^2, \quad (1)$$

$$\frac{P}{\rho\omega^3} = \frac{\tau\omega}{\rho\omega^3} = \tilde{c}_{P,0} + \tilde{c}_{P,1}\frac{\dot{V}}{\omega} + \tilde{c}_{P,2}\left(\frac{\dot{V}}{\omega}\right)^2, \quad (2)$$

where τ denotes the torque, and $\tilde{\boldsymbol{c}}_h = (\tilde{c}_{h,0}, \tilde{c}_{h,1}, \tilde{c}_{h,2})^\mathsf{T}$ and $\tilde{\boldsymbol{c}}_P = (\tilde{c}_{P,0}, \tilde{c}_{P,1}, \tilde{c}_{P,2})^\mathsf{T}$ are non-dimensionless coefficients. The head characteristic of a centrifugal pump is based on the linear Euler characteristic and extended by accounting for friction and shock losses, which can be well approximated by quadratic terms for centrifugal pumps, see e.g. (Kallesøe 2005, eq. (3.19)), (Sigloch 2013, fig. 9.5), (Gülich 2010, fig. 4.3), (Stepanoff 1957, fig. 9.8). Similarly, the torque characteristic is also found to follow a quadratic relationship (Kallesøe 2005, eq. (3.24)).

Equation 1 and Equation 2 can be rewritten in terms of normalized variables as:

$$h_\mathrm{n} = c_{h,0}\omega_\mathrm{n}^2 + c_{h,1}\omega_\mathrm{n}\dot{V}_\mathrm{n} + c_{h,2}\dot{V}_\mathrm{n}^2, \quad (3)$$

$$P_\mathrm{n} = \omega_\mathrm{n}\tau_\mathrm{n} = \omega_\mathrm{n}\rho_\mathrm{n}\left(c_{P,0}\omega_\mathrm{n}^2 + c_{P,1}\omega_\mathrm{n}\dot{V}_\mathrm{n} + c_{P,2}\dot{V}_\mathrm{n}^2\right), \quad (4)$$

where $h_\mathrm{n} = h/h_\mathrm{ref}$, $\dot{V}_\mathrm{n} = \dot{V}/\dot{V}_\mathrm{ref}$, $\omega_\mathrm{n} = \omega/\omega_\mathrm{ref}$, $P_\mathrm{n} = P/P_\mathrm{ref}$, $\tau_\mathrm{n} = \tau/\tau_\mathrm{ref}$, and $\rho_\mathrm{n} = \rho/\rho_\mathrm{ref}$ are the normalized head, discharge, speed, power, torque, and fluid density, respectively, h_ref, $\dot{V}_\mathrm{ref}$, ω_ref, $P_\mathrm{ref} = \tau_\mathrm{ref}\omega_\mathrm{ref}$, and ρ_ref are the corresponding reference values and $\boldsymbol{c}_h = (c_{h,0}, c_{h,1}, c_{h,2})^\mathsf{T}$ and $\boldsymbol{c}_P = (c_{P,0}, c_{P,1}, c_{P,2})^\mathsf{T}$ are dimensionless coefficients.

From a mathematical perspective, reference values can be chosen arbitrarily. In practice, however, they are chosen at the point of best efficiency, also referred to as the rated conditions (Chaudhry 2014, sec. 4.3), (Stepanoff 1957). This normalization facilitates the comparison of different pumps, as similar pumps will exhibit similar normalized characteristics. The effect of impeller diameter D on performance, described by head $h \sim D^2$, discharge $\dot{V} \sim D^3$, and power $P \sim D^5$, is implicitly accounted for through these reference quantities. Therefor pump scaling can be accomplished by adapting the reference values accordingly.

An additional advantage of Equation 3 and Equation 4 is the avoidance of division by zero at zero discharge $\dot{V} = 0$ and/or zero speed $\omega = 0$, which is essential for initializing simulations from rest. This contrasts with models within `Modelica.Fluid`, as noted in (Wetter 2013). Furthermore, using polynomials of degree higher than two would either violate the affinity laws or necessitate additional numerical handling to prevent division by zero.

It is also worth noting that, unlike in (Wetter 2013), Equation 3 is not constrained to be monotonically decreasing. Although the presence of a maximum can lead to dynamic instability to be avoided in practice, it is a physically observed phenomenon for centrifugal pumps. While steady-state solvers may fail to converge at this point, the TFS library does not assume steady-state conditions. Instead, it incorporates the fluid inertia by default and is capable of capturing transient behaviors such as surge limit cycles. Consequently, the numerical workarounds described in (Wetter 2013) become unnecessary. Nevertheless, Equation 3 and Equation 4 require modification to qualitatively account for reverse operation with discharge $\dot{V} < 0$, as discussed in section 3. In order to quantitatively cover all four quadrants of pump operation, it might be worthwhile to integrate the approach presented in (Chaudhry 2014, sec. 4.3) into the TFS in the future. Finally, pump efficiency is defined as $\eta = \rho g h \dot{V}/P$, where g is the standard gravitational acceleration.

2.2 Approximation based on measurement data

The six coefficients of the quadratic head and power approximation polynomials $\boldsymbol{c}_h = (c_{h,0}, c_{h,1}, c_{h,2})^\intercal$ and $\boldsymbol{c}_P = (c_{P,0}, c_{P,1}, c_{P,2})^\intercal$ can each be determined by solving a quadratic polynomial regression, i.e. solving the linear equation systems $\boldsymbol{A}^\intercal\boldsymbol{A}\boldsymbol{c}_h = \boldsymbol{A}^\intercal\boldsymbol{b}_h$ and $\boldsymbol{A}^\intercal\boldsymbol{A}\boldsymbol{c}_P = \boldsymbol{A}^\intercal\boldsymbol{b}_P$ for the coefficients $\boldsymbol{c}_h$ and $\boldsymbol{c}_P$ respectively, where the matrix elemets $A_{ij} = (\dot{V}_i/(\dot{V}_{\mathrm{ref}}\omega_{\mathrm{n},i}))^{j-1}$ and the vector elements $b_{h,i} = h_i/(h_{\mathrm{ref}}\omega_{\mathrm{n},i}^2)$ and $b_{P,i} = P_i/(P_{\mathrm{ref}}\omega_{\mathrm{n},i}^3)$. Thereby h_i, $\dot{V}_i$, ω_i and P_i are measurements of head, discharge, speed and power respectively and $\omega_{\mathrm{n},i} = \omega_i/\omega_{\mathrm{ref}}$ is the normalized measured speed. If only measurements at reference speed ω_{ref} are used, the normalized speed $\omega_{\mathrm{n},i} = 1$. The reference quantities h_{ref}, $\dot{V}_{\mathrm{ref}}$ and P_{ref} can e.g. be defined at maximum measured efficiency $\eta_{\mathrm{ref}} = \max \rho g h_i \dot{V}_i / P_i$, which has advantages that are shown subsequently. In addition reference quantities improve the condition number of the matrix $\boldsymbol{A}$, since coefficients $\boldsymbol{c}_h$ and $\boldsymbol{c}_P$ are then dimensionless and approximately of the same magnitude.

Figure 2 shows measurements and approximation polynomials of a sample development pump from the automotive supplier HELLA GmbH & Co. KGaA. It shows head h, efficiency η and power P in dependency of discharge $\dot{V}$ and normalized head h/ω_{n}^2, efficiency η and normalized power P/ω_{n}^3 in dependency of normalized discharge $\dot{V}/\omega_{\mathrm{n}}$. The reference speed was arbitrarily chosen as $\omega_{\mathrm{ref}} = 5440\,\mathrm{rpm}$ and the reference density $\rho_{\mathrm{ref}} = 1000\,\mathrm{kg/m^3}$. Different colors refer to different speeds ω and measurement data are highlighted with markers. Approximation 1 (solid) is based on measurements at reference speed $\omega_{\mathrm{ref}} = 5440\,\mathrm{rpm}$ only. In contrast approximation 2 (dashed) is based on measurements at all eight speeds $\omega = 2040\,\mathrm{rpm}$ to $6800\,\mathrm{rpm}$. Figure 2 shows that a transformation based on affinity laws projects the head, efficiency and power maps well onto single curves, i.e. the homologeous quantities can be well expressed as a function of homologeous discharge $\dot{V}/\omega_{\mathrm{n}}$. This is especially true for the head h. In contrast applying affinity laws for power P overestimates the efficiency η for low speeds, but the results might still be accurate enough if off design power at low speed is of minor importance. Also note that the available torque data at those low speeds had only one significant digit.

If reference power P_{ref} is defined as $P_{\mathrm{ref}} = \rho_{\mathrm{ref}} g h_{\mathrm{ref}} \dot{V}_{\mathrm{ref}}/\eta_{\mathrm{ref}}$ one can derive that the efficiency:

$$\eta = \eta_{\mathrm{ref}} \frac{x + c_h x^2 - (1 + c_h) x^3}{c_{P,1} + c_{P,2} x + c_{P,3} x^2}, \tag{5}$$

where $x = \dot{V}_{\mathrm{n}}/\omega_{\mathrm{n}}$ is the homologeous discharge. Hence applying affinity laws yields efficiency $\eta \sim \dot{V}/\omega$, as already shown in Figure 2. Consequently according to affinity laws efficiency $\eta \sim \dot{V}/\sqrt{h}$, since head $h \sim \omega^2$. Therefor curves of constant efficiency η are parabolas $h = c(\eta)\dot{V}^2$, where $c(\eta)$ is a parameter, see e.g. (Sigloch 2013, sec. 9.2).

Figure 3 shows the approximated map of a sample development pump from the automotive supplier HELLA GmbH & Co. KGaA based on measurements at reference speed $\omega_{\mathrm{ref}} = 5440\,\mathrm{rpm}$ only (equivalent to approximation 1 in Figure 2) and extended using affinity laws. Solid lines thereby refer to the same curves of constant speed ω as displayed in Figure 2. The reference speed line $\omega = \omega_{\mathrm{ref}}$ is displayed as thick solid. Dashed lines refer to parabolas of constant efficiency η and numbers 0.2, 0.5, 0.8, 0.9, 0.95 and 1 refer to the ratio of efficiency to peak efficiency η/η_{ref}. The peak efficiency curve $\eta = \eta_{\mathrm{ref}}$ is displayed as thick dashed.

Even if the dashed parabolas of constant efficiency in Figure 3 represent the principal pump behavior, it is well known that the efficiency decreases for off design speeds $\omega > \omega_{\mathrm{ref}}$ and $\omega < \omega_{\mathrm{ref}}$, yielding the well known pump map shape, see e.g. (Sigloch 2013, fig. 9-14). This is not yet considered by the model, but by means of a simple modification the model could in the future be improved by a efficiency reduction coefficient $c(\omega) \leq 1$ reducing the peak efficiency of individual speed curves $\eta_{\mathrm{ref}}(\omega) = c(\omega)\eta_{\mathrm{ref}}(\omega_{\mathrm{ref}})$.

Figure 2 furthermore shows, that for (radial flow) centrifugal pumps quadratic polynomials are suitable for the approximation. However note, that quadratic polynomials may not be suitable to approximate pumps with higher specific speed, e.g. mixed flow or axial flow pumps, since their characteristics may differ considerably, see e.g. (Sigloch 2013, fig. 9-16). Specific speed is thereby defined as (Chaudhry 2014):

$$\omega_{\mathrm{specific}} = \omega \sqrt{\frac{\dot{V}}{\sqrt{gh}^3}}. \tag{6}$$

Note that the sample development pump from the automotive supplier HELLA GmbH & Co. KGaA has a specific speed of 0.406.

Figure 4 shows mean relative errors of the approximations as shown in Figure 2 for series of measurements at constant speed ω. Colors correspond to head h (blue), power P (red) and efficiency η (black). As in Figure 2 approximation 1 (solid) is also in Figure 4 based on measurements at reference speed $\omega_{\mathrm{ref}} = 5440\,\mathrm{rpm}$ only and approximation 2 (dashed) is based on measurements at all eight speeds $\omega = 2040\,\mathrm{rpm}$ to $6800\,\mathrm{rpm}$. Figure 4 shows that the mean relative error regarding head h is for all speeds about one order of

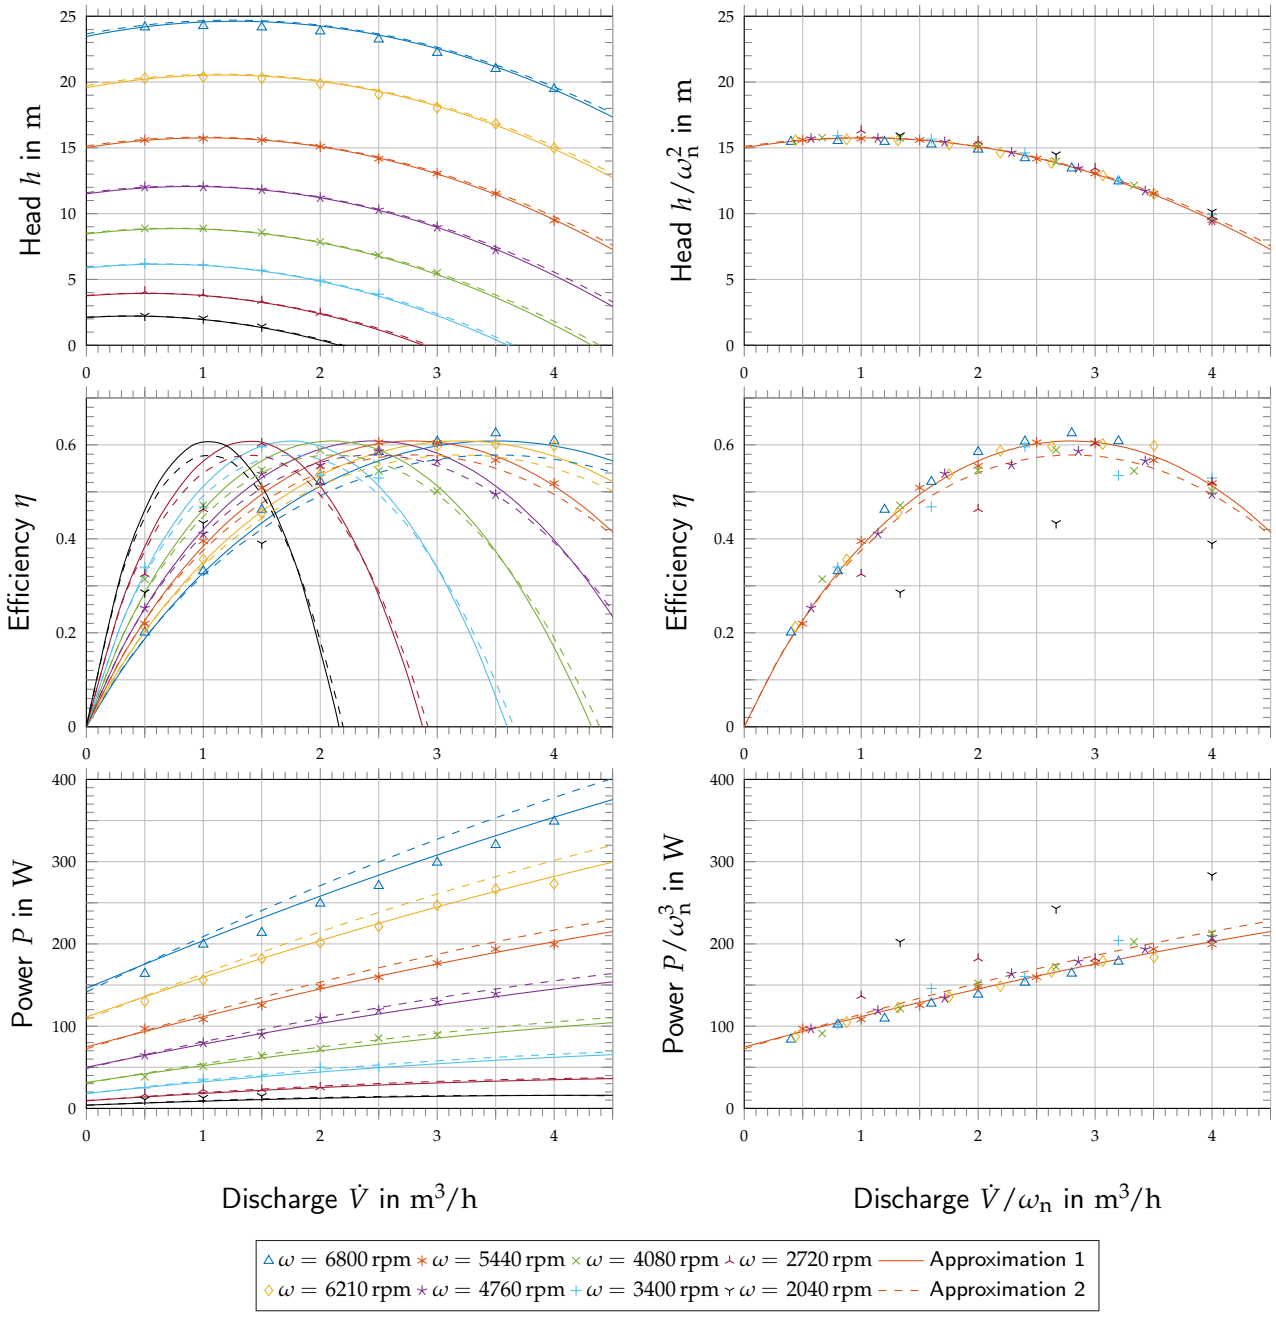

Figure 2. Measurements and approximation polynomials of a sample development pump from the automotive supplier HELLA GmbH & Co. KGaA.

magnitude smaller than the mean relative error regarding power P and efficiency η. The strongest outlier regarding head h is only 6.0 % and 4.0 % off for approximation 1 and 2 respectively, which is remarkable considering that the available head data at low speeds had only 2 significant digits. Including measurements at all eight speeds changes the mean error on average only slightly from $\mathrm{err}_{h,\mathrm{ap1}} = 1.5\,\%$ to $\mathrm{err}_{h,\mathrm{ap2}} = 1.3\,\%$ regarding head h, from $\mathrm{err}_{P,\mathrm{ap1}} = 8.2\,\%$ to $\mathrm{err}_{P,\mathrm{ap2}} = 8.7\,\%$ regarding power P, and from $\mathrm{err}_{\eta,\mathrm{ap1}} = 9.4\,\%$ to $\mathrm{err}_{\eta,\mathrm{ap2}} = 7.7\,\%$ regarding efficiency η, where the subscripts $(\bullet)_{\mathrm{ap1}}$ and $(\bullet)_{\mathrm{ap2}}$ refer to the first and second approximation respectively. This demonstrates that the approximation can not really be improved by including measurements at different speeds. However both approximations yield significant errors concerning power and efficiency of up to 40 % at low speeds, which highlights the need to extend the model as previously mentioned, if off design power and efficiency at low speeds matter.

2.3 Comparison of centrifugal pumps

A convenient way to obtain the six head and power coefficients $\boldsymbol{c}_h$ and $\boldsymbol{c}_P$ can be achieved by defining:

DOI 10.3384/ecp218325

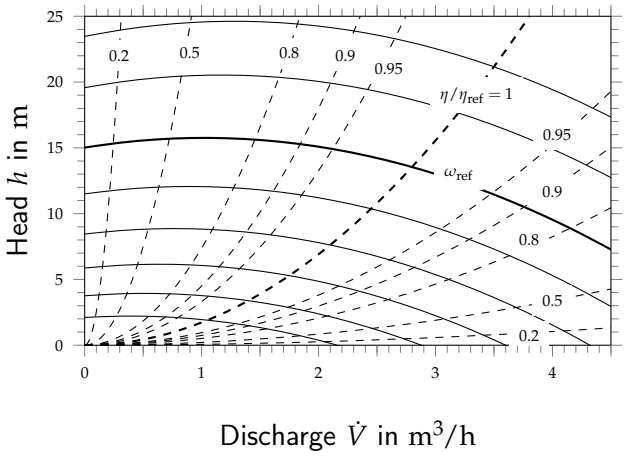

Figure 3. Map of a sample development pump from the automotive supplier HELLA GmbH & Co. KGaA.

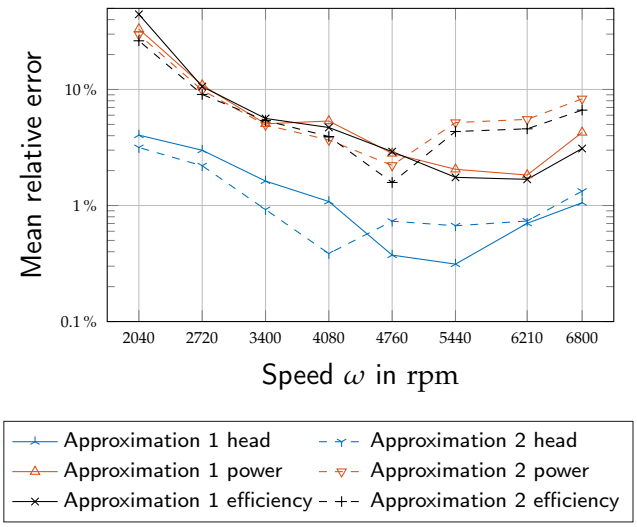

Figure 4. Mean relative errors of the approximations as shown in Figure 2 for series of measurements at constant speed ω.

1. the peak efficiency η_{ref}
2. the head at peak efficiency h_{ref}
3. the discharge at peak efficiency $\dot{V}_{\text{ref}}$
4. the normalized head at zero discharge $h_{0,\text{n}}$
5. the normalized discharge at zero head $\dot{V}_{0,\text{n}}$
6. the normalized power at zero discharge $P_{0,\text{n}}$

Items 2 to 5 provide three equations for the head coefficients $\boldsymbol{c}_h$, which yield:

$$c_{h,0} = h_{0,\text{n}}\,, \tag{7}$$

$$c_{h,1} = \frac{\dot{V}_{0,\text{n}}}{\dot{V}_{0,\text{n}} - 1} - h_{0,\text{n}} \frac{\dot{V}_{0,\text{n}} + 1}{\dot{V}_{0,\text{n}}}\,, \tag{8}$$

$$c_{h,2} = \frac{h_{0,\text{n}}}{\dot{V}_{0,\text{n}}} - \frac{1}{\dot{V}_{0,\text{n}} - 1}\,, \tag{9}$$

Table 1. Parameters of approximation 1 (ap1) and approximation 2 (ap2) of the sample development pump from the automotive supplier HELLA GmbH & Co. KGaA. as shown in Figure 2. The reference speed $\omega_{\text{ref}} = 5440\,\text{rpm}$ and the reference density $\rho_{\text{ref}} = 1000\,\text{kg/m}^3$.

	h_{ref} in m	$\dot{V}_{\text{ref}}$ in m³/h	η_{ref} in %	$h_{0,\text{n}}$	$\dot{V}_{0,\text{n}}$	$P_{0,\text{n}}$
ap1	13.5	2.80	60.8	1.11	2.06	0.440
ap2	13.6	2.80	57.9	1.11	2.09	0.403

Table 2. Mean, standard deviation, minimum and maximum values of normalized head at zero discharge $h_{\text{n},0}$, normalized discharge at zero head $\dot{V}_{\text{n},0}$ and normalized power at zero flow $P_{\text{n},0}$ for 18 WILO pumps available in the Modelica Buildings Library (Wetter et al. 2014) .

	mean	std	min	max
$h_{0,\text{n}}$	1.273	±0.128	1.101	1.516
$\dot{V}_{0,\text{n}}$	1.946	±0.087	1.784	2.090
$P_{0,\text{n}}$	0.499	±0.099	0.372	0.677

and items 1 and 6 provide three more equations for the power coefficients $\boldsymbol{c}_P$, which yield:

$$c_{P,0} = P_{0,\text{n}}\,, \tag{10}$$

$$c_{P,1} = -2P_{0,\text{n}} + c_{h,0} - c_{h,2}\,, \tag{11}$$

$$c_{P,2} = P_{0,\text{n}} + c_{h,1} + 2c_{h,2}\,. \tag{12}$$

Table 1 summarizes the parameters of approximation 1 (ap1) and approximation 2 (ap2) of the sample development pump from the automotive supplier HELLA GmbH & Co. KGaA. as shown in Figure 2. Those six coefficients (plus reference speed $\omega_{\text{ref}} = 5440\,\text{rpm}$ and the reference density $\rho_{\text{ref}} = 1000\,\text{kg/m}^3$) are sufficient to fully describe the pump characteristic.

The benefit of this approach is, that head at design point h_{ref} and discharge at design point $\dot{V}_{\text{ref}}$ may vary for different pumps according to their requirements. For example the design points of the 18 WILO pumps available in the Modelica Buildings Library differ significantly: their peak head h_{ref} ranges from 1.4 m up to 22 m, their peak discharge ranges $\dot{V}_{\text{ref}}$ from 2.9 m³/h up to 73 m³/h, their peak power P_{ref} ranges from 27 W up to 4.2 kW and their peak efficiency η_{ref} ranges from 24 % up to 77 %. However the three coefficients: 1) normalized head at zero discharge $h_{\text{n},0}$, normalized discharge at zero head $\dot{V}_{\text{n},0}$ and normalized power at zero flow $P_{\text{n},0}$ differ much less as listed in Table 2. Hence normalized pump characteristics differ only to a medium degree as shown in Figure 5 for 18 WILO pumps available in the Modelica Buildings Library (Wetter et al. 2014). Colors in Figure 5 refer to different pumps and the pump characteristics based on mean parameters as

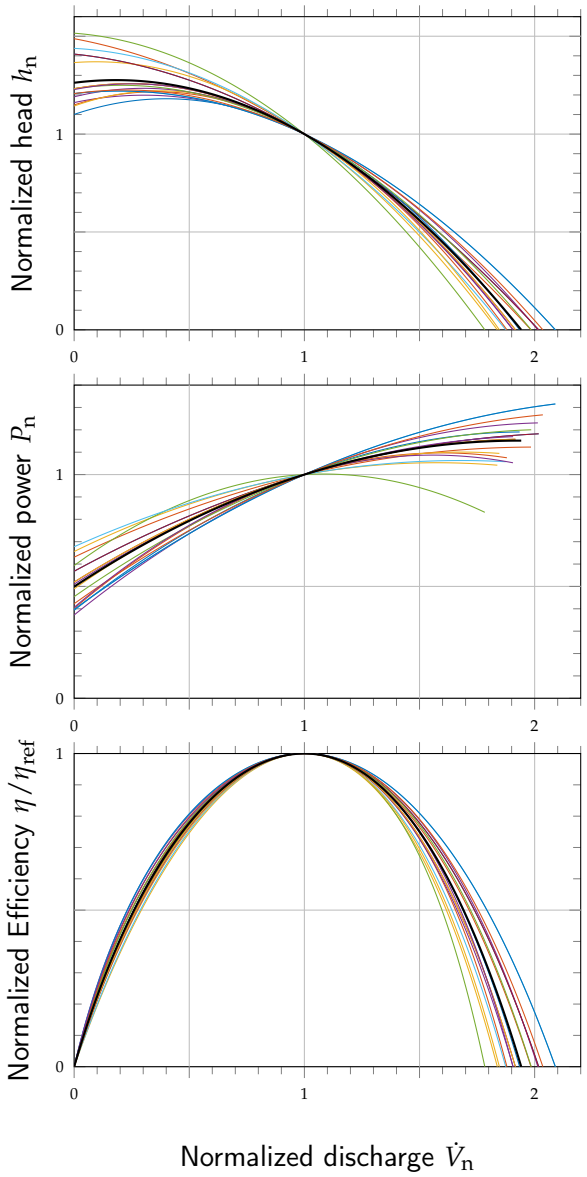

Figure 5. Comparison of 18 WILO pumps available in the Modelica Building Library (Wetter et al. 2014).

listed in Table 2 are marked thick black. The similarity is also based on the fact that the specific speed only varies from 0.42 to 1.21.

Note that (Sigloch 2013, sec. 9.2) also mentions a range of normalized power at zero flow of $P_{0,n} = 0.4$ to 0.6. The peak efficiency η_{ref} is also rather easy to predict where smaller and/or cheaper pumps usually reach lower peak efficiencies and larger, more efficient pumps can reach up to 90 % peak efficiency.

3 Example: Instationary behavior

To extend the pump map to negative discharge $\dot{V} < 0$, we adopt the head characteristic of Equation 3 by replacing the square term $\dot{V}_n^2$ by $\dot{V}_n|\dot{V}_n|$:

$$h_n = c_{h,0}\omega_n^2 + c_{h,1}\omega_n\dot{V}_n + c_{h,2}\dot{V}_n|\dot{V}_n|. \qquad (13)$$

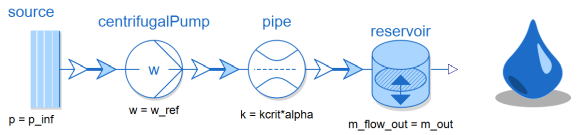

Figure 6. Exemplary system to investigate instationary pump behavior.

Note that this modification is a rather simple qualitative extension for negative discharge $\dot{V} < 0$ that is still able to predict the principle physical behavior as the quadratic term originates from friction that is $\sim \dot{V}|\dot{V}|$, see (Sigloch 2013, sec. 9.2). In order to quantitatively cover all four quadrants of pump operation, it might be worthwhile to integrate the approach presented in (Chaudhry 2014, sec. 4.3) into the TFS in the future.

Figure 6 shows an exemplary system to investigate instationary pump behavior. An open reservoir with a constant discharge `m_flow_out` $= \rho\dot{V}_{out}$ is fed through a flow resistance by a centrifugal pump at constant speed `w_ref` $= \omega_{ref}$. Depending on the constant discharge $\dot{V}_{out}$ and on the flow resistance the system may yield a limit cycle known as surge, such that the system does not reach a steady-state (Sigloch 2013, sec. 9.2). In this case the system can only be simulated when considering dynamic effects.

In the following we use head at zero discharge as new reference head $\hat{h}_{ref}$ and discharge at zero head as new reference discharge $\hat{V}_{ref}$:

$$\hat{h}_{ref} = h_{ref}c_{h,0}, \qquad (14)$$

$$\hat{V}_{ref} = \frac{\dot{V}_{ref}}{2c_{h,2}}\left(-c_{h,1} - \sqrt{c_{h,1}^2 - 4c_{h,0}c_{h,2}}\right), \qquad (15)$$

which simplifies Equation 13:

$$\hat{h}_n = \omega_n^2 + \hat{c}\omega_n\hat{\dot{V}}_n - (1+\hat{c})\hat{\dot{V}}_n|\hat{\dot{V}}_n|, \qquad (16)$$

where $\hat{h}_n = h/\hat{h}_{ref}$ and $\hat{\dot{V}}_n = \dot{V}/\hat{\dot{V}}_{ref}$ are normalized head and discharge and $\hat{c}$ is a coefficient:

$$\hat{c} = c_{h,1}\frac{h_{ref}\hat{\dot{V}}_{ref}}{\hat{h}_{ref}\dot{V}_{ref}}. \qquad (17)$$

The limit cycle can only occur when the discharge $\dot{V}_{out}$ is less than the critical discharge at maximum head $\dot{V}_{out} \leq \dot{V}_{crit}$. The corresponding critical normalized discharge can be derived based on the condition $\mathrm{d}\hat{h}_n/\mathrm{d}\hat{\dot{V}}_n = 0$ at reference speed $\omega_n = 1$ as:

$$\hat{\dot{V}}_{n,crit} = \frac{\hat{c}}{2(1+\hat{c})}. \qquad (18)$$

We consider a constant reservoir discharge $\dot{V}_{out} = 1/2\dot{V}_{crit}$ such that surge may occur depending on the system characteristics.

DOI 10.3384/ecp218325

Surge occurs, if the pump- and system characteristics do not intersect anymore. In the limiting case that means that pump- and system characteristics are tangential for the constant reservoir discharge $\dot{V}_{\text{out}}$:

$$\left.\frac{\mathrm{d}\hat{h}_{\text{p,n}}}{\mathrm{d}\hat{V}_{\text{n}}}\right|_{\hat{V}_{\text{out,n}}} = \left.\frac{\mathrm{d}\hat{h}_{\text{sys,n}}}{\mathrm{d}\hat{V}_{\text{n}}}\right|_{\hat{V}_{\text{out,n}}}, \tag{19}$$

where $\hat{h}_{\text{p,n}} = h_{\text{p}}/\hat{h}_{\text{ref}}$, $\hat{h}_{\text{sys,n}} = h_{\text{sys}}/\hat{h}_{\text{ref}}$ and $\hat{V}_{\text{out,n}} = \dot{V}_{\text{out}}/\hat{V}_{\text{ref}}$ are the normalized pump head, system head, and reservoir discharge.

To be able to derive analytical results later on, we assume a constant friction factor k for the system characteristics. Furthermore the normalized friction factor $\hat{k}$ is introduced:

$$\Delta p_{\text{sys}} = k\dot{m}\,|\dot{m}|\,, \tag{20}$$

$$\implies \hat{h}_{\text{sys,n}} = \hat{k}\hat{V}_{\text{n}}\left|\hat{V}_{\text{n}}\right|, \quad \hat{k} = k\frac{\rho\hat{V}_{\text{ref}}^2}{g\hat{h}_{\text{ref}}}. \tag{21}$$

Then Equation 19 yields the critical normalized friction factor $\hat{k}_{\text{crit}}$:

$$\hat{k}_{\text{crit}} = \frac{\hat{c}}{2|\hat{V}_{\text{out,n}}|} - (1+\hat{c}), \tag{22}$$

such that a normalized friction factor $\hat{k} \leq \hat{k}_{\text{crit}}$ yields surge.

Figure 7 shows simulation results of the exemplary system (Figure 6) for five different friction factors $k = \alpha k_{\text{crit}}$ with coefficient $\alpha = 0$, 0.5, 0.98, 1.02 and 2 (different colors). The ambient pressure `p_inf` $= p_\infty = 1\,\text{bar}$, the cross sectional area of the reservoir $A = 100\,\text{cm}^2$, the initial height of the reservoir $h_{\text{R},0} = 13\,\text{m}$, the initial pump discharge $\dot{V}(0) = 0\,\text{m}^3/\text{s}$, the density and reference density are $\rho = \rho_{\text{ref}} = 1000\,\text{kg}/\text{m}^3$ and the overall inertance $L = (4 \times 0.01)/\text{m}$. The constant reservoir discharge $\dot{V}_{\text{out}} = 0.5\dot{V}_{\text{crit}} = 0.512\,\text{m}^3/\text{h}$ yields a critical friction factor `kcrit` $= k_{\text{crit}} = 8.92 \times 10^4\,\text{Pa}\,\text{s}^2/\text{kg}^2$. The example is a second order system of nonlinear differential equations:

$$L\rho\frac{\mathrm{d}\dot{V}}{\mathrm{d}t} = \Delta p_{\text{p}} - (\Delta p_{\text{sys}} + \rho g h_{\text{R}}), \tag{23}$$

$$A\frac{\mathrm{d}h_{\text{R}}}{\mathrm{d}t} = \dot{V} - \dot{V}_{\text{out}}. \tag{24}$$

Note that the implicit part is linear (it is even diagonal and regular for $L, A \neq 0$), so it is a trivial task to solve the system for its states $\boldsymbol{x} = (\dot{V}, h_{\text{R}})^{\intercal}$, which is generally the case for the TFS.

Figure 7 shows that discharge $\dot{V}$ increases quickly from rest and reaches a quasi-static equilibrium shortly after initialization, since the flow rate dynamics limited by the inertance L are a lot faster than the reservoir dynamics and hence often the influence of the flow rate dynamics can be neglected and the system is quasi-static with respect to the flow rate dynamics.

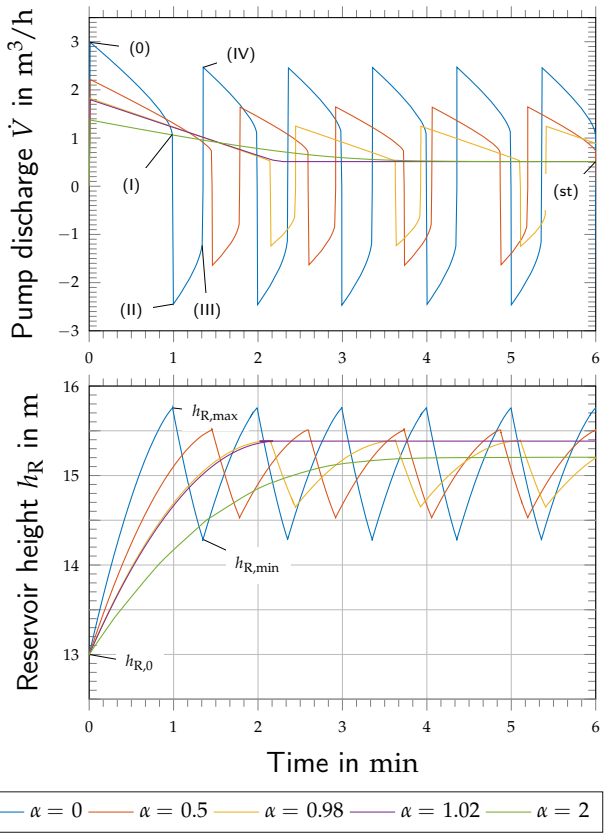

Figure 7. Instationary pump simulation for different pipe characteristics.

The initial quasi-static discharge $\dot{V}_{0+}$ depends on the system characteristics and hence on the coefficient α. The higher the coefficient α, i.e. the more friction, the lower the initial quasi-static discharge $\dot{V}_{0+}$. Afterwards the reservoir height h_{R} increases (time $t \leq (1 \text{ to } 2)\,\text{min}$) and the discharge $\dot{V}$ decreases. For coefficients $\alpha = 1.02$ and 2 the pump discharge $\dot{V}$ decreases until it balances the reservoir discharge $\dot{V}_{\text{out}}$ and the system reaches steady-state (st). The larger the coefficient α, i.e. the more friction, the lower is the steady-state reservoir height $h_{\text{R,st}}$.

In contrast for coefficients $\alpha = 0$, 0.5 and 0.98 the system yields a limit cycle, with critical points (I), (II), (III) and (IV). Note that the critical discharges $\dot{V}_{\text{I}}$ to $\dot{V}_{\text{IV}}$, the critical minimum and maximum reservoir heights $h_{\text{R,min}}$ and $h_{\text{R,max}}$, the periods of the positive and negative limit cycle T_+ and T_- and the overall period $T = T_+ + T_-$ depend on the coefficient α.

Figure 8 illustrates the quasi-static system behavior, defined by the intersection of the system characteristics (dotted) and the pump characteristics (solid). The three subplots and their respec-

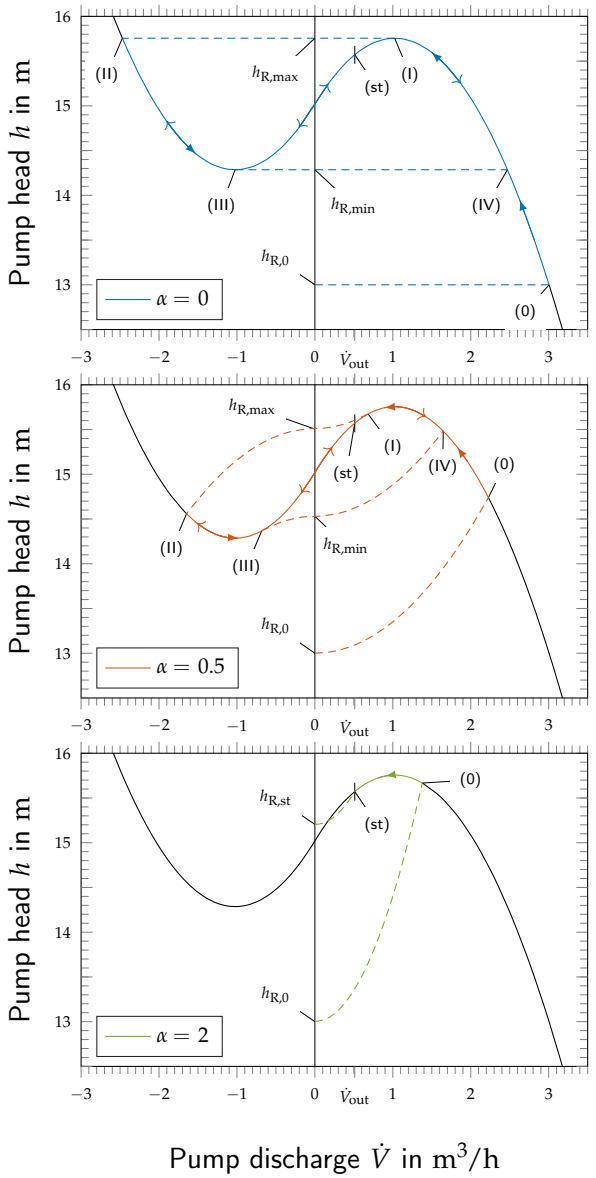

Figure 8. System behaviour for different pipe characteristics.

tive colors correspond to the three values of the coefficient $\alpha = 0$, 0.5 and 2. The y-axis intercept of the system characteristics represents the reservoir height h_R, and the curvature is proportional to the coefficient α. In contrast, all three subplots share the same pump characteristic since the pump speed ω is identical.

Initially, it can be observed that different values of α lead to different quasi-static initial discharges (0), resulting in different initial net inflows to the reservoir $\dot{V}_{0+} - \dot{V}_{out}$. Consequently, the reservoir height h_R increases more rapidly for $\alpha = 0$ compared to $\alpha = 2$. As the reservoir height h_R increases, the system characteristics shift vertically. The new intersection between the shifted system characteristics and the pump characteristics results in a decreasing pump discharge $\dot{V}$, thereby slowing the increase of the reservoir height h_R. This quasi-static evolution is indicated by filled arrows (⟶).

For $\alpha = 2$, the system eventually reaches the steady-state point (st), where the net inflow $\dot{V} - \dot{V}_{out}$ becomes zero, and the reservoir height h_R remains constant. This point is stable because any small deviation would still lead to an intersection between system and pump characteristics, generating a restoring effect that drives the system back to steady state.

In contrast, for $\alpha = 0$ and 0.5, the system reaches the critical point (I) before achieving steady state (st). At this point, the net reservoir inflow $\dot{V} - \dot{V}_{out}$ remains positive, and the reservoir height h_R continues to rise. However, beyond the critical point (I), no quasi-static intersection exists. The reservoir pressure decelerates the fluid, reducing the pump discharge $\dot{V}$, which in turn further decelerates and eventually reverses the flow. A new quasi-static equilibrium is reached only at the reversed pump discharge (II). During the rapid transition from (I) to (II), the pump (solid) and system (dashed) characteristics remain valid, and the pressure difference between them causes a sharp deceleration of the fluid. Meanwhile, the reservoir height remains approximately constant $h_R = h_{R,max}$. This fast transition is marked with arrows (⟶).

At point (II), the net inflow $\dot{V} - \dot{V}_{out}$ becomes negative, causing the reservoir height h_R to decrease. The intersection between the shifted system characteristics and the pump characteristics now evolves quasi-statically again (⟶). However, before reaching steady state (st), the system encounters the next critical point (III). At this point, the reservoir height h_R becomes too low to sustain reversed flow through the pump. The fluid is then accelerated by the pump, increasing the discharge $\dot{V}$, which further accelerates the fluid until a new quasi-static intersection is reached at point (IV). During the rapid transition from (III) to (IV), the pump (solid) and system (dashed) characteristics are again satisfied. The resulting pressure difference drives the flow reversal, while the reservoir height remains approximately constant $h_R = h_{R,min}$. This fast transition is indicated by arrows (⟶). The limit cycle then repeats, preventing the system from reaching the steady-state point (st).

3.1 Analytic verification

The behavior is well known, see e.g. (Sigloch 2013, sec. 9.2). To confirm the previous simulation results, analytic results are derived in the following.

First note that the critical discharges $\dot{V}_I$ to $\dot{V}_{IV}$ and the maximum and minimum reservoir heights $h_{R,max}$ and $h_{R,min}$ can be determined analytically by evaluating Equation 19 for given

normalized friction factor $\hat{k}$, which yields:

$$\hat{V}_{\mathrm{I,n}} = \frac{\hat{c}}{2(1+\hat{c}+\hat{k})}, \tag{25}$$

$$\hat{h}_{\mathrm{R,max,n}} = 1 + \hat{c}\hat{V}_{\mathrm{I,n}} - (1+\hat{c}+\hat{k})\hat{V}_{\mathrm{I,n}}^2, \tag{26}$$

$$\hat{V}_{\mathrm{II,n}} = \frac{\hat{c} + \sqrt{\hat{c}^2 - 4(1+\hat{c}+\hat{k})\left(1-\hat{h}_{\mathrm{R,max,n}}\right)}}{-2(1+\hat{c}+\hat{k})}, \tag{27}$$

$$\hat{V}_{\mathrm{III,n}} = -\hat{V}_{\mathrm{I,n}}, \tag{28}$$

$$\hat{V}_{\mathrm{IV,n}} = -\hat{V}_{\mathrm{II,n}}, \tag{29}$$

$$\hat{h}_{\mathrm{R,min,n}} = 1 - (\hat{h}_{\mathrm{R,max,n}} - 1). \tag{30}$$

Solving the second order system of nonlinear differential equations (Equation 23 and Equation 24) analytically is not trivial, but neglecting the flow rate dynamics, i.e. for zero interance $L = 0$, Equation 23 becomes analytic. Then one combine Equation 23 and Equation 24 and derive the first order nonlinear differential equation for the normalized reservoir height $\hat{h}_{\mathrm{R,n}}$:

$$\frac{\mathrm{d}\hat{h}_{\mathrm{R,n}}}{\mathrm{d}\tau} = -\hat{V}_{\mathrm{out,n}} \pm \hat{V}_{\mathrm{I,n}}\left(1 + \sqrt{1 \pm \gamma(1-\hat{h}_{\mathrm{R,n}})}\right), \tag{31}$$

where $\tau = t/t_{\mathrm{ref}}$ is the normalized time, $t_{\mathrm{ref}} = A\hat{h}_{\mathrm{ref}}/\hat{V}_{\mathrm{ref}}$ is the reference time, $\gamma = 4(1+\hat{c}+\hat{k})/\hat{c}^2$ is a coefficient and $(\pm)$ refers to the positive branch $\dot{V} > 0$ and negative branch $\dot{V} < 0$ of the limit cycle respectively. The first order differential Equation 31 can be solved analytically for each branch of the limit cycle, and one can obtain an implicit solution of the normalized reservoir height $\hat{h}_{\mathrm{R,n}}$ depending on the normalized time τ:

$$\tau = f_{\pm}(\hat{h}_{\mathrm{R,n}}) - f_{\pm}(\hat{h}_{\mathrm{R,0,n}}), \tag{32}$$

$$f_{\pm} = -\frac{2}{\hat{V}_{\mathrm{I,n}}^2\gamma}\Big(\hat{V}_{\mathrm{I,n}}g_{\pm} + \\ + (\pm\hat{V}_{\mathrm{out,n}} - \hat{V}_{\mathrm{I,n}})\ln\left|\mp\hat{V}_{\mathrm{out,n}} + \hat{V}_{\mathrm{I,n}}(1+g_{\pm})\right|\Big), \tag{33}$$

$$g_{\pm} = \sqrt{1 \pm \gamma(1-\hat{h}_{\mathrm{R,n}})}, \tag{34}$$

where f and g are auxiliary variables and $\hat{h}_{\mathrm{R,0,n}}$ is the initial normalized reservoir height. This also enables the calculation of the periods corresponding to the positive and negative branches of the limit cycle $T_{\pm}$:

$$T_+/t_{\mathrm{ref}} = f_+(\hat{h}_{\mathrm{R,max,n}}) - f_+(\hat{h}_{\mathrm{R,min,n}}), \tag{35}$$

$$T_-/t_{\mathrm{ref}} = f_-(\hat{h}_{\mathrm{R,min,n}}) - f_+(\hat{h}_{\mathrm{R,max,n}}), \tag{36}$$

and the overall period of the limit cycle $T = T_+ + T_-$, where $g_+(\hat{h}_{\mathrm{R,max,n}}) = g_-(\hat{h}_{\mathrm{R,min,n}}) = \sqrt{2}$ and $g_+(\hat{h}_{\mathrm{R,min,n}}) = g_-(\hat{h}_{\mathrm{R,max,n}}) = 0$.

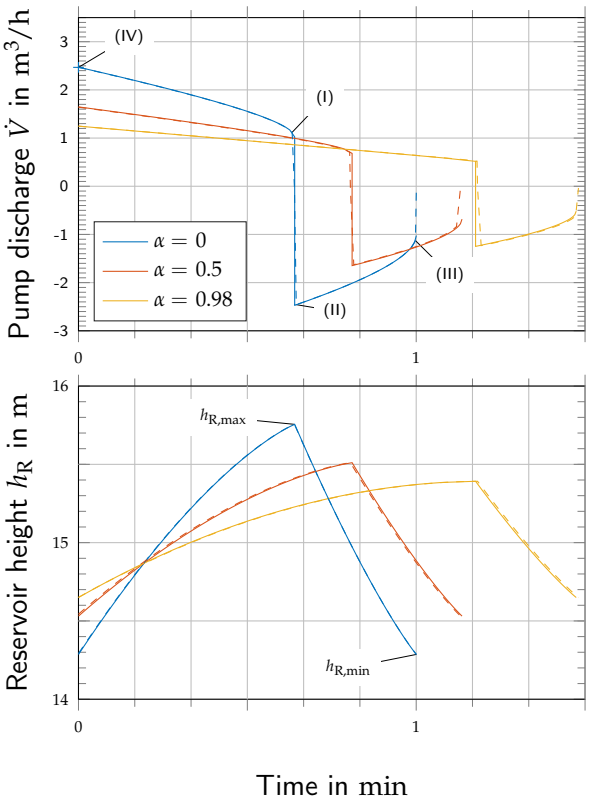

Figure 9. Comparison of analytical and dynamic simulation results for one limit cycle.

Figure 9 compares the analytic solution based on eqs. (32) to (34) (solid lines) with the numerical simulation results (dashed lines) of the first limit cycle as shown in Figure 7 that starts for $\alpha = 0$ at about 1 min 20 s, for $\alpha = 0.5$ at about 1 min 50 s and for $\alpha = 0.98$ at about 2 min 30 s. Colors refer to coefficients $\alpha = 0$, 0.5 and 0.98. Both results agree very well, i.e. Figure 9 verifies the analytic solution and the simulation model.

Figure 9 demonstrates, that the effect of the fluid inertia L is small, however considering its effect is crucial to solve the system. It is well known that nonlinear equation solvers may fail at the limit points (I) and (III), since a slight change in reservoir height $\dot{h}_{\mathrm{R}}$ causes a large change in discharge $\dot{V}$ if Equation 23 is solved algebraically ($L = 0$). There is no certainty that the solver of the nonlinear algebraic equation will converge at this step change in discharge. This is especially true for larger algebraic systems of nonlinear equations. When considering the effect of the fluid inertia the nonlinear algebraic equation turns into the differential equation. The implicit part of the system of differential equations is linear and it is a trivial task to solve for its states. From a physical point of view the dynamic equilibrium always exists and the implicit time integration method, which also has to solve a nonlinear equation system at every time step, is guided into the correct direction in

which the system will evolve. To be able to use an explicit time integration scheme the inertance L and the time step size have to match. In the future it might be promising to increase the inertance L up to a certain limit to enable real time simulation.

The example showed, that the simulation of limit cycles are possible with the TFS by default, since it takes the fluid inertia into account and avoids the common oversimplification of requiring quasi-static behavior. This actually simplifies the component models, since numerical modifications, as presented in (Wetter 2013), are no longer necessary. Note that while analytic calculations may help to verify simulation models for simple examples, modifications are very likely to cause analytic calculations to be neither possible nor feasible anymore. In these cases numerical simulation can still provide the opportunity to gain insight into system dynamics, if the simulation models proofed to be based on the correct physics.

4 Conclusion and Outlook

The proposed model for a centrifugal pump has proven to be a numerically robust model. The possibility to work with real pump behavior allows for instationary simulations. This is especially important when fault scenarios must be simulated. This also allows for a robust initialization of the models, as the model behavior follows the behavior from the real world. Fitting the pump data is simple, as no special care has to be taken to avoid instationary solutions, as the model can handle these well. An example of an instationary pump model has been validated against the theoretical solutions with an extremely well correlation. Furthermore, the models have been validated against data from measurements. The models have been validated for pump head, power and efficiency over a wide range of pump speeds: The pump head fit at all speeds stays very good (lower than 1 % relative error for speeds around ω_{ref}, lower than 3 % relative error at $\omega < \omega_{\text{ref}}/2$). The pump power fits the reference data well around ω_{ref} with errors of approximately 2 %. Even at $\omega = \omega_{\text{ref}}/2$ the error is smaller than 10 %. However at speeds below $\omega < \omega_{\text{ref}}/2$ the error quickly grows to around 40 %. A similar behavior can be seen for the pump efficiency: at $\omega_{\text{ref}}/2 < \omega < 1.25\omega_{\text{ref}}$ the relative error stays below 5.5 %, quickly growing to 45 % below half the reference speed. Hence it might be worth considering a decreasing peak efficiency at off design speeds as an extensions to similarity laws to obtain the well known pump characteristics. To further improve the model and quantitatively cover all four quadrants of pump operations, the approach presented in (Chaudhry 2014, sec. 4.3) is planned to be integrated into the TFS in the future.

Abstract

Cyclic frosting and defrosting operations constitute a common characteristic of air-source heat pumps in cold climates during winter. Simulation models that can capture simultaneous heat and mass transfer phenomena associated with frost/defrost behaviors and their impact on the overall heat pump system performance are of critical importance to improved controls of heat delivery and frost mitigation. This paper presents a novel frost formulation using an enthalpy method to systematically capture all phase-change behaviors including frost formation and melting, retained water refreezing and melting, and water drainage during cyclic frosting and defrosting operations. A Fuzzy modeling approach is proposed to smoothly switch source terms when evaluating the dynamics of frost and water mediums for numerical robustness. The proposed frost/defrost model is incorporated into a flat-tube outdoor heat exchanger model of an automotive heat pump system model to investigate system responses under cyclic operations of frosting and reverse-cycle defrosting.

Keywords: heat pump, reverse-cycle defrost, retained water, transient simulation, mode switch

1 Introduction

Cyclic frost accumulation and removal on the outdoor coil surface of air-source heat pumps are common in winter operations. As the system performance degrades due to blockage of free air flow passages and increased thermal resistance between coil walls and air streams, periodic defrost cycles are necessary to ensure consistent heat delivery and safe operations of the system. In practice, reverse-cycle defrost is among the most common strategies to implement by reversing the thermodynamic cycle to melt the accumulated frost. After that, the melted water can be evaporated as the coil continues being heated and can simultaneously drain from the coil surfaces due to gravity. Once the defrost cycle completes according to feedback controls or simply time-based controls, the refrigerant flow is reversed again to restore nominal heating operations. However, in case of an insufficient defrost operation, a portion of the melted liquid water is retained on the coil surface owing to surface tensions, which subsequently refreezes as solid ice when the system switches back to the heating mode where the outdoor coil operates as an evaporator. As a consequence, the next heating cycle can suffer from more significant performance degradation due to the presence of the ice layer as an additional thermal resistance compared to the previous heating cycle, which can lead to a shorter heating period before a necessary defrost cycle (Zhang, Li, and Hrnjak 2024). The issue is particularly important to operations of microchannel heat exchangers commonly adopted in automobile applications (including electric vehicles) whose performance is more sensitive to air flow blockage and thermal insulation due to the compact configuration.

Simulation tools that can capture the complicated heat and mass transfer phenomena of cyclic frosting-defrosting operations can be critically useful for the design and evaluation of improved defrost controls for air-source heat pumps that can mitigate frost/ice on the outdoor coil without excessively heating the coil during defrost cycles. Almost all existing frost/defrost models for heat pump systems focused on switches between frost formation and melting behaviors, omitting the impacts of retained water refreezing and melting on transients of cyclic frosting and defrosting (Qiao, Aute, and Radermacher 2018; Ma et al. 2023; Alam et al. 2024). Westhaeuser et al. (2023) derived a numerical model that accounted for frost formation and melting as well as retained water statuses in a lumped control volume. However, no general switching scheme was implemented for transitions between stages of frost and water processes, which hinders its applicability to describe heat pump transients under realistic mode switches between frosting and defrosting.

This paper presents a novel frost model that systematically captures all phase-change behaviors of frost and retained water/ice in a multi-phase multi-substance control volume using an enthalpy method. A Fuzzy modeling approach is proposed to smoothly switch source terms of governing equations to evaluate dynamics of the control volume based on underlying physical processes. The derived model is incorporated into a discretized flat-tube outdoor heat exchanger model of an automotive heat pump system. The system model is then simulated to investigate transients under cyclic operations of frosting/heating and reverse-cycle defrosting with retained water behaviors taken into consideration.

The remainder of this paper is organized as follows:

Section 2 describes model development for frost and retained water processes; Section 3 presents a discretized outdoor heat exchanger model incorporated with frost behaviors, and other component models to complete a heat pump system model; simulation results of the developed system model under cyclic frosting and defrosting are reported in Section 4, followed by conclusions summarized in Section 5.

2 Frost/defrost model

Frost formation and melting involve simultaneous heat and mass transfer. A common practice to model both processes relies on evaluating mass and energy balances of a frost control volume to characterize its dynamics which can be represented by a frost layer thickness and a lumped density (D. Kim, Braun, and Ramaraj 2018). While a control volume for water/ice can be constructed in a similar manner and interconnected with the frost volume to capture retained water/ice behaviors, significant model complexities are introduced as different phase presences and interactions between these control volumes need to be captured when the operating mode changes. Figure 1 depicts typical processes that occur on coil wall surfaces under cyclic frosting and defrosting, that consist of

- Process 1: frost formation on dry coils;
- Process 2: frost melting and water drainage;
- Process 3: retained water vaporization and drainage;
- Process 4: retained water refreezing and frost formation on ice.

It is important to note that transitions between these processes can follow different orders. Clearly, each stage during the process corresponds to different heat and mass transfer descriptions for control volumes and interfaces. Moreover, additional iteration variables (e.g., interface temperature or heat flux) can be introduced when modeling frost and water/ice mediums with individual control volumes. As a consequence, the overall model robustness deteriorates.

This work aims to develop a frost model with retained water/ice considered in a uniform model structure. A lumped film control volume that integrates frost, liquid water, and solid ice is developed using an enthalpy method (Alebrahim and Sherif 2002). The film dynamics under various operating modes and phase presences are captured by switching source terms of mass and energy balances.

2.1 A lumped film volume model

An advantage of the enthalpy method to model multiple mediums with phase change is that phase presences can be determined using the total enthalpy and mass fractions of each medium, eliminating the evaluation of internal heat transfer between them explicitly. Consider a one-dimensional lumped film control volume composed of frost and retained water/ice

$$m_{film} = m_f + m_{wi}. \tag{1}$$

The total enthalpy of the film is defined as

$$H_{film} = m_f h_f + m_{wi} h_{wi} \tag{2}$$

which is the sum of frost enthalpy and retained water/ice enthalpy. Carrying out an energy conservation analysis of the film volume yields

$$\frac{dH_{film}}{dt} = \dot{H}_{in} - \dot{H}_{out} + \dot{Q} \tag{3}$$

where the inlet enthalpy flow $\dot{H}_{in}$ corresponds to water vapor desublimation during frost formation, the exit enthalpy flow $\dot{H}_{out}$ corresponds to melted water drainage and vaporization during frost melting, $\dot{Q}$ represents heat transfer rate (convection or conduction) with ambient air and coil metal walls. It is important to note that the enthalpy flow source terms are only active corresponding to a specific operating mode (e.g, frost formation, frost melting), and the heat transfer rate changes signs when the heat flow directions reverse under mode switches.

Assume that the mediums of the film volume are in thermal equilibrium and their temperature gradients are negligible. As a result, a lumped temperature can be determined from the enthalpy. Note that frost is a mixture of dry air and ice. Equation 2 can be rewritten as

$$H_{film} = m_{ice} h_{ice} + m_{air} h_{air} + m_{wi} h_{wi} \tag{4}$$

where m_{ice} and m_{air} denote mass of ice and air of the frost layer, respectively. Apparently, the determination of the film temperature depends on operating modes. In case of frost formation, the retained water on the coil surface must be frozen before frost deposition happens, since a necessary condition of frost formation is that the surface temperature is below the water freezing point T_0 (e.g., 273.15 K). This physical insight indicates that the film undergoes frost formation process when the condition $H_{film} < H_{film,s0}$ holds where $H_{film,s0}$ represents the enthalpy when all retained water turns into solid ice at T_0 and is computed by

$$H_{film,s0} = m_{ice} h_{ice,0} + m_{air} h_{air,0} + m_{wi} h_{ice,0} \tag{5}$$

where $h_{ice,0}$ and $h_{air,0}$ represent specific enthalpies at the freezing temperature. During frost formation, the film enthalpy is proportional to temperature changes with a lumped specific heat capacity since there is no internal phase change inside the volume. As a result, the film temperature is obtained by

$$T_{film} = \frac{H_{film} - H_{film,s0}}{m_{film} c_{p,film}} + T_0 \tag{6}$$

DOI 10.3384/ecp218335

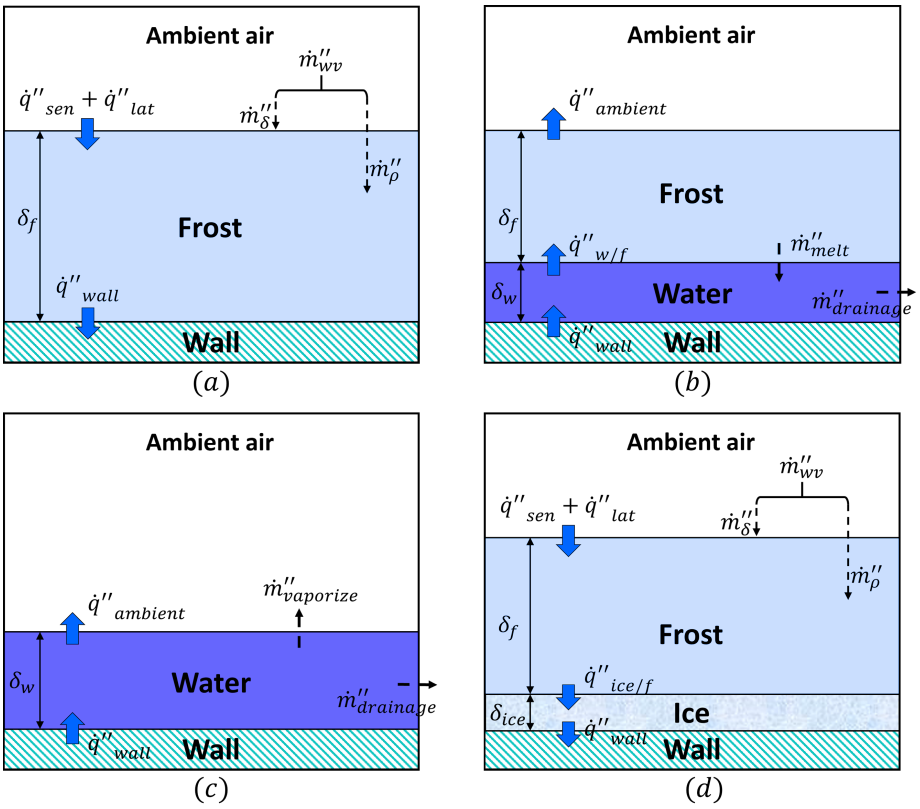

Figure 1. Frost and water/ice processes during cyclic frosting and defrosting: (a) Process 1: frost formation on dry coils; (b) Process 2: frost melting and water drainage; (c) Process 3: retained water vaporization and drainage; (d) Process 4: retained water refreezing and frost formation on ice.

where $c_{p,film}$ is a mass-weighted property and is determined by

$$c_{p,film} = \frac{c_{p,ice}m_{ice} + c_{p,air}m_{air} + c_{p,wi}m_{wi}}{m_{film}}. \tag{7}$$

Similarly, an enthalpy condition $H_{film} > H_{film,l0}$ can be employed to indicate the conclusion of the frost melting process as well as the switch to retained water drainage and vaporization, as shown in Figure 1 (c) where

$$H_{film,l0} = m_{ice}h_{w,0} + m_{air}h_{air,0} + m_{wi}h_{w,0} \tag{8}$$

defines a film enthalpy at T_0 when solely liquid water is present in the film volume. In this case, further heating of the film leads to a temperature above the freezing point, which can be determined using Equation 6 with $H_{film,l0}$ as a reference.

Clearly, the film undergoes phase changes associated with either the frost layer or the retained water/ice when $H_{film,s0} < H_{film} < H_{film,l0}$ is met, with a temperature at T_0. These processes include frost melting, and retained water refreezing or melting.

In summary, the film temperature can be retrieved from its enthalpy and mass composition at any time instance as

$$T_{film} = \begin{cases} \frac{H_{film} - H_{film,s0}}{m_{film}c_{p,film}} + T_0 & \text{if } H_{film} < H_{film,s0}, \\ \frac{H_{film} - H_{film,l0}}{m_{film}c_{p,film}} + T_0 & \text{if } H_{film} > H_{film,l0}, \\ T_0 & \text{otherwise.} \end{cases} \tag{9}$$

In terms of mass conservation, analyses are carried out for the frost layer and the retained water/ice layer separately. The frost mass is characterized by its thickness and density $m_f = \delta_f \rho_f A_s$ as mass transfer contributes to its growth and densification simultaneously. The mass conservation can then be formed as

$$\frac{d\delta_f}{dt} = \frac{\dot{m}_{\delta,in} - \dot{m}_{\delta,out}}{\rho_f A_s}, \tag{10}$$

$$\frac{d\rho_f}{dt} = \frac{\dot{m}_{\rho,in} - \dot{m}_{\rho,out}}{\delta_f A_s} \tag{11}$$

with a decomposition of the source mass flow rates into portions that correspond to mass transfer at the frost surface and within the frost layer. Finally, a mass balance of the retained water/ice layer is formed as

$$\frac{dm_{wi}}{dt} = \dot{m}_{wi,in} - \dot{m}_{wi,out}. \tag{12}$$

With the model setup presented above, transient behaviors of the lumped film can be described by its enthalpy, the frost layer thickness and density, and the retained water/ice mass. Other properties of the film are retrieved from these state variables. For example, an average film density is computed by

$$\rho_{film} = \frac{m_{film}}{\delta_f + m_{wi}/\rho_{wi}} \tag{13}$$

where ρ_{wi} represents water/ice density depending on the operating mode.

2.2 Switched source terms

2.2.1 Heat and mass transfer

Evaluations of the source terms that appear in the governing equations depend on operating modes and phase presences of the film. In the current work, coupled behaviors of the frost layer and water/ice layer are described in the following stages based on phase presences, which cover scenarios associated with cyclic frosting and defrosting operations of heat pumps

- stage 1: frost formation on retained solid ice, corresponding to Process 4 shown in Figure 1 (d);
- stage 2: melting of the retained ice and frost, corresponding to Process 2 shown in Figure 1 (b);
- stage 3: retained liquid water drainage and vaporization, corresponding to Process 3 shown in Figure 1 (c);
- stage 4: dry coil with no frost or retained water/ice.

To derive source terms of heat and mass transfer under frost formation at stage 1, an important assumption is that water vapor is saturated at the frost surface. The water vapor mass flow rate from air streams $\dot{m}_{wv}$, which is obtained by mass transfer calculations (see Eq. (41)), is divided into a portion that diffuses into the frost layer and another that deposits on the frost surface. The mass flow rate of water vapor that diffuses into the frost layer and contributes to its densification over the surface area A_s can be obtained according to Fick's law at the frost surface

$$\dot{m}_{\rho,in} = D_{eff} A_s \left.\frac{\partial \rho_{wv}}{\partial x}\right|_{x=\delta_f} \tag{14}$$

and is approximated in a finite-difference fashion across the film volume

$$\dot{m}_{\rho,in} \approx D_{eff} A_s \frac{\rho_{wv}(T_{fs}) - \rho_{wv}(T_{wall})}{\delta_f} \tag{15}$$

where $\rho_{wv}(T_{fs})$ and $\rho_{wv}(T_{wall})$ denote saturated water vapor density at the film surface and wall temperatures, respectively. The effective diffusion coefficient D_{eff} is evaluated using the following correlation (Breque and Nemer 2016)

$$D_{eff} = \frac{\varepsilon}{1 - 0.58(1-\varepsilon)} \tag{16}$$

where ε represents the frost porosity. Given a total water vapor mass flow rate from air streams $\dot{m}_{wv}$, the portion that deposits on the frost surface can be obtained by

$$\dot{m}_{\delta,in} = \dot{m}_{wv} - \dot{m}_{\rho,in}. \tag{17}$$

Since there is no mass flow leaving the frost layer during this stage, Equation 10 and 11 can be evaluated with $\dot{m}_{\delta,in}$ and $\dot{m}_{\rho,in}$, respectively. Furthermore, the retained water/ice layer yields no mass transfer, which leads to the mass m_{wi} remaining constant.

Heat transfer between the film volume and air streams consists of sensible and latent heat due to water vapor desublimation. Carrying out an energy balance at the film surface leads to

$$\dot{Q}_a = A_s k_{film} \frac{T_{fs} - T_{film}}{\delta_{film}/2} \tag{18}$$

which can be used to obtain the film surface temperature T_{fs}, given that the total heat transfer (include sensible and latent) from air streams $\dot{Q}_a$ (obtained by Eq. (43)) depends on the surface temperature as well. k_{film} is the film thermal conductivity which is determined in a density-weighted manner

$$k_{fim} = k_f + (k_{wi} - k_f) \frac{\rho_{film} - \rho_f}{\rho_{wi} - \rho_f}. \tag{19}$$

A correlation reported in (K.-S. Lee, W.-S. Kim, and T.-H. Lee 1997) is adopted to evaluate the frost thermal conductivity as a function of the frost density. Similarly, heat transfer from wall surfaces is calculated by

$$\dot{Q}_{wall} = A_s k_{film} \frac{T_{wall} - T_{film}}{\delta_{film}/2}. \tag{20}$$

As a result, the energy conservation in Equation 3 becomes

$$\frac{dH_{film}}{dt} = \dot{Q}_a + \dot{Q}_{wall} \tag{21}$$

for this stage. Note that the inlet enthalpy flow carried by water vapor is negligible compared to sensible and latent heat which is determined in an air flow model presented in the next section.

At stage 2, the retained ice is melted, followed by the frost melting process. To calculate the melting rate, a quasi-steady-state energy balance is employed

$$\dot{m}_{melt} = \frac{\dot{Q}_a + \dot{Q}_{wall}}{\Delta h_{sl}} \tag{22}$$

where Δh_{sl} represents the water heat of fusion. Typically, outdoor heat exchanger fans are off under defrost mode when the ambient temperature is below the freezing point and the ambient air cannot be employed to melt frost through convection. Therefore, the only mass transfer source of the frost layer is the melted water $\dot{m}_{\delta,out} = \dot{m}_{melt}$, which flows into the retained water/ice layer and implies $\dot{m}_{wi,in} = \dot{m}_{melt}$. Furthermore, it is assumed that the frost density remains constant during frost melting. The energy conservation shown in Equation 21 also applies to this stage.

DOI 10.3384/ecp218335

After frost is melted and with liquid water retained on coil surfaces, stage 3 focuses on transients of the retained water. Two primary processes are liquid drainage owing to gravity and vaporization as heating coil surfaces leads to mass transfer. It is challenging to quantify the water drainage rate physically since it relies on a number of factors such as surface orientation, wettability, etc. In the current work, a first-order model

$$\dot{m}_{drain} = \frac{m_{wi}}{t_{drain}} \tag{23}$$

is applied to describe the process (Westhaeuser et al. 2023). The drainage flow rate is proportional to the total retained water mass with a time constant t_{drain} which needs to be calibrated for a specific application.

The mass flow rate of vaporized water is determined by

$$\dot{m}_{vap} = c_{vap} A_s \left(\rho_{wv}(T_{film}) - \rho_{wv}(T_a)\right) \tag{24}$$

where c_{vap}[m/s] is a vaporization coefficient (Qiao, Aute, and Radermacher 2018), $\rho_{wv}(T_{film})$ is the saturated water vapor density evaluated at the film temperature, and $\rho_{wv}(T_a)$ is the water vapor density at the ambient temperature. Since both drainage and vaporization move water out of the film control volume, the final form of mass balance for this stage is

$$\frac{dm_{wi}}{dt} = -\dot{m}_{drain} - \dot{m}_{vap}. \tag{25}$$

Correspondingly, enthalpy flows that result from the retained water mass transfer are evaluated in energy conservation. The outlet enthalpy flow is determined by

$$\dot{H}_{out} = \dot{m}_{drain} h_{film} + \dot{m}_{vap} \Delta h_{lv} \tag{26}$$

where h_{film} denotes the film specific enthalpy and Δh_{lv} denotes the water heat of vaporization.

In case the retained water is completely removed from coil surfaces before a switch back to frosting conditions, heat is dissipated to the ambient air. This is indicated by m_{wi} below a small threshold. At stage 4, the film energy balance is describe by Equation 21 without mass transfer.

2.2.2 Switching algorithm

Source terms associated with all stages are computed at each time step. However, only those relevant to the current stage should be applied in evaluating the governing equations. A robust switching algorithm is crucial for realizing the proposed film model. In the current work, the T-S Fuzzy modeling approach (Takagi and Sugeno 1985) is adopted for this purpose.

A set of switching rules is first introduced based on characteristics of all possible stages described in Section 2.2.1. Apparently, the wall temperature constitutes a candidate for differentiating the frost formation process from other melting and dry heating stages. Specifically, stage 1 is active when the wall temperature is below the freezing point temperature T_0. Otherwise, one of the stages during defrosting is active. With frost presence, the film volume undergoes stage 2 until all the frost is melted. Numerically, this can be determined when the frost layer thickness is above a small threshold (for model robustness concerns). Similarly, the retained water presence is indicated by the retained water/ice layer mass, that also determines whether stage 3 or stage 4 is active. In summary, wall temperature T_{wall}, frost layer thickness δ_f, and retained water/ice layer mass m_{wi} are identified as linguistic variables to construct Fuzzy rules. For each variable, two Fuzzy numbers are created with unique membership functions. For instance, Figure 2 depicts membership functions associated with Fuzzy numbers N and P for the linguistic variable T_{wall}. It can be seen that values of both membership functions change around the freezing point temperature T_0 which corresponds to rules that depend on whether T_{wall} is above or below T_0. It is important to note that the piecewise membership functions are continuous and differentiable to avoid generating events during simulations. Fuzzy numbers associated with δ_f and m_{wi} are acquired similar to those shown in Figure 2 where membership functions associated with Fuzzy numbers N and P change values between 0 and 1 around a threshold. In this case, $\delta_{f,\varepsilon} = 0.01$mm and $m_{wi,\varepsilon} = 1e^{-5}$kg are applied as thresholds.

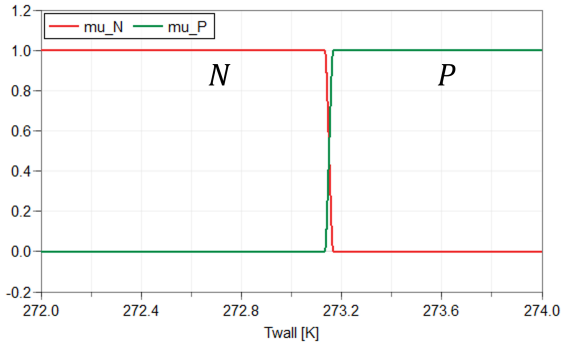

Figure 2. Membership functions associated with Fuzzy numbers for the linguistic variable T_{wall}.

After that, the following set of Fuzzy rules can be formed using Fuzzy numbers

1. stage 1 IF T_{wall} is N;
2. stage 2 IF T_{wall} is P AND δ_f is P;
3. stage 3 IF T_{wall} is P AND δ_f is N AND m_{wi} is P;
4. stage 4 IF T_{wall} is P AND δ_f is N AND m_{wi} is N,

to identify continuous mode switches under cyclic operations. Finally, numerical weights are assigned to source terms associated with each stage to realize mode switches between these stages through a defuzzification process re-

vealed below

$$\omega_1 = \mu_N(T_{wall}), \tag{27}$$
$$\omega_2 = \mu_P(T_{wall}) \times \mu_P(\delta_f), \tag{28}$$
$$\omega_3 = \mu_P(T_{wall}) \times \mu_N(\delta_f) \times \mu_P(m_{wi}), \tag{29}$$
$$\omega_4 = \mu_P(T_{wall}) \times \mu_N(\delta_f) \times \mu_N(m_{wi}). \tag{30}$$

which translates the Fuzzy rules to numerical outputs using membership function values. A weight for each stage is then obtained through normalization

$$\gamma_i = \frac{\omega_i}{\sum_{i=1}^{4} \omega_i}. \tag{31}$$

The final set of governing equations for the film model is presented as

$$\frac{dH_{film}}{dt} = \dot{Q}_a + \dot{Q}_{wall} - \gamma_3(\dot{m}_{drain} h_{film} + \dot{m}_{vap} \Delta h_{lv}) \tag{32}$$
$$\frac{d\delta_f}{dt} = \frac{\gamma_1 \dot{m}_{\delta,in} - \gamma_2 \dot{m}_{melt}}{\rho_f A_s} \tag{33}$$
$$\frac{d\rho_f}{dt} = \frac{\gamma_1 \dot{m}_{\rho,in} + (\gamma_3 + \gamma_4)(\rho_{reset} - \rho_f)/t_{reset}}{\delta_f A_s} \tag{34}$$
$$\frac{dm_{wi}}{dt} = \gamma_2 \dot{m}_{melt} - \gamma_3(\dot{m}_{drain} + \dot{m}_{vap}). \tag{35}$$

Note that in Equation 34 the second source term is a numerical treatment using a first-order filter to reset the frost density to an initial value for the next frosting cycle after all the frost is melted. It is necessary for simulations of cyclic frost behaviors since the assumption of a constant frost density is applied to model the frost melting process (stage 2). Alternatively, this can be realized using the reinit() method of the Modelica language.

3 Reversible heat pump system model

The developed film volume model captures transient behaviors of frost and retained water/ice on coil surfaces. Incorporating the film model into an outdoor coil model for a reversible heat pump enables investigation of system performance under cyclic frosting and defrosting operations. This section describes a discretized outdoor heat exchanger model, and then presents other component models as well as system model integration.

3.1 Flat-tube heat exchanger model

An outdoor flat-tube heat exchanger with 6 refrigerant flow passes arranged in 2 rows is discretized by dividing each refrigerant flow pass into two volumes and dividing the air flow path by tube rows. As a result, the heat exchanger is divided into a total number of 12 control volumes. Figure 3 depicts the heat exchanger configuration and discretization for a tube row.

Within each control volume, the reversible refrigerant dynamics are described by the following mass and energy

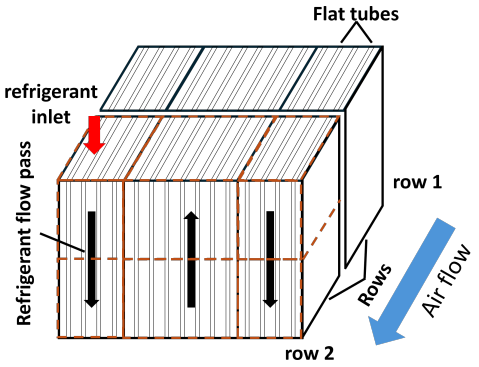

Figure 3. Flat-tube heat exchanger discretization.

balances

$$\frac{d(\rho_r V)}{dt} = \dot{m}_{in} - \dot{m}_{out} \tag{36}$$
$$\frac{d(\rho_r V u_r)}{dt} = \dot{m}_{in} h_{in} - \dot{m}_{out} h_{out} - \dot{Q}_r \tag{37}$$

along with a static momentum balance that correlates the refrigerant pressure drop with wall friction. The heat transfer rate to metal walls is obtained by

$$\dot{Q}_r = \alpha_r A_{wall}(T_r - T_{wall}) \tag{38}$$

where α_r is the heat transfer coefficient evaluated by an empirical correlation. The refrigerant pressure and enthalpy are selected as state variables, and all other thermophysical properties (e.g., T_r, u_r) are retrieved based on them with lookup table interpolation property models. It is important to note that the refrigerant flow descriptions are valid for arbitrary flow directions and handle reverse flow in a numerically sound way. Since the focus of this paper is on frost/defrost model formulations, readers are referred to (Ma 2024) for two-phase flow modeling details.

Metal walls of flat tubes and fins are modeled as lumped capacitance

$$C_{wall} \frac{dT_{wall}}{dt} = \dot{Q}_r - \dot{Q}_{wall} \tag{39}$$

where $\dot{Q}_{wall}$ is the heat transfer to the film and is defined in Equation 20.

The air-side heat and mass transfer over the film are modeled with a quasi-steady-state assumption due to their fast responses compared to the refrigerant flow or frost. A mass balance is formed as

$$\dot{m}_{in} - \dot{m}_{out} - \dot{m}_{cond} = 0 \tag{40}$$

where $\dot{m}_{cond}$ represents the water vapor mass transfer through condensation or desublimation, and is obtained by

$$\dot{m}_{cond} = \beta A_s(\omega_{in} - \omega_{sat}(T_{fs})) \tag{41}$$

DOI
10.3384/ecp218335

where β is a mass transfer coefficient evaluated using the heat and mass transfer analogy with Lewis number $Le = 0.89$, ω_{in} represents the inlet air humidity ratio, and $\omega_{sat}(T_{fs})$ represents the saturated air humidity ratio evaluated at the film surface temperature. The energy balance is formed as

$$\dot{H}_{in} - \dot{H}_{out} - \dot{Q}_a = 0 \tag{42}$$

where $\dot{Q}_a$ represents the total heat transfer rate that consists of sensible and latent parts, and is calculated by

$$\dot{Q}_a = \alpha_a A_s (T_a - T_{fs}) + \dot{m}_{cond} \Delta h_{lat}. \tag{43}$$

Here α_a represents the air-side heat transfer coefficient and Δh_{lat} is the latent of either vaporization or sublimation depending on the surface temperature. Note that the outlet enthalpy flow $\dot{H}_{out}$ includes those of the air stream as well as the condensed water. A lumped air-side pressure loss is calculated based on the outlet air of the heat exchanger instead of air streams in each channel.

3.2 Heat pump system model integration

The developed flat-tube outdoor heat exchanger model incorporated with frost/defrost is subsequently integrated into an automotive air-source heat pump system model. The heat pump can operate in heating or cooling/defrost modes by controlling a reversing valve. R1234yf is utilized as the working fluid. The system adopts a variable-speed compressor and an electronic expansion valve (EXV) as the expansion device. Moreover, an indoor flat-tube heat exchanger that is similar to the outdoor one but with different geometries is employed.

Modeling the indoor heat exchanger follows the same approach for the refrigerant flow, metal walls, and air flows as presented before. The only distinction compared to the outdoor heat exchanger model is the absence of the film model since no frost/defrost phenomenon occurs on the indoor side.

A semi-empirical compressor model is employed to calculate the compressor mass flow rate as well as discharge enthalpy using volumetric and isentropic efficiencies which are correlated as functions of discharge and suction pressures and the compressor speed. Furthermore, the shaft power is determined using the shaft torque and speed.

The EXV model follows a standard throttling process for both flow directions. The mass flow rate across the EXV is computed by

$$\dot{m} = K_v \sqrt{\rho_{in} |p_{in} - p_{out}|} \tag{44}$$

where K_v is a flow coefficient determined by lookup tables when the valve position changes to capture the valve characteristics under varying operating conditions.

The outdoor heat exchanger fan is modeled using performance tables to calculate the nominal fan power as well as volumetric flow rate that the fan delivers based on the pressure rise across the fan, which is equalized to the pressure drop of the heat exchanger. Then the actual performance of the fan is obtained by scaling nominal values with the fan speed.

The suction accumulator captures the refrigerant mass and energy conservations, similar to the heat exchanger model. However, the refrigerant exit quality is determined as a function of the liquid level.

Actuation signals for the heat pump system model include the compressor speed, outdoor fan speed, EXV opening, indoor air flow rate, and the reversing valve opening which controls the refrigerant flow direction and the system operating mode. A schematic of the heat pump system model is shown in Figure 4. Besides the major components described above, the system model also include connecting pipes, sensors, and controls. All component models are implemented using Modelon's Air Conditioning Library (`https://modelon.com/library/air-conditioning-library/`).

4 Simulation results

The developed heat pump system model is simulated to investigate system performance under cyclic frosting and reverse-cycle defrosting operations and to demonstrate capabilities of the developed film model in capturing frost and retained water/ice behaviors. Simulations are carried out using the Modelica tool Dymola 2024x with the Dassl solver and a tolerance of $1e^{-4}$.

The system is initialized at an off condition where the refrigerant pressure is equalized across the system. Vapor refrigerant resides in the indoor heat exchanger while two-phase refrigerant is stored in the outdoor heat exchanger which is in thermal equilibrium with the ambient. Upon a heating cycle startup, the compressor speed, outdoor fan speed, and indoor air mass flow rate are ramped up to their nominal values while the EXV opening is fixed. After the compressor speed settles, superheat control is activated to regulate the EXV opening using a PI controller, as shown in Figure 4. After a period of operation under frosting conditions, the system switches to a defrost cycle to remove the accumulated frost and restore system performance. A number of actuations are considered during mode switching. The EXV is fully opened while the compressor operates at a lower speed than the nominal value during defrost. In the meantime, the reversing valve is energized to redirect the refrigerant flow. On the air side, the outdoor fan is shut off. However, the indoor air mass flow rate remains the same as before in order to heat the refrigerant that flows back to the compressor in the reversed direction. Similarly, when the system switches back to the heating mode, the reversing valve is energized again and other actuators follow the same operations as heating cycles. It should be noted that vehicle driving cycles that have a significant impact on air flows are not considered in the simulated conditions. Consequently, air flow rates through both coils are determined by the given boundary

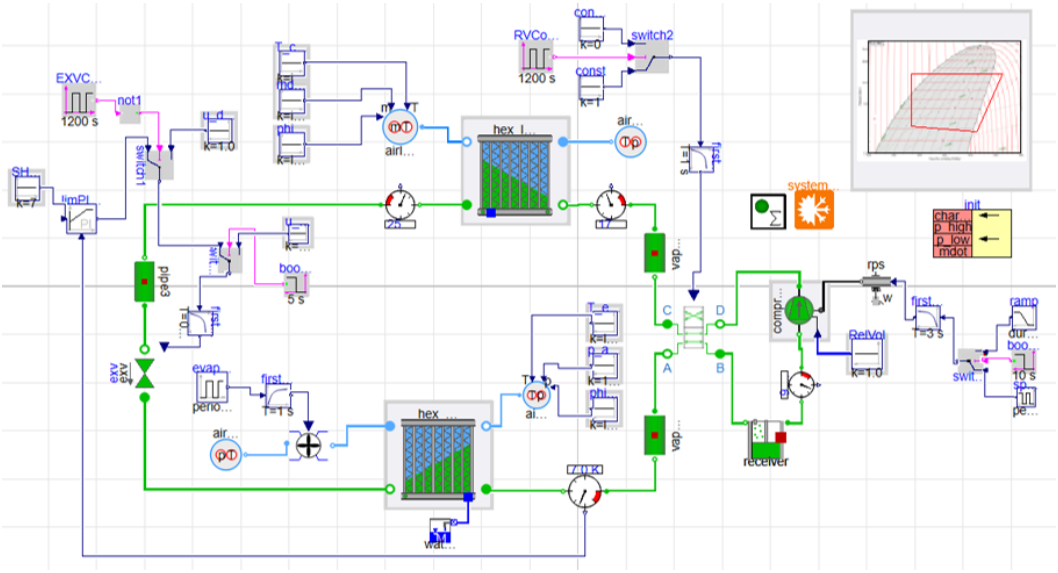

Figure 4. Heat pump system model schematic.

conditions.

In the current work, the indoor air condition is set to 20 C° with a relative humidity of 50%, while the outdoor ambient condition is 2 C° with a relative humidity of 70%. A simulation concerning 25-minute operations is carried out where the system operates in heating mode for 20 minutes before switching to a short defrost cycle, which lasts for 1 minute. After that, the system switches back to the heating model and runs for 4 minutes.

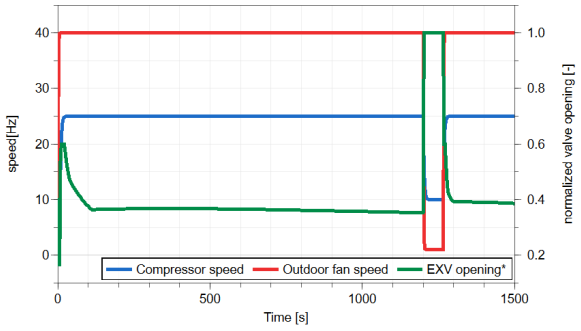

Figure 5. Actuation signals of the compressor and outdoor fan speeds and normalized EXV opening.

Figure 5 reveals the compressor speed, outdoor heat exchanger fan speed, and EXV opening corresponding to the operating characteristics described above. Figure 6 reports discharge and suction pressures. It can be seen that the discharge pressure settles at around 14 bar while the suction pressure at 2 bar after a startup period of 100 seconds. Then a gradual decrease of the discharge pressure can be observed during the heating cycle. This is due to frost formation on the outdoor heat exchanger that deteriorates heat transfer and leads to a slight decrease of the evaporating temperature. A dramatic drop of the discharge pressure at 1200 seconds is attributed to the actuation of the reversing valve and opening of the EXV. Ater the refrigerant flow is reversed, pressure difference across the compressor starts building up again similar to a startup operation until the reversing valve is energized to conclude the defrost cycle, which is followed by another heating cycle with notable performance degradation due to frost accumulation.

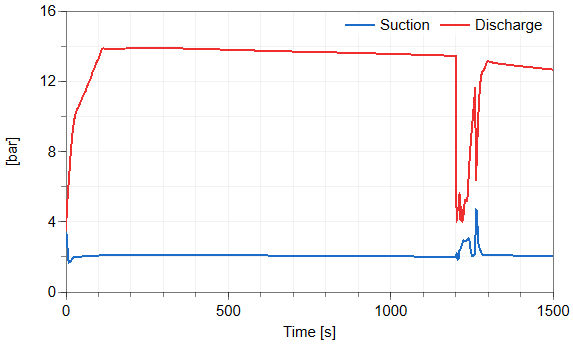

Figure 6. Simulation results of discharge and suction pressures.

The same trend can be observed in the indoor heating capacity and the compressor power, as shown in Figure 7. Clearly, the frost buildup leads to a reduction of the air-side capacity during the heating cycle. However, as a result the compressor power also decreases due to a smaller pressure ratio. During the defrost cycle, assuming that no additional heat source (e.g., electric heater) is available, the indoor capacity changes sign since the indoor heat exchanger operates as an evaporator, which indicates that the heat pump system absorbs heat from the indoor environment and can cause thermal discomfort.

Figure 8 examines evolution of the frost mass and the retained water/ice mass throughout cyclic operations, as a major contribution of the present work is to derive frost models with retained water/ice behaviors taken into con-

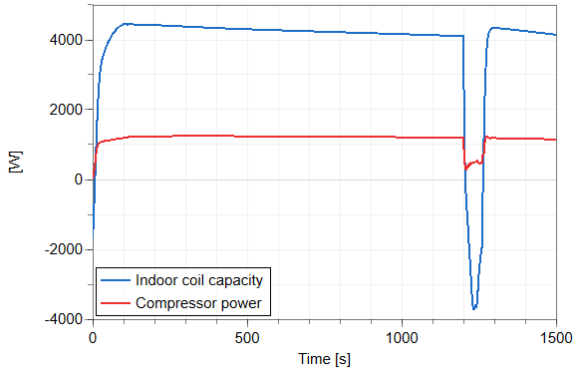

Figure 7. Simulation results of indoor air-side capacity and compressor power.

sideration. The film mass as the sum of them is also shown. The frost mass keeps increasing upon system startup, while no mass transfer associated with the retained water/ice occurs during this period. The accumulated frost is melted during the defrost cycle, which leads to an increased retained water mass. Meanwhile, the retained water drains away and vaporizes as coil wall surfaces are heated. However, the system switches back to the heating mode before a complete removal of the retained water. Consequently, the retained water refreezes on coil surfaces as frost starts buildup in the next heating cycle. This additional thermal resistance added on the heat exchanger surface and blockage of free air flow passages can accelerate system performance deterioration in the next heating cycle. These results demonstrate that the proposed model is capable of capturing the retained water refreezing phenomenon under cyclic operations.

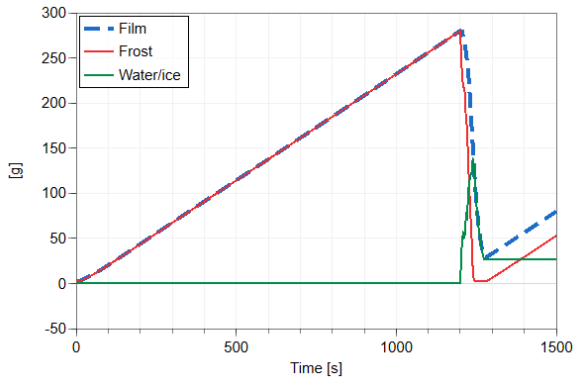

Figure 8. Simulation results of frost and retained water/ice mass.

Furthermore, Figure 9 reveals non-uniform film thicknesses across the outdoor heat exchanger. Film thicknesses of control volumes at the refrigerant flow inlet (the first control volume of tube row 2), in the middle of the refrigerant path (the first control volume of tube row 1), and at the refrigerant flow outlet (the last control volume of tube row 1) are shown. It is important to note that the refrigerant enters the heat exchanger at tube row 2, as tube row 1 is facing inlet air flows (see Figure 3). It can be seen that more frost accumulates in the control volume of tube row 1 than tube row 2. This is because the moist air first flows through tube row 1 where moisture content is greater than that of tube row 2 since a portion of water vapor carried in the air deposits on tube row 1. In addition, no frost behavior is observed in the control volume at the heat exchanger outlet due to the fact that the superheated refrigerant brings the coil surface temperature above the local dew point temperature of the moist air that results in dry coil operations there.

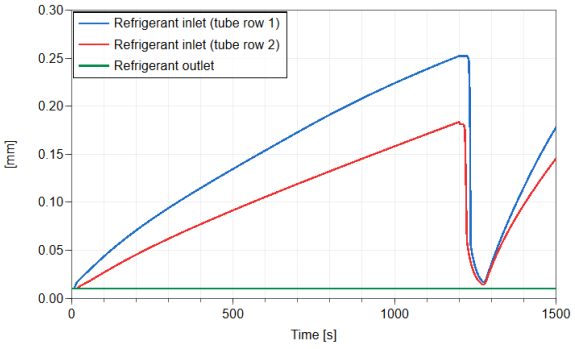

Figure 9. Simulation results of discretized film thicknesses of selected control volumes.

5 Conclusions

This paper presents a novel film volume model that integrates frost and retained water/ice behaviors using an enthalpy method. The film model captures possible operating modes that involve frost formation and melting, and retained water/ice refreezing and melting under cyclic frosting and defrosting operations. The advantage of using the enthalpy method to model these phase change behaviors is that it features a uniform model structure with switched source terms for various operating modes. A switching algorithm based on the Fuzzy modeling approach is proposed to avoid discontinuities under mode switches. The developed film volume model is incorporated into a discretized outdoor flat-tube heat exchanger model which is then coupled to other component models of an automotive heat pump system. The system model is simulated to investigate system responses under cyclic heating and reverse-cycle defrosting operations from a startup. Simulation results indicate that the developed model is capable of capturing the complicated cyclic transients of the refrigerant, air, frost, and retained water/ice in case of an insufficient defrost cycle. The proposed modeling approach can be extremely useful for improved defrost control designs and evaluations of air-source heat pumps as well as low-temperature refrigeration applications.

Future research efforts can focus on experimentally validating the model in scenarios of retained water/ice presences and utilizing the model to investigate the overall im-

pact of retained water refreezing and melting on system performance over multiple defrost cycles to aid performance improvements. Furthermore, the proposed modeling approach can be useful to investigate control strategies that optimize operating efficiencies while minimizing disruptions to the vehicle interior heating under frost conditions.

A Dynamic Analysis of Refrigerant Mass in Vapor Compression Cycles

Scott A. Bortoff, Vedang M. Deshpande, Christopher R. Laughman and Hongtao Qiao [1]

[1]Mitsubishi Electric Research Laboratories, Cambridge, MA, USA {bortoff, deshpande, laughman, qiao}@merl.com

Abstract

Numerical simulation of a thermofluid vapor compression cycle (VCC) model in Modelica, for example, can exhibit a variation in the total fluid (refrigerant) mass. This paper provides a dynamic analysis of a commonly used VCC model, identifies and analyzes the root cause of this variation, and proposes a number of remedies. The cause lies within the dynamic equations that result from application of the principle of mass conservation. In many common formulations, these equations express the conservation of mass as one or more differential equations that equate the time derivative of mass to zero. The resulting set of n ordinary differential equations (and a number of auxiliary algebraic equations) include the time derivative of a mass constraint function, but not the actual mass constraint function itself. As a result, this modeling formulation has the following properties: (1) equilibrium solutions of the system are neither isolated, nor exponentially stable; (2) a linearization about any equilibrium solution has at least one eigenvalue equal to zero, making an equilibrium solution stable, but not exponentially stable; (3) for a VCC model formulated using two fluid states per control volume, a one-dimensional equilibrium manifold exists containing all of the equilibrium solutions, and is parameterized by the total fluid mass; (4) an $(n-1)$ dimensional, stable, invariant manifold exists transverse to the equilibrium manifold, defined by the mass constraint function, and on which *analytic* solutions to the model evolve and the total fluid mass remains constant; and (5) *numerical* solutions may drift off of this manifold, resulting in an observed drift of fluid mass. These properties have consequences for simulation, control design, numerical model reduction, and state estimation. A number of methods to stabilize the mass constraint are proposed and a number of examples that illustrate the behavior, analysis and remedies are provided.

Keywords: vapor compression cycle, mass conservation, simulation, dynamic analysis

1 Introduction

Vapor compression cycles (VCCs) are the primary means of moving heat in almost all modern air conditioning systems. Physically, VCCs consist of one or more hierarchically organized loops of modular components such as heat exchangers, pipes, valves and compressors. The physics of fluid mechanics, usually including phase change and heat transfer is nonlinear and multi-scale in time and space, resulting in models that consist of large sets of coupled, nonlinear, numerically stiff but sparse differential algebraic equations. As such, the Modelica modeling language has proven to be well suited to this application, with its object oriented structure for organization and tools that support simulation of large sparse DAEs, and has generally found successful application in product development throughout the industry, which is continuously under pressures to innovate.

Often VCC model users need to run simulations over relatively long time horizons. For example, it is important to ascertain the annual performance of a building air conditioner, requiring many simulations over a one year time scale. Standard drive cycles in automotive applications are also relatively long time scale simulations. Several authors have reported that VCC models formulated under standard assumptions (conservation equations) do not conserve refrigerant mass, and that this has adverse practical consequences, especially for long time scale simulations. The refrigerant mass, or charge, seems to drift over the course of a simulation. Some choices of state can help alleviate the problem (Laughman and Qiao, 2015, 2016), although not entirely correct it. Practical methods of resetting states (Anderson et al., 2023) can help to reduce the "refrigerant mass drift," but require model modification and possibly manual intervention.

These results address the symptom of refrigerant mass drift in numerical simulations, but not its root cause. In this paper, we analyze a common model formulation of a VCC, identify mathematically the root cause of refrigerant mass drift, and describe two methods that can remedy the situation. The dynamic analysis results in an improved understanding of the structure and behavior of the resulting system of DAEs, with some perhaps surprising consequences and implications. For example, we show that equilibrium solutions to the systems of DAEs are stable, but not exponentially stable, which is often assumed to the the case. In fact, there is an equilibrium manifold of stable solutions to the set of DAEs. The equilibrium manifold is parameterized by the total refrigerant mass, and unavoidable numerical errors incurred during a numerical simulation will result in mass drift along the manifold.

This has implications for simulation, model-based control system design, and state estimation.

Fortunately, the structure suggests several remedies, which may be implemented as modifications to standard modeling constructs and result in exponentially stable models that do not exhibit refrigerant mass variation. This paper is organized as follows. We begin Section 2 with a VCC dynamic model resulting from application of standard mass, energy and momentum conservation assumptions. We analyze this model geometrically, proving existence of an integral submanifold of dimension one less than the state dimension, and existence of a one-dimensional equilibrium manifold. We show how this structure implies drift specifically in the refrigerant mass in a numerical simulation, illustrated by a simple VCC example. We then present two remedies in Section 3, with simulation examples. In Section 4 we also show how this behavior can manifest in a mechanical system model, which aids in understanding the situation, and shows that the results are general in nature and not restricted to only thermofluid cycles. We close in Section 5 by summarizing the results and stating a conjecture regarding more complex VCCs.

2 VCC Dynamics

A dynamic model of the thermofluid physics of a VCC generally begins from mathematical statements of distributed, one-dimensional mass, energy and momentum balance, such as

$$\frac{\partial(\rho A)}{\partial t}+\frac{\partial(\rho A v)}{\partial x}=0 \tag{1a}$$

$$\frac{\partial(\rho v A)}{\partial t}+\frac{\partial(\rho v^2 A)}{\partial x}=-A\frac{\partial P}{\partial x}-F_f \tag{1b}$$

$$\frac{\partial(\rho u A)}{\partial t}+\frac{\partial(\rho v h A)}{\partial x}=vA\frac{\partial P}{\partial x}+vF_f+\frac{\partial Q}{\partial x}, \tag{1c}$$

where P is a pressure, v is a velocity, u is a specific internal energy, ρ is a density, Q is a heat transfer rate, A is a cross-sectional area, V is a volume, F_f is a frictional pressure drop, x is a scalar spatial coordinate and t is time. These may be discretized in the spatial coordinate x resulting in a set of ordinary differential equations (ODEs)

$$\frac{d(\rho_j V_j)}{dt}=\dot{m}_k-\dot{m}_{k+1} \tag{2a}$$

$$\frac{d(\dot{m}_i l)}{dt}=\rho_j v_j^2 A_j-\rho_{j+1}v_{j+1}^2A_{j+1}+\frac{A_j+A_{j+1}}{2}\left(P_{j+1}-P_j\right)+F_{f,i} \tag{2b}$$

$$\frac{d(\rho_j u_j A_j)}{dt}=\dot{H}_k-\dot{H}_{k+1}+v_j jA_j(P_{j+1}-P_j)+vF_{f,i}+\dot{Q}_j, \tag{2c}$$

where the indices j and k correspond to gridding methods, and $\dot{m}_k$ denotes the mass flow rate at the boundaries of a finite control volume. See (Pat, 1980; Tummescheit, 2002; Laughman and Qiao, 2015, 2016) for details of modeling procedures and Modelica realizations.

State selection is dependent on the particulars of an application, but generally two states are selected for each control volume: A mixture variable, and another variable. Herein we choose pressure P and specific enthalpy h, which are common choices for VCC applications. However, the main results are not dependent on this specific choice. For compactness, define the full state $x=[P_1,h_1,P_2,h_2,\ldots,P_m,h_m]\in\mathbb{R}^n$ where m is the number of control volumes and $n=2m$, and express (2) as

$$\dot{x}=f(x,u), \tag{3}$$

where $u\in\mathbb{R}^p$ is a vector of control inputs, such as a compressor speed or an expansion valve opening. For simplicity, this formulation ignores states resulting from consideration of heat transfer to metal. These would have no bearing on the main results. Note that a Modelica model may not explicitly compute f, but rather it may express the dynamics in an implicit form. However, f exists mathematically and will make use of this fact.

In (2) the total refrigerant mass M is an explicit function of state:

$$M=g(x):=\sum_{i=1}^{m}=\rho_i(x_{2i},x_{2i+1})V_i. \tag{4}$$

Note that neither g nor M appear in (2). However, (2a) is a statement that $\dot{g}=0$. In typical use, g is used to set the initial condition $x(t_0)=x_0$ to correspond to a total refrigerant mass M_0 using

$$M_0=g(x_0). \tag{5}$$

2.1 Main Results

Since $\dot{g}=0$, we have

$$\dot{g}=\frac{\partial g}{\partial x}\cdot\dot{x}=\frac{\partial g}{\partial x}\cdot f=0. \tag{6}$$

Therefore, at any equilibrium solution x_e satisfying $f(x_e,u_e)=0$, we have

$$\frac{\partial g}{\partial x}|_{\substack{x=x_e\\u=u_e}}\cdot f(x_e,u_e)=0. \tag{7}$$

Expanding f into a Taylor's series about (x_e,u_e), we have

$$\frac{\partial g}{\partial x}|_{\substack{x=x_e\\u=u_e}}\cdot A=0, \tag{8}$$

where A is the Jacobian of f with respect to x, i.e., $A=\frac{\partial f}{\partial x}|_{\substack{x=x_e\\u=u_e}}$. Therefore

$$U_0:=\frac{\partial g}{\partial x}|_{\substack{x=x_e\\u=u_e}} \tag{9}$$

is the left eigenvector corresponding to a zero eigenvalue of A. Define V_0 to be the right eigenvector of A corresponding to the zero eigenvalue of A. Since A has one

DOI 10.3384/ecp218345

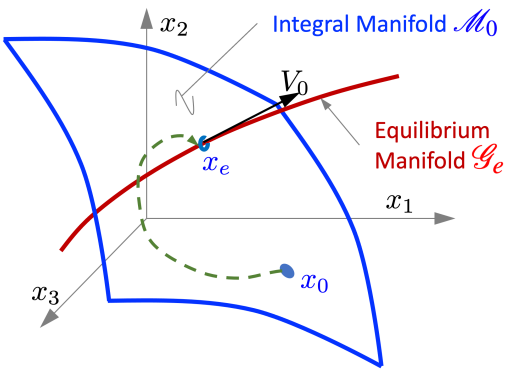

Figure 1. Integral manifold $\mathscr{M}_0$, equilibrium manifold $\mathscr{G}_e$, and a solution trajectory (green) for initial condition $x_0 \in \mathscr{M}_0$, converging to the stable equilibrium $x_e \in \mathscr{M}_0 \cap \mathscr{G}_e$.

zero eigenvalue (and the remaining $n-1$ eigenvalues are assumed to lie in the open left half plane), the equilibrium solution x_e is stable, but not exponentially stable. Further, x_e is not isolated, since $\tilde{x}_e = x_e \pm \varepsilon \cdot V_0$ is also an equilibrium for any $\varepsilon > 0$, by definition of the eigenvalue and eigenvector. Therefore, the linearized system

$$\delta\dot{x} = A\delta x + B\delta u$$

has an equilibrium subspace defined by the span of V_0, and therefore the nonlinear system (2) has a one-dimensional equilibrium manifold $\mathscr{G}_e$, which is tangent to V_0 at x_e, defined by those states x_e satisfying

$$0 = f(x_e, u_e) \tag{10a}$$
$$0 = g(x_e) - M_e \tag{10b}$$

which is parameterized by the refrigerant mass M_e (and also u_e). Finally, as as consequence, the nonlinear system has an $n-1$ dimensional integral manifold $\mathscr{M}_0$, implied by the fact that f lies within the tangent space of the $n-1$ dimensional submanifold defined by $dg = 0$, where d is the gradient operator. (An *integral manifold* $\mathscr{M}_0$ is invariant to the dynamics, meaning $x_0 \in \mathscr{M}_0 \rightarrow x(t) \in \mathscr{M}_0$ for all $t \geq t_0$.)

The situation is diagrammed in Figure 1, where an initial condition x_0 is defined to satisfy (10), the analytic solution $x(t)$ evolves on the $n-1$ dimensional integral manifold $\mathscr{M}_0$, which contains x_0, converging to the equilibrium solution x_e which lies in the intersection of $\mathscr{M}_0$ and $\mathscr{G}_e$. The equilibrium x_e is not exponentially stable because the eigenvector V_0 corresponding to the the zero eigenvalue is tangent to $\mathscr{G}_e$. As such, there is a family of $n-1$ dimensional integral manifolds $\mathscr{M}_k$, all transverse to $\mathscr{G}_e$, defined by the initial condition x_0. (These foliations are not shown in Figure 1 for clarity.) All of these results follow from the fact that A has one eigenvalue equal to zero, basic linear algebra and elementary nonlinear differential equation theory found in reference texts such as (Vidyasagar, 1993), (Khalil, 2002) and (Isidori, 1989).

2.2 Some Implications

This geometric structure has implications for numerical simulation, control design, model reduction and state estimation applications. Analytically, a solution $x(t)$ evolves on the $n-1$ dimensional integral manifold $\mathscr{M}_0$, and the effective dimension of the state vector is $n-1$, given an initial condition x_0, which determines the refrigerant mass M_0. However, a numerical simulation evolves in the full n-dimensional state space. Inevitable numerical errors at each discrete time step of any solver algorithm will result in an approximate solution that is not invariant to $\mathscr{M}_0$, i.e., the solution will drift off $\mathscr{M}_0$, onto some other $\mathscr{M}_k$. This drift is in exactly the direction of varying the refrigerant mass. Further, since the dynamics in the $\mathscr{G}_e$ direction are not exponentially stable, these errors are not corrected step to step. In effect, the drift is like a one dimensional random walk. The constraint $0 = g(x) - M_0$ is not stabilized.

In fact, there is a hidden state in the dynamics, corresponding to the direction of dg and locally associated to the eigenvector V_0. In a spectrally decomposed coordinate system this state is an open loop integrator driven by "noise" generated by numerical simulation errors, step to step. (The random walk analogy is very close, except the VCC simulation is deterministic.) For some simulations, this "noise" may be biased, which may be caused by simulation errors near the saturation curve, where the change in density is extreme, and in this case, a numerical simulation may seem to leak its entire charge of refrigerant.

It has been stated by some authors that the "mass is not a state" in such models, but this is not entirely correct. It is not an explicit element of x. However, the refrigerant mass is a state of the system, appearing as an open loop integrator in the spectrally decomposed coordinates. Since the x coordinates are used for simulation, the mass state is hidden, mixed among all the other states. This implies that any time domain simulation will exhibit drift in the refrigerant mass, regardless of the coordinates used, and regardless of the integration algorithm used. Some choice of coordinates (Laughman and Qiao, 2015, 2016) and also measures taken to enforce the mass constraint (Anderson et al., 2023) may result in a reduced magnitude of drift, owing to improved error control, but do not cause the mass constraint to be enforced.

For control, it is common to make use of model linearizations. Care must be taken in reducing the order of such models. Hankel norm methods which remove modes that are both weakly controllable and weakly observable, work only for exponentially stable systems. Matlab provides convenient tools for such purpose, but these will first extract the unstable (and weakly stable) part of the system by spectral decomposition, reduce the stable part, and then put the unstable part back, assuming that is what the user wants! Of course, for these applications, the user needs to remove the mode corresponding to the zero eigenvector first, because this mode is a modeling artifact. The true state dimension is $n-1 = 2m-1$.

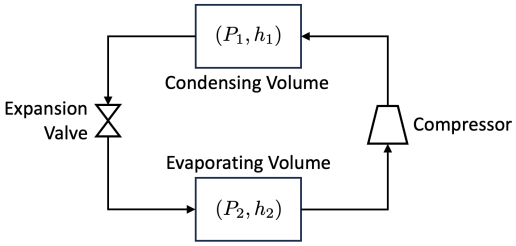

Figure 2. Two-volume vapor compression cycle.

2.3 An Example

Consider the simple two-volume VCC diagrammed in Figure 2, consisting of two control volumes labeled "condensing" and "evaporating" each with pressure-enthalpy states (P_1, h_1) and (P_2, h_2), respectively, a compressor and an expansion valve. The latter are modeled as algebraic functions relating the inlet and outlet states. Here the control input $u = [u_1, u_2]$ with the compressor speed u_1 and expansion valve count u_2. The state vector is $x = [P_1, h_1, P_2, h_2]$, and the dynamics are

$$\dot{x} = f(x,u), \quad x(t_0) = x_0 \tag{11a}$$
$$M = g(x) = \rho_1(P_1,h_1)V_1 + \rho_2(P_2,h_2)V_2\,. \tag{11b}$$

Linearizing the dynamics about an equilibrium solution confirms that 3 eigenvalues are in the open left half plane, and one is at the origin, with its left eigenvector U_0 aligned with the gradient of g. A simulation result with initial condition $P_1 = 2.6\,\text{MPa}$, $h_1 = 420\,\text{kJ/kg}$, $P_2 = 1\,\text{MPa}$ and $h_2 = 230\,\text{kJ/kg}$, constant values of the compressor speed (30Hz) and expansion valve (100 counts), and constant boundary conditions results in the transient response plotted in Figure 3. The refrigerant mass drifts for the 15s, coming to rest after the transient has transpired. Depending on the application, this amount of drift may or may not be acceptable. Importantly, it is entirely driven by numerical solver error, more or less the result of integrating a random signal.

2.4 VCC Models in (P,h,ρ) Coordinates

Formulating the VCC dynamics in (P,h,ρ) coordinates has been suggested as an approach to mitigate mass drift (Laughman and Qiao, 2015, 2016). These coordinates were derived by first expressing the dynamics in (P,ρ)-coordinates, and then adding a dynamic equation for h. Following this approach, assume the change of coordinates from (P,h) to (P,ρ) is well-defined in a region of interest. In the (P,ρ)-coordinates, denote the state vector as $y = [P_1,\ldots,P_m,\rho_1,\ldots,\rho_m]^T$. All the results from Section 2.1 also carry over to these coordinates. Next consider a linearized model around any equilibrium solution $\bar{y} \in \mathbb{R}^{2m}$, ignoring for simplicity the effect of any inputs,

$$\delta\dot{y} = A\delta y + B\delta z \tag{12a}$$
$$\delta z = C\delta y, \tag{12b}$$

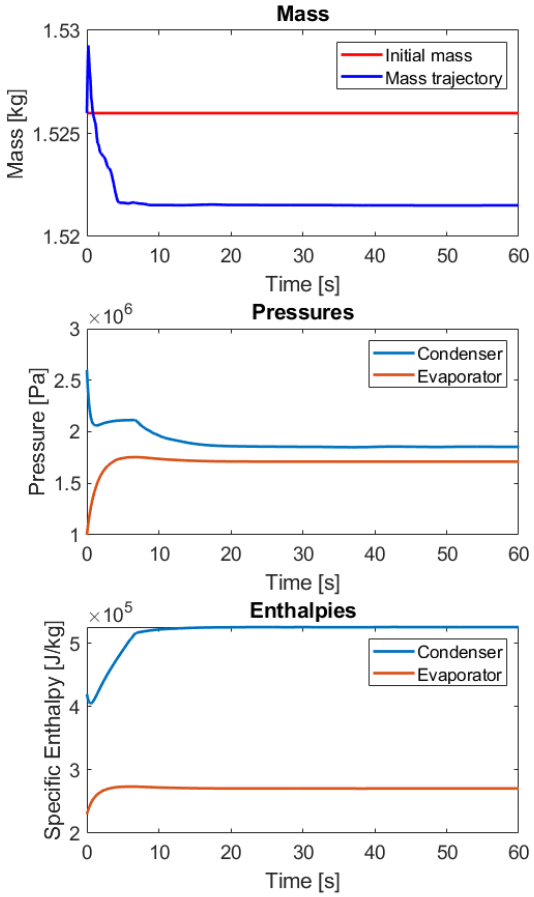

Figure 3. Refrigerant mass drift during initial transient.

where $\delta y = y - \bar{y}$, and $z \in \mathbb{R}^m$ is the enthalpy vector h, $\bar{z} \in \mathbb{R}^m$ is the equilibrium enthalpy vector, and $\delta z = z - \bar{z}$. The linearized enthalpy term δz is explicitly pulled out and expressed as an output function because (P,h,ρ)-coordinates use it as a third state in each control volume. Note that the linearized dynamics in (P,ρ) coordinates are $\delta\dot{y} = (A + BC)\delta y$.

In this notation, the corresponding linearization in (P,h,ρ) coordinates is

$$\delta\dot{y} = A\delta y + B\delta z \tag{13a}$$
$$\delta\dot{z} = C\delta\dot{y} = CA\delta y + CB\delta z. \tag{13b}$$

Note that the δz in (13b) is used on the right hand side of (13a), which means that in the original (P,h,ρ)-coordinate formulation, the h states, computed as solutions to m ODEs, are used in the $2m$ ODEs defining $\dot{P}$ and $\dot{\rho}$. Rewriting (13) in matrix form

$$\begin{bmatrix} \delta\dot{y} \\ \delta\dot{z} \end{bmatrix} = \begin{bmatrix} A & B \\ CA & CB \end{bmatrix} \begin{bmatrix} \delta y \\ \delta z \end{bmatrix}, \tag{14}$$

makes it clear that the system has m eigenvalues at zero, since the last m rows are linearly dependent on the first $2m$. As such a system expressed in (P,h,ρ)-coordinates will have a linearization with $m+1$ eigenvalues at the origin,

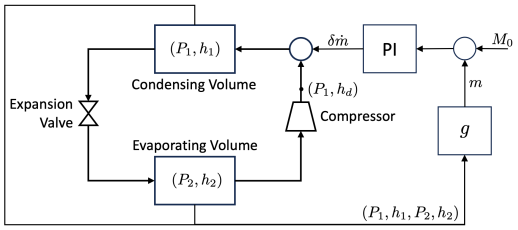

Figure 4. Two-volume vapor compression cycle.

and the nonlinear system will have an equilibrium manifold of dimension $m+1$ parameterized by the mass, and also the error between the m values of enthalpy h computed by the additional m differential equations and the algebraic constraint $h = h(P,\rho)$ that was differentiated. The improved accuracy in mass conservation reported in (Laughman and Qiao, 2015, 2016) is likely due to better solver error control in the density dynamics, but drift in a higher-dimensional manifold resulting in non-physical results is possible in long duration simulations.

3 Drifting Mass Remedies

We present two remedies. First, we can exponentially stabilize the total amount of mass in a cycle using a virtual feedback loop with integral action. Consider again the simple two-volume VCC diagrammed in Figure 2, now with a virtual mass feedback loop which acts to regulate the total amount of mass to the constant M_0, shown in Figure 4. This method requires minimal modification of the original model to allow for an additional virtual control input. The virtual input might be an added mass flow rate signal at the discharge port of the compressor, as shown in Figure 4, or alternatively it might be an added enthalpy signal at the discharge port of the compressor.

The PI feedback exponentially stabilizes the total mass, which can be understood by the Root Locus diagrammed in Figure 5. The "plant" here is the system from the virtual input to the measured mass output, which is $m = g(x)$. The plant includes a single pole at the origin, as discussed in Section 2, and $n-1$ poles in the open left half plane, where $n = 4$ for this example. The feedback loop including the PI compensator adds a second pole at the origin, and a zero in the open left half plane, at $s = -0.2$ for this example. Closing the feedback loop with positive gain causes the double poles at the origin to break away and move into the open left half plane, exponentially stabilizing the equilibrium. The action of feedback may change the dynamics of (3) but only slightly, because the dynamics on the integral manifold is invariant and the dynamics on the integral manifold are relatively insensitive to the virtual mass input. This is clear on Figure 5, where the 3 stable poles move very slightly from open to closed loop (the closed loop location is plotted over the open loop in the figure). The integral manifold $\mathscr{M}_0$ is not changed by the PI feedback.

Figure 6 shows the result of a simulation in which the

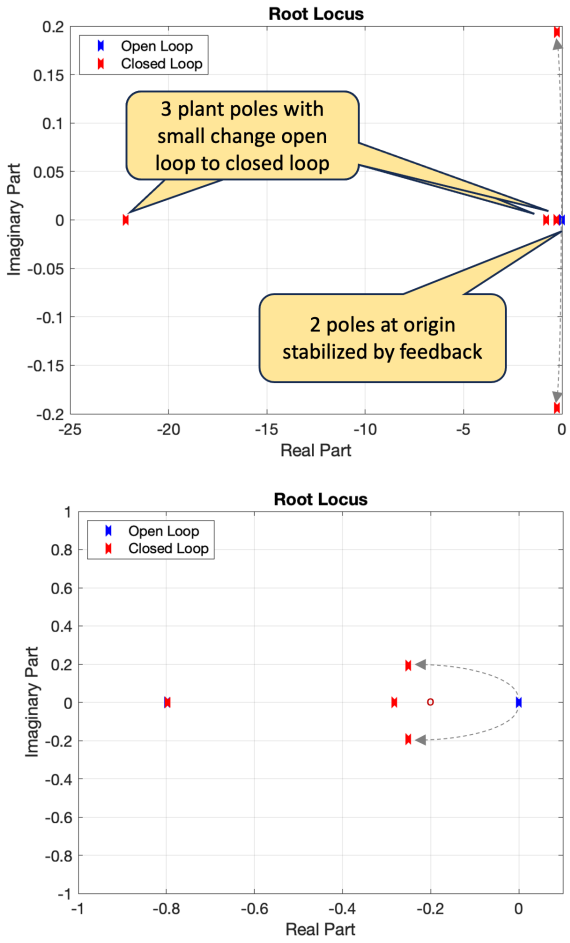

Figure 5. Root locus for the 2-volume system with virtual mass PI feedback (top), magnified to show poles and zeros near the origin (bottom). The PI zero is placed at $s = -0.2$. The 3 stable plant poles are relatively insensitive to the feedback, without visible displacement in the figure. The two unstable poles at the origin are moved to complex conjugate locations by the action of the virtual feedback loop.

virtual mass feedback is active, for the same initial conditions as in Figure 3. The feedback actively stabilizes the total mass and ensures that the equilibrium solution x_e is isolated and exponentially stable.

3.1 Stabilizing the constraint

Alternatively, following Gear (Gear, 1988; Brenan et al., 1996), a second method to stabilize the mass constraint is as follows. The modeled system (3) does not include the refrigerant mass constraint $0 = g(x) - M_0$. But Gear shows that the augmented system

$$\dot{x} = f(x,u) + \mu \cdot dg(x) \tag{15a}$$
$$0 = g(x) - M_0, \tag{15b}$$

where

$$dg = \frac{\partial g}{\partial x} \tag{16}$$

and μ is scalar Lagrange multiplier state, enforces the mass constraint explicitly and has an identical analytic so-

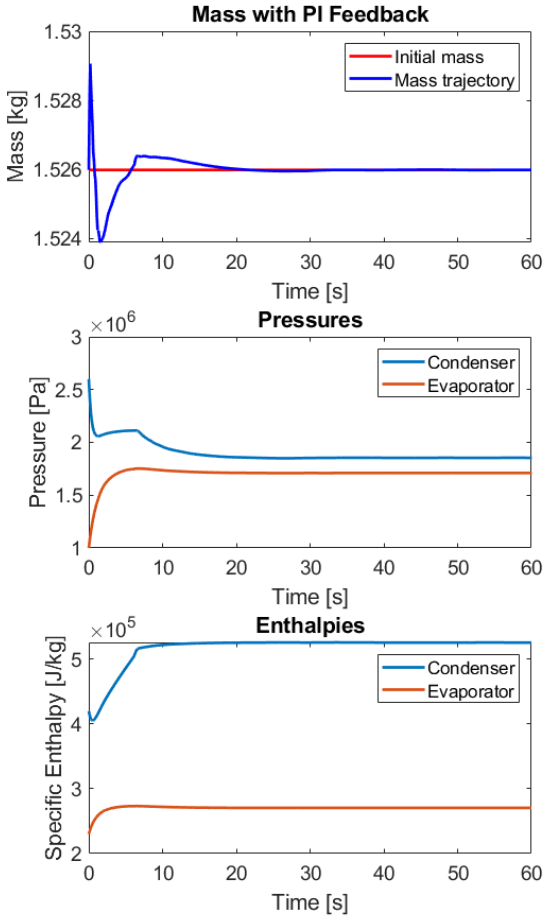

Figure 6. Refrigerant mass under the action of virtual PI feedback control for same initial condition as Figure 3.

lution as (3) with $\mu = 0$. Numerical solutions of (15) will therefore not suffer from drift from $\mathscr{M}_0$. However, the index of (15) is 2, so this system cannot be simulated directly using standard solvers.

The index can be reduced using the available methods provided in Modelica tools such as Dymola, but this could result in a complex and highly coupled model equations, since the gradient term dg contains all of the states and as a practical matter, most VCC models (3) are large in dimension to begin with. Alternatively, we may reduce the index manually using Baumgarte's method (Baumgarte, 1983). This involves replacing the constraint equation (15b) with a linear combination of g and $\dot{g}$, so that the new constraint equation is Hurwitz (roots in the open left half plane),

$$\dot{x} = f(x,u) + \mu \cdot dg(x) \tag{17a}$$
$$0 = \dot{g}(x) + \alpha_0 \cdot (g(x) - M_0), \tag{17b}$$

where the constant $\alpha_0 > 0$. System (17) is index 1 and may be simulated directly using standard solver algorithms. Note that $\dot{g}$ in (17b) is $dg \cdot (f + \mu \cdot dg)$ which not the same as $\dot{g}$ in Section 2, because the definitions of x and $\dot{x}$, respectively, have changed by the addition of the $\mu \cdot dg$ term in (17a).

To implement this scheme, the original model (3) needs modification by adding a single equation (17b) and adding

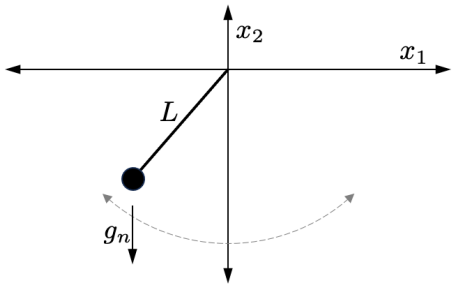

Figure 7. Cartesian pendulum.

the output injection terms $\mu \cdot dg$ to each of the state equations. This would require modification to the base classes of the modeling package, since they were probably not intended for this purpose, but the changes are relatively minor. System (17) may be less computationally complex compared to that obtained by reducing the index of (15) from 2 to 1 using the standard method of substitution of variables (or "dummy derivatives"). The method increases the dimension of the set of equations from n to $n+1$. But as a result, the constraint is stabilized, and the resulting equilibrium solution x_e is unique, isolated and exponentially stable. Numerical solutions will exhibit a small amount of error in the refrigerant mass during a simulation (as do any of the other states), on the order of the solver tolerance, but will not drift far from the initial condition because of the stabilization.

Implementing this approach for VCC models requires modifications to the base classes, which remains part of future work. Nevertheless, we illustrate the method using a simpler example in the following section.

4 Toy Pendulum Example

To show these results are not restricted to only VCC models, the dynamic analysis and remedies can be illustrated using the the quintessential Modelica example: The Cartesian pendulum, diagrammed in Figure 7, modeled as

$$\dot{x}_1 = v_1 \tag{18a}$$
$$\dot{x}_2 = v_2 \tag{18b}$$
$$\dot{v}_1 = -\lambda \cdot x_1 - b \cdot v_1 \tag{18c}$$
$$\dot{v}_2 = -\lambda \cdot x_2 - b \cdot v_2 - g_n \tag{18d}$$
$$0 = g(x_1, x_2) = x_1^2 + x_2^2 - L^2, \tag{18e}$$

where (x_1, x_2) is the Cartesian location of the bob, (v_1, v_2) is its velocity, λ is the Lagrange multiplier, g_n is the acceleration due to gravity, $b = 0.1$ is a damping coefficient introduced to stabilize the pendant position, and length $L = 1$. Realizing this model in Modelica, compiling in Dymola and simulating for $x_1(0) = 0.1$ gives the results in Figure 8, where Dymola reduces the index (from 3) and dynamically selects two states, here x_1 and v_1. There is of course no drift because the dimension of the dynamic states equals the number of degrees of freedom.

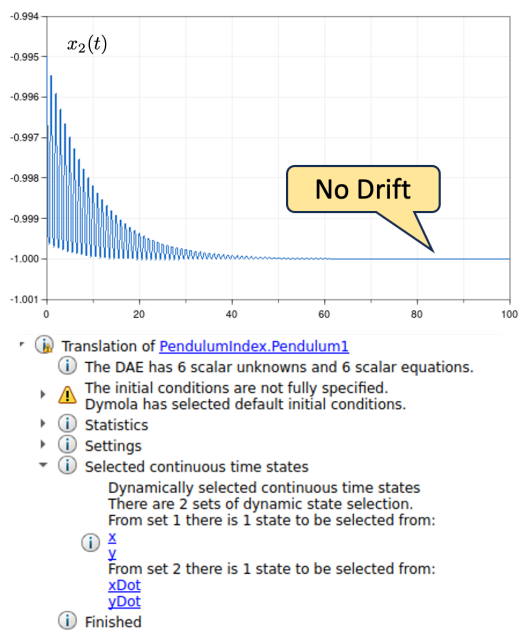

Figure 8. State selection results and simulation trajectory $x_2(t)$ of model (18).

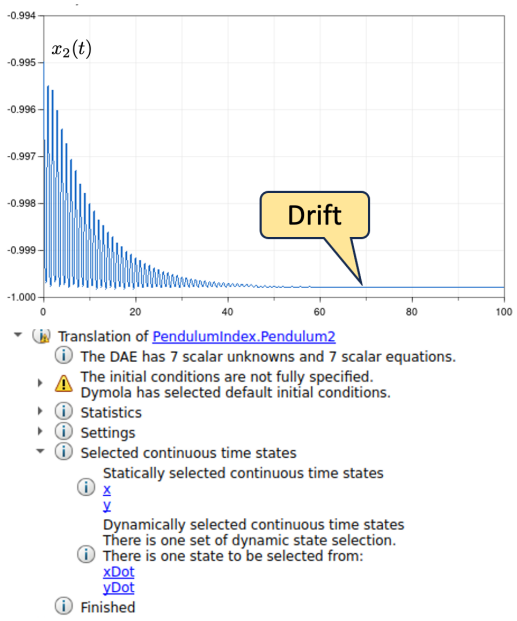

Figure 9. State selection results and simulation trajectory of $x_2(t)$ of model (19).

Now consider the system with the constraint (18e) replaced with its derivative,

$$\dot{x}_1 = v_1 \tag{19a}$$
$$\dot{x}_2 = v_2 \tag{19b}$$
$$\dot{v}_1 = -\lambda \cdot x_1 - b \cdot v_1 \tag{19c}$$
$$\dot{v}_2 = -\lambda \cdot x_2 - b \cdot v_2 - g_n \tag{19d}$$
$$0 = \dot{g}(x_1, x_2) = 2x_1 v_1 + 2x_2 v_2. \tag{19e}$$

This is analogous to VCC model with (19e) being similar to the mass flow rate constraint (2a). Realizing this model in Modelica, compiling in Dymola and simulating for $x_1(0) = 0.1$ gives the results in Figure 9, where Dymola reduces the index (from 2) and dynamically selects *three* states, here x_1, v_1 and x_2. Linearizing at the pendant equilibrium solution and computing eigenvalues results in the two stable eigenvalues that we expect, and a third eigenvalue at zero, associated with an eigenvector in the x_2-direction, precisely the direction of the missing constraint $g(x_1, x_2) = 0$ at the pendant equilibrium $(0, -1)$. The numerical solution is observed to drift along the vertical x_2 direction in Figure 9, away from the point $(0, -1)$.

Finally we augment (19) using Gear's method (Gear, 1988). The position constraint $0 = g(x_1, x_2)$ is added to the set, and the Lagrange multiplier μ multiplied by the gradient of g is added to the right-hand side of the ODEs (19a)-(19d), resulting in an index-2 DAE. Then we manually reduce the index from two to one using Baumgarte's method (Baumgarte, 1983), replacing the constraint equation $g = 0$ with $\dot{g} + \alpha_0 \cdot g = 0$, where $\alpha_0 > 0$, ($\alpha_0 = 1$ for convenience) resulting in the index-1 DAE

$$\dot{x}_1 = v_1 + \mu \cdot 2x_1 \tag{20a}$$
$$\dot{x}_2 = v_2 + \mu \cdot 2x_2 \tag{20b}$$
$$\dot{v}_1 = -\lambda \cdot x_1 - b \cdot v_1 \tag{20c}$$
$$\dot{v}_2 = -\lambda \cdot x_2 - b \cdot v_2 - g_n \tag{20d}$$
$$0 = 2x_1 v_1 + 2x_2 v_2 \tag{20e}$$
$$0 = \dot{g} + \alpha_0 \cdot (x_1^2 + x_2^2 - L^2). \tag{20f}$$

Again, there is a subtle but important point to consider: The $\dot{g}$ in (20f) is not the same as the $\dot{g}$ in (19e), because $\dot{x}$ has changed from the second to the third example. Realizing this in Modelica, compiling in Dymola and simulating for $x_1(0) = 0.1$ gives the results shown in Figure 10. Interestingly, Dymola reduces the index to 0, and dynamically selects three states, here x_1, v_1 and x_2, the same states selected for the second case. Linearizing the system at the equilibrium solution results in the two stable eigenvalues associated with the pendulum that we expect, and a third exponentially stable eigenvalue at $-\alpha_0$, associated with the stabilized constraint equation $\dot{g} + \alpha_0 \cdot g = 0$. The equilibrium solution is now exponentially stable. Although a numerical simulation of this system will suffer from a small amount of numerical error in the constraint ($g = 0$ is not exactly enforced), caused by Baumgarte's method (Bortoff, 2019) this can be controlled through the solver tolerance, and importantly the solution will not exhibit constraint drift, as shown in Figure 10.

5 Conclusion

Numerical simulations of some dynamic models of vapor compression cycles based on standard conservation equations may not conserve refrigerant mass, resulting in sim-

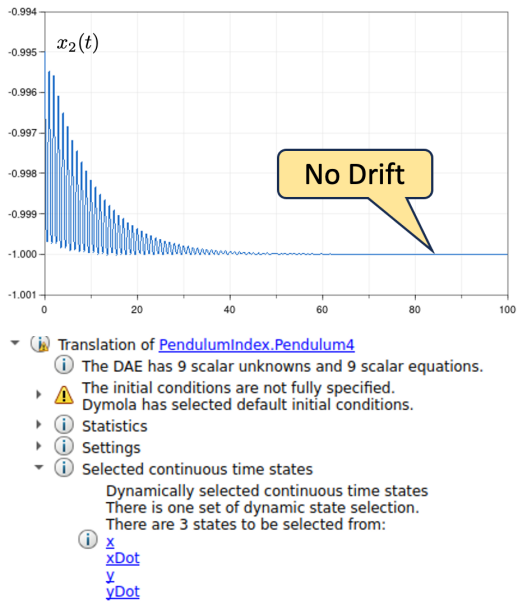

Figure 10. State selection results and simulation trajectory of $x_2(t)$ of model (20).

ulation failures especially for relatively long simulation times. This paper provides a dynamic analysis to ascertain mathematically the root cause of so-called refrigerant mass drift, resulting in an improved understanding of the dynamic model structure and behavior. The key result is that models derived using conventional assumptions and using conventional coordinates (two fluid states per control volume) are not exponentially stable, as is often assumed, and the n-dimensional state space may be decomposed into an $n-1$ dimensional integral manifold, and a transverse 1-dimensional equilibrium manifold. Numerical solutions will inevitably drift in the direction of the equilibrium manifold, manifesting as a varying refrigerant mass. Models that make use of higher dimensions such as (P,h,ρ) for each control volume, will exhibit higher dimensional equilibrium manifolds that may result in numerical drift in these spaces, leading to unphysical results. Two methods to remedy are proposed and shown to be effective with a thermofluid VCC example and also a classic pendulum example.

Modelling and Impact of Hydraulic Short Circuit Operation in Pumped Hydro Energy Storage

Inga Beyers[1] Lukas Krebeck[1] Astrid Bensmann[1] Richard Hanke-Rauschenbach[1]

[1]Leibniz University Hannover, Institute of Electric Power Systems, Appelstraße 9A, 30167 Hannover, Germany

Abstract

This paper investigates the hydraulic short circuit (HSC) operation of pumped hydro energy storage systems, specifically how it can be modelled and its impact on energy capacity, efficiency and operating range. Hydraulic short circuit operation enables power modulation during charging for fixed-speed pumped hydro systems, thereby allowing them to operate more flexibly. In this work, a pumped hydro storage system with 140.5 MW nominal charging power and 10 h nominal charging time is analysed. The storage is simulated via a dynamic, system-level model composed of detailed physical component models to accurately depict the HSC operating behaviour. HSC enables part-load operation from 39 MW to 107 MW but with significantly lower overall system efficiencies. The HSC operating limits are governed by the turbine's minimum flow and maximum power. The custom-built OpenModelica library employed for this analysis can be downloaded from `https://github.com/ibeyers/pumped-storage-lib`.

Keywords: energy storage, pumped hydro, hydraulic short circuit, flexibility, off-design operation

1 Introduction

This paper focuses on the hydraulic short circuit operation mode of pumped hydro energy storage systems. The role and operation of pumped hydro energy storage in the European electricity system have changed following the liberalisation of energy markets and the increasing integration of fluctuating renewable energy sources. Moving away from traditional arbitrage operation, pumped hydro systems now often participate in multiple markets and generate additional revenue from ancillary services, such as frequency regulation (Pérez-Díaz et al. 2015). As a consequence, the operational flexibility of pumped hydro storage systems has become a key focus area in the field of pumped hydro research and practice (Giese and Magnoli 2019). This is an issue because the operational flexibility of traditional fixed-speed pumped hydro is severely limited on the charging side. Since the power consumption of a fixed-speed pump is governed by the system head, deliberate power modulation is not possible during charging (Valavi and Nysveen 2018)[1]. Pumped hydro operators increasingly retrofit existing systems to enable more operational flexibility, while flexibility is already a central design consideration for new systems (Vagoni et al. 2024).

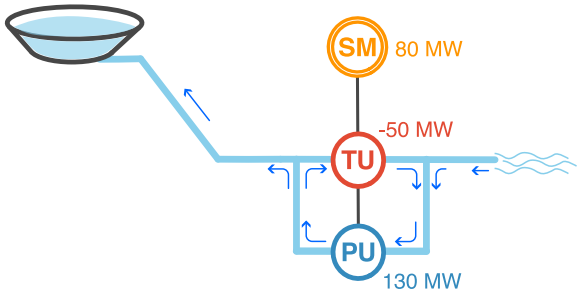

Figure 1. Illustration of hydraulic short circuit operation in a ternary machine set (pump, turbine and synchronous machine). During charging, a part of the flow is recirculated to the turbine, which delivers power and therefore reduces the system's net power consumption.

One approach to counteract this inflexibility and enable deliberate power modulation during charging is the so-called "hydraulic short circuit" (HSC) operation. Here, a portion of the pumping flow is redirected to a turbine, whose power delivery can be adjusted via the guide vane opening. This allows the system's net power consumption to be regulated by adjusting the turbine power delivery. This principle is illustrated in Figure 1. This mode requires at least two hydraulic machines, either in a single ternary machine set or two pump-turbines, with one operating as a pump and the other as a turbine. The advantage of HSC is that it can be retrofitted with relatively low capital expenditure, while the disadvantage is the low system efficiency (Vagoni et al. 2024). We recently investigated the operational flexibility and performance of different pumped hydro configurations, including HSC operation (Beyers, Krebeck, et al. 2025). In this work, we build on that previous work but focus on three aspects of hydraulic short circuit not yet addressed in the literature.

The first aspect is the implementation of the library, which was developed to simulate pumped hydro systems and HSC operation in the OpenModelica environment (Fritzson et al. 2020). Pumped storage research is

[1]Strictly speaking, it is not impossible but rather not advisable. Theoretically, pump throttling can be used to achieve a degree of freedom in pump operation (Alizadeh Bidgoli, Yang, and Ahmadian 2020). However, the resulting damage to the pump is unacceptable and pump throttling, therefore, does not feature in the continuous operation of pumped hydro storage systems

often conducted using proprietary software, and the results are then shared without a deeper insight into the underlying methodology and implementation, see, e.g. Ruppert et al. (2017) and Geiger and Riedelbauch (2023). Open source modelling can therefore contribute to open research and accelerate R&D efforts in this field. A well-executed open hydropower library for Modelica (OpenHPL) developed by Vytvytskyi (2019) exists; however, it currently cannot model the bidirectional operation of pumped hydro. Therefore, a custom library was developed[2]. The second aspect is an elaboration of the flow regimes that ensue during HSC operation. So far, the HSC mechanism in the entire hydraulic network has not been demonstrated in detail in the literature. By understanding the HSC mechanism, the impact of HSC operation on energy capacity, efficiency and operating range can be demonstrated very clearly. The third aspect is extending HSC with a thermal analysis. Practical experience at the Frades II pumped hydro plant has shown that hydraulic short circuit operation can lead to inadmissibly high water temperatures since the losses of the hydraulic machines heat up the circulating water (Pinto et al. 2024). This could significantly impact continuous operation and make HSC less suitable for retrofits of certain pumped hydro system types. To the authors' best knowledge, this aspect has never been formally investigated and therefore, warrants a first exploration.

Our paper will, therefore, deliver the following three contributions:

1. Focus on implementation aspects of modelling HSC.
2. A more detailed elaboration of flow regimes during HSC operation.
3. An investigation of non-isothermal HSC.

This paper is structured as follows: Section 2 details the system under consideration. Section 3 presents an overview of the methodology, including the implementation in a custom-built OpenModelica library. Section 4 presents the results and Section 5 concludes this work.

2 System under consideration

The system analysed in this work is a synthetic pumped hydro system. This is done to avoid a case-specific bias and instead develop general-purpose insights. The hydraulic scenario is taken from previous work (Beyers, Krebeck, et al. 2025). Key characteristics are:

- Upper reservoir with a geodetic head $\overline{h}_{\mathrm{geo}}$ of the reservoir water level ranging from 480 m (empty) to 520 m (full).
- Circular upper reservoir with tapered walls, with an opening angle of 30°.
- Upper reservoir sized so that 100 MW can be delivered for 10 h.
- Lower reservoir with an infinite capacity, such as a river or lake, which acts as a boundary with a constant head.
- Total waterway distance of 2.4 km.

The 500 m average geodetic head is explicitly chosen to keep this a generic scenario where all technical configurations are viable.

Within this hydraulic scenario, we consider a single ternary machine set with a dedicated pump and a Francis turbine. The machine set shaft is connected to a salient-pole synchronous machine. A block transformer steps up the synchronous machine voltage to the grid voltage (or steps down, depending on the direction of power flow). The hydraulic and electrical machines are sized to deliver 100 MW nominal discharging power and consume 140.5 MW nominal charging power at the grid connection point with a power factor $\cos(\varphi)$ of 0.9. In contrast to the previous paper, the machines here are sized for a symmetric charging and discharging duration of 10 h, resulting in higher charging power. Key parameters are summarised in Table 1.

Table 1. Selected parameters of hydraulic and electrical machines.

Component	*Parameter*	*Value*
Transformer	Nom. apparent power $S_{\mathrm{tr}}^{\mathrm{nom}}$	156 MVA
	Nom. high voltage $U_{\mathrm{tr,hv}}^{\mathrm{nom}}$	220 kV
Synchronous Machine	Nom. apparent power $S_{\mathrm{sm}}^{\mathrm{nom}}$	156 MVA
	Nom. stator voltage $U_{\mathrm{sm,st}}^{\mathrm{nom}}$	10.5 kV
	Nom. rotor speed $n_{\mathrm{sm,ro}}^{\mathrm{nom}}$	500 rpm
Turbine	Number of stages N_{s}	1
	Specific speed of stage $n_{\mathrm{q,tu}}^{\mathrm{nom}}$	24.0
Pump	Number of stages N_{s}	2
	Specific speed of stage $n_{\mathrm{q,pu}}^{\mathrm{nom}}$	41.0

3 Methodology

This section is divided into three parts: Section 3.1 describes the general modelling approach, Section 3.2 presents an overview of the components, and Section 3.3 discusses select aspects of the pumped storage library.

3.1 Modelling approach

In this work, we employ a system-level model formulation to account for all machines and their interactions up to the grid connection point. The model combines dynamic components and quasi-stationary components. The components are connected to each other to form a system model. Because the focus is on continuous operation, the system's dynamics are governed by the reservoir. The

[2]It should be noted that the library is currently under development. Its purpose is to answer the specific questions pursued by the authors and therefore does not cover all aspects of pumped hydro storage.

DOI 10.3384/ecp218353

filling and emptying of the reservoir result in a head variation, which forces the rest of the components into off-design operation. Faster dynamics (e.g., the inertia of rotating masses in machines) can be neglected compared to the slow dynamics of the reservoir. The other component models are therefore considered quasi-stationary; they undergo a sequence of stationary operating points set by the dynamic reservoir head variation. The system is simulated with a so-called "hot start" at nominal speed, i.e. the start-up sequence from standstill is not modelled. The passive sign convention is used in this work. Quantities flowing into a component (or the system) are positive, whereas quantities flowing out are negative. At the grid connection point, charging power is positive and discharging power is negative.

3.2 Component models

Our previous publication (Beyers, Krebeck, et al. 2025) describes the component models in detail. This section briefly reiterates key aspects.

Upper reservoir, conduits and point losses. The hydraulic waterway elements and the hydraulic machines are all characterised by head h and volumetric flow q, as is common in the field of fluid systems. The head is the total mechanical energy of a flow, expressed in a height in meters:

$$h = \frac{p(t)}{\rho g} + \frac{v(t)^2}{2g} + h_{\text{geo}} \tag{1}$$

It is composed of the pressure head $p(t)/\rho g$, the velocity head $v(t)^2/2g$ and geodetic head h_{geo}. Water is considered an incompressible medium with a constant density of $\rho = 1000\,\text{kg/m}^3$.

The reservoir is governed by a dynamic mass balance, expressed here through the reservoir volume V_{ur}:

$$\frac{\mathrm{d}V_{\text{ur}}}{\mathrm{d}t} = q(t) \tag{2}$$

The reservoir is characterised by a State-of-Charge (SOC) that relates the volume contained in the reservoir to the nominal water volume:

$$\text{SOC}(t) = \frac{V_{\text{ur}}(t)}{V_{\text{ur}}^{\text{nom}}} \tag{3}$$

The water volume in the upper reservoir and the water level $x(t)$ are linked through the geometric shape of the reservoir.

$$V_{\text{ur}}(t) = \frac{x(t)\cdot\pi}{3}\cdot\left(R(t)^2 + R(t)\cdot r + r^2\right) \tag{4}$$

with the radius at the bottom r and the top of the water volume $R(t) = r + x(t)\cdot\tan(30^\circ)$.

The components through which the water is transported are either conduits (distributed "pipe" elements such as the headrace, the penstock and the tailrace) or point losses, which include all other elements, (e.g., intake, rake, bends) that incur *local* losses. They are modelled as lumped, static components with conservation of mass and energy[3]. Conservation of energy is expressed through the extended Bernoulli equation (Pritchard and Leylegian 2011), which includes losses in the form of a friction head h_{fric}:

$$h_{\text{in}}(t) = h_{\text{out}}(t) + h_{\text{fric}}(t) \tag{5}$$

In this formulation, the change in internal thermal energy of the water through the friction losses is neglected. The friction head for the conduits with the length l, diameter d and friction factor $\lambda(t)$ is:

$$h_{\text{fric}}(t) = \lambda(t)\cdot\frac{l}{d}\cdot\frac{v(t)\cdot|v(t)|}{2g} \tag{6}$$

For the point losses the term $\lambda(t)\cdot\frac{l}{d}$ is replaced by an empirical friction factor ζ specific to each component.

Hydraulic machines. The hydraulic machines are modelled with mechanistic models, which combine Euler equations that reflect ideal machine behaviour with empirical/semi-empirical loss models. The pump model is based on Tuzson (2000), and the turbine model is from Nielsen (2015) and Reines and Svingen (2020).

To demonstrate the models, the parameterised pump and turbine performance maps are shown in Figure 2 a) (pump) and Figure 2 b) (turbine). Figure 2 a) contains the pump curves, plotting head over volumetric flow rate, combined with isolines for speed (dash-dotted) and relative efficiency (solid). The pump always operates at best guide vane opening, eliminating this variable from the pump map. The turbine map in b) is visualised differently since the adjustable guide vane opening offers an additional degree of freedom in operation. The map plots the volumetric flow rate over the turbine speed, with isolines of the same guide vane opening (dashed) and relative efficiency (solid). The turbine performance map is shown for the nominal head.

Electrical machines. Both the synchronous machine and the transformer are modelled with complex phasor equivalent circuit models (ECM), with constant parameters. This is a standard modelling procedure to describe stationary and quasi-stationary behaviour. It is described in reference works, such as Müller and Ponick (2009) and Oeding and Oswald (2016). The synchronous machine has an internal-voltage-based equivalent circuit model. It is complemented by separate loss functions, e.g., for iron losses (Engevik, Valavi, and Nysveen 2016), windage losses and additional losses (Pyrhönen, Jokinen, and Hrabovcová 2013).

[3]For steady, incompressible flow along a streamline, conservation of momentum leads to the same expression as conservation of energy (Pritchard and Leylegian 2011)

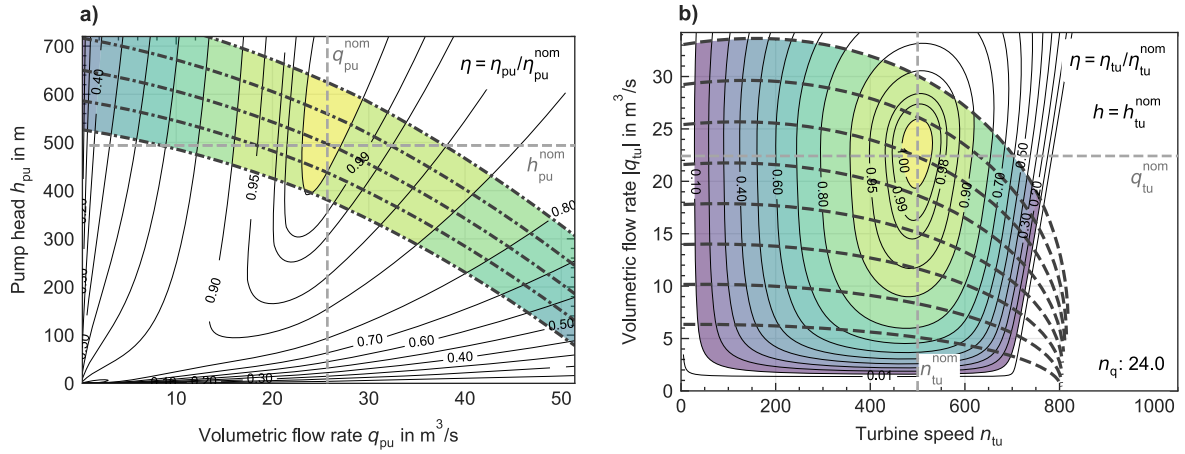

Figure 2. Parameterised pump model in a) and turbine model in b), shwon as performance maps. In the pump map, the dash-dotted curves are isolines of the same speed. The solid lines are isolines for the relative efficiency $\eta_{pu}/\eta_{pu}^{nom}$. In the turbine map, the dashed curves are isolines of the same guide vane opening. The solid lines are isolines for the relative efficiency $\eta_{tu}/\eta_{tu}^{nom}$.

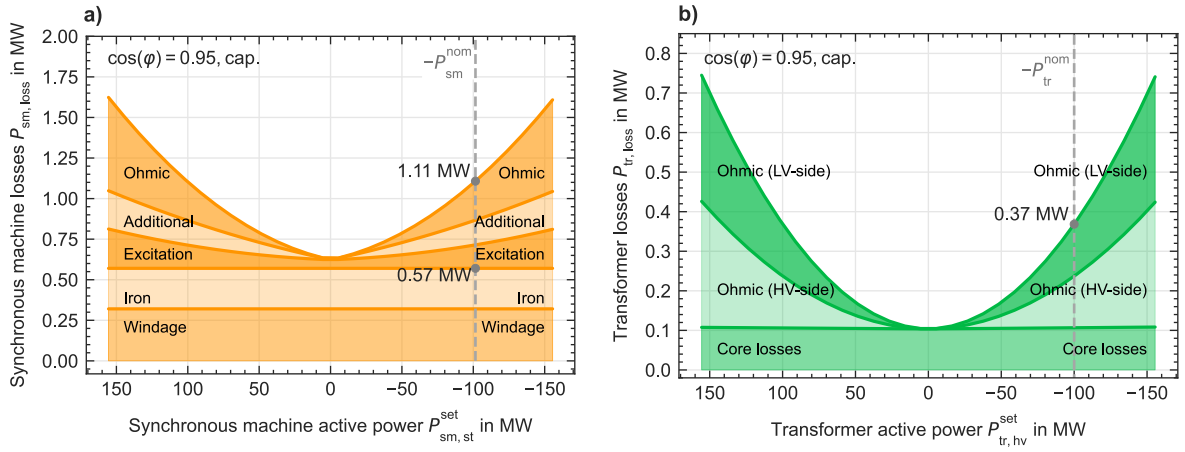

Figure 3. Loss breakdown of the parameterised synchronous machine model in a) and transformer model in b). Synchronous machine losses are plotted as a function of the active power on the stator side, $P_{sm,st}$, while the transformer losses are plotted as a function of the active power on the high-voltage side, $P_{tr,hv}$.

To provide insight into the model, Figure 3 a) shows the losses of the parameterised synchronous machine. The losses are plotted over the stator-side active power $P_{sm,st}$ at a capacitive power factor of $\cos(\varphi) = 0.95$ and nominal speed. The left side of the figure shows the motor mode (positive values, power drawn by the SM) and on the right side is the generator mode (negative values, power delivered by the SM). The losses are non-linear. At nominal discharging power, approximately 51 % of losses are constant losses (windage, iron) and 49 % are load-dependent.

The transformer is modelled with a T-shaped equivalent circuit model. The T-ECM includes a shunt element, which represents the core losses and causes a significant efficiency drop in low part-load. To illustrate the model's behaviour, the losses of the parameterised transformer are shown in Figure 3 b). The losses are plotted over the high-voltage-side active power $P_{tr,hv}$ at a capacitive power factor of $\cos(\varphi) = 0.95$. The losses are dominated by the Ohmic losses at nominal discharging power.

3.3 Implementation in a custom OpenModelica library

For this analysis, a custom-built OpenModelica library is employed, making use of the features of the Modelica language, i.e. multi-physics, equation-based and object-oriented modelling. General-purpose libraries lack required components for this analysis (e.g. a salient-pole synchronous machine) and are not necessarily parameterised for the scale of pumped hydro components. Therefore, the component models have been developed from the ground up to meet the specific modelling needs and model depth required. However, the custom models use the Modelica standard library for, e.g., units, icons, control elements, and connectors. The parameterisation of the component models is performed in separate Python scripts, where the resulting parameter sets are then copied to OpenModelica. The models used for this analysis are found in a subpackage called "ModelicaConference2025".

DOI 10.3384/ecp218353

Key aspects of the library are discussed in the following paragraphs.

The hydraulic elements, such as conduits, point losses and reservoirs, are modelled in an *acausal* manner. This has the advantage that a single model representation can be used for all modes of operation since the flow direction is not prescribed. This is important, as flow direction can vary between regular charging, regular discharging and hydraulic short circuit operation.

The library uses Modelica's object-oriented nature. There are four separate model layers: component models, subsystem models, full system models, and the control layer. The smallest unit is a component, where a "flat" model formulation is used. The hydraulic components are instantiated to build a hydraulic subsystem, referred to as the "waterway." The lower reservoir is a sink, and only the head is specified as a boundary condition. The waterway is then extended by the conversion machines (pump, turbine, synchronous machine, and transformer) to form a full system. Separating the waterway from the conversion machines has the advantage that different machine types and sizes can be tested in the same hydraulic system. Finally, the control layer is added by extending the full system, so that experimentation with different control strategies is possible. Where possible, ideal controllers in the form of implicit equations are implemented. Where explicit control loops are necessary, such as setting the turbine power to achieve a specified power at the grid connection point during HSC, they are implemented as PID (proportional-integral-derivative) control.

The full system model is shown in Figure 4. The shaft power outputs and inputs from the hydraulic machines are connected to the synchronous machine with causal input/output connectors. The electrical machines are only connected via causal input/output connectors, each with a set of connectors for power consumption and delivery. They are connected via sum-to-zero coupling of active and reactive power. The full system model includes auxiliary losses, which are modelled as an active power loss between synchronous machine and transformer. During discharging, the active power is set at the grid connection point and the power requirements are propagated back through the transformer and synchronous machine to the turbine component. During charging, the active power required by the pump is propagated in the other direction towards the grid connection point. The reactive power is determined from the active power at the grid connection point via a constant power factor in operation of 0.95 and communicated back to the synchronous machine component. In hydraulic short circuit operation, the turbine power is controlled via a PID controller to maintain the constant charging power setpoint at the grid connection.

4 Results and Discussion

The results are divided into four subsections. Section 4.1 analyses the impact of HSC operation at a single point in time, focusing on the flow conditions, the power split between machines, and the resulting efficiency. In Section 4.2, an entire HSC charging process is simulated over time. In Section 4.3, multiple HSC and regular charging/discharging processes are aggregated to quantify the system's energy capacity-power relationship, efficiency-power relationship, and operating range. Finally, Section 4.4 contains a brief consideration of the thermal behaviour.

4.1 Hydraulic short circuit operation at different power levels

To elaborate on the effects of HSC operation, the flow conditions and further variables are shown for two snapshots in time for 50 MW and 60 MW part-load charging, respectively, at a SOC of 0.5. Figure 5 is for a charging power of 50 MW at the grid connection point. At a SOC of 0.5, 50 % of the nominal water mass is stored in the reservoir and the total reservoir head is 502.77 m (comprising 480 m elevation at the reservoir bottom and a water level of 22.77 m). Recall that the head in the upper reservoir varies between 480 m (empty) and 520 m (full), yielding a relative water level of $22.77\,\mathrm{m}/40\,\mathrm{m} = 56.9\%$. Due to the tapered geometry, the relative water level and SOC differ.

The head values are shown in red at every connection point between two components. This is the total head from the extended Bernoulli equation, composed of pressure head, velocity head and geodetic head. These three contribute differently depending on the location in the waterway, but the proportions are not detailed here. Furthermore, the constant water level of the lower reservoir is set to $h = 0\,\mathrm{m}$, thus the total head is given relative to this reference level. The head difference between different points of the waterway displayed in Figure 5 is thus solely due to the friction losses in the conduits and fittings.

The pump has a power consumption of 134.55 MW at nominal speed and a pump head of $h_{\mathrm{pu}} = 504.91\,\mathrm{m}$. The resultant flow in this operating point is $24.8\,\mathrm{m}^3/\mathrm{s}$. The flow values are printed in blue above or beside the relevant conduits. The turbine needs to deliver -86.16 MW to the shaft to achieve 50 MW active power consumption by the transformer at the grid connection point. For this, $19.5\,\mathrm{m}^3/\mathrm{s}$ of the flow is redirected to the turbine. Only the remaining $5.3\,\mathrm{m}^3/\mathrm{s}$ flows up to the reservoir. Because of the low net flow in large parts of the waterway, the head losses are also comparatively low. For reference, in regular charging/discharging operation the head loss due to friction is $> 10\,\mathrm{m}$. In this HSC operating point, the pump must overcome only $504.91\,\mathrm{m} - 502.77\,\mathrm{m} = 2.15\,\mathrm{m}$ of total friction head loss for the entire waterway.

The net shaft power supplied by the synchronous machine rotor is 48.39 MW. The losses of the synchronous machine, the auxiliary losses, and the transformer losses are added to yield a total active power consumption of $P_{\mathrm{gc}} = 50\,\mathrm{MW}$ at the grid connection point. The total system efficiency can be calculated by dividing the hydraulic power flowing into the reservoir P_{ur} by the active power

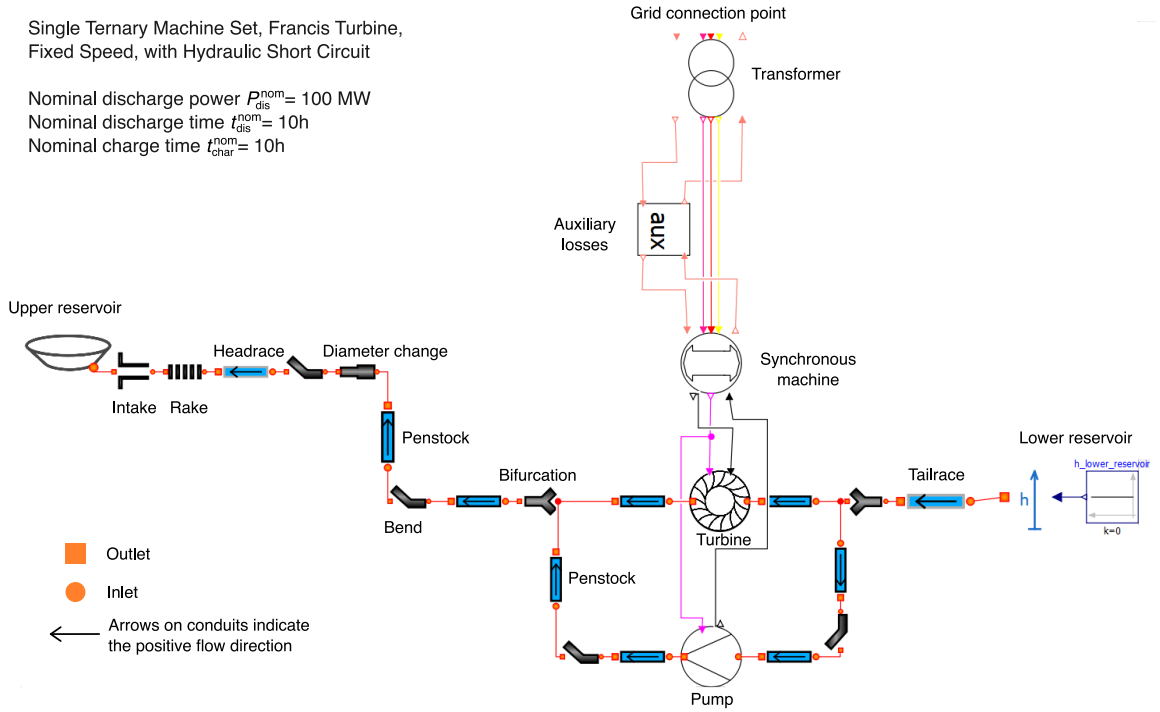

Figure 4. Full system model as implemented in OpenModelica. Note that because this is an abstract representation of the pumped hydro system, the dimensions of the waterway are not to scale.

supplied at the grid connection point P_{gc}:

$$\eta_{sys}(t) = \frac{P_{ur}(t)}{P_{gc}(t)} \tag{7}$$

with $P_{ur}(t) = h_{ur}(t) \cdot q(t) \cdot g \cdot \rho$. This operating point achieves an efficiency of 52.28 %, which is relatively low compared to efficiencies achieved in normal charging or discharging operations. It is important to note that the hydraulic short circuit efficiency cannot be estimated by multiplying all the component efficiencies because the power flow is not unidirectional. In hydraulic short circuit, there are two opposing power flows, each with its associated losses, which is the reason for the low total system efficiency. Figure 6 shows the same variables for 60 MW part-load and a SOC of 0.5, so the upper reservoir head ($h_{ur} = 502.77$ m) is identical to that in Figure 5. Conceptually, part-load charging with HSC is the same for 50 MW and 60 MW, however, three key aspects are highlighted below to better understand HSC operation. The first aspect is the complementary relationship between turbine power and charging power: a *low* HSC charging power (more part-load) requires higher turbine output (more negative power), while a high HSC charging power (less part-load) requires lower absolute turbine power. The second aspect is that the system efficiency is strongly influenced by the proportion of flow recirculated through the turbine. At 60 MW HSC charging power, less flow is recirculated through the turbine than at 50 MW ($17.3\,m^3/s$ vs. $19.5\,m^3/s$). Thus, more net flow reaches the upper reservoir, and the system efficiency is ultimately higher. The higher the flow through the turbine, the lower the system efficiency. Thirdly, the pump operating point is slightly different at 60 MW and SOC = 0.5 than at 50 MW and SOC = 0.5 because of the head friction losses. The headrace and the long diagonal penstock are the main drivers of the head friction losses. At 60 MW, the flow through these conduits is slightly higher, incurring higher losses, requiring the pump to supply a higher head (505.49 m vs 504.91 m at 50 MW). This shifts the pump operating point upwards and to the left on the pump curve (refer to Figure 2 a), which means the pump flow is slightly lower at $24.7\,m^3/s$ vs. $24.8\,m^3/s$ at 50 MW.

4.2 Hydraulic short circuit operation over time

Figure 7 demonstrates a complete 50 MW, constant-power HSC charging process over time to showcase the system dynamics. The simulation takes 4.6 s of computation time using a time step of 10 s. The upper reservoir starts at SOC = 0 and is terminated at SOC = 1 with a charging time of 44.5 hours. Figure 7 a) shows the pump head (solid line) and flow (dashed line) on the y-axis over the charging time on the x-axis. The main dynamic is the water level variation in the upper reservoir. Consequently, as the charging progresses, the pump sees an increasing head from 482.5 m to 521.8 m as the reservoir is filled and the water level rises. As the head increases, the pump flow decreases. On the pump curve (refer back to Figure 2 a), this corresponds to a leftward shift along the curve. The pump power consumption is largely governed by the pump flow.

DOI 10.3384/ecp218353

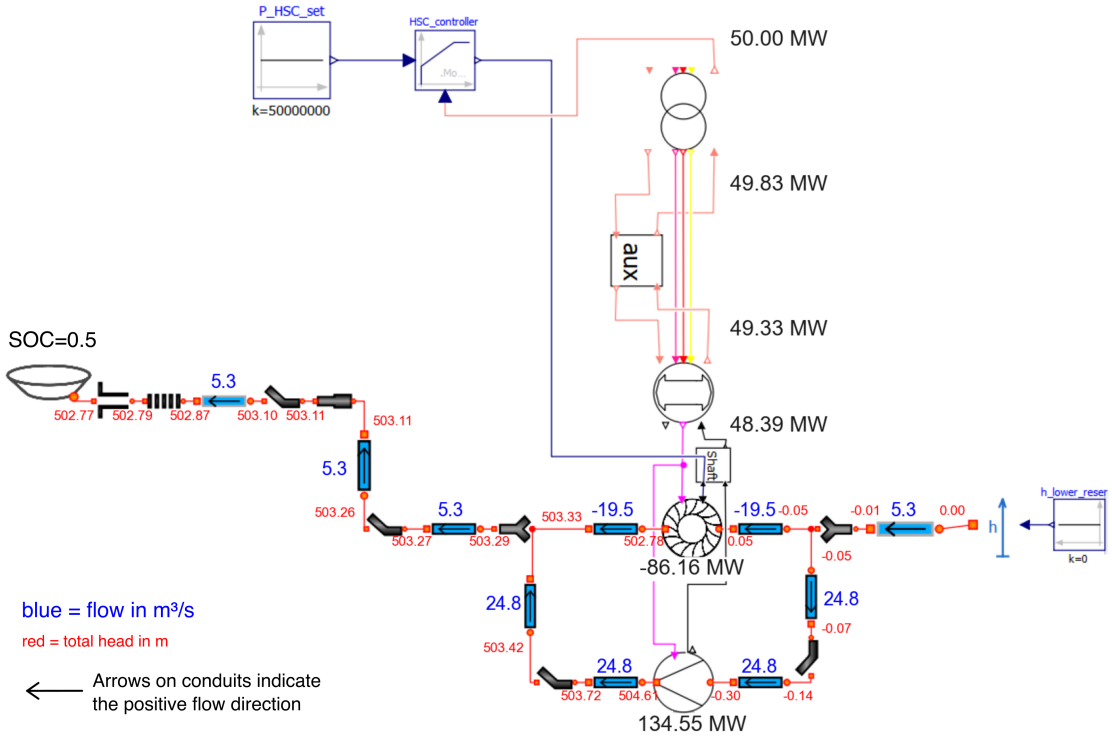

Figure 5. Snapshot in time of key variables of the pumped storage system during hydraulic short circuit operation. State-of-Charge is 0.5 and the charging power at the grid connection point is 50 MW. The flow values are printed in blue above or beside the relevant conduits. The head values are printed in red at every connection point between two components. The power values are printed in black next to the machines.

Therefore, as the flow decreases, the pump power at the shaft $P_{\mathrm{pu,sh}}$, shown in blue in Figure 7 b), decreases as well from 142.6 MW (start) to 128.1 MW (end). To achieve a constant power consumption of 50 MW at the grid connection point, the turbine power is controlled accordingly, by adjusting the guide vane opening. As shown in the red curve in Figure 7, the absolute turbine power $|P|_{\mathrm{tu,sh}}$ decreases with the pump power, enabling a constant power supply at the rotor of the synchronous machine ($P_{\mathrm{sm,ro}}$ in yellow). The total system efficiency is shown in Figure 7 c). The system efficiency starts at 50.7 %, achieves a maximum value of 52.4 % at 27.7 hours and then drops to 51.7% at the end.

4.3 Energy capacity, efficiency and operating range of the pumped hydro system.

Depending on the power supplied to or discharged from the system, the pumped storage system has a different energy capacity and system efficiency. These are referred to as the energy-power ($E-P$) and efficiency-power ($\eta-P$) relationships, which are presented and discussed in this section. To visualise these relationships, we employ the Ragone plot framework (Beyers, Bensmann, and Hanke-Rauschenbach 2023), which is briefly reiterated here. A constant-power charging process is simulated, starting from an empty system at SOC=0 and continuing until the process is terminated. Two quantities are computed from the charging process: the electrical energy capacity, calculated as $E = \int_0^{t=t_{\mathrm{end}}} P_{\mathrm{gc}} \mathrm{d}t$, and the average system efficiency, calculated as $\overline{\eta}_{\mathrm{sys}} = \int_0^{t=t_{\mathrm{end}}} \eta_{\mathrm{sys}} \mathrm{d}t / t_{\mathrm{end}}$. This process is repeated for a different P_{c} = constant charging power. All the capacity and average efficiency values are then combined and plotted in a single curve. The procedure for discharging is the same, except that the constant-power discharging starts at a SOC of 1 and continues until termination.

Figure 8 plots the resulting $\eta-P$ and $E-P$ curves versus the full range of possible charging/discharging powers on the x-axis. Regarding the visual presentation, the charging side is shown on the left, and the discharging is on the right. The x-axis ranges from high charging powers (left) to high discharging powers (right), with 0 MW at the center. Figure 8 a) shows the average efficiency $\overline{\eta}_{\mathrm{sys}}$. The first insight is that not all power levels are possible. The operating range is discontinuous, and there are three separate elements in the $\eta-P$ curve, each belonging to a mode of operation. The modes are annotated as follows: "1P" is charging with one pump, "1P1T" is the hydraulic short circuit charging with one pump and one turbine simultaneously, and "1T" is discharging with one turbine. 1T is possible between -36.1 MW and -102.9 MW. The system efficiency is generally high but drops in part-load and over-load. A charging part-load lower than 36.1 MW is not possible, because the turbine component has an built-in flow limit of $q_{\mathrm{tu}}^{\mathrm{min}} = 0.4 \cdot q_{\mathrm{tu}}^{\mathrm{nom}}$ to avoid cavitation phenomena in part-load (Pereira Jr. et al. 2019). Over-load is

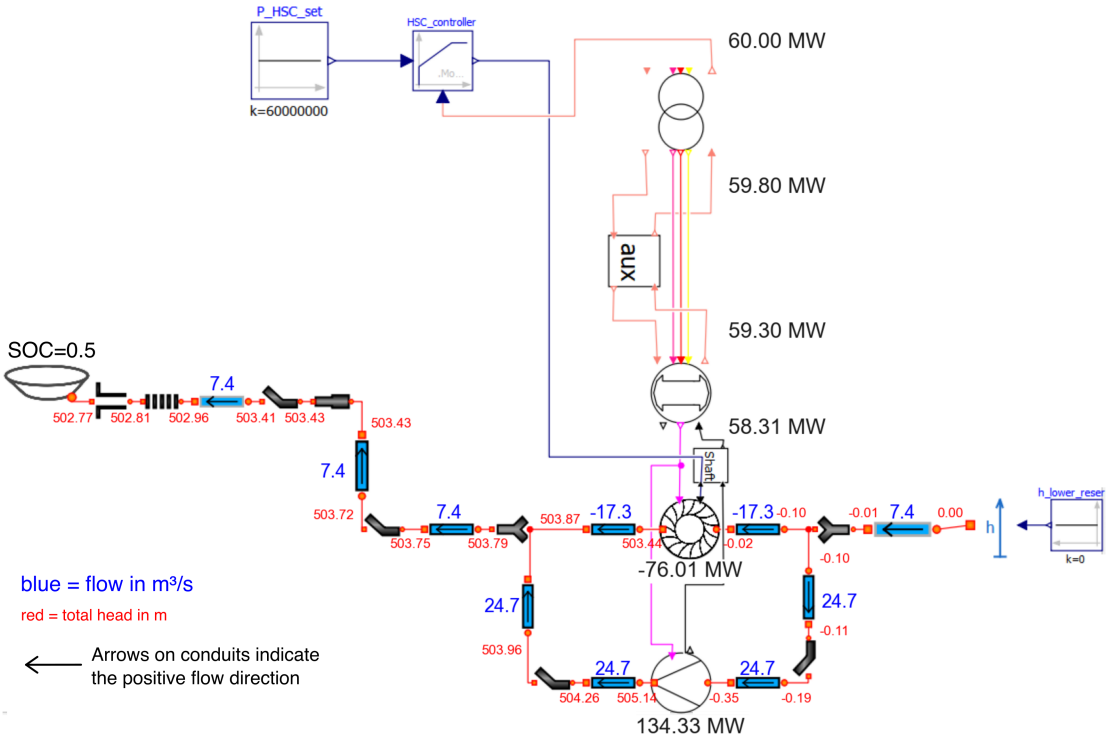

Figure 6. Snapshot in time of key variables of the pumped storage system during hydraulic short circuit operation. State-of-Charge is 0.5 and the charging power at the grid connection point is 60 MW. The flow values are printed in blue above or beside the relevant conduits. The head values are printed in red at every connection point between two components. The power values are printed in black next to the machines.

limited by the maximum turbine power of -105 MW.

Regular charging only with the pump (1P) does not comply with the constant-power framework since power variation is always present in fixed-speed configurations. To include regular charging anyway, its average power is shown as a single dot to distinguish it conceptually from the constant-power 1P1T and 1T operation. Hydraulic short circuit charging (1P1T) is possible between 39.8 MW and 107.1 MW. As discussed in Section 4.1, the efficiencies are generally lower than in regular operation and decrease further in part-load as more flow is diverted to the turbine. The turbine governs the HSC operating range. Because of the opposing relationship between turbine power and HSC charging power, the *minimum* HSC charging power of 39.8 MW is set by the *maximum* turbine power and the *maximum* HSC charging power of 107.1 MW is limited by the *minimum* turbine flow.

Figure 8 b) shows the energy capacity added to the system (charging) or removed from the system (discharging). E and P are linked by the charging/discharging duration. In Figure 8 b), dashed isochrone lines with varying slopes are plotted to mark points in the $E-P$ plane with identical charging/discharging durations. As a further reference, the energy stored in the full upper reservoir at SOC $= 1$ is plotted as a horizontal solid line. In discharging operation (1T), less energy capacity can be taken from the system than stored in the upper reservoir. In charging operation (1P), more energy capacity must be added to the system than ends up in the reservoir. In HSC operation (1P1T), the energy capacity curve has a pronounced turning point at 90.6 MW, which is not reflected in the efficiency curve. To understand this, recall that during a constant-power HSC charging process, the turbine power is continually lowered to match the lowering pump power (refer to Figure 7). At power values higher than 90.6 MW, the charging process is terminated prematurely because the minimum flow limit of the turbine is reached. The higher the HSC charging power, the earlier this limit is reached. Therefore, the capacity that can be added to the system drops until $P_{gc} = 107.1$ MW, which can only be supplied for 10 minutes[4].

In summary, HSC allows operational flexibility in part-load but at a significantly reduced efficiency. At higher HSC charging powers (closer to full load), the charging processes are cut short, significantly reducing charging energy capacity. At deeper part-load, the average system efficiency drops significantly.

4.4 Non-isothermal hydraulic short circuit operation

The original model formulation does not consider thermal effects since they are negligible during regular operation.

[4] Although E theoretically approaches zero, this is not considered relevant for continuous operation.

DOI 10.3384/ecp218353

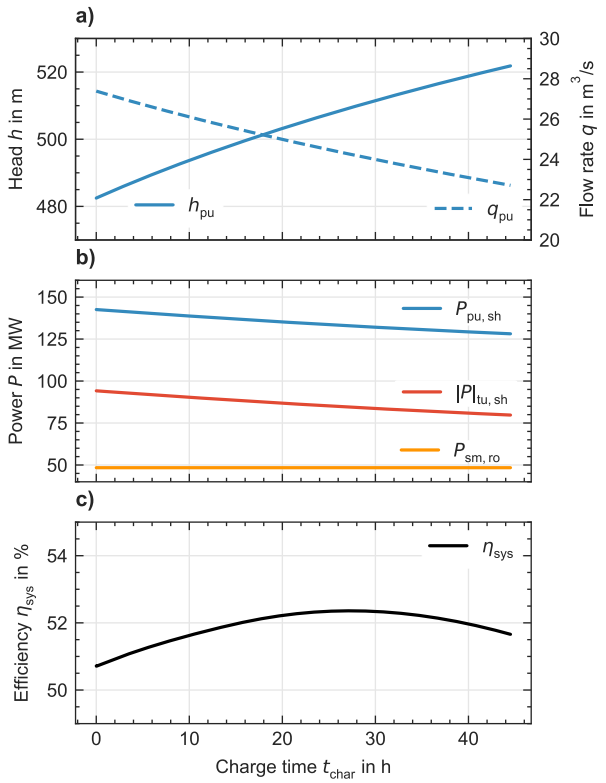

Figure 7. HSC operation at a charging power of $P_{gc} = 50\,\text{MW}$ simulated over time. Subfigure a) shows pump head and volume flow rate, b) shows the power values of turbine, pump and synchronous machine, while c) shows the system efficiency.

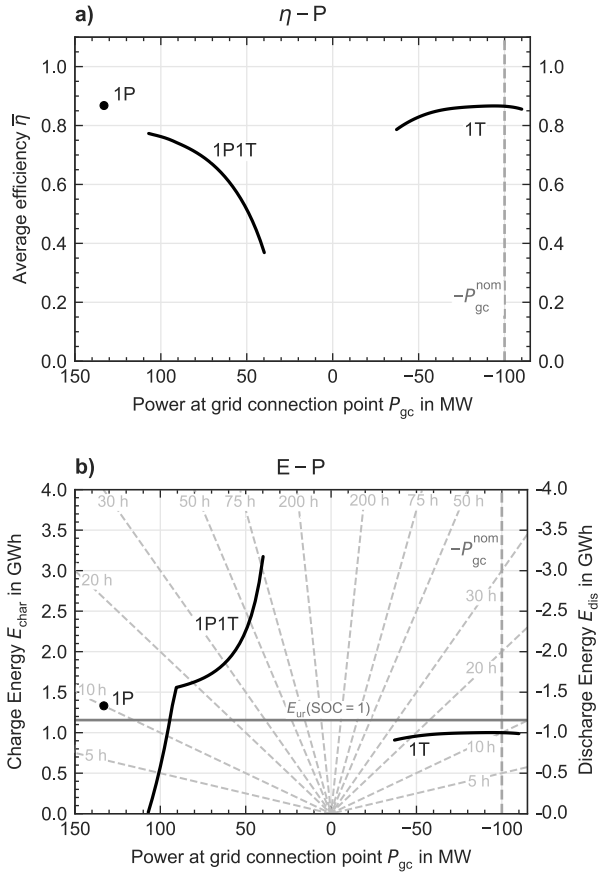

Figure 8. Efficiency-power ($\eta - P$) curves in a) and energy-power ($E - P$) curves in b) of the pumped hydro system at hand.

However, in a hydraulic short circuit, the water circulating between the machines can heat up to unacceptably high temperatures. An energy balance considering the internal thermal energy of the water is incorporated into the model to explore the thermal effects. For simplicity, we consider the entire pipe network of the hydraulic short circuit loop around the ternary machine set as a single control volume with a uniform temperature. In this control volume, the water mass is assumed constant since the incoming flow from the lower reservoir equals the outgoing flow to the upper reservoir and the variation in water density is negligible. The assumption of a uniform temperature in the HSC loop is an approximation, but the flow speeds are so large within the HSC loop that they override local effects on the timescales under analysis. The energy balance, assuming a constant water density, is:

$$m_{\text{HSC}} \cdot c_p \cdot \frac{dT_{\text{HSC}}}{\text{d}t} = \dot{m}_{\text{in}} \cdot c_p \cdot T_{\text{in}} + \dot{m}_{\text{out}} \cdot c_p \cdot T_{\text{HSC}} + P_{\text{loss,pu}} + P_{\text{loss,tu}} + P_{\text{fric}}. \quad (8)$$

The final temperature for a complete HSC charging process at $P_{gc} = 60\,\text{MW}$ is 20.72°C. For 50 MW, this becomes 21.05°C; for 39 MW, the final temperature in the HSC loop is 21.98°C. Therefore thermal effects are not an issue in the operating range determined by the machine sizing. The magnitude of the flow out of the HSC loop towards the upper reservoir is large enough to transport heat generated by losses away. A test in which the same system is equipped with a larger turbine reveals that the temperature within the HSC loop only becomes critical as flow toward the upper reservoir approaches zero. In that case, the relatively small water mass within in the HSC loop start notably accumulating the heat from machine losses since the heat is not transported away and into the upper reservoir. Critical temperatures exceeding 80°C are reached.

5 Conclusions and Outlook

This work developed a detailed physical model of a fixed-speed pumped hydro storage system with 100 MW nominal discharging power and a nominal charging and discharging duration of 10 hours. A hydraulic short circuit between the pump and the turbine was implemented to enable flexibility during charging operation. The effects of hydraulic short circuit operation were demonstrated both with instantaneous values and continuous operation over longer time periods. Instantaneous analysis of two different power levels (50 MW and 60 MW) highlights the complex component interactions during HSC operation. We recommend adopting the level of detail in this work for modelling HSC operating behaviour, specifically (i) an

accurate waterway network representation, (ii) hydraulic machine models with off-design performance relations, and (iii) consideration of the reservoir head variation. The system has a low efficiency in HSC operation. Therefore, strong economic incentives are needed for this mode of operation.

Several constant-power charging and discharging process simulations over time were combined to form $E-P$ and $\eta-P$ curves. This analysis shows that the operating range of the pumped storage system is not continuous. HSC enables part load charging between 39.8 MW and 107.1 MW. The HSC operating range is constrained by the turbine's maximum power and minimum flow limits. This should be considered when designing new pumped hydro systems. The available energy capacity drops significantly at HSC charging powers > 93 MW, a trend not apparent from the $\eta-P$ curve alone. This highlights the need to complement investigations of system efficiency with the energy capacity perspective.

The thermal analysis shows that HSC operation has only a small, negligible effect on the circulating water temperature in this specific pumped storage system. A brief investigation indicates that the temperature only becomes critical around flow regimes approaching zero flow towards the upper reservoir. Thermal considerations become relevant only when the pump and turbine powers are more evenly matched, and low flows towards the upper reservoirs are feasible operating points.

Overall, model-based investigations, such as the one conducted here, can reveal the operational flexibility potential of existing pumped hydro installations and systems in planning, thereby enabling these systems to contribute even more to modern decarbonised energy systems.

Abstract

Solar thermal technology is a promising solution for decarbonizing heat production in industrial applications and district heating networks. When combined with heat storage and advanced control strategies, it can cover a significant share of heat demands. However, designing and optimizing such systems is complex due to their dynamic behavior and the interplay of multiple physical phenomena. To better understand and design these systems, dynamic modeling tools are essential.

Modelica is particularly well-suited for this purpose. At Newheat, large scale solar thermal field models have been developed in the *Modelica* language using the *Dymola* environment. These models represent the thermal and hydraulic behavior of a solar thermal field at two different levels of complexity. Each is designed for different project phases, fast simulations for early-stage feasibility studies and slower but more detailed simulations for the engineering phase.

To assess the accuracy of both models, comparisons with measured data on an operational solar plant were performed. Results indicate that both models achieve high thermal accuracy, with errors of less than 4% in annual heat production. On the hydraulic side, the detailed model provides more precise results than the simplified one. The main drawback of this model being slow simulations in case of very complex solar field layouts.

Moving forward, these models will support various applications and enable scalable modeling of complex solar thermal systems, adapting to different project phases and requirements.

Keywords: solar thermal, ThermoFluidStream library, conceptual design, detailed engineering

1 Introduction

Newheat is a renewable and sustainable heat supplier, offering innovative and tailor-made solutions for major heat consumers worldwide: industrial sites and district heating networks. Its activity is to develop, design, build, finance and operate renewable heat plants, which can combine waste heat recovery, solar thermal, short and long-term thermal storage systems, optimized electrification solutions (industrial heat pumps, etc...) and, if necessary, combustion of renewable resources. The company currently has 6 sites in operation for a total of 40 MW of solar thermal fields installed.

Dynamic models of renewable heat components and plants are needed to estimate the performances and cost of the systems, and finally to assess the heat price defined in heat supply contracts over 15 to 25 years.

In the upstream phase of project development (conceptual design phase), models are used to explore all possible renewable heat production system configurations. The energy mix is not yet fixed, and an expected heat price must be assessed for several heat producer configurations, storage facilities and heat delivery points.

In the detailed engineering phase, dynamic models of complete systems are used for the detailed design of projects based on technical and economic criteria. At this stage, the hydraulic configuration of the installation and associated operating procedures (high-level control) are finalized, components are selected and specified, and location or implementation constraints (distances, soil, environment, etc.) are integrated.

NewLib models can also be used later in the construction phase to improve the Factory Acceptance Tests of the Programmable Logic Control when received, during commissioning to help tune the parameters of the

controllers, and finally in operation as digital twins to detect and diagnose faults.

In this paper, simple solar thermal field models used for conceptual design and more detailed models used for engineering needs are presented, compared, and validated against measured data from large scale solar thermal plants. After the presentation of the context and objectives in the present section, the rest of the paper is organized as follows:

- Section 2 presents the NewLib library, within the *Dymola* Environment, dedicated to the dynamic simulation of components and renewable heat production plants.
- Section 3 introduces the core of the NewLib library with special focuses on the media, pipe, heat exchanger and solar field models.
- Section 4 presents comparison results between NewLib models at 2 levels of details with measurements obtained from an operating solar plant.
- Section 5 summarizes the main messages of the present article and gives perspectives for the development roadmap regarding the NewLib library.

2 Presentation of the library

2.1 Overall presentation

Newheat has developed an in-house proprietary library called NewLib within the *Dymola* Environment, for internal purposes. It is not intended for public distribution or commercial release now. This *Modelica* Library:

- Is dedicated to the dynamic simulation of components and renewable heat production plants.
- Includes renewable heat components, control blocks and systems, tailored to the needs of its commercial projects.
- Provides multiple complexity levels of modeling for components, subsystems, materials, and fluids.
- Includes standardized interfaces enabling the interchangeability of component models of the same type in a system model.
- Enables annual simulations of renewable thermal plants within a few minutes (conceptual design phase).
- Uses the DASSL and CVODE solvers within the *Dymola* environment.

After benchmarking various thermofluidic libraries in the *Modelica* language – including the *MSL*, *IBPSA*, *Liquid Cooling*, *Thermal Power* and *ThermalSystems* – based on qualitative criteria as the library targeted industrial sector, the fluid port approach, the available media and the availability of models relevant to Newheat's need, as well as more quantitative KPIs like computation time and success rate of simulation in a parametric study, the *ThermoFluidStream* (*TFS*) library (Zimmer et al., 2022) was selected as a basis for the NewLib library, for the following reasons: Easy to use; Adequacy to Newheat's present and future needs; Robustness: based on an innovative numerical calculation scheme (Zimmer, 2020), designed to be robust even on complex thermo-fluid architectures; Fluid representation: partially compatible with the *Modelica* standard fluid library (MSL. Media).

The NewLib library is actively developed on *GitlLab*, therefore a methodology of continuous integration based on non-regression tests using the *Testing* library from Dassault (Hammond-Scott, 2022) is being followed.

2.2 Structure

The NewLib library is structured on packages as depicted in **Figure 1**. The core packages are the Components, Control and Media packages.

The Components package contains models of varying complexity representing the main components of a renewable thermal plant. These include producers such as solar fields, boilers and heat pumps; storage systems such as TTES (Tank Thermal Energy Storage), PTES (Pit Thermal Energy Storage), and BTES (Borehole Thermal Energy Storage); heat exchangers, including liquid/liquid plate heat exchangers and liquid/moist air finned-tube heat exchangers... Some of these models are largely inspired by other open-source libraries, such as *IBPSA* (Wetter, 2022). More specific models, including solar field models, will be described in more detail in this paper.

The Control package contains the models of the two levels of control commonly found in renewable heat plants. High-level control (HLC): 1. defines the conditions to enter and exit the different operating modes of the plants (and associated configuration of actuators) based on the different data acquisition made on site. For example, the operating modes of the solar field are standby, preheating, production, overheating prevention and overheating. In NewLib, the *Modelica_StateGraph2* library (Olsson, 2020) is used to develop the models of the HLC closely reflecting those implemented in operational plants; 2. defines the setpoints to be achieved by the Low-level control (LLC). LLC is responsible for applying and maintaining the setpoints defined by HLC. In practice, this typically involves regulation techniques, such as PID control. In NewLib, to ensure fast simulations, a model-based approach is used through an open loop control strategy. First-order filters are added to the command to eliminate nonlinear equations.

The Media package: Media models must be numerically robust, to avoid errors during dynamic simulations, as well as fast, accurate, and capable of computing the thermodynamic and transport fluid properties over a wide range of temperatures (and potentially pressures).

DOI 10.3384/ecp218363

Currently, only a monophasic and incompressible liquid model based on a polynomial formulation is available. This model has been extended to represent antifreeze and thermal oil heat transfer fluids from properties data as a function of the temperature to determine the corresponding polynomial coefficients.

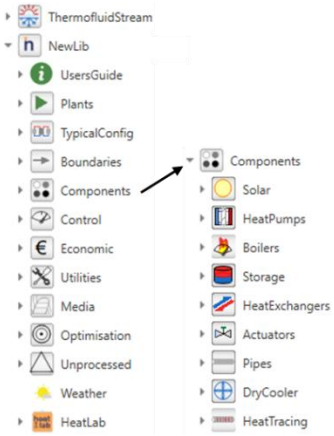

Figure 1. Packages of the NewLib library

2.3 The subsystem approach in NewLib

As part of Newheat strategic vision, NewLib library aims to provide a comprehensive framework – usable by Newheat's non-developer engineers – to all simulation requirements, from the conceptual design phase to the operational phase. Indeed, a Component-by-Component modeling approach raises several challenges, as shown in **Figure 2**:

- The model assembly may initially appear visually complex to new *Modelica* users.
- It requires configuring each component individually, often including low-priority or secondary parameters. This increases the risk of modeling errors due to incorrect settings.
- The handling of outputs becomes increasingly complex.

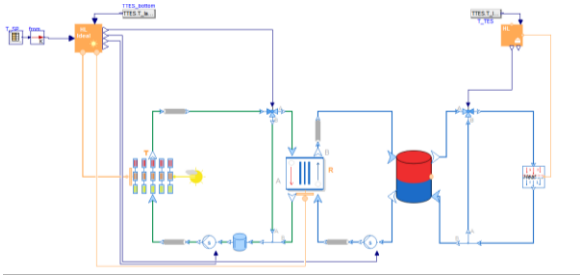

Figure 2. Component-by-Component modeling of a solar plant including a storage (TTES) loop

A first step in deploying NewLib across Newheat technical teams is to provide a user-friendly environment to it. That is the objective of the TypicalConfig package, which is an ongoing work. The package provides different templates for typical renewable heat production plants based on subsystem models (see **Figure 3**). A plant partition into 6 subsystems has been identified including Solar Field Subsystem, Storage Subsystem, Heat Consumer Subsystem, Heat Pump Subsystem, Heat Recovery Subsystem and HLC subsystem.

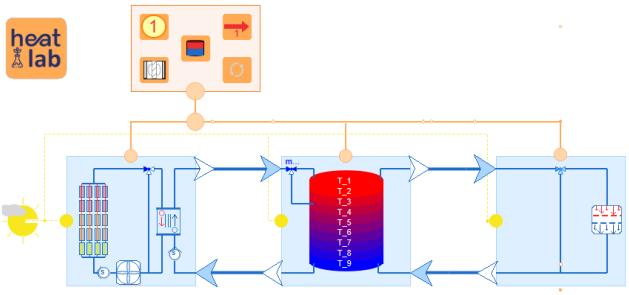

Figure 3. Subsystem modeling of Figure 2 Component-by-Component model of a solar plant

Each subsystem can model multiple hydraulic configurations that are commonly found in both operational plants and under development projects. For example, the solar field subsystem currently models two hydraulic configurations (see **Figure 4**):

- A direct configuration, where the solar field is directly connected to the thermal storage using a thermal oil as both the heat transfer fluid and the storage medium.
- An indirect configuration (used in **Figures 2** and **3**), used in all operational Newheat plants, where the thermal power from the solar field is transferred to the storage tank/user via a heat exchanger and a secondary circuit.

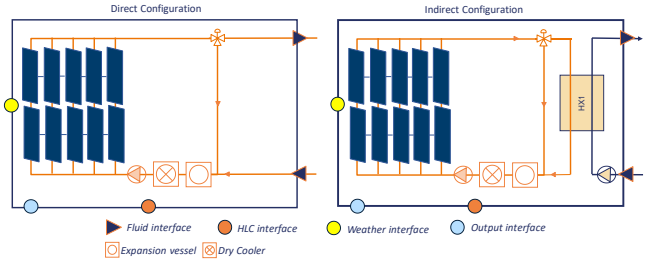

Figure 4. Hydraulic configurations of the solar field subsystem in NewLib

An error-proofing methodology is used to prevent the production of non-conforming parts in the conceptual design phase. The parameters of the subsystem components are classified into primary and secondary parameters. All primary parameters of the subsystem are defined by the user in a unique outer model called *Heatlab*. The other parameters are either pre-defined or calculated in an initial algorithm based on pre-conception rules.

The model outputs are managed using the *HideResult* annotation from *Modelica* language; KPIs (energy

balance, temperatures…) are calculated to provide a quick overview of the performances of each subsystem.

All main models of a subsystem are replaceable models, allowing for an easy switch from a conceptual design phase model, using simplified models, to a detailed engineering phase, using more complex dynamic models.

3 NewLib models description

This section provides a quick overview of the different models included in the NewLib library and usually used to represent large solar thermal plants. For each of these models both a conceptual design phase version and an engineering phase version are described.

3.1 Media models

To simulate low temperature solar thermal plants in the NewLib library, glycol water mixture (20% to 45% in volume), which is commonly used as a heat transfer fluid in those systems, is defined as a medium, with either constant properties or properties depending on the temperature of the fluid. It is considered incompressible. Polynomial equations are used to calculate the density (ρ), heat capacity at constant pressure (cp) and thermal conductivity (λ), an exponential form is used to model the dynamic viscosity (μ) of the medium:

$$\rho = a_{d,3}.T^3 + a_{d,2}.T^2 + a_{d,1}.T + a_{d,0} \quad (1)$$

$$cp = a_{c,2}.T^2 + a_{c,1}.T + a_{c,0} \quad (2)$$

$$\lambda = a_{l,2}.T^2 + a_{l,1}.T + a_{l,0} \quad (3)$$

$$\mu = A_e . exp(B_e/(T + C_e)) \quad (4)$$

With $a_{d,0}$, $a_{d,1}$, $a_{d,2}$, $a_{d,3}$, $a_{c,0}$, $a_{c,1}$, $a_{c,2}$, $a_{l,0}$, $a_{l,1}$, $a_{l,2}$, A_e, B_e and C_e being constant coefficients obtained by linear regression on fluid supplier documentation table data. If constant properties are chosen, properties of the fluid are calculated at a reference temperature defined as an input of the function. However, choosing this option can lead to significant errors in fluid pressures and/or temperatures in some cases. The main drawback of using variable properties media being larger CPU times. For specific studies during the engineering phase, hybrid media can be used. For instance, in hydraulic specification of the solar loop, constant cp, λ and ρ combined with variable μ media leads to fast results and good precision on pressure losses, while thermal accuracy is not required for this phase.

3.2 Pipes model

In the NewLib library, a single pipe model is used for both conceptual design and engineering phase. The energy balance in pipes is calculated considering a single fluid node where heat convection from inlet to outlet is calculated in a *heatTransfertElement* component from an enthalpy balance delayed by a *TransportDelayInit* component that accounts for the time delay from the inlet to the outlet of the pipe:

$$M.\frac{\partial h}{\partial t} = \dot{m}.(h_{in} - h_{out}) \quad (5)$$

$$\frac{\partial h(x,t)}{\partial t} + v(t).\frac{\partial h(x,t)}{\partial x} = 0 \quad (6)$$

Where h represents the specific enthalpy of the fluid, v represents the fluid velocity, M represents the inertial mass of the metal of the pipe and $\dot{m}$ represents the mass flow rate in the pipe. Heat losses to the external medium are calculated in a *PlugFlowHeatLoss* component, based on the plug flow model from *IBPSA* library. In this component, the outlet temperature is directly calculated from the solution of the heat equation considering only heat losses to the ambient:

$$T_{out} = T_{amb} + (T_{in} - T_{amb}).e^{-\frac{\tau}{R\rho c_p}} \quad (7)$$

With T_{amb} being the ambient temperature, τ being the residence time of the fluid in the pipe and R_{th} being the overall thermal resistance, calculated as:

$$R_{th} = \frac{2.\pi.L}{\frac{1}{r_1.h_{in}} + \frac{\ln(\frac{r_2}{r_1})}{\lambda_{pipe}} + \frac{\ln(\frac{r_3}{r_2})}{\lambda_{ins}} + \frac{1}{r_3.h_{out}}} \quad (8)$$

Where L is the pipe length, r_1, r_2 and r_3 are respectively the pipe inner radius and the insulation inner and outer radius, h_{in} and h_{out} are the inner and outer convection coefficients based on literature correlations (Yang et al., 2011, *The engineering Toolbox,* 2003) and λ_{pipe} and λ_{ins} are the thermal conductivity coefficients of the pipe and the insulation respectively defined from pipe suppliers data.

For the mass balance, constant mass flow rate is considered and the pressure losses in the pipe are defined as:

$$\Delta P = \Delta P_{reg} + \Delta P_{man} \quad (9)$$

Where ΔP_{reg} represents the regular pressure losses and is calculated considering the Darcy-Weisbach equation:

$$\Delta P_{reg} = f_D.\frac{L}{D_h}.\rho.\frac{V^2}{2} \quad (10)$$

Where f_D is the friction factor calculated from Cheng correlations (Cheng, 2008), suitable for all flow regimes.

And ΔP_{man} represents the manometric head, calculated as:

$$\Delta P_{man} = \rho.g.\Delta H \quad (11)$$

Where ΔH is the height difference between the inlet and outlet of the pipe and g the constant of gravity $g = 9.81\ m.s^{-2}$.

DOI 10.3384/ecp218363

3.3 Solar field models

The conceptual design phase solar field model in NewLib represents an equivalent solar collector consisting of a single thermal and hydraulic node. It calculates an equivalent pressure loss based on a rectangular solar field layout. The thermal part considers the heat exchange with the environment and enthalpy transport considering a delay due to the residence time of the fluid in the solar field as done for the pipe model.

The detailed engineering phase model, in contrast, explicitly represents manifolds and hydraulic singularities such as elbows and restrictions. Correlations of pressure losses in these singularities and in the regular parts are used. The thermal part is equivalent to the simplified model with a level of detail at the scale of the collector row rather than the overall solar field.

For both models, the energy balance in a single collector is calculated considering the overall thermal performance equation that is based on the quasi-dynamic equation from the ISO 9806 (ISO, 2017). This equations states that the power collected by the fluid (P_f) is the difference of the absorbed heat (P_{abs}) to the thermal losses (P_{loss}):

$$P_f = P_{abs} - P_{loss} \tag{12}$$

The power absorbed by the fluid is calculated as:

$$P_{abs} = S_{col}.\eta_{0,b}.fc.(K_b(\theta_l,\theta_t).G_b + K_d.G_d) \tag{13}$$

Where S_{col} is the surface area of the collector, $\eta_{0,b}$ is the optical efficiency of the collectors, $K_b(\theta_l,\theta_t)$ and K_d are the angle of incidence factors for direct and diffuse solar irradiations respectively, G_b and G_d are direct and diffuse solar irradiations respectively. fc is the so-called cleanliness factor that considers the reduction in the solar collector's performance caused by the accumulation of dirt, dust and other deposits (more details in §4).

The thermal losses are calculated as:

$$P_{loss} = S_{col}.\begin{pmatrix} c_1.(T_{mf} - T_{amb}) \\ +c_2.(T_{mf} - T_{amb})^2 \\ +c_3.u_{wind}.(T_{mf} - T_{amb}) \\ -c_4.(E_L - \sigma.T_{amb}^4) \\ +c_5.\frac{dT_{mf}}{dt} \\ +c_6.u_{wind}.(G_b + G_d) \end{pmatrix} \tag{14}$$

Where T_{mf} is the mean temperature of the fluid, T_{amb} is the ambient temperature surrounding the solar field, c_1, c_2, c_3, c_4, c_5, c_6 are respectively the heat loss coefficient, the coefficient of the temperature effect on the heat loss coefficient, the coefficient of the wind effect on the heat loss coefficient, coefficient of the sky temperature effect on the heat loss coefficient, the effective heat capacity and the coefficient of the wind effect on the optical efficiency, given by the collector model solar Keymark (Solar Keymark Network, n.d.), which is a certification of solar thermal collectors that provides a database of their coefficients in the ISO 9806 performance equation. Both models must be connected to the NewLib weather model to get weather input. In the NewLib library, the weather model uses weather data from Newheat onsite sensors as input to a *combiTimeTable* component of the *MSL*.

For the design phase model, the mass balance considers constant mass flow rate from inlet to the outlet of the solar field and pressure losses are calculated as:

$$\Delta P_{SF} = \Delta P_{collector} + \Delta P_{piping} \tag{15}$$

Where $\Delta P_{collector}$ and ΔP_{piping} are the pressure losses in the collectors and the pipes respectively.

In the collectors, the pressure losses are calculated as:

$$\Delta P_{collector} = \frac{\nu(T_0)}{\nu(T)}.a_0.\dot{V} + \frac{\rho(T)}{\rho(T_0)}.b_0.\dot{V}^2 \tag{16}$$

Where a_0 and b_0 are respectively the collector linear and quadratic pressure loss coefficients as given by its Solar Keymark, $\rho(T_0)$, $\nu(T_0)$ and $\rho(T)$, $\nu(T)$ are the density and dynamic viscosity at reference and actual temperature respectively and $\dot{V}$ is the volume flow rate in the collectors.

In the solar field pipes, the pressure losses are calculated as:

$$\Delta P_{piping} = \Delta P_{reg} + \Delta P_{sing} \tag{17}$$

Where ΔP_{reg} and ΔP_{sing} are the regular and singular pressure losses. The regular pressure losses are calculated as:

$$\Delta P_{reg} = \left(\frac{\dot{m}_{flow}}{\dot{m}_{flow,max}}\right)^2.\Delta P_{reg,max} \tag{18}$$

Where the maximal regular pressure loss in the solar field pipes is calculated from the Darcy-Weisbach equation using Cheng friction factor f_{D_i} at maximal fluid speed ($u_{max} = 2m/s$) in all the pipes constituting the most constraining path in the solar field:

$$\Delta P_{reg,max} = \sum f_{D_i}.L_i.\frac{\rho}{2}.\frac{u_{max}.|u_{max}|}{2.r_i} \tag{19}$$

$$f_{D_i} = \left(\frac{64}{\mathrm{Re}_i}\right)^a.\left(1.8\cdot\log\left(\frac{\mathrm{Re}_i}{6.8}\right)\right)^{2.(a-1).b} .\left(2.\log\left(3.7\cdot\frac{D_i}{rr}\right)\right)^{2.(a-1).(1-b)} \tag{20}$$

$$\mathrm{a} = \frac{1}{\left(1+\left(\frac{\mathrm{Re}_i}{2720}\right)^9\right)} \tag{21}$$

$$b = \frac{1}{\left(1 + \left(\frac{\mathrm{Re}_i . rr}{320 . r}\right)^2\right)} \quad (22)$$

Where rr is the relative roughness of the pipes and Re_i, L_i, D_i and r_i are the Reynolds number, length, nominal diameter and internal radius, respectively, of each pipe element constituting the most constraining path.

To calculate the most constraining path in the solar field, a rectangular solar field is considered, the pipes DN are determined in an initial algorithm by targeting a maximal velocity of 2m/s in each pipe.

In the engineering phase model, the hydraulic layout of the solar field is represented in much more detail. **Figure 5** shows the solar field of another large scale solar thermal plant currently under development in France, in implementation plan view and Dymola interface view of the equivalent model. The complex layout of this solar field is explained by irregular land availability. Pipes and manifolds are explicitly modeled, and regular and singular pressure losses are calculated.

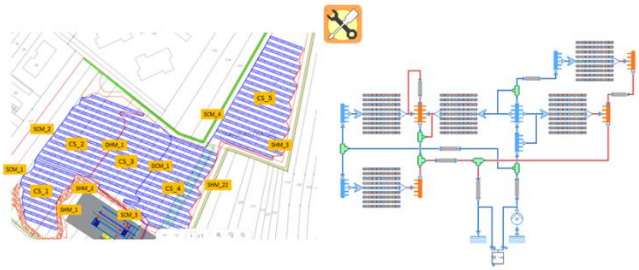

Figure 5. Implementation plan (left) and visualization of the equivalent model in Dymola using the NewLib library (right) of a complex solar field

Table 1 presents the main advantages and drawbacks of each model in the NewLib library.

Table 1. Design and engineering phase solar field models comparison in the NewLib library

	Design phase model	*Engineering phase model*
Advantages	Low CPU time Easy setup	Pressure loss precision
Drawbacks	Can not be used in engineering phase	Higher CPU time

3.4 Pump models

Design phase pump model in NewLib represents a flow generator. The mass flow rate is equal to the setpoint mass flow rate as:

$$\dot{m}_{flow} = \dot{m}_{flow,SP} \quad (23)$$

The electricity consumption of the flow generator is then estimated as follows:

$$P_{hyd} = \Delta P . \dot{V} \quad (24)$$

$$P_{elec} = \frac{P_{hyd}}{n_{tot}} \quad (25)$$

Where P_{hyd} and P_{elec} are respectively the hydraulic and electrical powers of the pump, n_{tot} is the total efficiency of the pump as defined by the user.

The engineering phase pump model in NewLib is based on the *MSL* model (*Modelica.Fluid.Machines.BaseClasses.PartialPump*). From the characteristic curve at nominal rotational speed $\dot{N}_{nom}$, a polynomial function Pc_{nom} is identified:

$$H_{m,nom} = Pc_{nom}(\dot{V}) \quad (26)$$

With $H_{m,nom}$ being the pump head at nominal rotational speed and $\dot{V}$ the volumetric flow rate. From this polynomial function, the pump head is deduced for every rotational speed $\dot{N}$ and volumetric flow rate $\dot{V}$ as:

$$H_m = \left(\frac{\dot{N}}{\dot{N}_{nom}}\right)^2 . Pc_{nom}(\dot{V} . \frac{\dot{N}_{nom}}{\dot{N}}) \quad (27)$$

Similarly, a polynomial function Pw_{nom} is calculated for the mechanical power of the pump from nominal values at different volume flow rates:

$$\dot{W}_{nom} = Pw_{nom}(\dot{V}) \quad (28)$$

The mechanical power of the pump ($\dot{W}$) is then calculated for different rotational speeds $\dot{N}$ as:

$$\dot{W} = \left(\frac{\dot{N}}{\dot{N}_{nom}}\right)^3 . Pw_{nom}(\dot{V} . \frac{\dot{N}_{nom}}{\dot{N}}) \quad (29)$$

The pressure loss (Δp) is directly deduced from the pressure head (H_m) as:

$$H_m = \frac{\Delta p}{\rho . g} \quad (30)$$

Considering constant fluid density ρ.

Then, electricity consumption is evaluated from a constant combined mechanical and electrical efficiency ε_{elec}:

$$\dot{P}_{elec} = \frac{\dot{W}}{\varepsilon_{elec}} \quad (31)$$

3.5 Heat exchanger models

For design phase simulations, an ε-NTU heat exchanger model is implemented in the NewLib library. In this model, the energy balance, constituting the heat exchange between the 2 sides of the heat exchanger is calculated from:

$$\dot{Q} = \varepsilon . \dot{Q}_{max} \quad (32)$$

DOI 10.3384/ecp218363

$$\dot{Q}_{max} = C_{min.}\Delta T_{max} \quad (33)$$

$$\Delta T_{max} = T_{h,in} - T_{c,in} \quad (34)$$

Where $\dot{Q}$ and $\dot{Q}_{max}$ are respectively the actual and maximal exchanged heat, C_{min} is the minimal capacity flow rate ($c_p \cdot \dot{m}_{flow}$) and ΔT_{max} is the maximal temperature difference in the heat exchanger. ε is the counter-flow configuration heat exchanger efficiency defined as:

$$\varepsilon = \begin{cases} \dfrac{1 - exp[-NTU \cdot (1-R)]}{1 - R \cdot exp[-NTU \cdot (1-R)]}, if\ R < 1 \\ \dfrac{NTU}{1 + NTU}, if\ R = 1 \end{cases} \quad (35)$$

With NTU (number of transfer units) defined as:

$$NTU = \frac{U.A}{C_{min}} \quad (36)$$

With U being the overall heat transfer coefficient and A the equivalent surface area of the heat exchanger. R is the heat flow rate ratio, defined as:

$$R = \frac{C_{hot}}{C_{cold}} \quad (37)$$

Where C_{cold} and C_{hot} are the capacity flow rates on the cold and hot side of the exchanger respectively. For the mass balance, constant flow rate is imposed on both sides of the heat exchanger, and pressure losses are calculated as follows:

$$p_{loss} = k_l.m_{flow} + k_q.m_{flow} \quad (38)$$

Where k_l and k_q are constant coefficients defined as inputs or calculated from nominal operating point.

The engineering phase heat exchanger model in NewLib is also based on the ε-NTU method. Additional parameters are proposed to the user to define a specific heat exchanger model with the exact number of plates and other geometrical design parameters such as corrugation angle, joint thickness or expansion factor, to calculate the number of heat transfer-effective plates.

4 Validation and Application

4.1 Use case plants description

In 2019, Newheat, the city of Narbonne in the south of France and the operator of its district heating network agreed to develop a large-scale solar thermal plant to maximize the proportion of renewable energy on the network as it develops. The objective was to replace, as much as possible, the use of gas boilers with the production of solar energy, covering most of the network's needs during the summer period, from April to October. Newheat oversaw the entire project and bears full responsibility for its various stages (design, development, construction, operation for a 25-year period). The project has received financial support from ADEME's *Fonds de Chaleur* and the Occitanie Region (France).

The solar plant project called NARBOSOL commissioned in 2021 consists of a solar field, a thermal storage tank (hot water), to offset periods of solar heat production and consumption by the heating network, and a technical room containing the programmable logic controller (PLC) and all the hydraulic equipment (pumps, valves, heat exchangers, measuring instruments, etc.). Main characteristics of NARBOSOL plant are presented in **Table 2**.

Table 2. NARBOSOL solar thermal plant main parameters.

Parameter	*Value*
Location	43.183°N, 2.967°W
Solar field aperture area (m²)	3200
Solar field peak power (kW)	2700
Solar collectors tilt (°)	35°
Storage volume (m^3)	1000
Solar heat transfer fluid	Glycol 30%
Storage fluid	Water
Annual production (MWh)	2200

4.2 Solar field Modeling

The NARBOSOL's solar field consists of 202 Savo 15 SG solar collectors (Savosolar Oyj, 2020) divided into two subsolar fields. The first subsolar field contains 12 rows, each with a range of 8 to 12 serial collectors, while the second subsolar field contains 7 rows, each with a range of 7 to 10 serial collectors (see **Figure 6**). Both subsolar fields are connected to the hydraulic skid from a cold and a hot manifold to feed all the rows with the heat transfer fluid. Balancing valves are used to equally distribute the system's total flow in each row as a function of serial collector number.

Figure 6. Aerial view of NARBOSOL solar thermal plant in Narbonne (France)

Newheat uses remotely accessible supervision technologies to monitor the plant's status and modify its parameters to maintain optimal operating conditions. All data transmitted from the sensors (temperature, pressure,

mass flow, electric consumption…) installed in NARBOSOL are recorded with a time step of 1 min in a proprietary data base. In this paper, data recorded in 2024 at NARBOSOL is used to compare the performance of both approaches in modeling the solar field and other components of the solar loop in NewLib, dedicated to the conceptual design phase and the detailed engineering phase.

Evaluation of the cleanliness factor of NARBOSOL

The cleanliness factor fc (see **Equation (13)**) of a solar field model is a parameter that affects the optical efficiency of the collectors by reducing the incident solar power.

To assess the annual mean cleanliness factor value of NARBOSOL plant, an assembly model was developed. It includes the conceptual design phase model of the solar field and other physical components such as pumps and pipes from the NewLib library. One-minute frequency measurements of weather data (Global Tilted Irradiation - GTI, wind speed, and ambient temperature), volume flow rate, and inlet temperature are used as inputs of the model. The model calculates the 8760 hourly thermal power delivered to the fluid by the solar field in 2024. **Figure 7** shows the graphical representation of this assembly model in the *Dymola* environment.

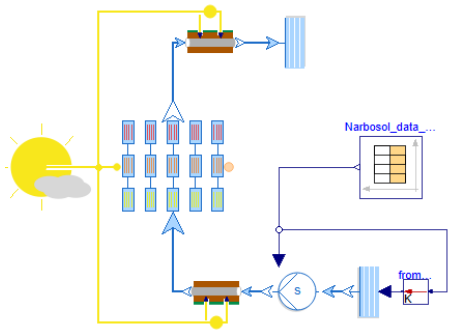

Figure 7. Graphic view of the design phase model of NARBOSOL's solar field in NewLib

A parametric study is then carried out using this assembly model, in which the root means square error (RMSE) is computed by comparing the model results with the measured thermal power as a function of the cleanliness factor.

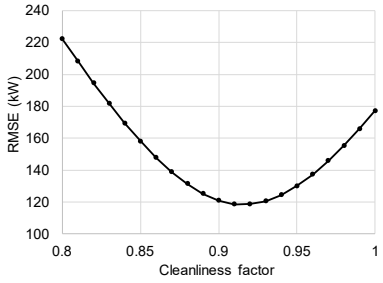

Figure 8. Parametric study for the evaluation of the cleanliness factor

Figure 8 presents the results of this parametric study. The graph clearly shows the value of the cleanliness factor of 92 % that minimizes the RMSE.

Solar field models evaluation

In this section, the performance of both NewLib solar field models (§3.3) is evaluated. To do so, 2 assembly models of the NARBOSOL plant, similarly to **Figure 7**, are developed using NewLib library's conceptual design phase models and engineering phase models. Simulations are carried out using these 2 assembly models on 1-minute step data from September 2024 at NARBOSOL.

The results are compared with the measurements from September 2024 in terms of monthly cumulative energy (**Figure 9**), thermal power (**Figure 10**), and hydraulic characteristic curve of the solar field (**Figure 11**). For both models, the value of the cleanliness factor of 92 % determined in the previous section is used. The 30% glycol water medium with variable properties (see §3.1) is used in both simulations.

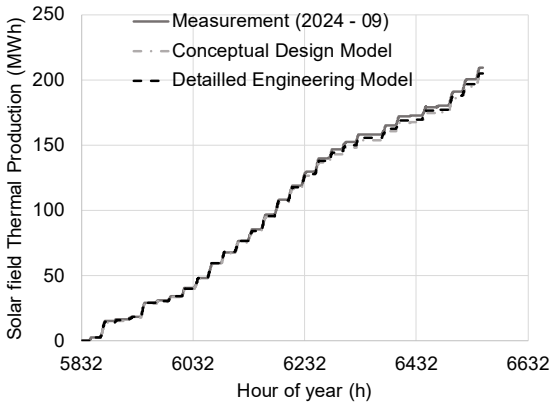

Figure 9. Cumulative Energy provided by the solar field in September 2024

Figure 9 shows a very good agreement between both models and measurement. In September 2024, the energy delivered to the fluid by the NARBOSOL solar field was measured at 209.4 MWh, while the calculated values were 202.9 MWh (3% error) and 205.0 MWh (2% error) for the conceptual design model and the detailed engineering model, respectively. These results suggest that the level of detail at the overall solar field scale used in the conceptual design model is sufficient to accurately represent the thermal performances of large-scale solar fields. Better agreement between measured and simulated data in the first half of the month can be explained by sunnier days during this period. The model being more accurate when less irradiation variations.

Figure 10 further confirms this result in terms of thermal power on two chosen cloudy and sunny days. Finaly, this graph strengthens the observation that the conceptual design model provides a very good estimation of the solar field's thermal performance despite its simplified level of detail. The correlation coefficient over the whole month

DOI 10.3384/ecp218363

on solar field thermal power is 0.9904 for the conceptual phase model compared to 0.9908 for the more detailed one.

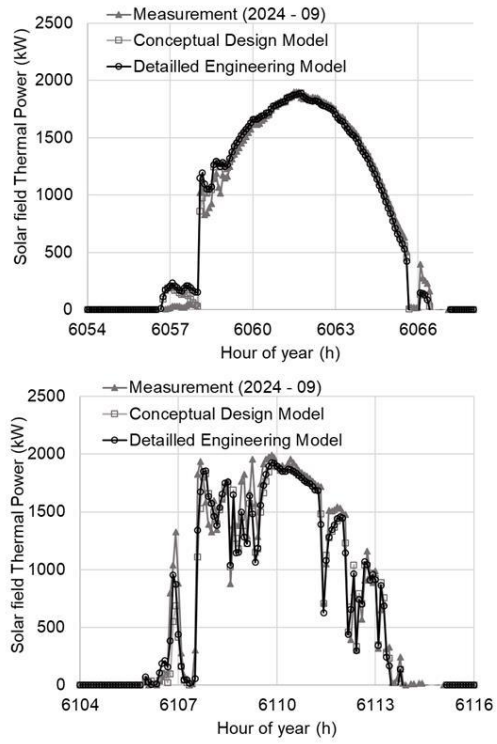

Figure 10. Solar thermal power result comparison between both models and measured data for a sunny day (top) and a cloudy day (bottom)

However, results on the solar field pressure drop (see **Figure 11**) show that the conceptual design model is unable to predict the hydraulic behavior of the solar field. In the case of NARBOSOL's model, this result is due to the estimation of the most constraining path in the solar field, based on the assumption of a rectangular solar field, which is far from the real configuration in this case. In the detailed engineering model, the hydraulic layout of the solar field is represented in much more detail, including pipes, manifolds and a refined representation of each sub-solar field with the actual number of collectors in series for each row. As shown in **Figure 11**, this level of detail enables highly accurate results on pressure loss prediction.

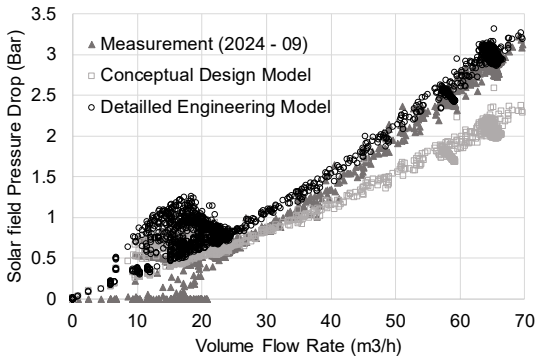

Figure 11. Hydraulic characteristic curve of the solar field for both model representations and measured data

Solar field complete loop modeling

In this final section, NewLib's detailed engineering models are integrated within a larger Component-by-Component assembly model of the solar field loop, which includes:

- A centrifugal pump model (see §3.4), a heat exchanger model (see §3.5), a singular pressure drop model of the hydraulic skid, and other standard models of hydraulic components such as a 3-ways valve and an expansion vessel.
- The HLC model which calculates the operating modes of the solar field loop (§2.2).
- LLC Models of the solar field, valve, pump and heat exchanger which determines the commands to be sent to reach the HLC model setpoints.

The centrifugal pump model is based on the technical specifications of the ETL 065-065-160 pump from KSB. It defines the pump head and the shaft power as a function of rotation speed and volume flow rate. Then a constant combined mechanical and electrical efficiency of 0.95 x 0.95 x 0.95 is assumed, which reflects losses in the pump/electric motor coupling, frequency inverter, and electric motor. The heat exchanger model is based on a nominal operating point defined by inlet/outlet temperatures of 91.2 °C / 67.1 °C on the primary side and 63 °C / 88.5 °C on the secondary side, with an exchanged thermal power of 1.9 MW. **Figure 12** presents a visualization of the described assembly model in the *Dymola* environment.

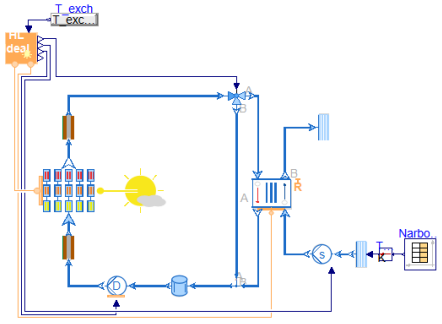

Figure 12. Model of NARBOSOL's solar field loop in NewLib as seen in Dymola

A simulation is launched on 1-minute frequency weather and inlet temperature of the secondary loop data in September 2024 at NARBOSOL, as inputs of the model. Results of heat power comparison are presented in **Figure 13** for a cloudy day. A very good agreement between simulation and measurement data is observed. The correlation coefficient is 0.9769 over the whole month.

Table 3 shows measured and simulated September 2024 energy balances in the solar loop. Regarding thermal energy, the deviation is limited, with a 2% difference between calculated and measured values.

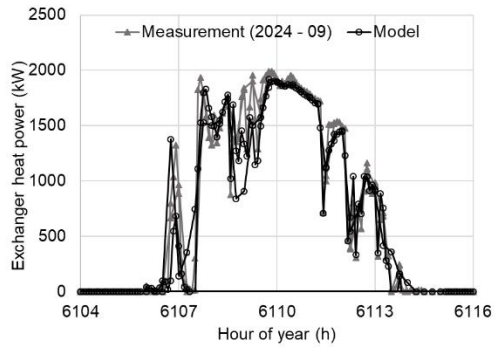

Figure 13. Heat supplied to the tank result comparison between both models and measured data

The centrifugal pump electrical consumption is also well estimated, with a deviation of 11 % compared to the measurements. This higher deviation in the pump electrical consumption can be partly attributed to differences between the actual equipment and its technical specifications.

Table 3: Energy balance comparison for September 2024 between both models and measured data

	Measurements	Model
Thermal solar Energy	209.4 MWh	211.8 MWh
Energy provided to storage	207.4 MWh	212.5 MWh
Electric pump consumption	1.8 MWhe	2.0 MWhe

5 Conclusion

In this paper, the 2 different modeling approaches available in the NewLib library are presented. Comparisons of these 2 modeling approaches with measured data on an operating solar plant have been carried out.

On the one hand, the conceptual design phase model of the solar field in NewLib provides robust thermal results but cannot be used for hydraulic conception purpose during the engineering phase of projects due to its lack of accuracy in pressure losses prediction. On the other hand, the detailed solar field model offers significantly improved accuracy in pressure loss calculations and combined with medium representation can lead to acceptable simulation time. The NARBOSOL case serves as a prime example of these advantages.

Future perspectives of this work for each phase of Newheat projects are:

- Conceptual design phase: Finalization of the template-based approach to streamline model development.
- Engineering phase: Development of detailed models for key components, including heat exchangers and valves, to enhance system accuracy.
- Operational phase: Refinement of detailed models to facilitate the implementation of a digital twin approach, ultimately optimizing maintenance operations, such as fault detection like leak identification, and improving overall system performance.

These advancements pave the way for more accurate simulations and the potential for real-time optimization in future applications.

Further Application of Modelica-Based Nuclear Power System Simulation: A Review of Home-Tasks in Different Scenarios Driven by Model and Data

Ao Zhang [1] Xiang Wang [1]

[1] College of Nuclear Science and Technology, Harbin Engineering University, China, {zhangao, xiang.wang}@hrbeu.edu.cn

Abstract

System simulation is inherently an applied technology, driven by specific application demands. The Modelica language enables equation-based, system-level, multi-domain, and visual modeling, facilitating researchers conducting system simulation studies of nuclear power systems. This paper introduces the custom-built AESE library on the OpenModelica platform. Examples in AESE are provided to illustrate the development and simulation of system models for conventional pressurized water reactors (PWRs) and high-temperature gas-cooled reactors (HTGRs). The paper also describes tasks completed under different application scenarios, including hardware-in-the-loop simulation, multi-objective optimization, system identification, and rapid optimization, using model-driven and data-driven approaches with the AESE library. The further application of simulation models and data has significant practical and engineering value. This paper serves as a valuable reference for the intelligent application of energy system models in the context of advanced engineering challenges.

Keywords: Modelica, Nuclear Power System, Model-driven, Data-driven

1 Introduction

System-level simulation provides a framework for understanding and analyzing the behavior of complex systems, enabling enhanced design and optimization. Multi-domain system-level modeling has gained significant popularity in seamlessly integrating physical models from various domains using a unified modeling language. This approach helps to overcome interface issues between different domain-specific software and enables the modeling of comprehensive and complex real-world systems (Mattsson et al. 1998).

Modelica, as an example of a multi-domain system modeling language, employs mathematical equations to uniformly describe physical processes across different domains. It offers visual modeling capabilities to represent the topology of a system and enables the solution of steady-state and transient simulations by solving algebraic and differential equations. The Modelica language has been widely used in the aerospace, shipbuilding, automotive, energy, and other fields (Briese et al. 2020; Soriano et al. 2016; Andreasson et al. 2013).

Nuclear power systems (NPSs) are inherently complex and face increasing demands for shorter development cycles, higher safety standards, and smarter operation. While traditional offline Modelica-based simulations have successfully supported reactor design and thermal-hydraulic analysis (Casella and Leva 2005; Cammi et al. 2011), the full potential of system simulation extends beyond this. Driven by the need for more intelligent system management and accelerated development, system simulation is evolving to support multiple practical scenarios that leverage both models and data. This work specifically focuses on the expanded application of Modelica-based NPS simulation across diverse technical dimensions:

a) Hardware-in-the-loop simulation (HILS), which enables integrated control verification by coupling physical hardware with digital models. For complex NPSs, the pressure to shorten development cycles and meet stringent safety requirements necessitates comprehensive control system testing to avoid costly failures. These demands have driven recent advancements in HILS (Mihalič et al., 2022). Although Modelica is widely used in offline NPS simulations, its application in system-level HILS research for nuclear systems remains limited.

b) Multi-objective optimization (MOO), which facilitates system-level design exploration by resolving trade-offs among competing objectives. In large-scale systems like NPSs, single-objective optimization often fails to represent the comprehensive requirements of engineering applications (Zhang and Wang 2024). Therefore, greater attention is given to multi-objective optimization problems that incorporate complex constraints. These objectives are often interdependent and cannot be optimized simultaneously, requiring coordinated strategies to identify Pareto-optimal solutions under varying conditions.

c) System identification, which leverages operational data for rapid prediction and data-driven modeling, supporting fast evaluation and intelligent optimization. A

significant amount of data generated during nuclear power operation remains underutilized. However, emerging data-driven multi-objective (DDMO) optimization frameworks aim to bridge this gap. By coupling system identification algorithms with MOO, these frameworks enable efficient exploration of design spaces, enhance productivity, and improve predictive capabilities for future operational states.

These application scenarios underscore the diverse and critical roles that system simulation can play in modern NPS development. As depicted schematically in Figure 1, they encompass physical integration, algorithmic coordination, and data utilization, collectively forming a comprehensive modeling–application framework. This paper builds upon this framework by first introducing the general modeling approach using the AESE library (Section 2), then presenting these three representative applications in detail (Section 3), and finally concluding with a summary and outlook (Section 4).

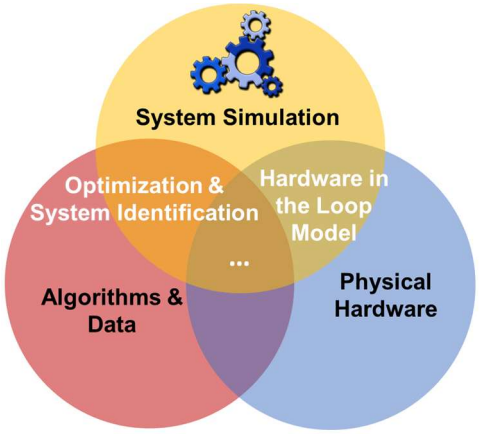

Figure 1. The further application directions of system simulation discussed in this paper

2 System Simulation

2.1 Framework

A custom-built Advanced Energy Systems Engineering (AESE) library (Zhang and Wang 2024) in OpenModelica (Fritzson et al. 2020) was developed in this study to describe various advanced energy systems. Figure 2 depicts the AESE architecture and the hierarchical structure of its He-Xe CBC system sub-library. Designed for modularity and openness, the library separates component models from working fluid models, allowing easy adaptation to future fluid models. Modelica facilitates this by supporting a high-level component library framework, defining standardized interfaces, and using inheritance or substitution for detailed component implementations. The following briefly outlines the modeling and simulation of two typical nuclear energy systems: the pressurized water reactor (PWR) and the high-temperature gas-cooled reactor (HTGR).

2.2 Pressurized Water Reactor (PWR)

The PWR-NPS consists of a nuclear reactor and two energy conversion loops (Figure 3). This study created a direct propulsion PWR-NPS model using Modelica, based on the "NS Mutsu" nuclear merchant ship (Peng 2009). The model, focused on a pressurized water reactor, describes fluid flow, heat transfer, phase changes, and power output. It was visually built (Figure 4) using adapted components from the ThermoPower (Casella and Leva 2024) and AESE libraries, including a reactor with a point kinetics model, a steam generator (SG) with drum and one-dimensional flow parts, condensers, turbines, pumps, and control units. Steady-state tests (Table 1) and dynamic analysis (Figures 5-7) verified the model's accuracy (Zhang et al. 2024). These results demonstrate that the Modelica-based model is capable of simulating and validating both steady-state and dynamic operations of conventional PWRs in the nuclear field.

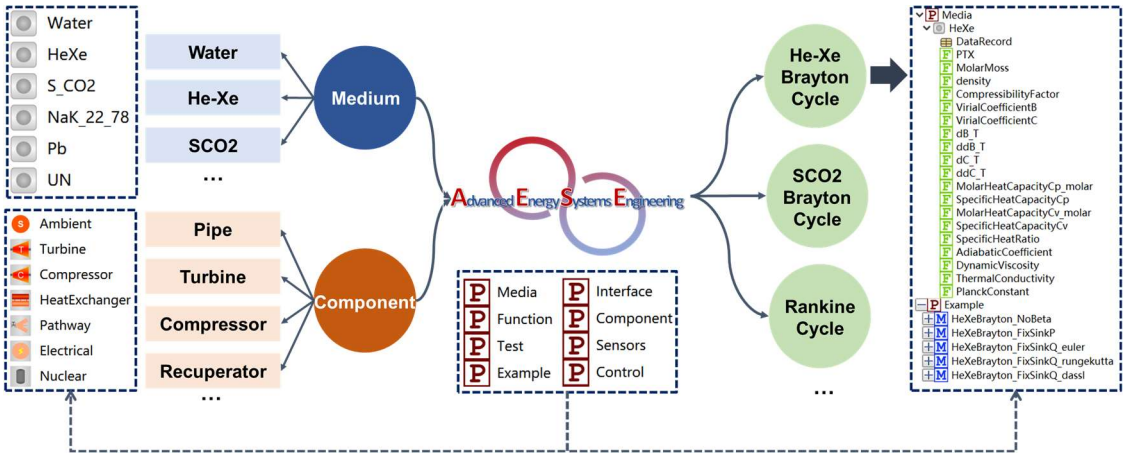

Figure 2. Schematic of the advanced energy systems engineering (AESE) library (Zhang and Wang 2024).

DOI 10.3384/ecp218373

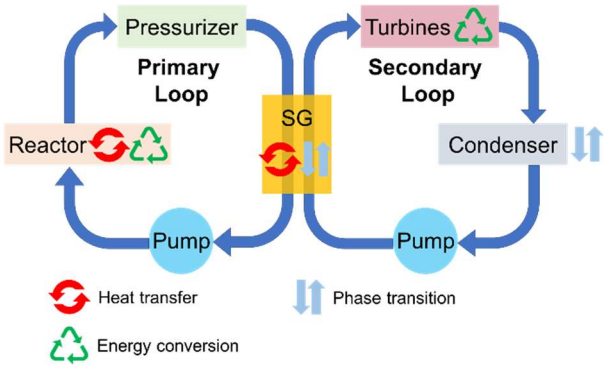

Figure 3. Structure of PWR-NPS (Zhang et al. 2024).

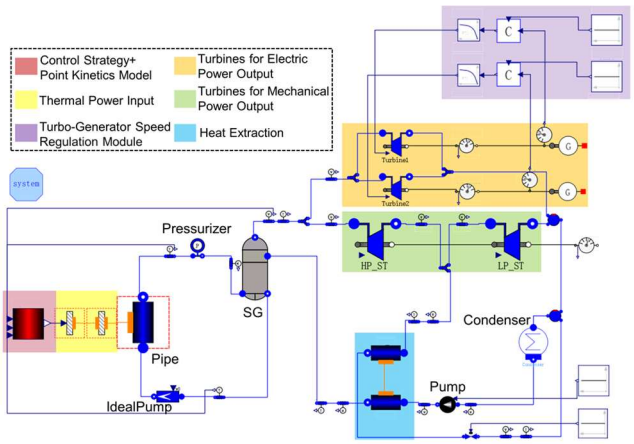

Figure 4. Simulation model of the PWR-NPS (Zhang et al. 2024).

Table 1. Steady-state simulation results.

Parameter	Reference	Result	Error
Reactor thermal power (MW)	36	35.81	0.52%
Temperature of SG primary side inlet (K)	558.15	555.18	0.53%
Temperature of SG primary side outlet (K)	544.15	544.82	0.12%
Pressure of SG secondary side (MPa)	3.9	3.72	4.61%
Feedwater temperature of SG secondary side (K)	433.15	431.28	0.43%
Steam temperature of SG secondary side (K)	524.15	519.19	0.95%
Steam output of SG (kg/s)	17	17.31	1.82%
Mechanical power output of steam turbine (MW)	7.35	7.38	0.41%

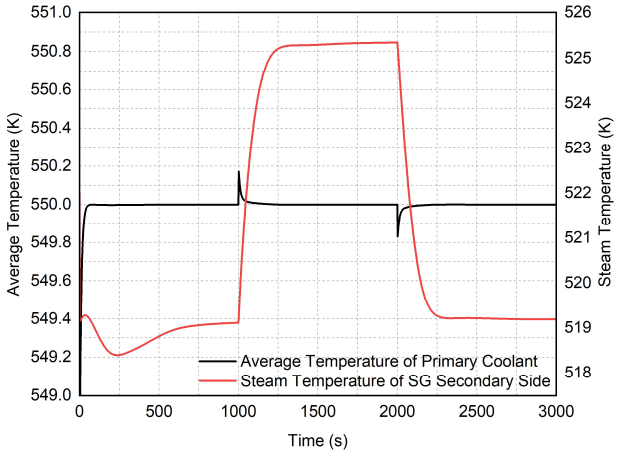

Figure 6. Transient heat transfer process on the secondary side of the SG (Zhang et al. 2024).

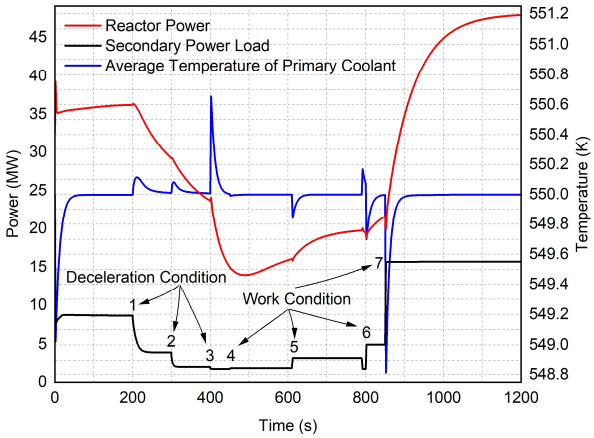

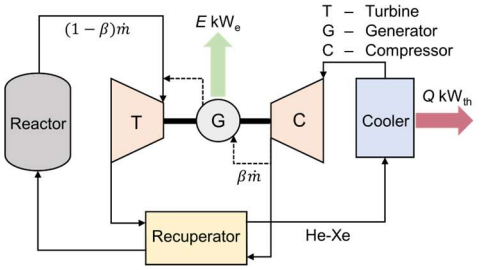

Figure 7. Transient simulation results of the NPS (Zhang et al. 2024).

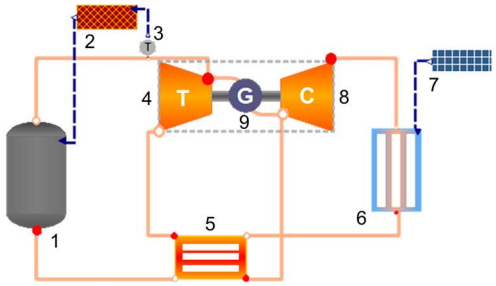

2.3 High-Temperature Gas-Cooled Reactor (HTGR)

The HTGR enables efficient coupling with the Brayton cycle via its high outlet temperature, while Brayton cycle research focuses on system configuration and gas property effects. The AESE library also includes a He-Xe property

library and supports closed-Brayton-cycle (CBC) systems (Figure 8a), offering new tools for simulating He-Xe CBC systems (Figure 8b). The presence of Xe in He causes deviations from ideal gas behavior, addressed by Tournier et al. (2006) using a binary noble gas calculation theory. Figure 9 displays the core physical properties (left) and their Modelica-based implementation in the AESE library (right). We validated He-Xe properties against literature (El-Genk et al. 2007), performed steady-state (Figures 10-11) and transient analyses for the He-Xe CBC-NPS, and assessed system performance across design parameters (Figure 12), guiding future optimization and design (Zhang and Wang 2024). These results indicate that the Modelica-based model supports pioneering studies of advanced reactor concepts in the nuclear field.

3 Further Applications in Different Scenarios

After validation, NPS models hold significant potential for valuable applications in equipment design and operation. For example, system models can drive real hardware to enable rapid control loop validation in HILS; support optimization algorithms for MOO design in large-scale systems; and utilize simulation data to drive intelligent algorithms for system identification and rapid optimization. Models can be further expanded and applied across various scenarios and dimensions.

DOI
10.3384/ecp218373

3.1 Hardware in the Loop Simulation (HILS)

HILS links a physical object with a computer-based simulation model for testing, accurately capturing the controller's dynamic, static, and nonlinear characteristics, making it a highly realistic simulation technology.

To study the variable operating condition responses of nuclear-powered engineering ships (NPES), we initially developed a desktop-level HILS model framework (Zhang et al. 2024). The HILS platform framework (Figure 13) integrates software, hardware, and a communication chain (Zhang et al. 2024), with the system model executed in OpenModelica and real-time signal transmission handled via an Arduino module. This configuration enables real-time coupling between the virtual NPES system and physical controllers for realistic validation and testing scenarios.

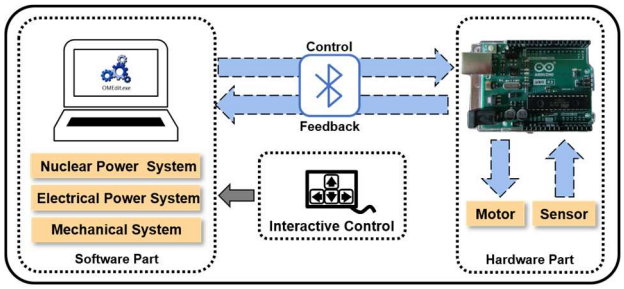

Figure 13. Framework of the HILS platform for an NPES (Zhang et al. 2024).

Both the offline model and the HILS software-level model are shown in Figure 14. The offline model uses the "Transient Signal Module," while the HILS model employs the "HILS Signal Module," enabling hardware communication via an Arduino module (COM3 port, signal pins) for control signals and sensor data. Real-time user interaction is supported through keyboard inputs, processed by signal control logic. The offline model is primarily used for preliminary system validation, whereas the HILS model allows real-time interaction with physical hardware for controller testing and signal feedback.

Figure 15 shows the HILS signal filtering process for the NPES, averaging the signal every second. The PID control was critical during the NPES's three-stage deceleration, as demonstrated by the velocity curve in Figure 16.

These results confirm the feasibility and effectiveness of the Modelica-based HILS platform for simulating and analyzing the dynamic responses of NPES under variable operating conditions. The key advantage of Modelica lies in its ability to represent multi-domain system models and integrate them with real hardware components, enabling the construction of more comprehensive and organically coupled HILS frameworks.

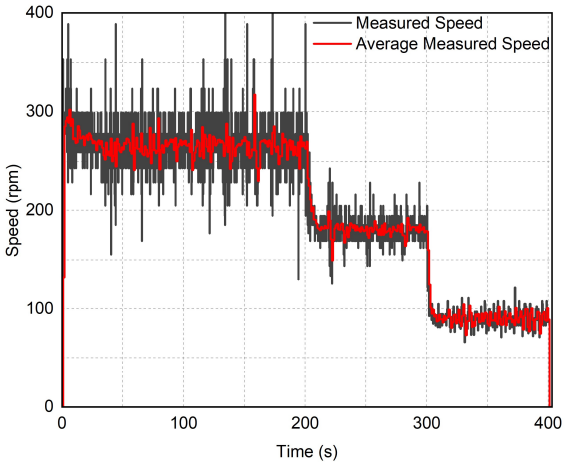

Figure 15. Simple filter process of the collected hardware response signal (Zhang et al. 2024).

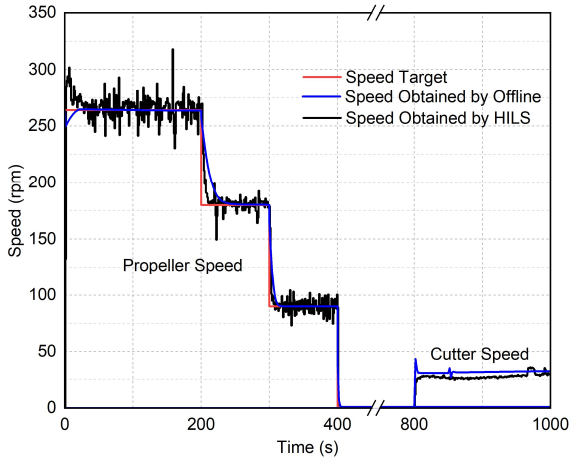

Figure 16. Data recording of hardware response and comparison of propeller speed control in HILS full condition experiment (Zhang et al. 2024).

3.2 Multi-Objective Optimization

In the He-Xe CBC system, multiple performance targets cannot be simultaneously maximized under the same operating condition, which necessitates a multi-objective optimization (MOO) approach. The NSGA-II algorithm (Deb et al. 2002) is applied within the feasible domain to achieve balanced optimization across conflicting objectives.

We implemented an NSGA-II optimization framework in Python (Jazzbin et al. 2020), coupled with the He-Xe CBC system model in OpenModelica via OMPython (Ganeson 2012) for MOO calculations (Zhang and Wang 2024). Figure 17 illustrates the MOO methodology architecture. OMPython links the NSGA-II algorithm to OpenModelica, relaying parameter settings for simulation and returning results to the optimization process. The MOO objectives include system efficiency, specific work, and the Brayton cycle system's equivalent volume with turbomachinery aerodynamic load distribution.

Figure 18 illustrates the Pareto optimal solution set obtained by optimizing two selected objectives, and Figure 19 shows the Pareto optimal solution set for three-objective optimization with different population sizes.

These results demonstrate the Modelica-based model's capability to integrate additional algorithms to support complex MOO studies in energy systems.

3.3 System Identification

System identification is essentially system approximation, aiming to find a model with acceptable accuracy from the data. The resulting model is an approximate representation of the actual system (Ljung 2010). The surrogate model obtained after system identification can accelerate the computational process, helping to reduce the time spent on repetitive calculations or iterations of system models. This is particularly beneficial in scenarios such as multi-objective optimization design and multi-dimensional model coupling calculations.

In the identification of steady-state systems, we constructed a result dataset based on simulations with a variety of different design parameters. The resulting dataset was used to train a neural network model, establishing a proxy for the system-wide input-output mapping. The BPNN is structured with an input layer, hidden layers, and an output layer (Figure 20). Nodes in the input layer represent the system's design parameters. The output layer includes the system's operational or performance parameters, such as temperatures and pressures at various device nodes, system efficiency, specific work, and aerodynamic loading. Each output parameter is mapped through a multi-node hidden layer, collectively forming a comprehensive model that represents the input-output relationships across the entire system.

Figure 21 compares the simulation results and network model calculations for 10 sets of randomly generated design parameters. The maximum relative error was approximately 1%, which indicates that the precision of

the constructed network model is acceptable. Furthermore, the network model, which can surrogate the original model, can be efficiently reused to meet a wider range of computational needs or scenarios.

We are also working on the identification of dynamic system models in AESE, using dynamic mode decomposition (DMD) methods to predict the system's evolution over the long term or during a specific phase (Figure 22), as well as using controlled dynamic mode decomposition (DMDc) methods for rapid prediction of multi-condition transient scenarios (Figure 23). DMD extracts coherent spatiotemporal structures from system data, while DMDc incorporates control inputs to capture input–output dynamics (Zhang et al. 2025). The rapid prediction of a system's transient response aids in efficiently and intelligently handling dynamic data changes, and is of great significance for scenarios such as fast optimization of control systems, lifespan prediction, and fault diagnosis of NPSs.

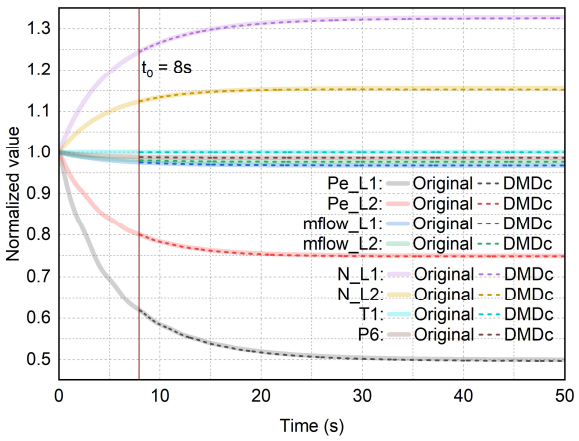

Figure 22. Dynamic prediction of key system parameters based on DMD (Zhang et al. 2025).

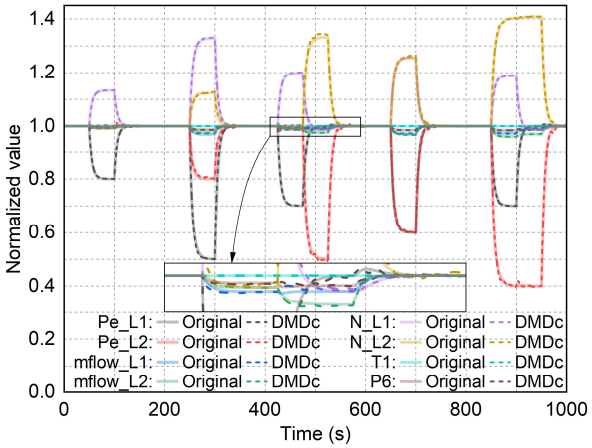

Figure 23. Dynamic prediction of key system parameters based on DMDc (Zhang et al. 2025).

3.4 Rapid Multi-Objective Optimization

As mentioned in the previous section, MOO can be more efficient due to the rapid computation enabled by the surrogate model formed after system identification.

During the optimization process, even with parallel computing, the process remains complex and time-consuming. This paper integrates the BPNN algorithm into machine learning to establish a data-driven multi-objective (DDMO) optimization framework (Figure 24). Using this framework, the system model simulation is not directly embedded in the MOO algorithm. Instead, a large

DOI
10.3384/ecp218373

dataset is first generated through simulations under various design parameters to collect data on different design levels of the system model. Using the BPNN algorithm, a network model is trained based on this dataset to accurately map the original system simulation model. Then, this network model is integrated into the MOO algorithm framework for the optimization design of the system.

Figure 25 presents the results of MOO for the He-Xe CBC system for different numbers of individuals (I) and generations (G) for both model-driven multi-objective (MDMO) and DDMO approaches. The results show consistency between the two modes of optimization. The DDMO optimization had significantly shorter computation times than the traditional MODO approach (Table 3). The DDMO shows faster optimization while maintaining accuracy. Even considering the impact of computer performance fluctuations, the data clearly shows that the DDMO framework accelerated the optimization process by over 10000 times.

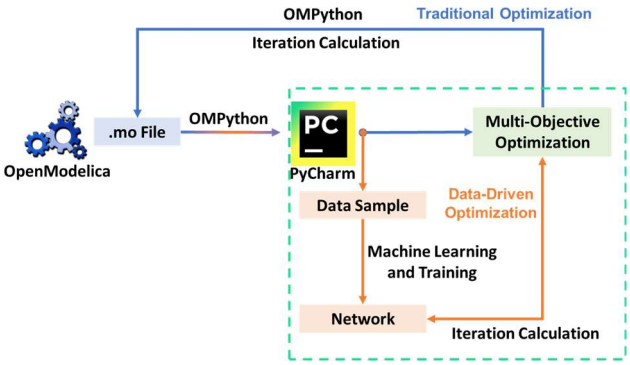

Figure 24. DDMO optimization framework.

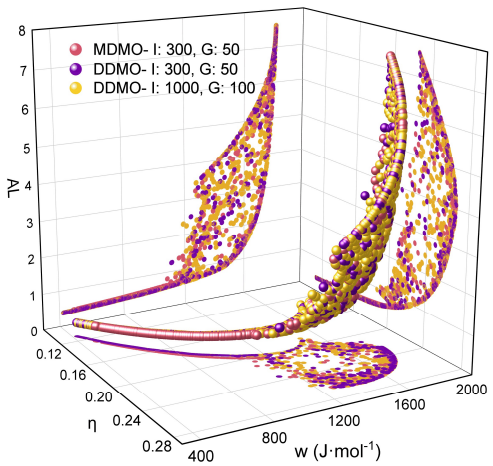

Figure 25. Results of the DDMO.

Table 2. Comparison of calculation times for two optimization methods.

Project	*MDMO*	*DDMO*	*DDMO*
Dual objectives	I: 50 G: 100	I: 50 G: 100	I: 1000 G: 100
η-w	75189.5 s	2.2 s	260.7 s
η-AL	58801.6 s	1.9 s	241.8 s
w-AL	56538.8 s	2.1 s	255.3 s
Triple objectives	I: 300 G: 50	I: 300 G: 50	I: 1000 G: 100
η-w-AL	164502.9 s	55.8 s	185.7 s

4 Conclusions

This paper provides a brief introduction to the AESE library developed for energy systems, particularly NPSs, based on the Modelica language on the OpenModelica platform. It summarizes the modeling and simulation validation of two classic types of models and specifically describes four scenarios for the further application of system simulation models.

Based on Modelica for multi-domain visualization development targeting NPSs, and benefiting from the openness of the OpenModelica platform, system models can be more conveniently integrated with hardware or algorithms to complete tasks such as hardware-in-the-loop simulation, multi-objective optimization, and system identification, addressing task requirements in design verification, operational control, fault diagnosis, and other scenarios in practical engineering with greater accuracy, safety, and speed. Model development is not limited to merely establishing models; further application of models also holds practical significance. Making good use of models and their data can lead to higher productivity.

In current applications, data-driven surrogate models often exhibit strong specificity, which is closely related to the datasets of their particular application targets. As a result, the advantages of surrogate models have not received sufficient attention. To enable more generalized rapid design and optimization of nuclear energy systems, our next step will focus on abstracting the essential nature of energy system models and integrating identification algorithms. This will allow intelligent participation and decision-making throughout the entire design and operation process within a moderately generalized NPS. In addition, to compensate for the limited accuracy of system simulation in modeling key components, the integration of Modelica-based system simulation with other three-dimensional computational tools also deserves further attention.

Abstract

In a context of massive penetration of Renewable Energy Sources (RES) in the grid, it is of prime importance for Transmission System Operator (TSO) to correctly represent these components in their day-to-day dynamic simulations used to assess system stability, both in operational and planning situations. Well-parametrized generic Power Electronics Interfaced Resources (PEIR) models have emerged as a viable option for TSOs for large-scale stability situations, and are largely available in commercial power system software. However, despite previous efforts in the open-source community, especially in the Modelica one, there is a lack of a complete, up-to-date, and industrial-grade library. This paper presents the current status of the Dynaωo Modelica library for standard PEIR models that tries to fill this gap. The library's architecture and content, the implementation choices, and already existing industrial usages of the models are presented in detail, alongside validation cases and results.

Keywords: Western Electricity Coordinating Council (WECC), International Electrotechnical Commission (IEC), Power Electronics Interfaced Resources, Modelica, Dynawo

1 Introduction

Transmission systems are undergoing significant transformation due to the massive penetration of PEIR with the increased integration of RES and High-Voltage Direct Current (HVDC) connections.

Adding these new components to the system significantly impacts its dynamic behavior, which is crucial for accurately assessing system stability. The primary role of the electrical TSO is to ensure the security and stability of the system at all times through both preventive and corrective actions, supported by continuous monitoring and simulations. To achieve this, it is essential to accurately model and integrate these new components into time-domain simulations.

However, creating dedicated Root-Mean-Square (RMS) dynamic models for each new installation has proven to be a non-sustainable approach, due to the large number of new connections to the grid each year and the difficulty in obtaining open and transparent descriptions of the controls for intellectual property reasons. Two strategies are currently used by the different TSO across the world to tackle this issue: use black-box models directly provided by the Original Equipment Manufacturer (OEM) or/and require well-parametrized generic models allowing to correctly represent the installation behavior (EirGrid 2022; NGESO 2024; TenneT 2024).

Even if generic models can cover a large spectrum of phenomena, only adapting their parameters to the project-specific settings allows one to properly fit the response of many different installations. These standard models are mainly proposed by two entities: the IEC and the WECC. IEC 61400-27-1 international standard describes Wind Turbine (WT) and Wind Power Plant (WPP) models (61400-27-1:2020 2020). The WECC standard contains models for WPP, Photovoltaics (PV) and Battery Energy Storage Systems (BESS) installations (Pourbeik 2014).

A large part of these generic models is available in power systems commercial software such as DIgSILENT Power Factory, Siemens PTI PSS®E, or General Electric PSLF. However, in these environments, even if the general block diagram structures are visible and readable, the individual blocks and their implementation choices are hidden: this could lead to possible discrepancies in the results that are difficult to explain (Villena-Ruiz et al. 2019; Franke, Guironnet, and Cardozo 2024). On the other hand, Modelica is a high-level and open-source modeling language (Fritzson and Engelson 1998), (Mattsson, Elmqvist, and Otter 1998), which is particularly well-suited to offer transparent and unambiguous modeling of power system components in general (L. Vanfretti et al. 2013) and RES in particular.

Open-source implementations of WECC generic models have been proposed and released both in Dynaωo (Nuschke et al. 2021) and OpenIPSL (Fachini, Luigi Vanfretti, et al. 2021) Modelica libraries in recent years. Nevertheless, both efforts only cover part of the currently available WECC models due to the fast evolution of the standard. On the IEC side, the standard course of evolution is slower but the main previous work (Carbonell et al.

2023) focused on the implementation of the Edition 2020 Type IV model, which is not the mostly used by OEMs as of today from RTE's, the French TSO, experience. Recent contributions around Modelica and generic models were rather focused on improvements to the standard models, either to make them more adapted to weak grid conditions (Carbonell et al. 2023), to compare them and provide recommendations for further improvements (Franke, Guironnet, and Cardozo 2024) or to better match power hardware in the loop results (Fachini, Chang, et al. 2025), than on the completeness of the libraries. As a result, there is a lack of a complete, up-to-date and industrial-grade collection of generic RES models in Modelica. This paper tries to fill this gap by presenting the current status of the Dynaωo Modelica library which contains all the necessary standard models to cover all kinds of new RES installations that would like to connect to the grid. This open-source library will facilitate the collaboration between the different power system's stakeholders, offering a basis for discussions on the unavoidable implementation choices and easing the diffusion and usage of generic models in the academic and industrial communities.

The main contributions of this paper are thus the following:

- A presentation of a complete, up-to-date and industrial-grade Modelica collection of generic models for any kind of RES.
- A description of the modeling approach and the implementation choices done in the library.
- An introduction on the current and foreseen industrial usages of the RES models in RTE.

The paper is organized as follows. Section 2 presents the complete set of PEIR generic models available in the library as well as its global architecture. Section 3 and section 4 are dedicated to the IEC and WECC parts of the library, respectively. They provide an overview of the models, a description of the Modelica implementation, a focus on the newly implemented parts of the controls as well as on the final available models, and conclude with a models validation paragraph. Section 5 introduces two envisioned usages of the library from RTE's perspective. Finally, section 6 draws conclusions and presents potential next steps on this topic.

2 Library Content and Architecture

The Dynaωo Modelica library[1] contains at least one generic model for any kind of RES installation.

The models can be found under a PEIR package, as shown in Figure 1, containing both converter and plant models. Plant models are of prime importance for the TSOs as they are the ones that will be used in day-to-day operational and planning large-scale studies; converter models can also be useful if one wants to focus on the fast transient driven by the converter controls. For both packages, application-specific and non-specific models have been implemented.

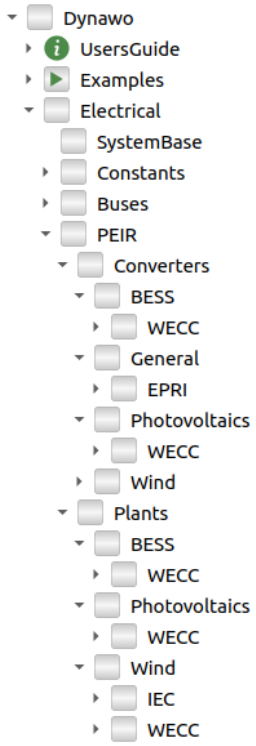

Figure 1. PEIR package in Dynaωo Modelica library.

- Application-specific models for BESS, PV and WPP described in IEC and WECC standards. The list in Table 1 will be presented in detail in the rest of this paper.
- Models with non-specific application "*General*" (i.e. could be used for PV, WPP or BESS components) from IEC and WECC standards or from projects related to grid following or grid forming converters. This part of the library is out of the scope of this paper.

These models have been developed by combining different individual modules available in the control part of the library under a dedicated PEIR package and physical electrical parts such as lines, transformers, and injectors.

PEIR	***Subtype***	***Available models***
Wind	Type III WT	IEC (61400-27-1:2020)
	Type III WPP	IEC (61400-27-1:2020), WECC

3 IEC Models

3.1 Overview and Modelica implementation

The IEC 61400-27-1 standard specifies generic and modular dynamic models suitable for power system stability studies. These models may be used to represent the dynamic behavior of WPP at their Point of Connection (PoC) to the transmission network and of WT at their output terminal. The overall structure of the WPP model proposed in the standard can be found in (61400-27-1:2020 2020).

- The **WPP control and communication** model, also known as Power Park Control (PPC), is in charge of controlling the active and reactive power (P,Q) of the whole plant at the PoC, by computing and sending appropriate orders to the WT. The ancillary services required by TSO, like primary voltage regulation or frequency sensitive mode are handled in the PPC. The PPC is mainly involved in slow dynamics (several seconds).

- The **WT** model is intended to represent an aggregation of a set of identical Wind Turbines. The WT is receiving an active power order p_{WTref}[2] and a voltage or reactive power order (depending on the chosen control mode) x_{WTref} from the PPC. These orders are used to compute reference active and reactive currents, which are then limited to respect the physical limits of the unit. These currents $(i_{\text{pcmd}}, i_{\text{qcmd}})$ are then injected based on the synchronization angle θ_{Pll} given by the Phase-Locked Loop (PLL). The control does not incorporate any inner current loop, so the converter is modeled solely as a current source. The WT control is involved in faster dynamics than the PPC (from ms to a few seconds) and is, for example, essential to represent the Fault Ride Through (FRT) behavior.

- **AUX** model is intended to represent auxiliary equipments which may be, for instance, STATCOMs or static VAR compensators. They have not been implemented at the moment but will be considered in future works.

- **Power Collection System (PCS)** represents an aggregation of the internal network between the WT and the PoC. In large WPPs, it is a crucial part of the model as there could be dozens of kilometers of cables in the real installation. The IEC standard does not specify a clear and unambiguous model for the PCS, even if it proposes a method to compute aggregated parameters based on the real installation complete internal network characteristics. In the Modelica implementation proposed in this paper, it has been decided to represent the PCS with a classical Π line model : $(R+jX)$ line impedance and $(G+jB)$ shunt admittance.

The overall Modelica implementation of the WPP models has been made to be as close as possible to what is specified in the standard. The only deviations at this level are the following:

- f_{sys} has been replaced by *omegaRef* which is the notation used in Dynaωo for the system frequency (which means the rotation speed of the reference frame in which the phasors are computed).

- A measurement block has been inserted to obtain the WPP terminal complex voltage and current.

- An additional input *tanPhi* has been considered for the WT model (in the standard *tanPhi* is considered as a fix parameter).

3.2 Models description

3.2.1 Type IV Model

Type IV WT, also called full-converter WT, are interfaced to the grid with a AC/DC and then a DC/AC converter. This creates a decoupling between the mechanical system of the WT and the electrical system. Moreover, this type of WT has a very flexible control that can be used to offer support functions to the grid. The implementation of the Type IV model based on the Ed. 2020 of the IEC 61400-27-1 standard is presented in details in (Carbonell et al. 2023). A first version of the standard was published in 2015 which is still used by many vendors. Considering this, an implementation of the IEC Type IV Ed. 2015 has been added to the Dynaωo library. The main differences between the two editions of the standard are described below and summarized in Table 2.

- **Dedicated measurement module**: The 2020 version includes a dedicated grid measurement module that is used once for protection and once for control at the WT level and once for the PPC at the WPP level. In the 2015 version, there is no such centralized measurement module, and the filtering process is made independently in each control or protection sub-module. The centralized version used in the 2020 version avoids duplicating the declaration of the time constants and decreases the risk of inconsistencies.

- **WT electrical system**: The 2020 version includes an electrical system module to represent electrical components between the generator system (which is the output of the converter) and the point where the WT is connected. It would typically be used to represent the MV/LV transformer of the WT. In the 2015 version, this electrical system module is just a circuit breaker that will disconnect the WT based on the flag

[2] All variables and parameters shown for the models are in per unit (pu). In Dynaωo library, a *Pu* is added to the variable and parameter names, it is removed in this article for better readability.

F_{OCB} (Open Circuit Breaker). The 2015 version of this module can be extracted from the 2020 version just by setting $r_{es} = x_{es} = g_{es} = b_{es} = 0$. Considering this, the electrical system module is implemented for both versions.

- **Reactive current injection**: The additional reactive current to be injected during fault differs between the two versions. In the 2015 version, it is proportional to the voltage measured at WTT terminal u_{WTT}, with a dead-band $[u_{db1}, u_{db2}]$: $i_{qv} = K_{qv}(u_{db1} - u_{WTT})$ when $u_{WTT} \leq u_{db1}$; while in the 2020 version, it is proportional to the derivative of u_{WTT} : $i_{qv} = K_{qv}(\Delta u_{db1} - \Delta u_{WTT})$ when $\Delta u_{WTT} \leq \Delta u_{db1}$. This derivative is computed with a time constant t_{Uss}, if t_{Uss} is very large this becomes equivalent to the 2015 version, while if t_{Uss} is small the converter will inject reactive current only with fast variations of voltage.

- **Over-Voltage Ride Through (OVRT)**: In addition to the Under-Voltage Ride-Through (UVRT) operation, the 2020 version also includes an OVRT operation. This aims to adapt the reactive current order if voltages exceed a given parameter U_{qRise}. The control path for additional reactive current in the case of OVRT is the same as in the case of UVRT but with the opposite reaction, considering that this path reacts to voltage variations (see previous point). This part of the control is not present in the 2015 version, which means that there is no particular operation in case of over voltages.

- **WPP description**: The 2020 version includes a full description of WPP including PPC with its two main control blocks (active and reactive power controls) along with the communication and measurement modules. Two variants are proposed for the communication module : a linear one consisting of lead-lag transfer functions applied to every communicated variable, and a pure delay one. At this time, only the linear variant has been implemented but the pure delay variant could be developed in the future to better observe some dynamics. In the 2015 edition, a draft version of PPC active and reactive control blocks was proposed in the standard, but without any general structure to build the full WPP model. The choice made in the Dynaωo implementation is to use the structure proposed in the 2020 version and put into it the 2015 control blocks to build 2015 WPP models.

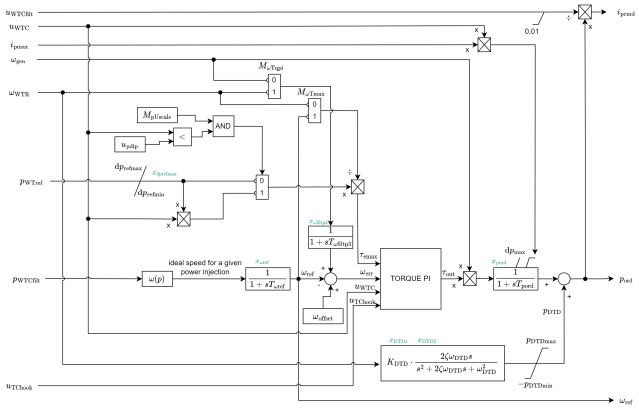
Additionally, it is important to keep in mind that there are two variants of Type IV WT : Type IV A and IV B, the only difference being that Type IV B includes an additional module giving a simplified representation of the mechanical part.

	2015 version	***2020 version***
Measurement	Electrical quantities independently filtered.	Centralized measurement module.
Electrical system	Not in the norm but added in the Modelica implementation.	Classical PI-system between converter and WT terminal.
UVRT reactive current injection	Included and proportional to the voltage u_{WTT}.	Included and proportional to the derivative of the voltage u_{WTT}.
OVRT reactive current injection	Not included.	Included.
WPP	No main structure in the norm but modeled in Dynaωo based on the 2020 structure with the 2015 control blocks.	Full description of WPP including PPC with P and Q/U controls, communication and measurement modules.

Table 2. Summary of the main differences between 2015 and 2020 versions of the IEC 61400-27-1 standard and additional Modelica implementation

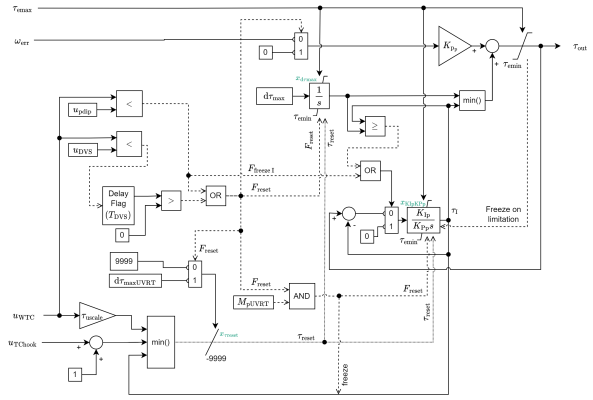
3.2.2 Type III Model

The Type III model represents a wind power plant with Doubly-Fed Induction Generators (DFIG). It shares many of its sub-models with the Type IV model. The differing models are presented in more detail below:



- **Active power control** of the wind turbine control, including its sub-model, the **Torque PI controller** (see Figure 2). Its general behavior is influenced by an $\omega(p)$ lookup-table that provides the angular velocity at which the turbine should rotate when it is injecting a certain active power. The specific implementation choices in these controllers, especially integrators, limiters and their interactions, are delicate and can have a large influence on model behavior.

- **Two-dimensional aerodynamic** model (see Figure 3). It models the energy conversion from available wind power p_{avail} to what the wind turbine passes on to the mechanical rotor. This is influenced by the rotor blades' pitch angles θ and the turbine's angular velocity ω_{WTR}.



- **Pitch angle control** (see Figure 4). It uses two PI controllers to control the pitch angle, one associated with rotor speed $\omega_{WTR} - \omega_{ref} + K_{PX}(p_{ord} - p_{WTref})$ and one with generator power $p_{ord} - p_{WTref}$.

- **Generator system models** (see Figure 5). Two generator system models have been implemented: **III-A**

DOI 10.3384/ecp218383

with an explicit model of the current control loop and **III-B** with a simple model of a crowbar-circuit.

All the figures are extracted from (*COLib, a collaborative open-source dynamic simulation library for power systems* 2025).

3.3 Models validation

The 2015 version of the Type IV model has been validated by comparing the results with the detailed 2020 version. For the Type III model, in-depth comparisons against the results obtained with the DIgSILENT PowerFactory (DIgSILENT 2024) models have been done. Indeed, a structured qualitative validation procedure has been conducted for the components implemented in OpenModelica (Fritzson, Pop, et al. 2020) as follows:

- Set up the model with inputs and outputs in both simulation environments.
- Define test cases with varying input signals.
- Run the simulations and visually compare output signals using OMPython[3] and powfacpy[4].

[4] github.com/FraunhIEE-UniKassel-PowSysStability/powfacpy

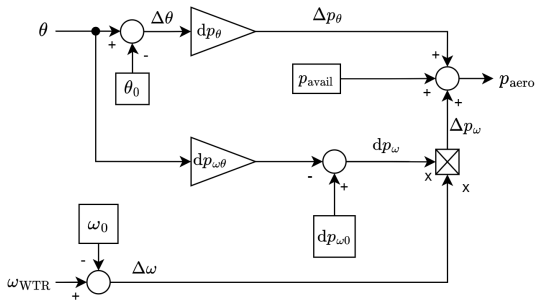

Figure 3. IEC Type III Two-Dimensional Aerodynamic Model.

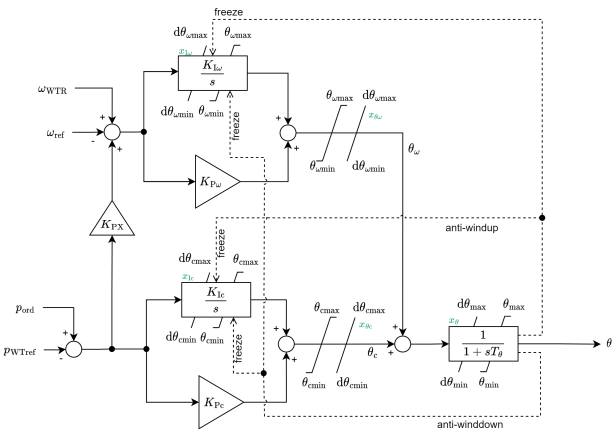

Figure 4. IEC Type III Pitch Angle Control Model.

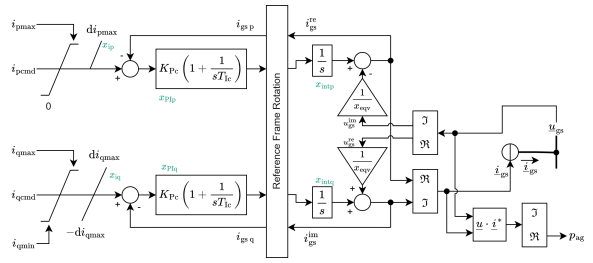
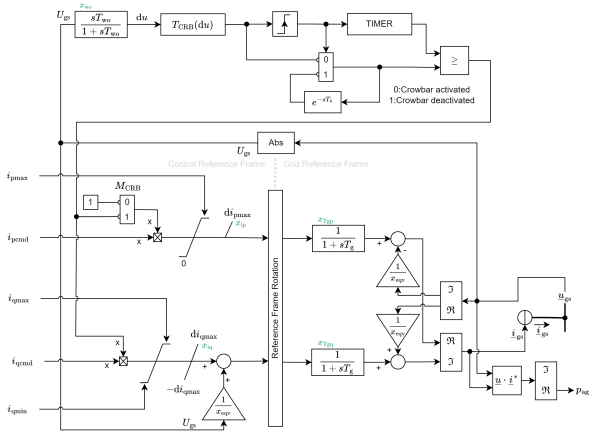


Exemplary results are presented in Figure 6 showing a test case of the validation of the P control model. Several step variations of the input voltage at the converter u_{WTC} are performed, and it is seen that the outputs of the P control model, active power order of the WT p_{ord} and the active current command i_{pcmd}, in OpenModelica and DIgSILENT PowerFactory are identical. In Figure 7, several step variations are done on the input active current command i_{pcmd} of the Type III-A generator system model. The real active current injection i_{gsre} is observed at the output. A perfect match is observed between both implementations.

Figure 8 displays the response of the complete wind turbine model in a Single Machine Infinite Bus (SMIB) configuration to a change of the active power reference setpoint P_{ref} ($= p_{\mathrm{WTref}}$). The responses of both models are very similar, even if not completely identical. All these results allow to validate the WT Type III Modelica implementation.



4 WECC Models

4.1 Overview

WECC generic models represent second generation generic renewable energy systems that are interfaced with the grid through power electronics converters, like PV, Wind Turbine Generator (WTG), and BESS. These models are used in transient stability studies where the electric

controls and converters are modeled along with the plant controls.

The WECC RES models are implemented by combining the different individual blocks (REPC_*, REEC_* and REGC_*) that represent the controls of an installation as seen in the Figure 9a for PV plants for example. These three control systems and the mechanical system models are presented below :

- The plant control - **Renewable Energy Plant Controller** (REPC_*) models - sets the main controls of the plant : voltage or reactive power control and frequency-dependent active power. The REPC_A model is available in Dynaωo and could be used for PV, WTG, and BESS.

- The electrical control - **Renewable Energy Electrical Controls** (REEC_*) models - includes the local inverter functionalities such as FRT characteristic with fast reactive current injection, local voltage and reactive power control, and current limitation with respect to the priority given to active or reactive current. This control system calculates the active and reactive current set-points *idCmd* and *iqCmd*. Three models are available in Dynaωo : 1) the REEC_A model that is recommended for WTG and now for PV, 2) the simple REEC_B model that was recommended for PV, 3) and the REEC_C model that is recommended for BESS where the State Of Charge (SOC) is modeled allowing negative current (i.e. consumption).

- The generator/converter control - **Renewable Energy Generator/Converter** (REGC_*) models - is the last part of the control and interfaces with the network. It enables the conversion of the current set-points calculated by the REEC part into the final currents (or voltages) delivered to the network. Three models are available in Dynaωo : 1) the REGC_A for current source models, 2) the REGC-B, and 3) REGC-C for voltage source models. All these three blocks could be used for PV, WTG, and BESS models.

- The **WTG mechanical side models** for Type III and Type IV WTGs. All mechanical models introduced in the WECC are available in Dynaωo : the drive-train shaft dynamics models WTGT_A used for Type

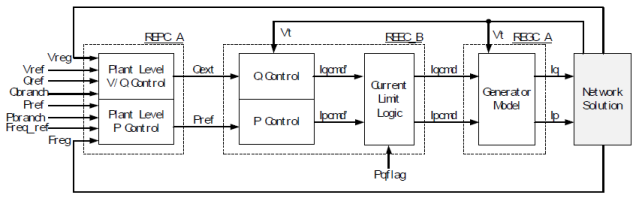
III WTGs and WTGT_B used for Type IV WTGs. These models represent the rotor speed changes and resulting torsional oscillations after faults or sudden wind speed changes. The pitch controller (WTGP_A and WTGT_B), the torque controller (WTGQ_A), and the aero-dynamics (WTGA_A) models are used to properly model a Type III WTG.

Table 3 presents the current list of possible model combination in Dynaωo Modelica library for PV, WTG Type III, WTG Type IV and BESS. Noting that the new models introduced by the WECC standard, such as REEC_D, REEC_E, REPC_C and REPC_D, are currently being implemented, and will be completing the current list.

4.2 Modelica implementation

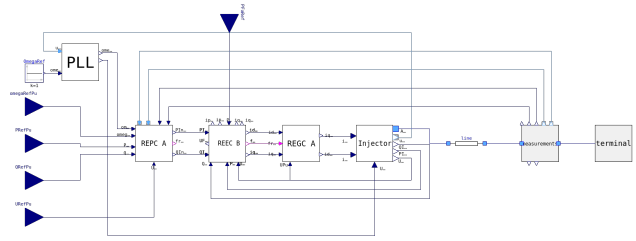
As shown in Figure 9b, the implementation in Dynaωo Modelica library follows the same structure as presented in (Ellis, Behnke, and Elliott 2013) for the **IBR level control** where the three control blocks are interconnected and receiving measurements from the network. Inside each of these blocks, the controls are described through a *block-diagram* approach following the latest version of the *Model User Guide for Generic Renewable Energy System Models 2023* (Ramasubramanian 2023).

In the Dynaωo Modelica implementation, each IBR is connected to the grid through a **terminal**. The following blocks, shown in Figure 9b represent the connection between the IBR and the network :



- The current **injector**, where the interface to the grid is a current source, calculates the real and imaginary currents that IBR model will inject. The dq transformation is done inside this block and is described through *equation-based* approach. For voltage source models, the dq transformation is done inside the REGC model.
- The **PLL** is added in all the models to calculate the voltage phase θ needed for the dq transformation. This block is described in a *block-diagram* approach. In the WECC standard, the PLL is neglected for the REGC_A and REGC_B models and only represented for the REGC_C model. In Dynaωo, the PLL was initially added in all models to overcome some numerical issues by adding some dynamics to the voltage phase instead of calculating it instantaneously.
- A classical Π **line** is modeled to represent an aggregation of the Inverter-Based Ressource (IBR) unit transformer and the step-up transformers and is connected to the Point of Common Coupling (PCC).
- Finally, the **measurement** block calculates variables needed for the plant control : the complex voltage and current, and the active and reactive power at the PCC. Note that the other variables needed for the PLL, the electrical control, and generator controls are measured at the injector level.

4.3 Models description



The first WECC generic models implementation in Dynaωo has been presented in (Nuschke et al. 2021), where REPC_A, REEC_A, REEC_B, REGC_A, and WTGT_A are described for PV and WTG modeling. This paper will focus on the new models added such as the REEC_C model enabling the representation of BESS, and the voltage-source models REGC_B and REGC_C for voltage-source interface with the grid.

4.3.1 Electrical control REEC_C model

The REEC_C model is quite similar to the REEC_A model; thus, in Dynaωo Modelica library, these models share the same base-model. Here, some of the differences are highlighted. Table 4 summarizes the key point differences.

(a) WECC PV current source model *(Ellis, Behnke, and Elliott 2013)*

(b) WECC PV current source model implementation in Dynaωo Modelica library

Figure 9. WECC PV current source model.

- The **reactive current injection** during fault is different. The REEC_C injects reactive current actively when the voltage at the injector is different than the reference voltage, unless the gain is set to zero or the deadband is extremely wide. However, the REEC_A has a switching logic between different states in normal operation state, during and after voltage dips, for the reactive current injection mainly related to Type III and Type IV WTG.

- The **d-axis current limits** are different. The minimal d-axis current *idMin* in REEC_A is 0, while the REEC_C model takes the negative value of *idMax*, enabling the charging and discharging of the battery. The limits of the d-axis and q-axis are calculated in the *CurrentLimitsCalculationC* model (equation-based block in REEC_C) depending on the state of charge of the battery, the P/Q priority flag and the Voltage Dependent Limitations (VDL) look-up tables.

- An additional path exists in REEC_C for the **state of charge** and includes an integrator block with a time constant t_{battery}, that represents process of charging and discharging. *SOC*0 is the initial state of charge of the battery and is a parameter in per unit given by the user, having a value between 0 and 1. *SOCMax* and *SOCMin* are, respectively, the maximum and minimum allowable state of charge.

  Values of the active current maximum and minimum limits are conditioned by the SOC. When the maximum state of charge is reached, the minimal active current is forced to zero, the battery cannot store anymore energy. When the minimum state of charge is reached, the battery cannot inject energy anymore. When $SOCMin < SOC < SOCMax$, the active current limits values will depend on the P/Q priority and the VDL look-up tables as explained in (Ramasubramanian 2023).

	REEC_A	***REEC_C***

d-axis current limits	$idMin = 0$	$idMin = -idMax$ when not fully charged
SOC	Not included.	Included.

Table 4. Summary of the main differences between REEC_A and REEC_C

4.3.2 Generator control models

All REGC_* models have common parts, such as the inputs and the calculation of the reference q-axis current $iqRef$; this is implemented in a base common model for REGC. Here are some differences between the three models. Table 5 summarizes the key point differences.

- The **inner-current control-loops** : The REGC_B was proposed to remediate the numerical instability issues of the REGC_A in weaker networks by having a voltage source interface. However, the inner-current control-loops are still neglected, as in REGC_A. The REGC_C includes a generic representation of the inner-current control-loops with PI controllers on the d and q axes.

- The **interface with the grid** : In REGC_A, a current-source interface, the outputs of the block are the reference d-axis $idRef$ and q-axis currents $iqRef$ that will be connected to the injector block. In both REGC_B and REGC_C models, a voltage source behind an impedance (*RSource*, *XSource*) is added, with values in per unit, to emulate the source impedance of the Voltage Source Converter (VSC).

  In the Dynaωo Modelica implementation, a *VSourceRef* block is implemented, taking as an input the d-axis and q-axis current references along with the measured voltage dq components $udInj$, $uqInj$ and calculating the d-axis and q-axis voltage references following Listing 1. Then a dq to RI transformation is done, resulting in the real *urSource* and imaginary *uiSource* voltage components that will be interfaced with the grid (Listing 2).

4.4 Model Validation

4.4.1 BESS model

The REEC_C model in Dynaωo is integrated in the BESS model. This model has been validated against results found in (Pourbeik and Petter 2017) for a SMIB test case, in OpenModelica (Figure 10) and in Dynaωo engines.

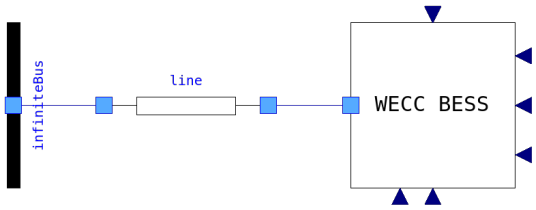

Figure 10. BESS SMIB test case in OpenModelica.

The BESS model comprises the REPC_A, REEC_C and REGC_A control models. It is connected to an infinite bus through an impedant line ($X_{\text{line}} = 2.0661 \cdot 10^{-6}$ pu, base $Sn_{\text{ref}} = 100$ MVA). The initial operating point for the battery is : $P = 0.5$ pu , $Q = 0$ pu (base $SNom = 6$ MVA) - as shown by the plot in Figure 11 - and $U = 1$ pu (base $UNom = 225$kV).

At t = 1 s, a voltage dip ($U = 0.55pu$) is applied at the infinite bus to mimic a three-phase short-circuit in the external network and is then removed at t = 1.5 s (fault clearing). At the fault insertion, the fast reactive current injection starts acting and the reactive current rapidly reaches its maximum value as seen in Figure 11 for *iqCmd*. This value is maintained until the fault clearance. On the active side, it is the normal control path that reacts to the fault by increasing the active current reference to try to maintain the active power despite the voltage dip. However, this increase is limited by the maximum current limitation and the reactive current increase (Q priority). P and Q in Figure 11 confirm this behavior and allows validating the model implementation thanks to a perfect match with the reference results (Pourbeik and Petter 2017).

The active power P plot in Figure 11 also demonstrates that the BESS is able to discharge (producing active power), which is the expected behavior as the initial state of charge $SOC0 = 0.5$ is between the accepted range [$SOCMin = 0.2$, $SOCMax = 0.8$]. The discharge time is much longer than the simulation time considered here.

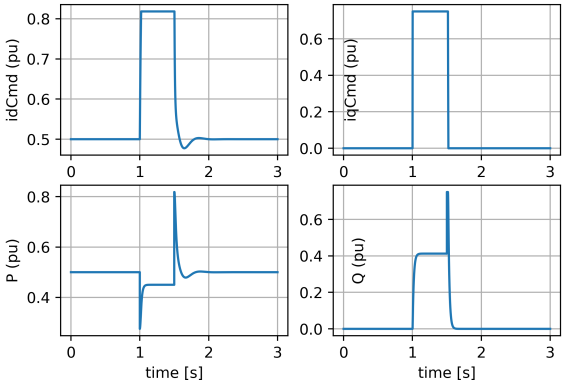

Figure 11. Validation results for a voltage dip - WECC BESS. On the top left, the active current *idCmd* is plotted, on the top right, the reactive current *iqCmd*. On the bottom left, the active power P is plotted and on the bottom right, the reactive power Q. The values are in per unit base $SNom$, $UNom$. Reference results are found in (Pourbeik and Petter 2017).

5 Applications

5.1 Models Validation and Operational Stability Assessment

The Modelica IEC and WECC models presented in the previous sections are used in the model validation process introduced into the French Connection Network Code (CNC) in February 2024 (RTE 2025). Indeed, for each new PEIR installation connected to the grid, the CNC requires the tuning of a generic dynamic model. One of the main criteria for grid code compliance is that the dynamic responses of the tuned generic model closely match those of the proprietary model used by the producer during simulation performance tests and those of the installations during real field tests. To assess the accuracy of this tuning, RTE has defined a set of standardized tests (e.g., three-phase faults, active/reactive power setpoint changes, voltage dips or surges at the point of connection) and associated compliance criteria (Cardozo et al. 2023) and developed an open-source tool (Marin et al. 2024) named DyCoV[5]. Its purpose is to automate the comparison process between:

[5]https://github.com/dynawo/dyn-grid-compliance-verification

1. Signals generated using the tuned generic IEC or WECC model, implemented within the Dynaωo Modelica library,

2. Reference signals obtained from the proprietary model used by the producer, typically simulated in a commercial tool, and from real field tests.

These comparisons are performed over the full set of standardized tests. The overall function of DyCoV is illustrated in Figure 12. The input format are Dynaωo parameters (*par*) and dynamic data (*dyd*) files to describe the tuned generic model and *csv* or comtrade files for the reference signals. In short, DyCoV applies consistent signal processing techniques to both sets of signals, enabling meaningful comparisons. The tool then computes a set of Key Performance Indicators (KPIs), such as the Maximum Error (MXE), Mean Error (ME) and Mean Absolute Error (MAE) between two signals during a disturbance. Finally, DyCoV generates a detailed *pdf* report that includes the test conditions, signal comparisons, computed KPIs, and an evaluation of compliance against RTE's predefined thresholds.

An example of such a report, focusing on an active power setpoint test, is shown in Figure 13 and Figure 14. On Figure 13, the reference signal from the proprietary model is plotted in orange and the tuned generic model, in blue. The event simulated is a step order in active power at t = 20 s. It can be seen that both models are settling around the same point in time at t = 20.93 s. However the reaction time is very different as the reference model reacts with a pure delay. This validation methodology aligns with the principles of the IEC standard (61400-27-1:2020 2020).

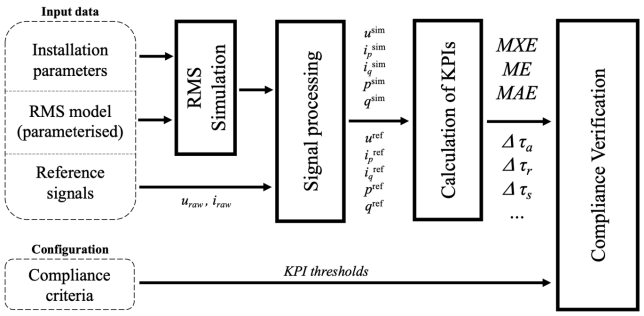

Figure 12. Functional diagram of DyCoV, RTE's dynamic grid compliance verification tool

Crucially, from a Modelica perspective, DyCoV relies entirely on the open-source implementation of IEC and WECC generic models developed within the Dynaωo library. All simulations and compliance assessments are therefore performed using transparent, reproducible, and openly available models.

The validated tuning of the generic models are then stored to complement RTE's historical dynamic data base for time-domain simulations and stability assessment in order to be used in the near future in the operational evaluation of transient, voltage, or small-signal stability.

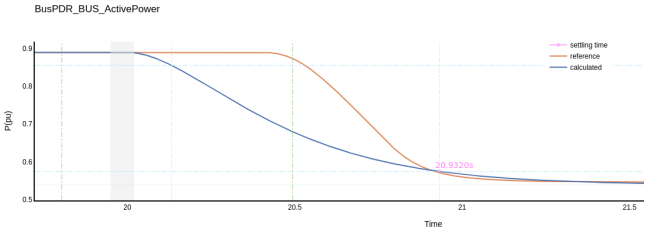

Figure 13. Extract of a DyCoV report. Generic WECC tuned model in blue and proprietary model in orange.

Compliance thresholds on the curves:

	Pre-event			Event		
	MXE	ME	MAE	MXE	ME	MAE
P	0.05	0.02	0.03	0.05	0.02	0.03

Compliance checks on the curves:

	Pre-event			Event			
	MXE	ME	MAE	MXE	ME	MAE	Compl.
P	0.000829	0.000829	0.000829	0.191	0.0841	0.102	False

Figure 14. Extract of a DyCoV report. KPIs calculated based on Figure 13.

5.2 Prospective studies

Another interesting usage for standard IEC and WECC models are prospective studies. Indeed, TSOs can construct a set of parameters for these models that fulfills the minimal requirements from their CNC and then use this set of parameter as default value for the future units.

Such a strategy allows the TSOs to conduct stability studies in prospective situations and to anticipate future issues as well as to easily test the impact of modifications in the CNC, such as a change in the dynamic performance requirement for primary voltage regulation for example.

6 Conclusion and Perspectives

This paper presents the current status of the Dynaωo Modelica library for PEIR components. It notably introduces the library's architecture and content then details the IEC and WECC models available with a special focus on the recently added parts. Models introduced can be simulated in OpenModelica and Dynaωo engines. Amongst the different features of the library, it is important to notice:

- *its completeness*: at least one model is available for any kind of RES installation, and a special effort is done to try to follow the standard evolution.

- *its transparency*: it is an open-source library, thus including the implementation choices for each and every individual block.

DOI 10.3384/ecp218383

- *its industrial quality*: it is already used in the network connection procedure by RTE and so in the associated discussions with stakeholders.

The next efforts will concentrate on two different parallel axes. On the one hand, there are still evolutions on the standard and especially on the WECC side that introduce new and improved control modeling options. It is necessary to keep working on the library to support the newest versions of the models: one key point will be the implementation of newly proposed *Grid Forming* standard models. On the other hand, the industrial usages of the models will increase on RTE side with expected use in operational stability studies and the continuation of exchanges with stakeholders in the connection process. This will help improve the overall quality of the library and make it even more robust.

Dynamic modelling of an Ammonia to Power application at high efficiency using a solid oxide fuel cell system

Michele Bolognese[1] Emanuele Martinelli[1] Luca Pratticò[1] Matteo Testi[1]

[1]Fondazione Bruno Kessler, Italy, mbolognese@fbk.eu

Abstract

Ammonia is a promising zero carbon and sustainable hydrogen carrier that can be used as a fuel in solid oxide fuel cells (SOFC) by offering advantages related to the ease of storage and the possibility of being used directly without an external reformer. In this study, a Modelica-based dynamic model of an 'Ammonia to Power' (A2P) system was developed by integrating ammonia decomposition kinetics, electrochemical reactions, all the system-level components and the main control loops. A novel Balance of Plant (BoP) configuration is proposed, featuring a five-way heat exchanger that recovers waste heat primarily using the fuel stream as the thermal energy vector instead of air. The model evaluates transient responses to operational perturbations, the behavior of the different control loops, and recirculation percentage rates to optimize system performance. Efficiency is calculated as the ratio of the power output from the SOFC to the power derived from the fresh ammonia line.

Keywords: SOFC, Ammonia, BoP, High temperature fuel cell

1 Introduction

The sustainable energy transition needs carbon-neutral solutions to meet the worldwide increasing energy demand (16 TW in 2010 to 23 TW in 2030 and 30 TW in 2050) while minimizing the environmental impacts (Dresselhaus and Thomas 2001). In this contest, green hydrogen produced from renewable energy sources (RES) plays a crucial role and is considered a potential alternative to fossil fuels. However, the establishment of a hydrogen economy faces substantial hurdles that must be addressed. Beyond the necessity of large-scale production of renewable-based green hydrogen, there are also long-standing challenges related to transportation, distribution, storage, and end-use of hydrogen that need a solution. Therefore, it is essential to develop innovative and effective strategies that can facilitate sustainable energy transition. In this perspective, the potential of utilizing ammonia as a hydrogen carrier for on-site power generation via ammonia decomposition is systematically discussed (Zhai et al. 2023). Hydrogen possesses a high gravimetric energy density of approximately 120 MJ/kg, surpassing conventional fuels like gasoline (44 MJ/kg) but the volumetric energy density of hydrogen is lower, so it requires larger vessels for storage and transportation. Different physical and material-based technologies have been explored for the dense storage of hydrogen but physical processes such as liquefaction and compression, which are used for storage and transportation, are energy intensive. For instance, hydrogen liquefaction consumes about 13.8 kWh/kg of liquid hydrogen, which corresponds to approximately 40% of hydrogen's energy content (Zhang et al. 2023). Similarly, hydrogen compression to high pressures, such as 700 bar, is essential for applications like fuel cell vehicles to achieve acceptable storage compactness. This process is energy-intensive; for instance, a study reported that using multiple pressure stages in refueling stations can reduce compressor power consumption by 17%, highlighting the significant energy demands of hydrogen compression. On the other hand, material-based storage, such as zeolites and metal hydrides, can provide a hydrogen storage capacity of up to 13 wt%., but these technologies often face challenges related to technological readiness levels (TRL). Higher energy densities are obtained with hydrogen storage in the form of chemicals such as methanol (12.5 wt %) or ammonia (17.65 wt%). Ammonia (NH_3) has emerged as a promising hydrogen carrier and carbon-free fuel, offering a unique combination of high hydrogen content, established global infrastructure, and compatibility with various energy conversion technologies. Historically, the ammonia synthesis via the Haber-Bosch (HB) process has been fundamental in worldwide agriculture and industry, by enabling the large-scale ammonia production via nitrogen and grey hydrogen produced via steam methane reforming, under high temperature and pressure operating conditions. The potential of ammonia as an energy carrier spans multiple applications, including internal combustion engines (ICE (Tornatore et al. 2022)), gas turbines (Pashchenko 2024a) , and fuel cells (Pashchenko 2024a; Qi et al. 2023; Pashchenko 2024b). Among these, solid oxide fuel cells (SOFCs) stand out for their ability to utilize ammonia directly as a fuel, bypassing the need for external hydrogen production or cracking processes. This direct utilization enables SOFC systems to achieve high power densities while producing only nitrogen and water as byproducts, aligning with the goals of a sustainable energy future (Dhawale et al. 2023). Several authors studied the configurations of direct ammonia SOFC system and their performance (Cinti et al. 2016; Nemati et al. 2025; Ayerbe et al. 2024). In their work, Cinti et al. have demon-

strated the improved efficiency of a direct ammonia SOFC system if compared to a hydrogen-based one. Nemati et al. have shown the importance of the anode off-gas recirculation and pre-cracking to improve the efficiency and reduce the impact of nitriding. The dynamic behavior of the A2P BoP is notably complex due to the interaction among its various functional zones, subcomponents, and control loops. This study addresses this challenge by developing a comprehensive dynamic model in Modelica language, serving as a prototyping tool that enables the analysis of overall system performance, including the direct ammonia solid oxide electrolyzer, the external cracker, and the waste heat recovery system under various operating scenarios. Additionally, the incorporation of advanced control loops and recirculation strategies offers new insights into the system-wide dynamics and operational stability, contributing novel understanding to the field of P2A plant integration and control

2 Methodology

Dynamic modeling is crucial to understanding and optimizing the behavior of an energy system balance of a plant under different operational conditions by simulating complex interactions between the system components. Dynamic modeling activities can also be a useful guide for the development of a control strategy to enhance overall system efficiency, flexibility, and reliability. Modern process modeling has evolved beyond simple material and energy balance calculations to become a strategic tool for managing and better understanding the potential of prototypes by gaining a competitive advantage (Ayerbe et al. 2024). Robust models enable rapid adaptation to market changes and serve as repositories of corporate knowledge. Models also capture valuable experimental data that aid in process optimization, redesign, and patent development. This creates a continuous improvement cycle in which each use enhances the value of the model, increasing the return on investment, and driving innovation. The Modelica language (Mattsson and Elmqvist 1997; Qiu et al. 2024) enables the simulation of complex systems such as the balance of plant (BoP) of hydrogen systems by using non-causal modeling, reusable components, and equation-based formulation. Non-causality allows the same equations to be used for forward and inverse kinematics, enhancing adaptability across engineering applications. In addition, the use of proper media for the fuel and air stream ensures accurate thermodynamic property calculations that are fundamental for calculating a heat and material balance that gives crucial information regarding the design of the overall system. In this study, one-dimensional equidistant discretizations is applied to each component of the BoP model. Furthermore, diffusion phenomena were neglected by simplifying the simulation.

2.1 BoP Model Description

This work presents the development of an 'Ammonia to Power' (A2P) plant model based on solid oxide fuel cell technology, which incorporates all other components of the system. In Figure 1, the functional Process and Instrumentation Diagram (P&ID) is presented:

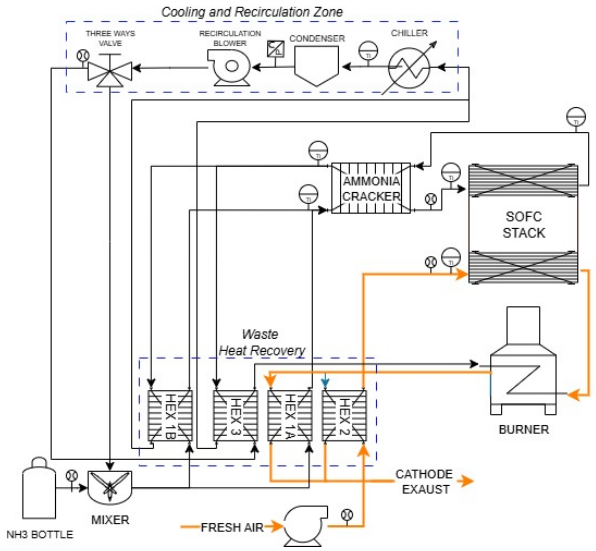

Figure 1. Functional Process and Instrumentation Diagram (P&ID) with fuel loop (black line) and air loop (orange line)

In the P&ID, the air flow loop is identified in orange, while the fuel flow loop appears in black. Each component is clearly labeled, and the regions associated with the waste heat recovery system, as well as the fuel cooling and recirculation circuits, are marked with dashed outlines for easy identification. To contribute to the development of an efficient and sustainable ammonia-based energy solution, this study aims to provide information on system design, operation, and control strategies. The key core of the system is represented by a solid oxide fuel cell stack, but particular attention was paid to the waste heat recovery and recirculation aspect of the anode off-gas within the AMON project. In Figure 2, the layout of the BoP model is presented using the Modelon Impact (Modelon 2025) interface.

From the layout in Figure 2, it is possible to distinguish the hot BOP that works at high temperature from the cold BOP starts from the condenser (block 6) and finishes downstream of the recirculation blower (block 9). Moreover, it is possible to also notice that other components of the Modelon library (joints and splits) were used to couple and split the fuel and air streams in the Hot BoP.

The BoP components in Figure 2 are numbered and described in the following.

1) Stack

The stack model is based on the Fuel Cell library (Andersson et al. 2011) by Modelon Impact (*Fuel Cell Library* 2025; Modelon 2025). The model was modified by implementing ammonia cracking in the anode channel. The stack model was validated by considering the polarization curves obtained in FBK test benches for other works within the AMON project. Moreover, to the stack an ac-

DOI 10.3384/ecp218395

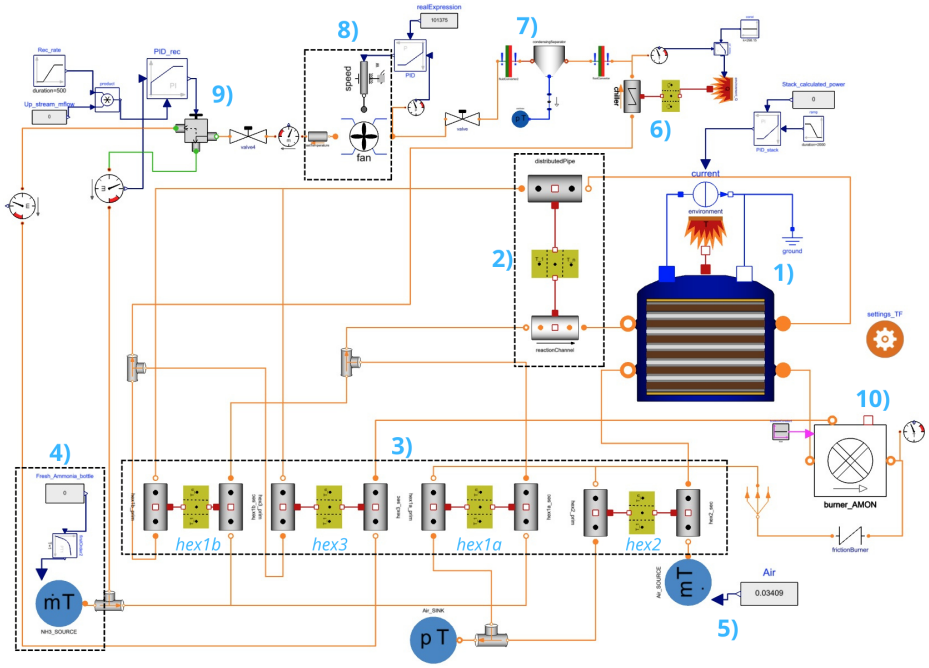

Figure 2. Layout of Ammonia to Power BoP model in Modelon Impact.

tive control loop based on a PID that controls the current delivered by the stack is applied in order to control the desired power for the different operating modes.

2) External Cracker

The External Cracker model is based on the use of the Modelon Standard Library by using the reaction channel and distributed pipe model that are connected to the metal wall model in counterflow mode.

3) Heat Exchanger Network

The model of the heat exchanger network is based on 4 heat exchangers that are calibrated according to the technical datasheet provided within the AMON project. In addition, several split and joint components of the Modelon library were used to modify the mass flow rates of the four different HEXs. In particular, air, which typically serves as the thermal carrier for the high-temperature balance of plant (BoP) components in SOC technologies, is used only 10% to preheat the recirculated fuel mixture (NH_3 and N_2), while the remaining portion is used to preheat the air entering the stack. Each heat exchanger (HEX) consists of a distributed pipe connected to a metal wall.

4) Fresh Ammonia Sourcer

This is an ideal ammonia source model at 25 °C and the ammonia mass flow rate required by the system is calculated as a function of the current delivered from the stack and the utilization of the fuel:

$$\dot{m}_{\mathrm{NH_3}} = \frac{n_{\mathrm{cell}} I}{2 U_{\mathrm{fuel}} F} \frac{2}{3} MM_{\mathrm{NH_3}} \tag{1}$$

where n_{cell} is the number of cells in the stack, I is the current, U_{fuel} is the fuel utilization (equal to 0.7), F is the Faraday constant and $MM_{\mathrm{NH_3}} = 0.017031\,\mathrm{kg/mol}$ is the molecular weight of ammonia.

5) Air Source

This is an ideal air source model at 25 °C with the mass flow rate defined as follows:

$$\dot{m}_{\mathrm{Air}} = \frac{n_{\mathrm{cell}} I}{4 U_{\mathrm{Air}} F} Y_{\mathrm{O_2}} MM_{\mathrm{Air}} \tag{2}$$

where U_{Air} is air utilization (equal to 0.11), $Y_{\mathrm{O_2}}$ is the oxygen content of the air (0.2094%) and $MM_{\mathrm{Air}} = 0.028965\,\mathrm{kg/mol}$ is the molecular weight of the air.

6) Chiller

The chiller is an ideal and simplified model of a simple pipe connected to a thermal power source that chills the Off Gas Anode (AOG) to 25 ° C using a specific PID component to modulate the cooling power required.

7) Condenser

The Condensing Separator model is a Modelon library component based on a condensing volume that efficiently separates water from a generic gas stream. A specific condensate medium is used by implementing two medium converters that can couple the medium used for the fuel and the condensate one.

8) Recirculation Blower

This is a simplified model of an axial fan in which the characteristics of the fan with respect to the volume flow rate V_{flow} and the power absorbed by the fan P_{fan}, have been implemented as follows:

Moreover, a time constant τ affects the equations that govern the mass flow rate (m_{flow}) and power consumption (P) as can be seen in the following equations:

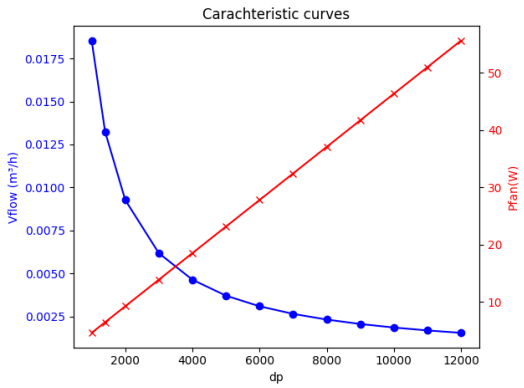

Figure 3. Characterization curves of the recirculation fan

$$\tau \frac{dm_{\text{flow}}}{dt} + m_{\text{flow}} = V_{\text{flow}_{\text{in}}} dA_{\text{inflow}} \tag{3}$$

$$\tau \frac{dP}{dt} + P = P_{\text{fan}_{\text{in}}} \tag{4}$$

where dA_{inflow} is the mass density calculated in the mass port upstream of the component.
The speed of the recirculation blower is controlled by a PID controller to maintain the upstream pressure higher than the environmental pressure during transitions between different operating modes.

9) 3-Ways recirculation valve

This three-way valve model is designed for single-phase medium applications and belongs to the ThermalPower 1.28 library of Modelon (Modelon 2025). The valve assumes turbulent, non-choked flow with static mass and energy balances and no actuator dynamics. By default, the flow characteristic is linear, but can be customized.

10) Ammonia Catalytic burner

The burner model is a fixed volume combustion chamber of the Modelon library. In this study, it was modified according to the A2P system by replacing fossil fuels with a mixture of hydrogen (H_2) and ammonia (NH_3). Energy calculations use the Lower Heating Value (LHV) of the H_2/NH_3 blend.

3 Main processes

In this section, the main processes implemented in the A2P dynamic model are described. A particular medium NASA-based of 5 elements (H_2, NH_3, H_2O, N_2, O_2) was created to implement Ammonia in the fuel composition.

3.1 Ammonia cracking Processes

For ammonia cracking, the studies by Kishimoto et al. (Kishimoto et al. 2017) and Lucentini et al. (Lucentini et al. 2021) were considered. The model of Kishimoto et al. was applied to the cracking of ammonia within the anode channel of the stack (block 1), as they developed an experimentally validated ammonia decomposition reaction (R_{kish}) for a Ni-YSZ anode. The reaction model developed by Lucentini et al. (R_{luc}) for the decomposition of ammonia over Ni-Ru supported on CeO_2 was applied to the external cracker reaction channel (block 2). The following equations present the ammonia degradation reaction rates for both the stack and the external reformer:

$$R_{\text{kish}} = S_{\text{Ni-pore}} A^{\text{Ni-pore}} \exp\left(-\frac{E}{RT}\right) p_{\text{NH}_3}^{a} \left(p_{\text{H}_2} + c\right)^{b} \tag{5}$$

$$R_{\text{luc}} = \frac{k K_1 C_{\text{NH}_3}}{\left(1 + K_1 C_{\text{NH}_3} + \sqrt{\frac{C_{\text{H}_2}}{K_4}}\right)^2} \tag{6}$$

In this study, the materials constituting the storage cell and the cracker catalyst are not yet defined, so the same materials of the reference papers were considered by using the same values of the coefficients for the two reaction rates. Subsequently, the ammonia decomposition reaction of Lucentini et al. is calibrated considering the coefficient values valid for $5Ni1Ru/CeO_2$ by implementing the geometric characteristics of the cracker presented in Table 1, which refers to the equivalent diameter of the pipe having the same cross section as the rectangular channel of the cracker plates.

Table 1. Technical specifications of the external cracker

Parameters	Value	Unit	Description
n_{plates}	34	–	Number of plates
A_{heat}	0.4	m^2	Heat exchange area
length	20.7	cm	Total length
height	13.7	cm	Total height
width	7.7	cm	Total width
d_{eq}	2.5	cm	Equivalent diameter
ε_{bed}	0.245	–	Porosity of the bed
f_v	0.196	–	Catalyst volume fraction

In this study, the external cracker was considered as a fixed-bed reactor; thus, the concentration of ammonia and hydrogen is calculated only over the void volume. The amount of catalyst needed within the reactor bed (g_{cat} [g]) depends on the temperature and the conversion percentage, as shown in Figure 4.

3.2 Electrochemical Process

In this study, the structure of the stack model is based on the Modelon Fuel Cell Library, which utilizes the coupling between the anode channel, the elementary cell, and the cathode channel. Within the elementary cell, a simplified equivalent electrical circuit was used to characterize the polarization curves of the simulation by comparing them with the experimental data obtained at the FBK test bench using a short stack of 6 cells provided by Solydera. More

DOI
10.3384/ecp218395

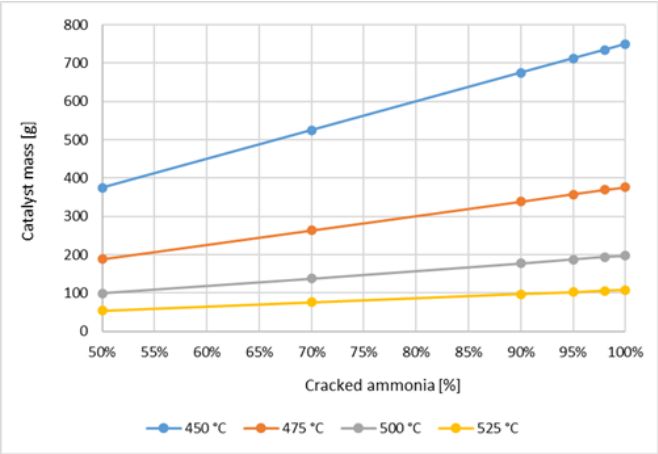

Figure 4. Ammonia cracking percentage as a function of temperature and mass of the catalyst.

details of these validation activities are presented in another FBK study at the Modelica Conference.

Taking into account the desired rangeability of the operating conditions of the A2P system within the AMON project, the cell voltage in the cell model was calculated by considering only ohmic losses.

$$V_{\text{cell}} = E_0 - \text{ASR}(T)\, j_{\text{cell}} \tag{7}$$

where E_0 is the Nernst voltage, j_{cell} is the current density, and ASR is the area specific resistance calculated as follows:

$$E_0 = \frac{1}{n_e F}\left(\Delta g_{\text{reaction}} + RT_{\text{cell}} \ln\left(\frac{p_{H_2O}}{p_{H_2} p_{O_2}^{0.5}}\right)\right) \tag{8}$$

$$\text{ASR}(T) = \text{ASR}_0 + \exp\left[\frac{E_a}{R}\left(\frac{1}{T_{\text{cell}}} - \frac{1}{T_0}\right)\right] \tag{9}$$

$$j_{\text{cell}} = \frac{I}{A_{\text{cell}}} \tag{10}$$

For this work, a value of $\text{ASR}_0 = 0.34 \times 10^{-4}\,\Omega/\text{cm}^2$ and an activation energy $E_a = 24.8 \times 10^3\,\text{kJ/mol}$ were used with a reference temperature $T_0 = 600\,^\circ\text{C}$, obtaining a relative error less than 3%, consistent with previous work on SOC technologies performed in other EU projects.

3.3 Condensation Process

The condensation process follows a first-order differential equation governed by the condensation time constant τ_{sat}. This parameter controls the rate at which water vapor condenses into liquid and is defined as follows:

$$\tau_{\text{sat}} \frac{d}{dt}\dot{m}_{\text{water}} + \dot{m}_{\text{water}} = \dot{m}_{\text{feed}}(X_{\text{feed}} - X_{\text{sat}}) + k_{\text{molar}} \max(\varepsilon - \dot{m}_{\text{water}}, y_{H_2O} - y_{\text{sat}}) \tag{11}$$

Table 2. Stack Technical Parameters

Parameters	Value
Active Area [cm^2]	320
Number of cells	80
Max Current [A]	128
Fuel Utilization [%]	70
Max Power [kW]	8

where

- X_{feed} is the water mass fraction in the inlet stream,
- X_{sat} is the saturated water mass fraction, calculated as:

$$X_{\text{sat}} = \frac{y_{\text{sat}}}{1 - y_{\text{sat}}} \cdot k_{\text{molar}} \cdot (1 - X_{\text{feed}}) \tag{12}$$

where y_{sat} is the saturated mole fraction of water vapor calculated as a function of temperature T and pressure p:

$$y_{\text{sat}} = \frac{p_{\text{sat}}(T)}{p} \tag{13}$$

Here, $p_{\text{sat}}(T)$ the saturation pressure is calculated as a function of temperature and is a medium parameter.

The factor of molar ratio k_{molar} is calculated as the ratio of the molar fraction of water to the molar fraction of gas without water:

$$k_{\text{molar}} = \frac{MM_{H_2O}}{MM_{H_2\text{dry_gas}}} \tag{14}$$

3.4 Combustion of H_2 / NH_3 mixture

In the burner model, the following oxidation reactions for H_2 and NH_3 have been integrated into the combustion reaction by implementing a specific stoichiometric matrix:

$$H_2 + \frac{1}{2}O_2 \rightarrow 2H_2O \tag{15}$$

$$NH_3 + \frac{3}{4}O_2 \rightarrow \frac{3}{2}H_2O + \frac{1}{2}N_2 \tag{16}$$

These reactions assume ideal conditions under the assumption of complete combustion, where all reactants are fully converted into products, primarily water vapor and nitrogen gas, with no unburned residues or intermediate species.

3.5 Heat Recovery System

In this study, particular attention was paid to the heat recovery system of the thermal energy coming from the high temperature SOFC and the additional burner. The heat heat recovery system is composed of 4 heat exchangers:

- **hex1a** (fuel-fuel): preheating of the recirculated fuel and fresh ammonia mixture by using the 50% of mass flow rate of anode fuel from the stack after the heating of the external cracker
- **hex1b** (fuel-fuel): preheating of the non-recirculated fuel that feeds the burner by using the 50% of mass flow rate of anode fuel from the stack after the heating of the external cracker
- **hex2** (fuel-air): preheating of the recirculated fuel and fresh ammonia mixture by using the 10% of exhaust gas mass flow rate from the burner
- **hex3** (air-air): preheating of fresh air by using the 90% of exhaust gas mass flow rate from the burner

All the HEXs mentioned above are in counterflow configuration; the specific geometries were implemented coherently with the design data of the AMON project. In the following figure is possible to see the trends of hot and cold fuels vs the longitudinal distance of each heat exchanger.

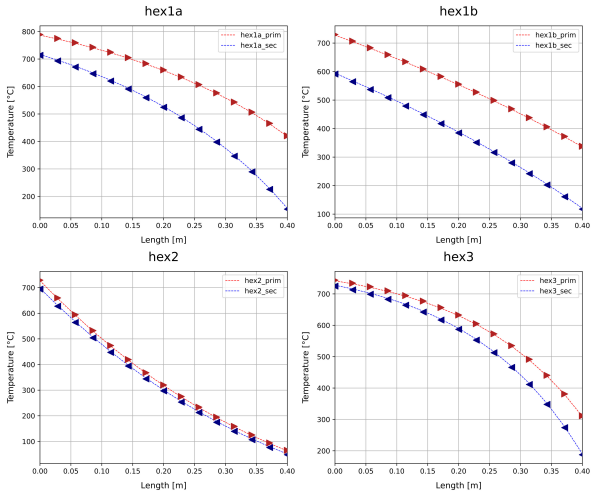

Figure 5. Trends of temperature of hot and cold sides vs distance for each HEX.

Figure 5 shows the temperature profiles along the length of four heat exchanger configurations (hex1a, hex1b, hex2, hex3), illustrating heat transfer between primary and secondary fluids. The decreasing primary and increasing secondary temperature trends suggest counterflow or parallel flow behavior, influenced by variations in the design of the heat exchanger and operating conditions.

4 Results

In this section, the main results of the BoP model are presented. An initial simulation of 200,000 seconds was performed, with an elapsed time of approximately 14 to 15 minutes, to verify the behavior of the external reformer. Setting a fuel recirculation rate at 88 % and a power at 8 kW (nominal condition). In Figure 6, it is possible to see that during the simulation time, the NH_3 conversion rate of the external reformer and the related trends of NH_3 molar fraction and inlet/outlet fuel temperatures reaches converge and the outlet NH_3 molar fraction is around 3% in a consistent way with the decision-making decisions made during the design phase of the system for the AMON project.

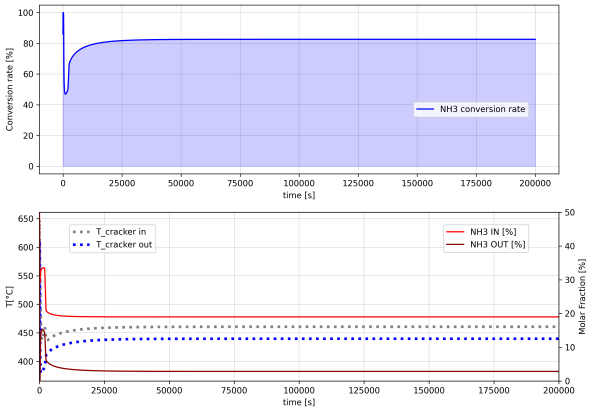

Figure 6. External cracker behaviors at nominal condition with 88 % of recirculation rate. Ammonia conversion rate [%] (upper plot), inlet and outlet cracker fuel temperature, and NH_3 molar fraction (lower plot)

Eventually, considering the same simulation, the relative pressure profiles of air (blue line) and fuel (red line) are presented in Figure 6.

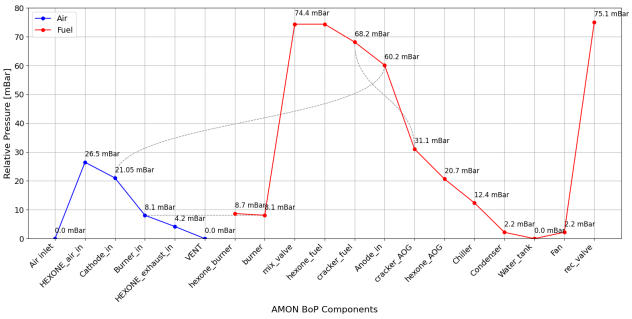

Figure 7. Pressure drops trends for all the components of the BoP model [air channel in blue and fuel channel in red]

It can be observed that the fuel pressure profile is higher than that of air, with a recorded pressure difference of approximately 39 mbar under nominal conditions (8 kW) in this simulation. This configuration ensures that the anode pressure at the stack inlet is higher than the cathode stack pressure, which is a crucial safety measure to prevent backflow or mixing risks. The fuel loop achieves a peak pressure of 74.4 mbar through fan-driven circulation, with a pre-recirculation pressure drop of approximately 73 mbar. This results in a recirculation rate of 88%, while 12% is directed to the burner. On the other hand, the air pressure profile achieves a maximum pressure of 26.5 mbar upstream of the heat recovery system. Afterward, a short sensitivity analysis of the fuel mass flow rate recircu-

DOI
10.3384/ecp218395

lation rate was performed to select the best configuration. The fuel that is recirculated after the cracking, electrolysis process, chilling, and condensation is a mixture mainly composed of N_2. In Table 4, four different cases with a recirculation rate of 80, 85, 88, and 90 % have been evaluated.

Considering the design decisions made during the design phase of the system, the 88% fuel recirculation rate was chosen as the optimal solution because it allows the recirculation of the blower operation to be respected in terms of the maximum flow rate and achieves an efficiency of 73.13%, which is above the 70% target of the AMON project.

Finally, in Figure 8, the transitions between full load (8 kW) and partial mode (2.4 kW) were simulated in order to verify the behaviors of the control loops dedicated to the modulation of current for the power control of the stack, the control of the AOG recirculation (CL_fan) by modulating the rpm [Hz] of the blower, and the control of opening/closing of the 3-way valve (CL_3ways). Moreover, in the same figure it is possible to see the trend of the overall efficiency of the system, which is calculated as follows:

$$\eta_{\text{BoP}} = \frac{P_{\text{stack}}}{LHV_{NH_3} \cdot \dot{m}_{NH_3,in}} \tag{17}$$

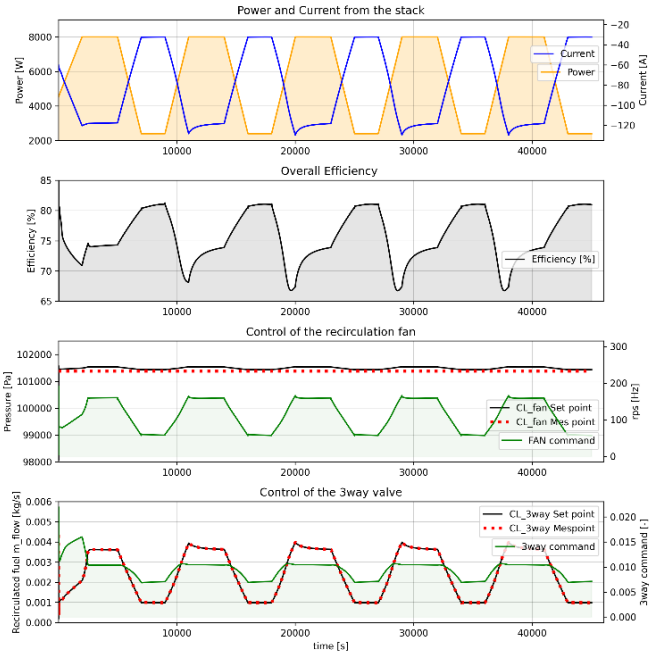

Figure 8. Dynamic simulation results of Full to Partial Mode transitions: Power and Current of the stack (upper), Overall Efficiency of the system (medium-high), Control of recirculation fan (medium-low), and Control of the 3-way valve (lower plot).

It is possible to see that the control of the stack power by modulating the current is quite stable. However, during the transition from partial to full operation, the overall efficiency of the system experiences a transient decrease. This initial drop in efficiency occurs only in the first moments after the switch, but subsequently stabilizes within the typical range associated with full load operation, which was previously calculated as approximately 72–74%.

Moreover, the CL_3ways control loop governing the 3-way valve demonstrates consistent stability, while the CL_fan control loop for the recirculation fan shows minor deviations from the set point (around 200 Pa). These deviations are sufficiently small to be considered negligible, so the control loop can be considered to function correctly by maintaining the required pressure set point. Overall, despite some small adjustments required, the control strategy implemented in the model exhibits robust stability and good dynamic response, ensuring reliable operation under varying load conditions.

5 Conclusion

This work presents a description and comprehensive analysis of a Modelica-based dynamic model of an Ammonia2Power (A2P) system utilizing the coupling of a direct ammonia solid oxide fuel cell and an external reformer. With the integration of detailed ammonia decomposition with different catalysts for the external reformer and the stack, the electrochemical processes, and an innovative BoP addressing enhanced waste heat recovery, the model enables in-depth analysis of system behavior under different operating modes. Two different simulations were performed, one addressed to calculate heat and material balance (after 200000 s of stationary behavior) and one dedicated to the transitions between full and partial modes. Furthermore, the simulation results demonstrate that the proposed system can achieve a high ammonia conversion rate and efficient heat recovery, with an AOG recirculation rate of 88% and stable operation in full (8 kW) and partial (2.4 kW) modes. The pressure profile of both fuel and air streams was calculated, ensuring safe operation by maintaining anode pressure higher than the cathode pressure, minimizing backflow risks. Finally, the dynamic Modelica-based modeling approach provides valuable insights into the transient behavior of the system, the impact of AOF recirculation and heat integration on the overall efficiency of the system, and the effectiveness of control strategies. This study confirms the technical feasibility and potential of ammonia as a vector and hydrogen carrier for direct utilization in SOFC BOP. The model acts as a robust tool to guide the design phase of the prototype and the optimization of future A2P systems, supporting the transition to sustainable energy and carbon-neutral solutions. Future work will focus on the implementation of a proper state machine for the control strategy, further refinements of control loops, and verification of emergency scenarios to evaluate system safety in order to enhance system flexibility and reliability under real-world operating conditions.

Table 3. Sensitivity Analysis for Different Recirculation Rates (80, 85, 88, 90%)

	Case 1	**Case 2**	**Case 3**	**Case 4**
Recirculation Fraction	80%	85%	88%	90%
m_{flow} AOG [kg/h]	12.492	15.12	17.856	20.628
T_{AOG} [°C]	230	239	241	244
Efficiency [%]	71.20	73.30	74.40	75.01
NH_3 fresh m_{flow} [kg/h]	2.16	2.11	2.08	2.06
Δp recirculation fan [mbar]	46.96	56.99	72.94	95.49
NH_3 cracking rate [%]	93.91	92.94	83.00	84.51
$X_{\text{NH}_3,\text{cracker out}}$ [%]	3.95	3.23	2.85	2.48
$X_{\text{NH}_3,\text{stack out}}$ [%]	1.6e−6	0.002	0.05	0.17
Air required [kg/s]	0.0310	0.0308	0.0306	0.0305
Chiller [kW]	1.007	1.219	1.407	1.603

Abstract

Interest in ammonia as an energy carrier is growing due to its superior storage and transport properties compared to hydrogen. The objective of this work is to construct a useful tool for predicting the behavior of a solid oxide fuel cell (SOFC) stack fed directly with ammonia. This configuration is particularly interesting because the internal cracking of ammonia eliminates the need for an external cracker, thus reducing the overall cost of the system. The ammonia decomposition reaction was implemented in the anode channel of the stack and calibrated against literature results. The model was then validated in the ohmic region only by calculating the area specific resistance (ASR) and comparing the results with experimental data collected at the Bruno Kessler Foundation (FBK) laboratory. This SOFC model can therefore be used as a starting point for the analysis of a scale-up application.

Keywords: Solid oxide fuel cell, High temperature fuel cell, Internal ammonia cracking, Experimental validation

1 Introduction

With the European Union setting a target of zero greenhouse gas emissions by 2050 (EuropeanCommission 2022), the need for sustainable, low-impact solutions for energy generation has become critical. According to the 1.5 °C scenario outlined by the International Renewable Energy Agency (IRENA 2024), hydrogen will account for up to 14% of total final energy consumption. It will also play a central role in the decarbonisation of hard-to-decarbonise industries (e.g., steel, chemicals and refineries), in the storage of excess renewable energy to provide flexibility to the grid, and in supporting long-distance transport directly or via hydrogen carriers. Among the potential hydrogen carriers, ammonia is a promising option due to its carbon-free nature and high hydrogen storage capacity; it offers favourable gravimetric (17.88 %wt) and volumetric (10.7 kg_{H_2} per 100 l) hydrogen densities, and, in its liquid form, it achieves a volumetric energy density of 12.9 MJ/l, surpassing that of liquid hydrogen at 8.6 MJ/l. The ammonia liquefaction process requires less extreme conditions, achieved at -33.3 °C at atmospheric pressure or about 10 atm at ambient temperature (Wang et al. 2022), making ammonia a better solution for long distance energy transport. It is also the second most produced and traded chemical in the world, 70% of which is used as a base for fertilisers and the remainder as an input for industrial processes, such as a refrigerant or in the manufacture of synthetic fibres, plastics and explosives (IEA 2021).

Fuel cells are electrochemical devices that convert chemical energy directly into electrical energy, without the need for combustion or intermediate conversion into mechanical energy; this makes them more efficient than traditional combustion generators. The basic working principle of fuel cells is the electrochemical reaction between a fuel and an oxidant, typically hydrogen and oxygen, respectively. In a solid oxide fuel cell (SOFC), the oxygen supplied to the cathode is reduced to form oxygen ions (O^{2-}), which then flow through the electrolyte to the anode. There, the O^{2-} ions combines with hydrogen to form water, releasing two electrons that will flow to the cathode through an external electrical circuit (reaction 1). The hydrogen required at the anode can be supplied directly or can be produced by the cracking of more complex fuels, such as methane and ammonia. The primary advantage of SOFCs is that they operate at high temperatures; this creates an environment in which complex fuels (with ammonia being the fuel of choice in this particular case study) spontaneously decompose at the anode electrolyte, releasing hydrogen directly into the anode channel (see the configuration on the right-hand side of Figure 1). If an external fuel processor were needed to extract hydrogen from the fuel, the system's complexity would increase, and the costs would rise concomitantly.

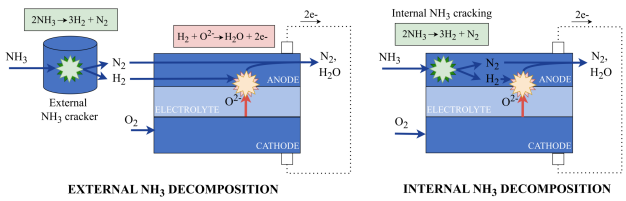

Figure 1. Ammonia decomposition in different configuration (indirect on the left, direct on the right) of a solid oxide fuel cell system.

In the present case study, a model of a short SOFC stack operating at elevated temperatures and fed directly with ammonia was developed and validated; this configuration is of particular interest because it allows the direct decomposition of ammonia in the anode channel, according to the endothermic reaction 2 ($\Delta H = 46.18\ kJ/mol$), without the need for an external cracker as required in indirect ammonia fuel cells (Lyu et al. 2023).

$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \tag{1}$$

$$NH_3 \rightarrow \frac{3}{2}H_2 + \frac{1}{2}N_2 \tag{2}$$

Different equations were proposed to quantify the ammonia conversion performance over different catalysts (Wan et al. 2021; Zheng et al. 2023); Kishimoto et al. have developed and validated Equation 3, on which is presented the ammonia decomposition model in subsection 2.1 (Kishimoto et al. 2017). This reaction model was then implemented in the anode channel of the substack to obtain the final direct ammonia stack model. The stack model was then validated with experimental data collected on a test bench provided by SolydEra S.p.A. at the Fondazione Bruno Kessler laboratory; the stack consists of 6 cells connected in series with an active surface of 80 cm^2. The values of the operating parameters have been obtained from the experimental setup, while, for reasons of confidentiality, the material structure and the geometric organisation of the stack used in the model have been taken from literature works. To determine the applicability of the model and verify its robustness, the discrepancy between the experimental and simulation results was calculated for each test described in subsection 2.4.

This work focuses on understanding ammonia-based energy conversion and also provides a practical tool for analysing the operation of a SOFC stack that does not require the use of an expensive external cracker. This tool can also be used for future scale-up applications within a complex Balance of Plant (BoP).

2 Methods

The methodology adopted in this work is investigated using the Modelica language and Modelon Impact as tool. Modelica is an open-source language for modelling complex systems covering multi-domains such as mechanical, electrical, thermal and control. Modelon Impact is a cloud-native Modelica modelling and simulation platform, which offers a suite of libraries with preconfigured and validated components to help users get started in building their systems. In this work, building blocks from Modelon's Fuel Cell Library (FCL) have been employed. The FCL is primarily used for modelling, simulation, analysis, and control of fuel cell design and operation.

To build a direct ammonia solid oxide fuel cell (SOFC) stack model, it is first necessary to create a suitable ammonia medium and calibrate the ammonia decomposition reaction model. This reaction model is then implemented

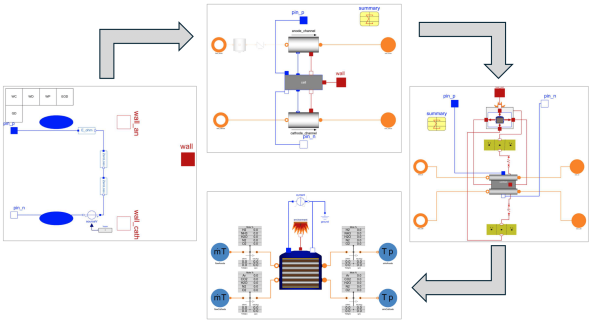

Figure 2. Cell, substack, stack and stack simulation models. Arrows indicate the dependence of nested models, from innermost to outermost models.

in the anode channel of the substack model, which also comprises the cell and cathode channel models. The cell model calculates the cell voltage by estimating the area specific resistance $ASR\ [\Omega/cm^2]$; the values of the parameters used in Equation 10 are found experimentally. The substack model is encapsulated within the stack model, where the heat loss characteristics are defined. Finally, a stack simulation model is created to define the boundary conditions from the experimental setup and to validate the stack model. The nested structure used for the stack validation is shown in Figure 2.

2.1 Ammonia Decomposition Reaction

A medium containing ammonia (H_2, NH_3, H_2O, N_2 and O_2) was created with thermodynamic properties taken from the Modelon NASA database (McBride, Zehe, and Gordon 2002) and compared to the NIST database (NIST 2023) for verification. An ammonia decomposition model was then subsequently created and validated with the reaction channel model shown in Figure 3.

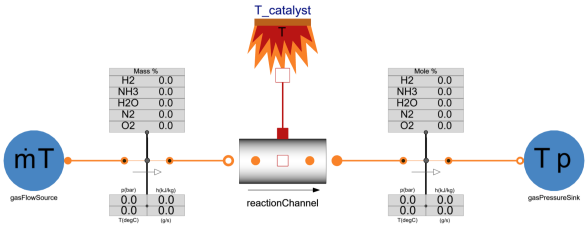

Figure 3. Discretised reaction channel model created to calibrate the ammonia decomposition reaction.

The ammonia decomposition reaction model, embedded within the reaction channel, was built on the basis of the work of Kishimoto et al., who validated Equation 3 against experimental results varying the catalyst temperature, ammonia mass flow rate or hydrogen mole fraction in the input fuel (Kishimoto et al. 2017).

$$R_{dec} = CE\ S_{Ni-pore}\ A^{Ni-pore}\ \exp\left(-\frac{E}{RT}\right) \cdot \cdot \left(p_{NH_3}\right)^a \left(p_{H_2} + c\right)^b \tag{3}$$

DOI 10.3384/ecp218405

For the reaction calibration, the unit volume reaction rate R_{dec} $[mol/m^3 s]$ was calibrated with the conversion efficiency parameter CE $[-]$. The other coefficients were chosen according to the calibration performed by (Kishimoto et al. 2017), assuming the same material properties as the Ni-YSZ catalyst used in the validation process; this material is one of the most commonly used in commercially available SOFC stacks, which makes it relevant to the case study. To obtain the decomposition reaction rate in $[mol/s]$, R_{dec} is multiplied by the catalyst volume V_{cat} $[m^3]$, calculated as $V_{cat} = V_{ch} \cdot f_{cat}$, where f_{cat} $[-]$ is the ratio of catalyst volume to channel volume. As the ammonia decomposition reaction is endothermic, (Kishimoto et al. 2017) also provides an estimate of the heat flow Q_{reac} $[W]$ withdrawn from the reaction with Equation 4.

$$Q_{reac} = \Delta H \, R_{dec} \, V_{cat} \tag{4}$$

The change in enthalpy ΔH $[J/mol]$ caused by the decomposition reaction is evaluated as $\Delta H = -40265.95 - 24.23214T + 0.00946T^2$, where T $[K]$ is the fluid temperature within the channel for each discretization.

The geometric and operational parameters considered for the reaction channel model are given in Table 1. The assumptions that were considered during the modelling design phase are reported in the following list:

Table 1. Geometrical and operating parameters adopted in the reaction calibration model.

Var.	Value	Unit	Description
N	10	-	discretization number
m_{flow}	1.266e-6	kg/s	NH_3 mass flow
p	101325	Pa	system pressure
T_{cat}	600, 650, 700	°C	catalyst temperature
D	8.3	mm	channel diameter
L	10, 20, 40	mm	catalyst length
f_{cat}	0.01	-	catalyst fraction
ε	2.5e-5	m	pipe roughness

- the reaction takes place only within the catalyst volume V_{cat}, which is considered fully active, and at a constant temperature T_{cat} $[°C]$ along the channel.
- the ammonia mass flow m_{flow} $[kg/s]$ is calculated from the volume flow V_{flow} $[ml/min]$ under normal conditions using the ideal gas law;
- D $[m]$ is the equivalent diameter, calculated from the cross-section of the rectangular channel;
- the pressure drop dp $[Pa]$ along the channel is calculated for all flow regimes with Equation 5, where the friction factor λ is found from the Reynolds number Re and the absolute surface roughness ε;
- the heat transfer coefficient α $[W/m^2K]$ is calculated over the entire Reynolds number (Re) range and for each discretisation with the Equation 6, where Nu_{ave} represents the average Nusselt number for the section and λ $[W/mK]$ is the conductivity of the fluid;

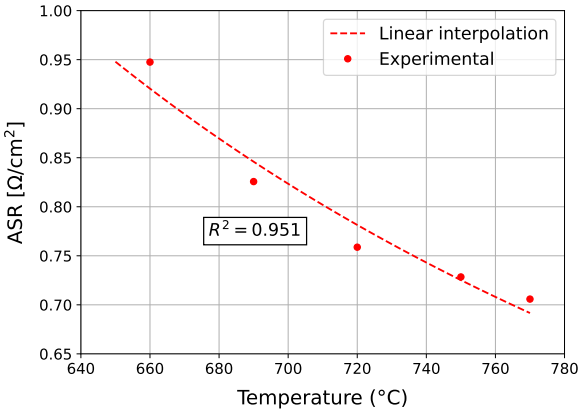

Figure 4. Experimentally found ASR values and values obtained from Equation 10 are plotted against average stacked temperature.

$$dp = \lambda(Re, \varepsilon) \, \frac{L}{D} \, \rho \frac{v^2}{2} sign(v) \tag{5}$$

$$\alpha = \frac{Nu_{ave} \, \lambda}{D_{hyd}} \tag{6}$$

2.2 Cell Model

The `FuelCell.Membranes.SOFC.Simplified` cell model includes mass flow, electrical and thermal connectors. The former are used to import data on the pressure, temperature and composition of the media flowing into the anode and cathode channels from the substack model at a higher level; these data relate only to the amount of gases required for the hydrogen oxidation reaction to occur (i.e., Reaction 1) and are then used to calculate the thermodynamic state of these gases at the electrode-electrolyte interface. The electrical connectors are used to construct the electrical circuit of the cell.

The electrical circuit is built within the cell to allow the calculation of the cell voltage V_{cell} $[V]$ with the Equation 7; the circuit is represented by two pins, a block that calculates the Nernst voltage E_0 with Equation 8 and a block that calculates the voltage drop due to internal losses in the cell ΔV_{losses}.

$$V_{cell} = E_0 - \Delta V_{losses} = E_0 - (V_{act} + V_{ohm} + V_{conc}) \tag{7}$$

$$E_0 = -\frac{1}{n_e F} \left(g_{reaction} + RT_{cell} \ln \left(\frac{p_{H_2O}}{p_{H_2} \cdot p_{O_2}^{0.5}} \right) \right) \tag{8}$$

According to Andersson et al., the internal cell losses can be estimated by Equation 9, where $ASR(T)$ $[\Omega/cm^2]$ is the area specific resistance of the cell, which depends only

on the temperature of the cell (Andersson et al. 2011). E_a $[J/mol]$ is an activation energy representing all the possible losses the current experiences as it passes through the stack's electrical circuit, while ASR_0 is the reference area specific resistance measured at the reference temperature T_0 $[K]$. This simplification is necessary in this case study because the materials used in the SOFC stack are covered by trade secrets, so using the parameters and coefficients required by the specific activation, ohmic and concentration loss models would have been misleading.

$$V_{cell} = E_0 - ASR(T) \cdot j_{cell} \tag{9}$$

$$ASR(T) = ASR_0 \cdot \exp\left[\frac{E_a}{R}\left(\frac{1}{T_{cell}} - \frac{1}{T_0}\right)\right] \tag{10}$$

$$\ln ASR = \frac{E_a}{R}\frac{1}{T} + \left(\ln ASR_0 - \frac{E_a}{RT_0}\right) \rightarrow y = mx + q \tag{11}$$

The experimental ASR_0, E_a and T_0 values, reported in Table 2, are obtained by solving Equation 11 for the experimental points given in Figure 4 (Zendrini et al. 2021), where the average furnace temperature is determined by averaging the anode and cathode gas temperatures at the inlet and outlet. This average value is considered to be representative of the thermal conditions of the stack for ASR calculations, but it is dependent on the internal geometry and materials of the stack. Therefore, it cannot be validated with relevant results in the current case study.

Table 2. Values of the coefficients used in the $ASR(T)$ equation for the calculation of cell internal losses when the stack model is run with pure ammonia.

	Unit	Experimental	Simulation
ASR_0	Ω/cm^2	0.92	0.4
E_a	kJ/mol	21.028	21.028
T_0	$^\circ C$	660	660

The simulation values in Table 2 are found following the procedure described in subsection 3.2. It should be noted that the activation energy is kept constant, but ASR_0 varies; this allows large deviations in the cell voltage trend to match experimental curves, as shown in Figure 8.

2.3 Substack Model

The `FuelCell.Stacks.SOFC.SubStack` model includes the anode, elementary cell and cathode channels. These models are then connected thermally, electrically and in terms of mass flow; gas streams are introduced into the anode, where ammonia is decomposed, and cathode channels. The mass ports connect the two channels to the cell, only transporting the necessary species for the membrane reaction. The excess gas then flows through the channel and out of the stack. The thermal ports establish the electrodes' temperature, with a third port assigned to the cell temperature and excess heat; this heat flow must be dissipated through the end plates and side wall of the stack and transmitted to the stack-level heat box model.

Table 3. Geometrical parameters adopted for the description of the substack model (Omer et al. 2023).

Var.	Value	Unit	Description
N	10	-	number of discretizations
n_{cells}	6	-	number of cells
A_{cell}	80	cm^2	active cell area
w_{cell}	7.3	cm	cell width
l_{cell}	10.96	cm	cell length
$h_{an,ch}$	0.4	mm	anode channel height
$h_{an,el}$	0.66	mm	anode electrode thickness
h_{el}	0.02	mm	electrolyte thickness
$h_{cath,el}$	0.03	mm	cathode electrode thickness
$h_{cath,ch}$	0.8	mm	cathode channel height
Cylindrical analogy			
$d_{an,ch}$	6.1	mm	anode channel diameter
$d_{cath,ch}$	8.6	mm	cathode channel diameter

The performance of the stack is significantly influenced by the geometrical dimensions of the channels. Due to the confidential geometrical structure, the stack configuration studied by Omer et al. is considered as a reference (Omer et al. 2023): the materials constituting the anode, electrolyte and cathode electrodes are among those most commonly used in commercial applications (Ni-YSZ, YSZ and LSM, respectively), and the geometrical characteristics are close to the external appearance of the stack present in the FBK laboratory. The geometrical parameters adopted in this case study are reported in Table 3.

It should be noted that the active cell area presented in the reference case is 100 cm^2, so the cell size has been scaled to match the 80 cm^2 of the case study, while maintaining the structure along the cell axis perpendicular to the flow direction. The fraction of catalyst in the anode channel f_{cat}, presented in subsection 2.3 for the ammonia decomposition reaction, is unknown for the test bench, but

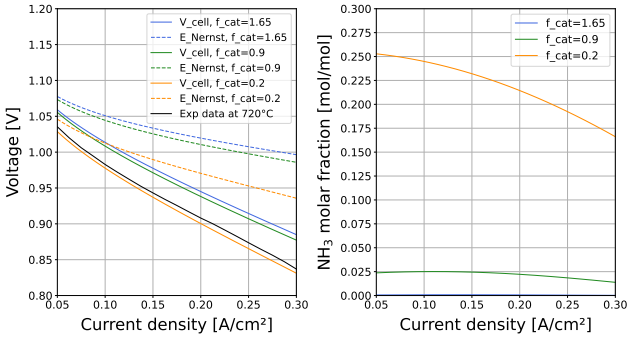

Figure 5. Simulated Nernst voltage and cell voltage (left) of the stack model at 710 °C as a function of varying catalyst fractions within the anode channel. Corresponding ammonia molar fraction at the anode outlet (right).

DOI 10.3384/ecp218405

it has a strong influence on the H_2 availability, which then determines the Nernst voltage (Equation 8). The volume of the anode electrode V_{cat} was calculated using the data provided in Table 3 following the procedure described in subsection 2.1 on ammonia decomposition and neglecting the catalyst porosity. The result, $f_{cat} = 1.65$, leads to the almost complete ammonia conversion, causing issues when calculating the Nernst voltage, as shown in Figure 5: the higher the ammonia converted, the more hydrogen available to the cell, resulting in an upward shift of the polarisation curve. Therefore, $f_{cat} = 0.2$ is used; calibrating this parameter would have been possible also by measuring the ammonia outlet of the anode channel with a mass spectrometer.

The substack model uses Equation 5 for the pressure drop calculation, so the calculation of the Reynolds number Re is greatly influenced by the anode and cathode channel diameters in Table 3; they are determined by cylindrical analogy, based on the channel's height only, ignoring the electrode's height, which is the same procedure used for the ammonia decomposition reaction calibration in subsection 2.1.

2.4 Stack Model

The experimental test bench consists of six planar oxygen-ion conducting cells electrically connected in series. In its nominal state, the stack operates at ambient pressure, 0.78 V cell voltage, and 400 A/cm^2 current density for a total nominal power of 150 W. The stack is enclosed in a furnace containing electric heaters to bring the temperature of the air near the stack to a set temperature T_{set}, which is then maintained by a proper temperature control; the anodic and cathodic gases are heated to this temperature before entering the stack. Therefore, no thermal insulation has been considered in the stack model and both gases have the set temperature presented in Table 4.It would be possible to calculate dispersion through the furnace insulation at a later stage by taking into account the difference between the average furnace temperature and the ambient temperature. However, this is beyond the scope of this study.

The `FuelCell.Stacks.SOFC.Stack` model had to be simplified because it only accepts a minimum number of substacks equal to 2, whereas in the case study there is only a short stack of 6 cells. Therefore, the $nbr_{substack}$ dependent variables are simplified, and the manifold models are removed. This stack model then extends the electrical, thermal and mass flow connections and incorporates the substack model and the heat box model, which would represent the conductive, convective and radiative heat losses from the furnace to the environment.

The operating conditions adopted during the experimental analysis are reported in Table 4; the performance of the stack is evaluated for the five temperatures set within the ohmic region of the polarisation curve, i.e., where the voltage decreases with a linear trend, thus from $J = 0.05\ A/cm^2$ to $J = 0.30\ A/cm^2$ in Figure 6.

Table 4. Operating conditions adopted for the tests conducted on the test bench in the FBK's laboratory.

Var.	Value	Unit	Description
$T_{set,1}$	650	$°C$	furnace set temperature
$T_{set,2}$	680	$°C$	furnace set temperature
$T_{set,3}$	710	$°C$	furnace set temperature
$T_{set,4}$	740	$°C$	furnace set temperature
$T_{set,5}$	760	$°C$	furnace set temperature
U_{fuel}	0.75	-	utilization rate at 32A
U_{air}	0.10	-	utilization rate at 32A
$\dot{V}_{NH_3}$	1.189	Nl/min	volume flow rate
$\dot{V}_{air}$	31.876	Nl/min	volume flow rate
$\dot{m}_{NH_3}$	1.506e-5	kg/s	mass flow rate
$\dot{m}_{NH_3}$	6.862e-4	kg/s	mass flow rate

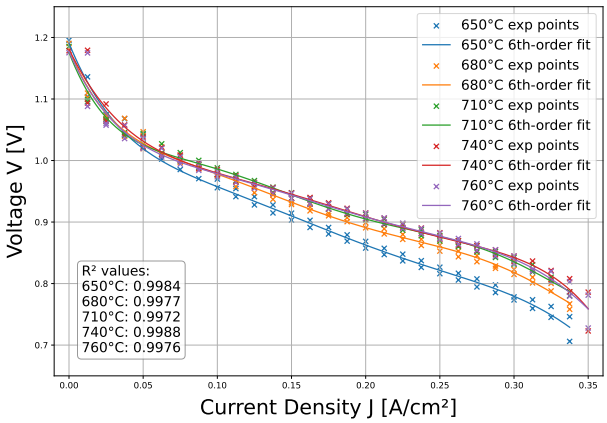

Figure 6. These are the experimental polarisation curves obtained from operating the test bench. The continuous lines were obtained by interpolating the average values of the experimental points using a sixth-order polynomial equation. The coefficient of determination R^2 for each temperature is shown to demonstrate how well the fitted values represent the experimental data.

3 Results and Discussion

The aim of the dynamic simulations, conducted for each of the models presented in the previous subsections, is to obtain the same performance as that obtained experimentally, with the smallest possible relative error ($\varepsilon_{\%}$) for each time step.

$$\varepsilon_{\%} = \left| \frac{V_{exp} - V_{sim}}{V_{exp}} \right| \tag{12}$$

3.1 Ammonia Decomposition Reaction Calibration

The amount of converted ammonia was calculated by transforming the NH_3 volumetric flow into mass flow using the ideal gas law under normal conditions. This step was necessary to compare the simulation results with those found in the literature; the conversion percentages are derived as the ratio between the decomposed ammo-

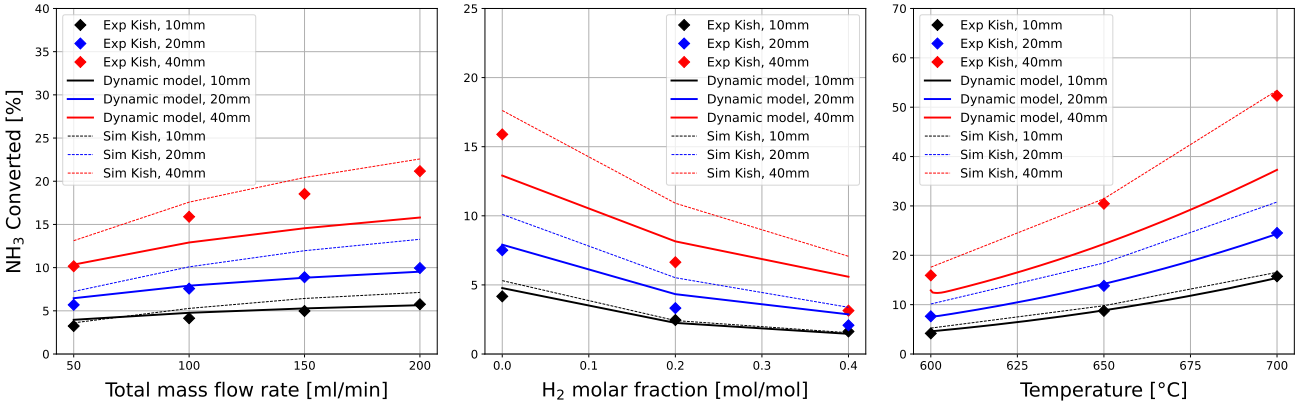

Figure 7. Comparison between the performance of the ammonia decomposition model and that obtained from simulations of the same operating conditions as described in the literature (Kishimoto et al. 2017). Discrepancies are calculated considering the experimental results with Equation 12, for both the simulation results obtained by Kishimoto et al. and the results obtained with the dynamic reaction channel model in the current case study.

nia volumetric flow and the incoming one. The calibration process results, shown in Figure 7, are obtained using $CE = 0.85$ (Equation 3). It is important to note that the discrepancy was obtained by comparison with the experimental results found in the reference article and not those from their simulations (Kishimoto et al. 2017).

It is evident that the reaction model aligns with the ammonia conversion curve for catalyst lengths of 10 mm and 20 mm, exhibiting smaller discrepancies compared to the results reported in (Kishimoto et al. 2017). However, higher discrepancies are observed when the catalyst is 40 mm long. This discrepancy, indicating a reduced conversion performance with a catalyst length of 40 mm, can be attributed to the observation that the gas exhibits increased dilution within the terminal segment of the catalyst and that the increased presence of hydrogen also reduces the ammonia conversion rate R_{dec}. This phenomenon could be attributed to the application of a lumped pseudo-1D model; however, this assertion needs to be validated by reproducing the experimental apparatus and also verifying that no potential factor has been overlooked by the authors of this case study.

This calibration process is considered a necessary step in obtaining a reaction that, when incorporated into the final SOFC stack model, can simulate the internal ammonia cracking.

3.2 Choice of ASR Values

It is important to comment on the value of the $ASR(T)$ coefficients that are used in the stack model. The experimental values are derived from the polarisation curve in the linear region, thus making $ASR_{exp}(T)$ dependent only on the average temperature of the stack, as shown in Figure 4. Consequently, all types of losses that result in a cell voltage drop from the open-circuit voltage value $OCV = E_0|_{I=0A}$ are included. However, it has been observed that, during the simulation, the cell model iteratively solves Equation 8 using the local values of partial

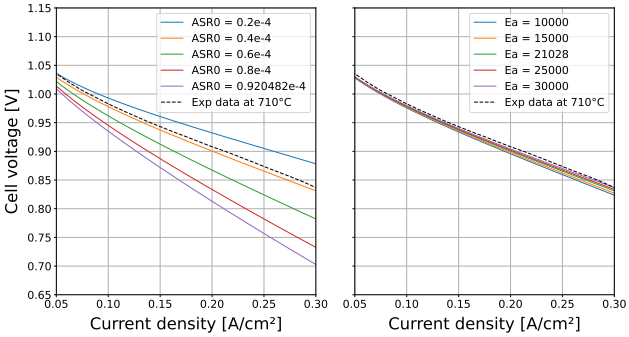

Figure 8. The two plots show a sensitivity analysis performed for operating the stack at 710 °C while keeping E_a, in the left plot, and ASR_0, in the right plot, at the experimental values.

pressures, which are determined by the cell performances: higher current requires higher hydrogen oxidation, thus the Nernst voltage decreases (see Figure 5). This decreasing effect is already taken into account in the calculation of the derivative of the polarisation curve to be calculated, so if the experimental values (Table 2) of ASR_0 and E_a were used in the model, the internal losses of the cell would be overestimated. A sensitivity analysis is presented in Figure 8 to explain the phenomenon above.

3.3 Stack Validation

Once the most influential parameters presented in subsection 2.4 are set, the stack operation is simulated under the operating conditions shown in Table 4. In Figure 9, V_{cell} values obtained from the dynamic simulation of the stack model are compared to the V_{cell} values derived from the polynomial fitting of experimental data in the ohmic current density range; the graph is represented with continuous curves to demonstrate, moment by moment, the discrepancy between the model's predictions and the actual cell voltage values. The stack model is considered validated, as the maximum value of the discrepancy is 2.18% at T=760 °C.

DOI
10.3384/ecp218405

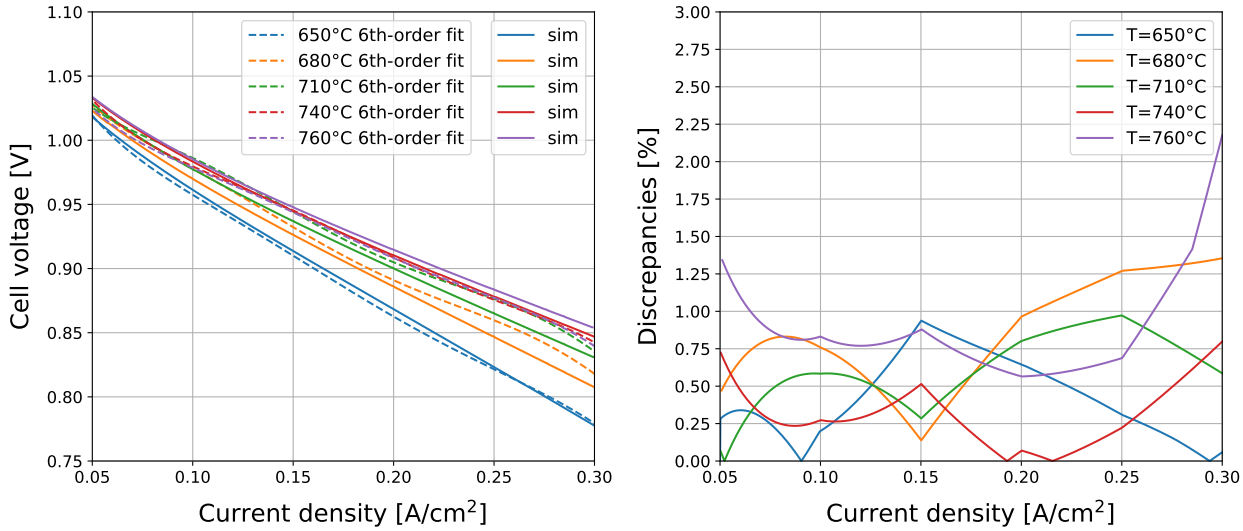

Figure 9. Comparison between the interpolated experimental polarisation curves and those obtained from the dynamic simualtion of the stack model over the selected ohmic range of current density. The discrepancy values (right) diagram are obtained with Equation 12 for each point on the polarisation curve, with a maximum value of 2.18% at T=760 °C.

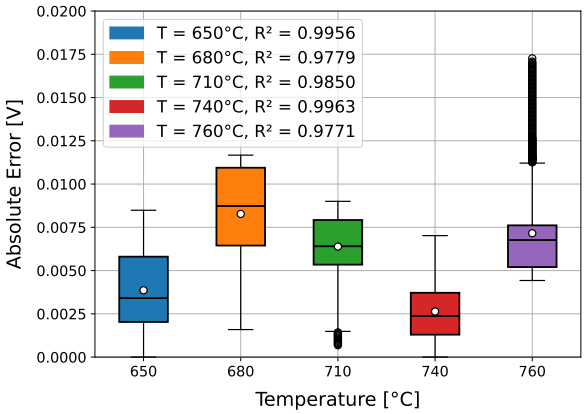

Figure 10. Boxplot of absolute voltage error distribution across temperatures. Each box shows the median, interquartile range and variability of the error between experimental and simulated values, with the mean error represented by a white circle.

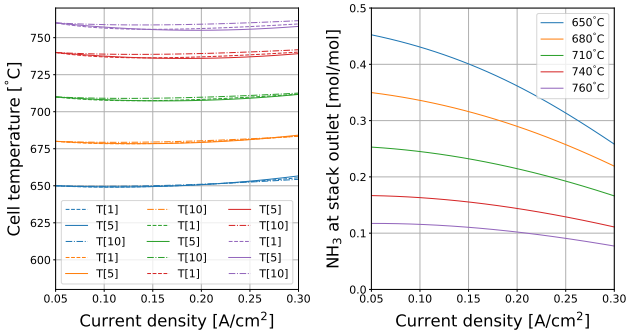

Figure 11. Cell temperature diagram (left) at the first, fifth (which represent the middle section of the cell) and tenth discretisation. Ammonia molar fraction in the anode off gases (right).

Figure 10 shows an analysis of the absolute error distribution to evaluate the performance of the model at different operating temperatures; the coefficient of determination R^2 has also been calculated and plotted for each temperature to help quantify the fit of the model to the experimental data. High R^2 values, such as 0.9956 at 650 °C and 0.9963 at 740 °C, indicate that the model can capture the variability in the experimental data. Lower values, such as 0.9779 at 680 °C and 0.9771 at 760 °C, are still considered good, as the model was built with some general assumptions that can be further investigated to improve the overall performance.

Figure 11 shows an overview of the cell performance in different sections along the longitudinal axis in terms of cell temperature and amount of ammonia left at the end of the anode channel. In fact, as explained in subsection 2.1, the ammonia conversion performance is strongly dependent on temperature; therefore, a higher amount of unconverted ammonia is expected at lower temperatures. This is confirmed by the fact that the experimental polarisation curve at 650°C (Figure 6) shows high concentration losses at high current density due to the low presence of hydrogen and hence lower ammonia conversion efficiency. As the temperature difference between the cells increases due to ammonia decomposition, thermal stress on the cell material is increased, leading to problems in cell operation and reduced lifetime. Installing a mass spectrometer at the end of the stack, makes it possible to quantify the amount of ammonia remaining and thus validate also the conversion performance of the stack. By simulating the operation of the stack for longer periods, the thermal inertia can be assessed, determining the performance at different temperatures, although continuous polarisation and depolarisation tests are not performed due to the need for further details on the test bench.

4 Conclusions and Future Works

The work presented in this paper resulted in the validation of two models built with a lumped pseudo-1D approach: firstly, an ammonia decomposition model built on equations presented and validated in the literature; secondly, a SOFC stack model fed directly with ammonia, built from the structure of a test bench in the laboratory and then validated with the operating parameters used in the laboratory and experimental and polarisation curves. The validated ammonia decomposition reaction model was necessary to implement the ammonia decomposition reaction that occurs within the anode channel of the stack model when it is operated at high temperatures.

The optimal performance of the ammonia decomposition reaction and the ability of the stack model to capture more than 97% of the experimental data, with a maximum relative error of 2.18%, prove the robustness and reliability of the model in investigating the performance of a solid oxide fuel cell stack fed directly with ammonia.

This high accuracy can be further improved by adding some considerations, previously simplified for the purpose of the article, such as recalibrating the ammonia decomposition reaction based on new experimental results or setting up an optimisation problem to obtain optimal values for the area specific resistance ASR_0 and the activation energy E_a; the same approach could also be used to estimate the best coefficients for the parameters of the activation, ohmic and concentration losses equations neglected in this case study. This would extend the current range of application of the stack. These considerations arise naturally from the fact that the material and geometric structure of the stack are covered by trade secrets. Therefore, this model is intended as a basis for refining the description of the test bench model and enhancing simulation performance.

The model's objective is to obtain a dynamic response from the stack to changes in operating conditions, such as the transition between nominal load and partial load. This enables the prediction of model outputs and the optimisation of stack performance. In addition, this highly accurate model can be used as a basis for scale-up investigations and can be implemented in a Balance of Plant (BoP) model, which represents all components in an industrial plant configuration, including control loops; a highly accurate stack model allows the evaluation of operating parameters to be adopted for optimal plant performance and the optimisation of control strategies in real cases.

Abstract

Electrolysis systems are the key technology to produce hydrogen from renewable energy sources. The modeling and simulation of proton exchange membrane (PEM) electrolyzers and the connected power grid present challenges due to highly fluctuating capacities in the available electrical power. Our study focuses on the modeling of the electrolyzer and its balance of plant with varying power supply resulting from renewable energy sources. The balance of plant contains a water supply system, the electrical power supply and processes for treating the produced hydrogen, in particular drying. The electrolyzer model is validated using steady-state and dynamic data from the literature and it is shown that the developed model accurately represents those measurement results. Furthermore, we implement an empirical degradation model to assess the effects of different use-cases on the efficiency of the electrolyzer.

Keywords: PEM electrolysis, hydrogen, dynamic simulation, two-phase flow, degradation

1 Introduction

A water electrolyzer is a device that is used to split water into hydrogen and oxygen using electrical energy. The production of hydrogen is essential for the chemical industry, because it is the feedstock of many processes. Moreover, hydrogen is also widely discussed as a future energy carrier (Hancke, Holm, and Ulleberg 2022; Hou and Yang 2024). To produce hydrogen in a sustainable way, the combination of electrolyzer and renewable energy sources is the key (Hou and Yang 2024; Reimann, Kohlenbach, and Röntzsch 2023). The operation characteristics of renewable energy sources, such as wind energy farms and photovoltaics, are inherently dynamic. Therefore, an electrolyzer connected to a power grid with a large share of renewable energy sources should be able to handle dynamic capacities.

There are various water electrolyzer technologies on the market, each with specific properties. Our study focuses on proton exchange membrane (PEM) electrolyzers because of the following arguments. This type of electrolyzer is able to operate dynamically due to its low temperature requirements. As well, low operating temperatures allow for a fast start-up. A further advantage of the PEM electrolyzer is that it can be operated at high pressures and therefore reduces the power required to compress hydrogen for storage applications (Hancke, Holm, and Ulleberg 2022).

To assess the performance of different electrolyzers or design an electrolzyer for a specific application, detailed simulation models are needed. Electrolyzers are generally operated in combination with other systems of various engineering disciplines. Therefore, the use of Modelica as a modeling language is ideal as many Modelica libraries focusing on the modeling of energy system are available and can be used to investigate future energy systems.

PEM electrolyzer models with different levels of detail have been published in the literature (Engel et al. 2025; Hancke, Holm, and Ulleberg 2022; Reimann, Kohlenbach, and Röntzsch 2023; Krenz et al. 2024). A novelty of our approach presented in this work is that we combine a detailed physics-based electrolyzer system model with an empirical degradation model published by (Schofield et al. 2025).

In the current study, an electrolyzer is investigated under steady-state and dynamic operating conditions. To assess the effects of fluctuating power supply on the efficiency and degradation of an electrolyzer, the electrolyzer is connected to a wind turbine as a power supply and meteorological data are used to generate operation profiles. The combination of an electrolyzer with a renewable energy source is arguably a relevant use case for hydrogen production in the future.

In the following section, the working principle and the main features of the PEM electrolyzer are introduced. The third section discusses the function and modeling of the specific components selected to build the electrolyzer system model. In the fourth section, we focus on the simulation of steady-state and dynamic operation and study the predicted degradation. The results obtained are compared with data from the literature.

2 PEM Electrolyzer Model for System Simulations

The PEM electrolyzer model discussed in this study was developed using the commercially available Modelica libraries TIL, TILMedia and the TIL3_Addon_HydrogenEnergySystems each in version 2025.1 (TLK-Thermo GmbH 2024). Dymola 2024x is used as modeling and simulation environment

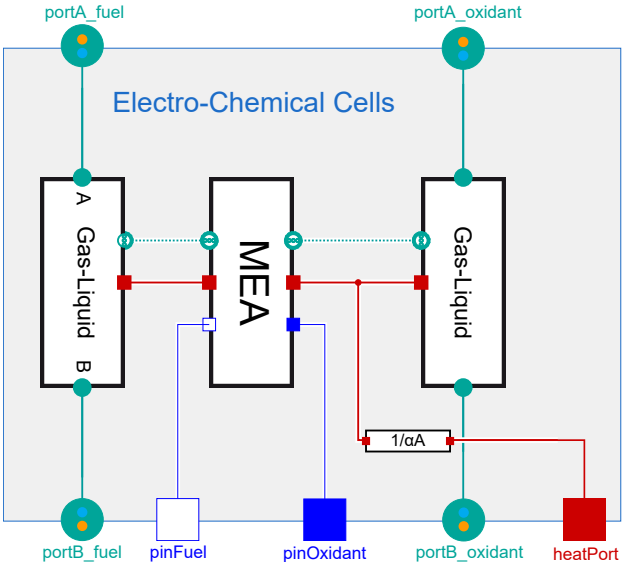

Figure 1. Structure of the stack model divided into fuel and oxidant channels and a membrane electrode assembly. Turquoise lines represent mass transfer. Dashed lines symbolize diffusive mass transfer and full lines convective mass transport. Heat transfer is marked by red lines and electrical current by blue lines.

(Dassault Systèmes SE 2024). A novelty of our approach is to combine a physics-based model with an empirical degradation model to assess the effects of degradation in realistic operating scenarios. The electrolyzer model is divided into three subdomains representing the fuel channel, the membrane electrode assembly (MEA) and the oxidant channel, as shown in Fig. 1. To calculate spatially resolved results, the model is divided into smaller discretization elements in the flow direction, but keeping the structure given in the figure. This way, the local formation and transport of product gases and water can be observed. To simulate a full stack consisting of multiple cells, one representative cell is simulated in detail and the results scaled-up by multiplying the results of the single cell by the number of cells in the stack, as described by (Tang 2016) for a fuel cell.

2.1 Electrochemical Foundation and Balances

To describe the operation of an electrolyzer, we start by introducing the relevant balance equation, and then we derive the most important metrics of the electrolyzer. On the oxidant side of the electrolyzer, water is supplied to the stack oxidant port A, as shown in Fig. 1. As typical for PEM electrolyzers, water is supplied to the anode channels of the electrolyzer only. Because the membrane is permeable to water, water is transported towards the cathode, as described in the next section. On the anode electrode water is split up into protons and oxygen:

$$\text{Anode}: \quad \mathrm{H_2O} \rightarrow 2\mathrm{H^+} + 2\mathrm{e^-} + \frac{1}{2}\mathrm{O_2} \tag{1}$$

On the cathode, protons and electrons form hydrogen molecules:

$$\text{Cathode}: \quad 2\mathrm{H^+} + 2\mathrm{e^-} \rightarrow \mathrm{H_2} \tag{2}$$

In summary, the overall reaction reads:

$$\mathrm{H_2O} \rightarrow \mathrm{H_2} + \frac{1}{2}\mathrm{O_2} \tag{3}$$

The products and water leave the system at the fuel port B and oxidant port B. Heat can be removed using a heat port. In the electrolyzer, a two-phase flow is typical since the water is supplied in liquid state and the products are gases. To split water into oxygen and hydrogen, electrical power must be supplied to the electrolyzer. The calculation of the required electrical power is described in the following paragraph. In the model, the current is supplied directly to the MEA as shown in Fig. 1.

To derive the minimal power required for the electrolysis, a steady-state operation is assumed in the following equations, but the model is formulated for dynamic operation. The following mass balance holds for the electrolyzer:

$$\dot{m}_{\mathrm{H_2O,in}} - \dot{m}_{\mathrm{H_2O,out}} - \dot{m}_{\mathrm{H_2,out}} - \dot{m}_{\mathrm{O_2,out}} = 0 \tag{4}$$

The first law of thermodynamics for the electrolyzer reads:

$$\dot{H}_{\mathrm{H_2O,in}} - \dot{H}_{\mathrm{H_2O,out}} - \dot{H}_{\mathrm{H_2}} - \dot{H}_{\mathrm{O_2}} + \dot{Q} + P = 0 \tag{5}$$

The second law of thermodynamics is stated as follows:

$$\dot{S}_{\mathrm{H_2O,in}} - \dot{S}_{\mathrm{H_2O,out}} - \dot{S}_{\mathrm{H_2}} - \dot{S}_{\mathrm{O_2}} + \frac{\dot{Q}}{T} = \dot{S}_{\mathrm{prod}} \tag{6}$$

We assume an isobaric and isothermal reaction, so that the reactants and products have the same pressure and temperature.

Combing the first and the second law results in a new equation:

$$\dot{G}_{\mathrm{H_2O,in}} - \dot{G}_{\mathrm{H_2O,out}} - \dot{G}_{\mathrm{H_2}} - \dot{G}_{\mathrm{O_2}} + P = T\dot{S}_{\mathrm{prod}} \tag{7}$$

Here, the relation for the Gibbs free energy is used:

$$G = H - TS \tag{8}$$

A special relation holds when no entropy is produced: The minimum work needed to split a water molecule is given by the Gibbs free energy of the reaction ΔG_R:

$$\Delta G_R = \Delta H_R - T\Delta S_R \tag{9}$$

It is the difference of the reaction enthalpy ΔH_R and the product of the cell temperature T and reaction entropy ΔS_R. The terms of the equation are explained below. The Gibbs free energy of the reaction can be directly linked

DOI
10.3384/ecp218413

to the voltage between the electrodes using the number of transferred electrons z and the Faraday constant F:

$$U_{\text{rev}} = -\frac{\Delta G_R}{zF} \tag{10}$$

The Gibbs free energy of the reaction depends on the temperature, the pressure and the composition of reactants supplied to the electrolyzer.

Another important voltage, the so-called thermoneutral voltage, can be derived from the reaction enthalpy:

$$U_{\text{TN}} = -\frac{\Delta H_R}{zF} \tag{11}$$

When operated at this voltage an adiabatic electrolyzer will operate at constant temperature (Bernt 2019), assuming no temperature gradients in the electrolyzer. Otherwise, the reversible heat of the reaction leads to a change in the cell temperature. The reversible heat is calculated using the electrical current and the thermoneutral and reversible voltages:

$$\dot{Q}_{\text{rev}} = I(U_{\text{rev}} - U_{\text{TN}}) \tag{12}$$

In addition to the reversible heat, the losses occurring in an operating cell produce irreversible heat flows. Those losses are directly related to the entropy production rates, as presented by (Struchtrup 2014). The major losses to be considered in an electrolyzer cell are activation, Ohmic, and mass transfer losses and are introduced in the following section.

2.2 Electrochemical Transport Models

In the following, the transport in the MEA is presented. The water content λ_{W} represents the amount of water in the membrane according to (Springer, Zawodzinski, and Gottesfeld 1991). In the electrolyzer, the membrane is always equilibrated with liquid water on the oxidant side and therefore water content is assumed to be constant according to (Springer, Zawodzinski, and Gottesfeld 1991):

$$\lambda_{\text{W}} = 22 \tag{13}$$

The proton conductivity of the membrane is directly affected by its water content and is modeled as stated by (Springer, Zawodzinski, and Gottesfeld 1991):

$$\sigma_{\text{mem}} = (0.5139\lambda_{\text{W}} - 0.326)\exp\left(1268\,\text{K}\left(\frac{1}{303\,\text{K}} - \frac{1}{T}\right)\right) \tag{14}$$

Using the proton conductivity σ_{mem}, the membrane thickness δ_{mem} and the active area A, the electrical resistance of the proton conduction can be calculated:

$$R_{\text{mem}} = \frac{\delta_{\text{mem}}}{\sigma_{\text{mem}} A} \tag{15}$$

The irreversible voltage loss is then calculated by the following relation:

$$\Delta U_{\text{ohm}} = R_{\text{mem}} I \tag{16}$$

The activation loss is calculated using a Tafel equation with the parameters crossover current density i_{X} and the exchange current density i_0:

$$\Delta U_{\text{act}} = \frac{RT}{\alpha z F}\log\left(\frac{i + i_{\text{X}}}{i_0}\right) \tag{17}$$

Since the losses on the fuel side are comparatively small, they are neglected and only the oxidant side is considered.

Furthermore, the mass transfer losses are accounted for employing a limiting current density of $i_L = 6\,\text{A/cm}^2$ (Crespi et al. 2023):

$$\Delta U_{\text{conc}} = \frac{RT}{\alpha z F}\log\left(\frac{i_L}{i_L - i}\right) \tag{18}$$

The degradation of electrolzyer cells during operation is a current topic of research and of great importance when addressing economic viability questions. In the literature, different models for catalyst and membrane degradation can be found. A major drawback of the currently published models is their high computational demand. Therefore, an empirical model fitted by (Schofield et al. 2025) is implemented in the electrolyzer model.

$$\frac{d\Delta U_{\text{deg}}}{dt} = \begin{cases} 30\,\mu\text{V/h} & \text{if } 0 < i < 1\,\text{A/cm}^2 \\ 30\,(\mu\text{V cm}^4)/(\text{A}^2\,\text{h})\,[i(t)]^2 & \text{otherwise} \end{cases} \tag{19}$$

The data used for the calibration of the degradation model originate from accelerated stress tests and, therefore, might overpredict the rate of degradation under real operating conditions.

The cell voltage is then calculated using the losses ΔU introduced before and the reversible cell voltage U_{rev}:

$$U_{\text{cell}} = U_{\text{rev}} + \Delta U_{\text{ohm}} + \Delta U_{\text{act}} + \Delta U_{\text{conc}} + \Delta U_{\text{deg}} \tag{20}$$

With the cell voltage, the heat release from the reaction can be calculated:

$$\dot{Q} = I(U_{\text{cell}} - U_{\text{TN}}) \tag{21}$$

The main functions of the membrane in the electrolyzer are proton conduction, electric insulation and separation of the species. However, a real membrane is not fully impermeable to the species in the electrolyzer. Therefore, both the produced gases and water can partially travel through the membrane. The transport of the produced gases is driven by a partial pressure difference, while the transport of water occurs due to an absolute pressure gradient and because of electro-osmotic drag (EOD).

The permeation is modeled with the following equation and using parameters published by (Ahluwalia and Wang 2007) :

$$\dot{n}_{\text{drag,i}} = \frac{K_i A}{\delta_{\text{mem}}}\Delta p_i \tag{22}$$

For the calculation of the EOD, a constant drag coefficient $\varepsilon_{\text{EOD}} = 2.5$ is used (Ma et al. 2021). The water transfer is then calculated using the electric current:

$$\dot{n}_{\text{EOD}} = \frac{\varepsilon_{\text{EOD}} I}{F} \tag{23}$$

The heat produced by the reaction is transported to the fluid channels as described in the next section.

2.3 Fluid Channels

Fluid channels are required to supply the anode with water and remove reaction products from the electrolyzer. The channels are connected to both sides of the MEA as shown in Fig. 1. The electrochemical reaction produces gaseous products that mix with liquid water on the anode side. Therefore, it is necessary to consider two-phase flow characteristics when modeling the flow inside the fluid channels. In this study, we use a phase-separate modeling approach that allows us to model a thermal and chemical non-equilibrium of the gas and liquid phases. The relevant equations for describing the flow in the electrolyzer are outlined below.

First, the most important quantities of the two-phase flow are introduced. The void fraction is defined as the volume ratio of gas and total volume:

$$\varepsilon = \frac{V_g}{V} \tag{24}$$

The overall volume is the sum of the volumes occupied by gas and liquid phases:

$$V = V_g + V_l \tag{25}$$

The mass balance for the gas phase, denoted by the index g, is given by the following relation:

$$\varepsilon \frac{d\rho_g}{dt} V - \rho_g \frac{dV_l}{dt} = \dot{m}_{g,in} + \dot{m}_{g,out} + \dot{m}_{PC} + \sum \dot{m}_{MT,g,i} \tag{26}$$

Here, the time derivative of the liquid volume is given by

$$\frac{dV_l}{dt} = \beta \frac{dT}{dt} \frac{m_l}{\rho_l} + \frac{1}{\rho_l} \frac{dm_l}{dt} \tag{27}$$

with β being the isobaric expansion coefficient. Using a smooth limiter, it is always guaranteed that small amounts of liquid and gas phase are present in each control volume to avoid singularity.

Using an explicit formulation of time derivative of the density avoids symbolic manipulation of the equation system and thereby simplifies the solution (Richter 2008):

$$\frac{d\rho}{dt} = \left(\frac{d\rho}{dh}\right)_{p,\xi} \frac{dh}{dt} + \left(\frac{d\rho}{dp}\right)_{h,\xi} \frac{dp}{dt} + \left(\frac{d\rho}{d\xi}\right)_{p,h} \frac{d\xi}{dt} \tag{28}$$

For the liquid phase the mass balance reads:

$$\frac{dm_l}{dt} = \dot{m}_{l,in} + \dot{m}_{l,out} - \dot{m}_{PC} + \dot{m}_{MT,l} \tag{29}$$

Both equations are explicitly coupled by a possible phase change given by the common term $\dot{m}_{PC}$.

For the pressure calculation, a mechanical equilibrium of both phases is assumed:

$$p_g = p_l \tag{30}$$

The pressure is derived from the gas phase. The momentum balance is formulated in steady-state.

The gas phase consists of a mixture of hydrogen, oxygen and water vapor.

$$\begin{aligned} m_g \frac{d\xi_i}{dt} = {} & (\xi_{i,in} - \xi_i)\dot{m}_{g,in} + (\xi_{i,out} - \xi_i)\dot{m}_{g,out} \\ & + (\xi_{\text{condensed,i}} - \xi_i)\dot{m}_{PC} + \xi_i \dot{m}_{MT,g,i} \end{aligned} \tag{31}$$

Here, the mass fraction vector $\xi_{\text{condensed,i}}$ contains zeros except for a one at the position representing water. Since the liquid phase consists of water as one pure species in the model only, no explicit formulation of the species balance is required for the liquid.

The energy balance is formulated for each phase separately. However, for the current study, a thermal equilibrium is assumed:

$$T_g = T_l \tag{32}$$

For the gas phase, the energy balance reads:

$$\begin{aligned} m_g \frac{dh_g}{dt} = {} & (h_{g,in} - h_g)\dot{m}_{g,in} + (h_{g,out} - h_g)\dot{m}_{g,out} + (h_l - h_g)\dot{m}_{PC} \\ & + \sum (h_{i,MT} - h_g)\dot{m}_{MT,g,i} + \dot{Q} + \varepsilon V \frac{dp}{dt} \end{aligned} \tag{33}$$

The liquid phase energy balance is as follows:

$$\begin{aligned} m_l \frac{dh_l}{dt} = {} & (h_{l,in} - h_l)\dot{m}_{l,in} + (h_{l,out} - h_l)\dot{m}_{l,out} - (h_l - h_g)\dot{m}_{PC} \\ & + (h_{MT} - h_l)\dot{m}_{MT,g,i} + \dot{Q} \end{aligned} \tag{34}$$

The heat transfer from fluid to membrane and the bipolar plate is calculated using a temperature difference and a fixed heat transfer coefficient:

$$\dot{Q} = \alpha A \Delta T \tag{35}$$

For the forced convection a constant heat transfer coefficient of $\alpha = 2000\,\mathrm{W/(m^2K)}$ is used, reflecting that the exact geometry of the channels in the bipolar plate is unknown. Furthermore, the heat loss to the environment is calculated using the stack surface area and the heat transfer correlations for free convection from the literature (Klan and Thess 2013). The heat transfer area was calculated according to (Tjarks 2017).

Analogously to heat transfer, the mass transfer processes are calculated using a mass transfer coefficient and a concentration difference.

$$\dot{m} = \beta A \Delta c \tag{36}$$

The interface mass transfer of water is driven by a concentration difference between actual and saturated state:

$$\dot{m}_{\text{PC}} = \beta_{\text{PC}} A (c_{\text{sat}} - c) \tag{37}$$

To simplify the calculation, an ideal transport can be assumed, whereby the concentration c and the saturation concentration c_{sat} are set equal. Due to intense mixing, the produced gases are typically saturated with water.

3 Electrolyzer System Model

The modeled electrolyzer system is shown in Fig. 2. To produce hydrogen of defined quality in a PEM electrolyzer, a water supply system, an electrical connection to a power supply, and a hydrogen treatment system are necessary. The modeled hydrogen treatment system consists of two drying stages, thermal drying and adsorptive drying, followed by a compressor. In the following, the subsystems and their specifications are discussed in detail.

Stack

An electrolyzer previously analyzed in the literature (Crespi et al. 2023) is modeled and simulated in this work. A summary of the most relevant stack parameters is given in Table 1. Two separators are directly connected to the stack to remove liquid water from the gas flows on fuel and oxidant side. On the oxidant side, the removed water is fed to the liquid loop again. The oxygen produced by the electrolyzer is released to the environment. On the fuel side, further treatment of the liquid water was not modeled. However, the produced hydrogen gas, which is typically moisture-laden, undergoes further treatment in the subsequent steps.

Table 1. Parameters of the modeled electrolyzer stack.

Quantity	Symbol	Unit	Value
Nominal Current	I	A	410
Nominal Power	P_{el}	kW	60
Number of cells	n_{C}	1	65
Active Area	A_{MEA}	cm^2	214
Membrane Thickness	δ_{mem}	mm	0.322
Thermal Capacity	C_{Stack}	kJ/K	155.0

Water Supply and Cooling Loop

The water supply system circulates water in the cathode loop and feeds to the electrolyzer to replace water consumed by the electrochemical reaction. In addition, the circulated water is employed for the thermal management of the electrolyzer. Therefore, a chiller is integrated into the water loop that can reject heat to a cooling circuit. In addition, a storage tank is included to buffer water consumption and act as a thermal capacity. To refill water a pump is modeled. The supply water is assumed to be deionized.

Hydrogen Treatment System

The purification unit consists of two different drying processes. In the first step, water is removed from the produced hydrogen by lowering its temperature below the saturation point using a heat exchanger connected to a cooling circuit. In order to fulfill the typically strict requirements for the hydrogen purity, an adsorptive drying process is implemented downstream of the thermal drying process. In this study, a temperature swing adsorption (TSA) system is modeled as suggested by (Tjarks et al. 2018) using the TIL Adsorption Library (TLK Energy GmbH 2024). The TSA system consists of two adsorbers that are operated alternately. Both adsorbers are filled with Zeolith as an adsorbent (Tjarks et al. 2018). When hydrogen is produced, one adsorber is used to remove water from the fuel gas. The adsorption process is driven by a gradient in the chemical potential of water in the fuel gas and adsorbed water. During operation, water accumulates in the adsorber until it reaches a defined loading state. When this loading state is reached, the adsorbers are switched and the adsorber that was in the drying operation is then regenerated using a recirculation system. In the recirculation loop, hydrogen is heated up to 160 °C then enters the adsorber and gets humidified inside. A blower is used to recirculate hydrogen with a defined flow rate. The water is removed from the hydrogen after leaving the adsorber by lowering the temperature of hydrogen below its saturation point using the environment or a cooling circuit as the heat sink. To switch between the two adsorbers, eight control valves are utilized.

After the purification stages, hydrogen is compressed to a defined level. This step is necessary to increase the volumetric energy density of hydrogen.

While the electrolyzer is modeled in detail as described above, the pumps and compressors are modeled with constant efficiencies. For the heat exchangers, a finite-volume-approach was employed (Richter 2008). The heat transfer coefficients are assumed to be constant. In addition, a constant separation efficiency is assumed in the water separator models shown in Fig. 2. All efficiencies and other significant parameters are summarized in Table 2. The pressure levels and the nominal coolant flow rate are adjusted according to (Crespi et al. 2023).

Table 2. Parameters of the component models in the electrolyzer system.

Quantity	Symbol	Unit	Value
Compressor Efficiency	$\eta_{\text{comp,isen}}$	1	0.7
Recirculation Blower	$\eta_{\text{b,isen}}$	1	0.4
Pump Efficiency	P_{el}	kW	0.97
Separator Efficiency	η_{sep}	1	0.99
Hydrogen Storage Pressure	p	bar	200
Cathode Pressure	p	bar	30

4 Steady-State and Dynamic Operation of PEM Electrolyzer

This section provides an overview of the simulation results obtained with the proposed model. First, steady-state operation and calibration of the stack are discussed. Next, dynamic operation scenarios are investigated. Finally, the degradation of the stack during dynamic operation is explored.

4.1 Steady-State Operation

Data from the literature data published by Crespi et al. (2023) is used to calibrate and validate the model discussed in the previous section. The operating conditions are given in Table 2. First, the geometry of the model is adjusted according to the data given in the paper of Crespi et al. (2023) also shown in Table 1. Next, a calibration is performed using steady-state measurement data of the same publication recorded at different operating temperatures and current densities. Data used to validate the model are not used in the fitting process.

The exchange current density $i_0 = 1.05 \times 10^{-7}\,\mathrm{A/cm^2}$, the effective membrane thickness $\delta_{\mathrm{mem,eff}} = 455\,\mu\mathrm{m}$ and the crossover current density $i_X = 0.02\,\mathrm{A/cm^2}$ have been used in a fitting process to obtain an accurate representation of the electrolyzer data published by Crespi et al. (2023) . Only data for an operating temperature of 50 °C were used for the fitting. The other part of the data, at operating temperatures of 45 °C and 60 °C, were used for validation.

In Fig. 3, the results of the calibration and validation can be found. Overall, the model accurately reflects the measurement data. The highest deviation between the measurement and the simulations is observed for small current densities. The mean absolute deviation is 0.013 V for all simulated operating points. The maximum deviation between simulation and measurement is 0.035 V .

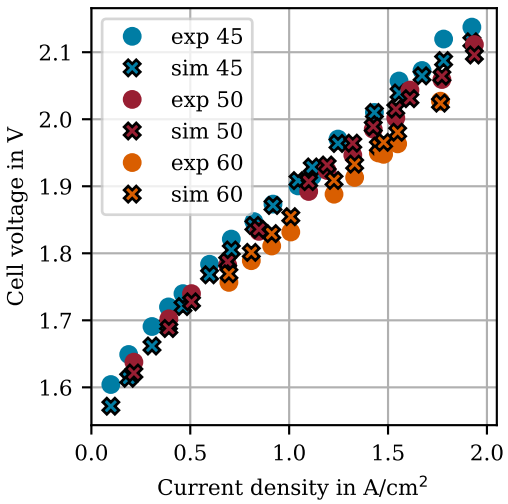

Figure 3. Comparison of measured and simulated voltages at different temperatures and current densities. The other operating conditions are set according to Table 2.

4.2 Dynamic Operation

One application of a PEM electrolyzer is the direct connection to a renewable energy source, such as a wind farm. Renewable energy sources such as wind and photovoltaics are highly fluctuating due to the weather conditions at the location of the electrolyzer. The aim of this section is to investigate whether the developed model can accurately simulate the response of the electrolyzer to a time-varying power supply. First, the calibration of the thermal capacity of the cooling circuit is conducted. Next, the gas volumes on the fuel side are calibrated and the pressure build-up investigated. Finally, the dynamic operation is studied with regard to efficiency, safety and degradation of the electrolyzer.

Warm-Up of the Electrolyzer

For an electrolyzer connected to a renewable and weather-dependent energy source, it is important to see how fast it can reach the desired operating temperature and produce

DOI 10.3384/ecp218413

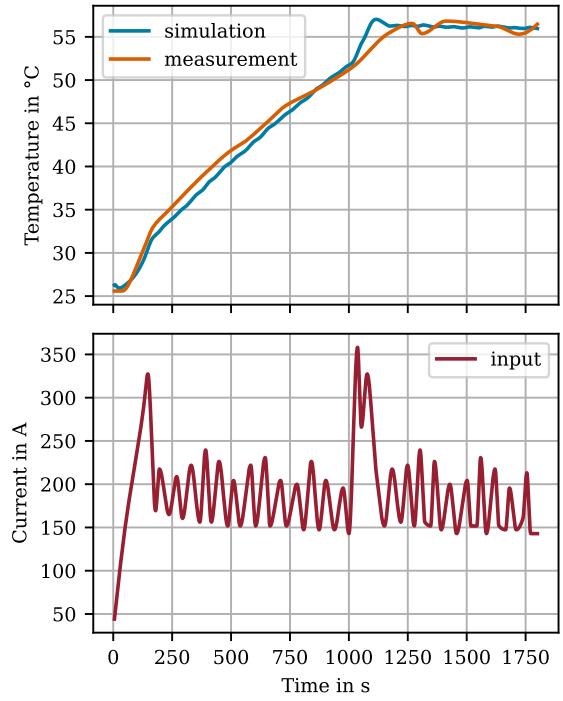

Figure 4. Comparison of simulated and measured temperatures during start-up and operation of the electrolyzer with varying current input with an average of I = 188 A.

hydrogen with high efficiency. In the work of Crespi et al. (2023), the warm-up of an electrolyzer system under given power capacity profiles is shown. The heat produced in the electrochemical reaction is utilized to warm up the electrolyzer from ambient temperature. The measurements are shown in Fig. 4. A mean current of 188 A is supplied to the electrolyzer. During warm-up the pump in the cooling circuit is deactivated so that no heat is drawn from the system. The amount of heat produced by the reaction depends on the voltage of the cell and thereby on the current supplied to the electrolyzer. The warm-up scenario measured by Crespi et al. (2023) is used in this study to calibrate the model parameters. The adjusted parameter is the water mass in the cooling circuit.

The results of the measurement and the simulation with different parameter values for the water mass are shown in Fig. 4. A steady-state is reached after about 1100 s. In the electrolyzer simulation results, it becomes obvious that the mass of water has a significant influence on the warm-up process due to the high heat capacity of water. The water mass in the liquid loop is adjusted to 50 kg in the calibration process.

The simulation of another warm-up cycle is shown in Fig. 5. Compared to the warm-up shown in Fig. 4, the average current supplied to the electrolyzer is 211 A. A quasi-steady-state temperature is reached after approximately 800 s after the start-up, both in simulation and measurement. In addition to the temperature curve, a comparison of the simulated and measured cathode pressures is shown over time. A total volume of 9.5 L was assumed for

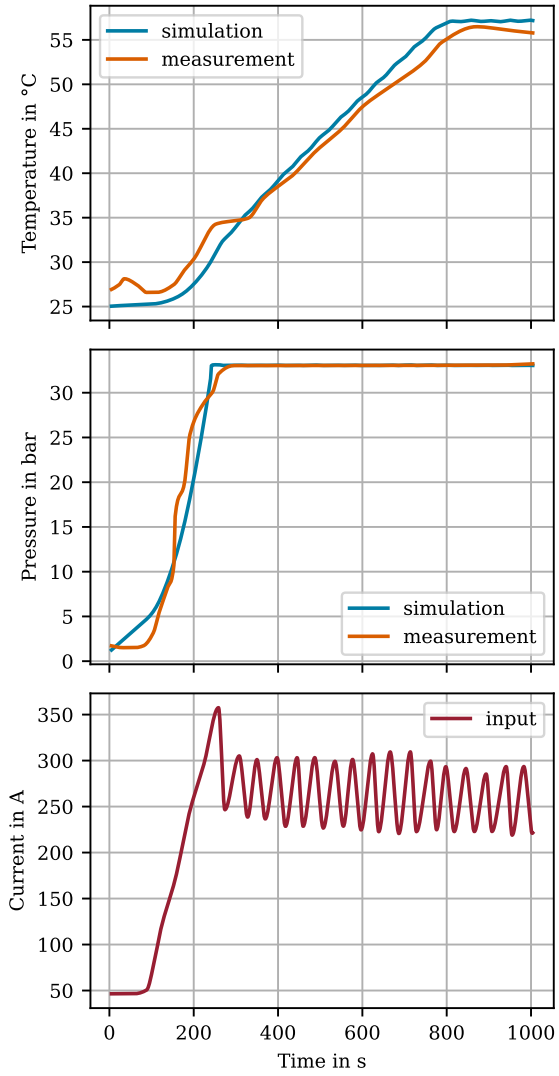

Figure 5. Comparison of simulated and measured temperatures during start-up and operation of the electrolyzer with varying current input with an average of I = 211 A. Simulated and measured pressure build-up are also shown.

the gas on the fuel side of the electrolyzer. The pressure build-up is predicted to be more uniform by the simulation model than in the measurement. In the curve representing the measurement, different slopes are visible that cannot be linked to the input of the current density. In particular, the pressure plateau at the beginning of the recorded data does not appear to be in agreement with the input current. However, quasi-steady-state of the cathode pressure is reached in measurement and simulation after about 240 s.

Electrolyzer Connected to a Wind Turbine

As future energy systems become more dynamic, flexibility in operation is crucial to adapt to fluctuating demands and decentralized production.

In order to operate the electrolyzer model with a dynamic electrical power supply, the scenario of a wind turbine is selected. Therefore, a power supply profile is cre-

ated on the basis of wind data from the DWD for Braunschweig (German Meteorological Service (DWD) 2025). The hourly data indicate the wind speed at ground level. For the calculation of the electrical power generation by the wind turbine, a simplified approach is employed based on (Heier 2022). The wind turbine has a hub height of 45 m and a rotor diameter of 44 m. Using the simplified model, the hourly electrical power supply from the wind turbine to an electrolyzer is calculated for one week in March 2023. The ambient temperature is set to $T_{\text{amb}} = 8\,^{\circ}\text{C}$, which is the average for this month.

Table 3. Electrolysis system simulation results for a week of operation in March 2023 for an electrolyzer with and without grid connection.

Quantity	Symbol	Unit	Value
With Grid Connection			
Hydrogen Produced	m_{H_2}	kg	83.51
Electrical Energy Consumption	E_{el}	kWh	4534.9
Average Efficiency	η	1	0.6138
Without Grid Connection			
Hydrogen Produced	m_{H_2}	kg	79.9
Electrical Energy Consumption	E_{el}	kWh	4367.59
Average Efficiency	η	1	0.6097

To study the effect of different operation strategies, we analyzed two scenarios in terms of the efficiency that can be achieved and the amount of hydrogen that can be produced. For the first scenario, a grid connection of the electrolyzer is assumed. If the available power from the wind turbine falls below 5 kW, it is assumed that the electrolyzer operates at a minimum power that is supplied by the electrical grid. This power is the minimum to keep the electrolyzer at operating temperature. In the second scenario with no grid connection, the electrolyzer is turned off if the available electrical power from the wind turbine falls below a 1 kW threshold. As a result, the electrolyzer temperature decreases due to heat losses to the cold environment. In both scenarios, the maximum power is limited to 60 kW.

The simulation results of both operation scenarios are plotted in Fig. 6. In the figure, the stack temperature, the hydrogen production rate, and the power supply are plotted against time. In the stack temperature, differences are visible in the times when no electrical power is available from the wind turbine. Large temperature decreases can be seen during times when no power is supplied by the wind turbine. The grid-connected electrolyzer remains at an operating temperature of roughly 50 °C due to the additional power supplied by the grid. In both hydrogen production and in the power supply, the effect of the grid connection is shown as an offset when there is no electricity from the wind turbine.

To calculate the efficiency of the system, the hydrogen production rate is integrated and multiplied by the lower heating value (LHV) of hydrogen $\text{LHV}_{\text{H}_2} = 120\,\text{MJ/kg}$. The result is then divided by the time integral of electrical power consumed by the stack, pumps, blower and compressor. This yields the efficiency of the system:

$$\eta = \frac{m_{\text{H}_2}\,\text{LHV}_{\text{H}_2}}{E_{\text{el}}} \tag{38}$$

The integral results of the calculated scenarios are summarized in Table 3. Due to the energy supplied by the grid, which is used when no electricity is available from the wind turbine, the hydrogen production of the grid-connected electrolyzer system is about 4.5 % higher than the electrolyzer without a grid connection. For the same reason, the electrical energy consumption of the grid-connected system is also higher. Moreover, the efficiency of the grid-connected system is higher. This is because hydrogen production at low current densities is very efficient and on the other hand the grid-connected electrolyzer benefits from higher operating temperatures, where operation is slightly more efficient.

Furthermore, the simulated results of the hydrogen concentration on the oxidant side were monitored to check if the flammability limit of hydrogen in oxygen is exceeded at certain operating points. The hydrogen concentration on the oxidant side depends on the permeation and the recirculation rate. It could be observed in the simulation results that the hydrogen concentrations on the anode are higher for the electrolyzer without a grid connection. In the case of the electrolyzer without grid connection, the flammability limit is exceeded at times when the power is reduced rapidly. As a result, countermeasures would have to be taken. For the grid-connected electrolyzer, the limit is never exceeded. Generally, for an accurate description of the transient accumulation of hydrogen during operation, the model needs further parameters, such as volumes of components and materials.

The simulation times for both the grid-connected and the non-connected electrolyzer scenario shown in Fig. 6 are about 75 s on a laptop equipped with an Intel i7-1360P processor.

Prediction of the Degradation in the Electrolyzer

An empirical degradation model (eq. 19) published for the PEM electrolyzer was implemented in the electrolyzer model. To assess the degradation predicted by the empirical model, the simulation of the electrolyzer connected to the wind turbine was conducted again, but for the entire period of March 2023. The grid-connected electrolyzer was selected due to its higher efficiency.

After one month of simulated operation, the voltage of an average single cell in the electrolyzer stack increased by approximately 0.045 V. Extrapolating this result over a period of the year would result in an increase of voltage

DOI
10.3384/ecp218413

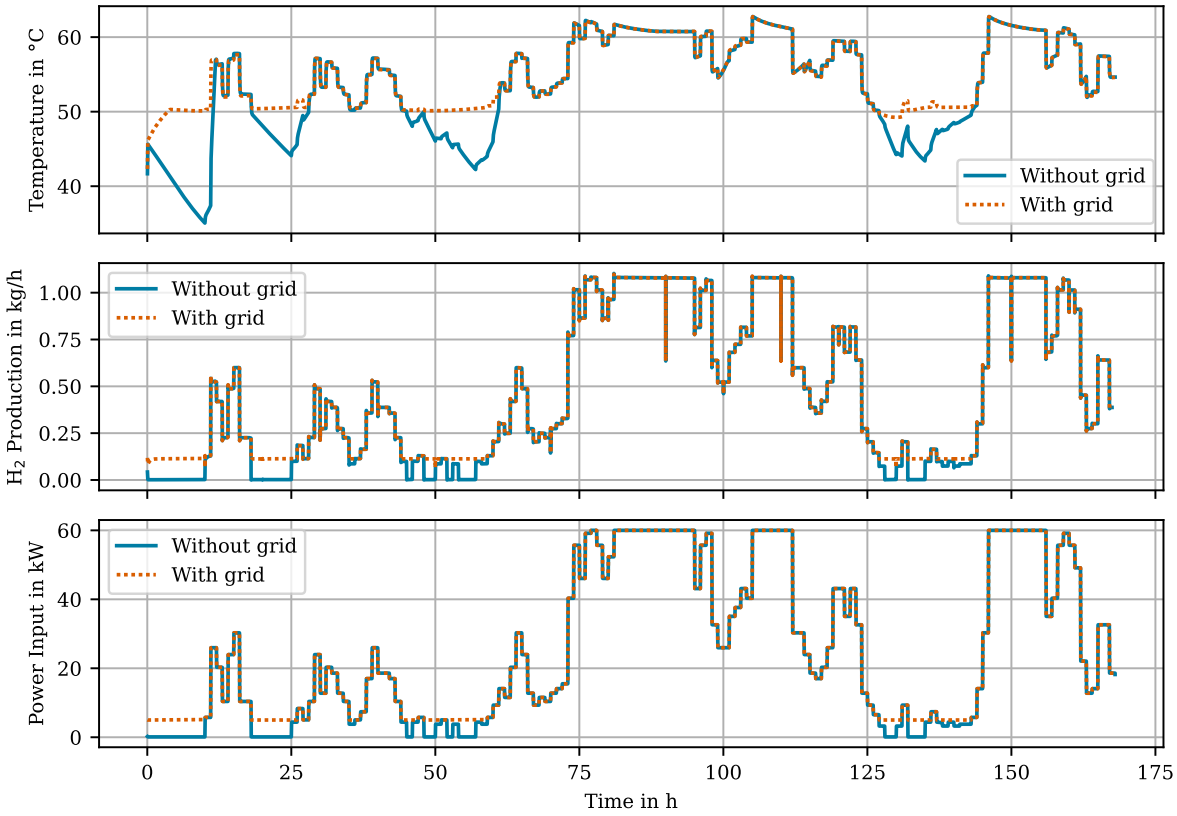

Figure 6. Simulation results of a 60 kW electrolyzer connected to a wind turbine with and without connection to the electric grid. The operating temperature, hydrogen production and power input of both scenarios are compared for the first week of March 2023.

by 0.54 V per single cell. When comparing this extrapolated result to the operating voltages published by (Crespi et al. 2023), the increase of voltage due to degradation would lower the efficiency drastically. In comparison to irreversible degradation results published by (Krenz et al. 2024), the degradation rates reported here for the electrolyzer model are high and result from the fact that irreversible and reversible degradation are not separated in the model. More detailed degradation models are reported in the literature and might help to improve the predictions (Rakousky 2016; Krenz et al. 2024).

The obtained result also demonstrates how important dynamic physics-based simulation models are to check the plausibility of calculated degradation results and to verify degradation models developed using lab-scale electrolyzers. In particular, the ability of physics-based simulation models to study realistic operating scenarios in short time frames makes them invaluable.

5 Conclusion and Outlook

In this study, a newly developed electrolyzer model was presented and investigated under steady-state and dynamic operating conditions. The dynamic model was validated for steady-state operating and dynamic scenarios using measurement data.

First, the model was parametrized according to Crespi et al. (2023) and then unknown parameters were fitted to measurement data of the same publication. The fitted model agrees well with the measured polarization curve for three different operating temperatures. Next, the dynamic response of the electrolyzer model was adjusted by fitting the liquid mass and the gas volume of the fuel to measurement data. Again, a good agreement of the measurements and simulation is achieved. In both investigated operation points, the simulated stack temperatures match the measurements accurately. Furthermore, the pressure build-up in the cathode volume of the stack is predicted accurately by the simulation model.

In the last step, a dynamic load profile was generated based on real-world wind data. Two operating scenarios for the generated load profile were analyzed, one with and another without grid connection of the electrolyzer. The efficiency of grid-connected electrolyzer is higher than that of the standalone electrolyzer. The difference can be attributed to the operating phases with relatively low load, where the efficiency of hydrogen production is high. Furthermore, it was found that the hydrogen accumulation in the electrolyzer not connected to the grid is problematic in phases with low power supply. Finally, the degradation rate under dynamic load conditions was investigated, again using the load profile of the wind turbine. Here, an overprediction of the degradation rate by the implemented model was identified using the system simulation. In the future, more detailed degradation models, such as the one proposed in (Krenz et al. 2024), could be implemented.

Nomenclature

Abbreviations

MEA	Membrane Electrode Assembly
PEM	Proton Exchange Membrane
TSA	Temperature Swing Adsorption

Latin Symbols

A	Area, m^2
c	Concentration, $mol/(m^3)$
C	Heat capacity, J/K
F	Faraday Constant, C/mol

Model-Based Control Design for a Multi-Stacks SOC System

Axelle Hégo[1] Félix Bosio[1] Sylvain Mathonnière[1]

[1]Univ. Grenoble Alpes, CEA/LITEN, 17 Rue des Martyrs, 38054 Grenoble Cedes 9, France, {axelle.hego, felix.bosio, sylvain.mathonniere}@cea.fr

Abstract

In response to growing interest in high-temperature electrolysis, CEA-Liten has developed multi-stack Solid Oxide Cell (SOC) testing equipment comprising four electrolyser stacks. Each stack includes multiple cells, and together they form a module housed within a shared thermal enclosure and connected to a balance of plant. This setup supports the development of innovative control strategies, essential due to the stacks' sensitivity to operating conditions. To mitigate risks and costs associated with testing new strategies directly on the physical system, a Model in the Loop approach was implemented. The model replicates the real module's characteristics and operational capabilities, allowing safe and efficient design and validation of control strategies. Various transition scenarios between operating conditions—tailored to diverse production needs and constraints—were developed and validated using the model before real-world implementation. This paper presents the model-based control methodology and compares experimental results with simulations.

1 Introduction

Hydrogen (H_2) production based on water electrolysis can contribute significantly to the decarbonisation objectives of the energy and industry sectors. High Temperature Electrolysis (HTE) based on Solid Oxide Cell (SOC) technology is currently in industrialisation phase with the start of MW scale demonstrators (Iyer et al. 2024). Solid Oxide Electrolyser (SOEL) systems are composed of modules containing several stacks in the same thermal enclosure and supplied by the Balance of Plant (BoP) with gases at the required conditions (composition, temperature, pressure) and with electrical current. In this context, CEA-Liten has developed a highly instrumented four stacks module presented in (Cubizolles et al. 2024). The operation of such modules is complex due to high sensitivity for some operating parameters, such as pressure or current. It is also time-consuming and cost-expensive in terms of human resources and equipment. Using multi-physic modelling is interesting to investigate behavior of the system and test new control strategies without risking to damage the real components. Once validated on the model, the new control strategies can be implemented in the real Programmable Logic Controller (PLC) and validated on the real module.

System modelling has two broad applications : design and sizing at the early phase of a project and model-based control development (Iyer et al. 2024). For this second application, the Model in the Loop (MiL) methodology is used. This methodology aims at developing low (PID) to high-level (Model Predictive Control (MPC)) control laws by leveraging the modelling of actuators and using return states of the modelled system as input to the control models (Aoun et al. 2019). Extensions of this methodology are Software in the Loop (SiL) where the algorithm control itself is compiled and tested with a simulated model and then Hardware in the Loop (HiL) in which the hardware itself (controller hardware in this case) is included, most of the time requiring real-time simulations (Zimmer 2019). This paper presents a MiL methodology based on a plant modelling using Modelica language, an export of this model as a Functional Mock-up Unit (FMU) (Modelica Association 2014) and then a co-simulation in Simulink (The MathWorks Inc. 2025a) where the control development has been implemented. This workflow can be used on almost all types of system such as in (Cech et al. 2017) with a steam turbine model, (Wang et al. 2017) with a model of refrigerant system for vehicle, and (Ensbury, Horn, and Dempsey 2020) with a vehicule model. Concerning model-based control for SOC, most studies are focuses on the coupling with other systems (nuclear, solar, etc) (Iyer et al. 2024). To the authors' knowledge, few studies have investigated specific control. In (Botta et al. 2019), SOFC and SOEC 1D dynamic stacks are modelled using Modelica and then PI controllers are defined to manage temperature of these two modes. In (Pohjoranta et al. 2015), MPC

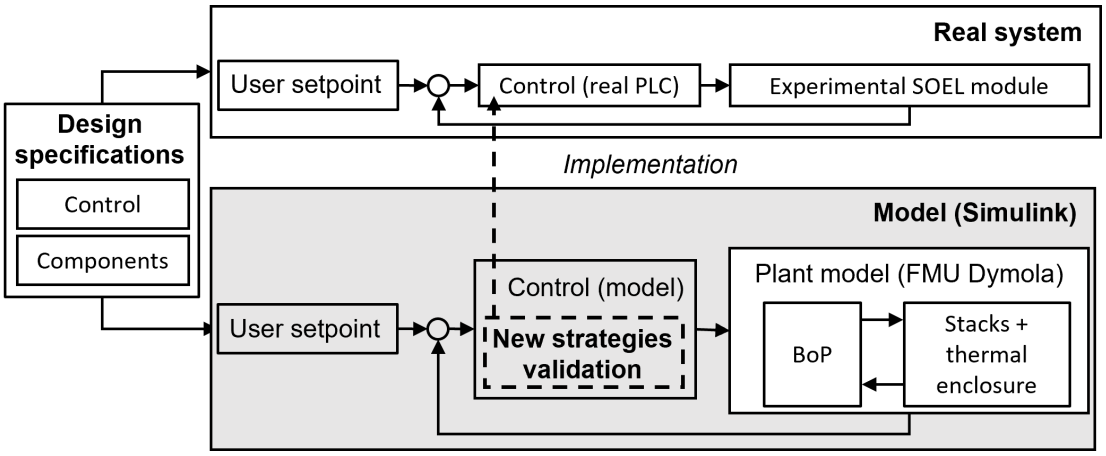

Figure 1. Overview of model-based design for control applied on a SOEL module

approach is applied on SOFC stack temperature based on experimental data of a SOFC system. In the present work, control strategies to change operating conditions are applied on a complete one-module system model and its real system counterpart. These strategies involve stacks' temperatures, gases flow rates (thus composition), current and voltage regulation.

This paper describes the methodology applied to the multi-stacks one-module system of the CEA-Liten by presenting a global model overview in Section 2. The represented system is briefly described as well as the corresponding Dymola model. The control model and control strategies are also presented. Illustration of high-level control strategies are presented in Section 3 towards a comparison between experimental and simulated data. Section 4 concludes with perspectives and challenges of the study.

2 Model and methodology

2.1 Model overview

This study focuses on a model of the multi-stacks testing equipment presented in (Cubizolles et al. 2024). A complete system model is developed using different software tools as shown in Figure 1. The Modelica language is tailored to represent complex multi-physics dynamics whereas the Simulink software is ubiquitous for control development, therefore they were selected for the development of respectively the plant model and the control model. The Functional Mock-up Interface (FMI) standard is well suited for encapsulating systems of ordinary differential equations and more generally for Modelica models, therefore in order to exchange data between those two models, the plant model was encapsulated in a Functional Mock-up Unit (FMU) based on this standard to be co-simulated in Simulink software along with the control model.

The FMU of the plant model comprises about 30 inputs which correspond to the actuator commands provided by a control model. The FMU outputs are about 90 and represent state returns representing simulated sensors which describe model system behavior. All the components of this complete system model are configured using real system specifications such as datasheet of components, measured quantities and control loop implemented in real PLC.

2.2 Plant model on Dymola

The dynamic plant model is composed of three interconnected subsystems: fuel loop, air loop and hotbox. The BoP refers to the fuel loop and the air loop which supply the conditioned fluids to the hotbox subsystem. The hotbox comprises four stacks designed and manufactured by CEA (individual power of 2.5 kW_{DC}), heaters, Heat EXchanger (HEX) and the thermal enclosure (hotbox) in which they are contained. Figure 2 is a simplified Process Flow Diagram (PFD) of the electrolysis configuration of the system.

- The **fuel loop** corresponds to the steam and hydrogen conditioning upstream of the hotbox and downstream until venting. The HEXs in series (Figure 2 (A) and (B)) heat the inlet fuel using heat from fuel downstream from the stacks. The heater (C) is controlled to supply hotbox subsystem with fuel at required temperature. The unconverted steam/H_2 mix in the reactant line downstream from the stacks and HEX is condensed in (E) before venting.

- The **air loop** is fed by the blower (Figure 2 (b)) and a by-pass ensures the flow rate. Upstream from the blower, a HEX (a) removes excess humidity from the air with water cooling. Then, inlet air is heated up by HEX (c) using heat from air downstream from the stacks and the heater (d) before the hotbox. As

DOI 10.3384/ecp218425

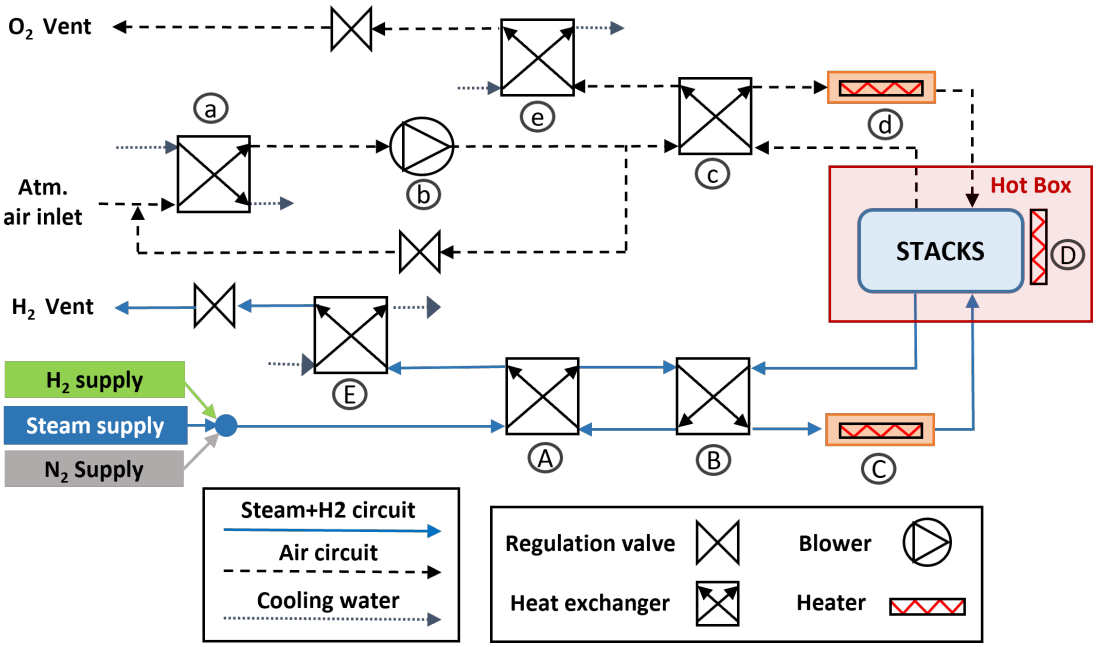

Figure 2. Process flow diagram of SOEL system from (Cubizolles et al. 2024)

with fuel, air downstream from stacks and HEX is cooled down before vent.

- **Gas feeding** of the loops are represented with gas sources of fixed pressures (Modelon Pressure boundary components) where media of Fuel Cell library media are used. Fuel media corresponds to "PreDefined.IdealGases.FastSteamHydrogen" composed of H_2O, H_2 and N_2. Air media corresponds to "PreDefined.IdealGases.FastMoistAir" composed of H_2O, N_2 and O_2.

- In the **hotbox subsystem**, fluids (air & reactant) flow through HEXs that connect the upstream and downstream flows from stacks for each medium. Then, the air and reactant are distributed respectively at the anode and cathode of the four stacks. The four stacks are positioned in a 2×2 vertical grid in a thermal enclosure comprising three heaters (Figure 2 (D)). In order to model the hotbox subsystem, the four stacks are represented by a vector of stack model based on SOFC stack component of a commercial Fuel Cell Library (Andersson et al. 2011) and connected fluidically and electrically in parallel. The stack model is composed of two reaction pipes (anode and cathode) which exchange mass and heat information with a electrochemical model. It corresponds to a reduced model based on experimental data and a CEA's Single Repeat Unit (SRU) model (Laurencin et al. 2011). Stacks' temperatures are computed through four thermal models (one per stack) taking into account conductive heat transfer, and, through a source term added to the heat equation, heat generated by electrochemical reaction and the gases enthalpy difference. The thermal model of the hotbox is composed of a network of thermal capacities representing stacks environment (heaters, stacks' supports) and the walls (~130 heat capacitors) without the stacks themselves. The four stacks included in the hotbox are each represented with 41 continuous state variables that are used to perform a thermal mapping of the stack. The stacks environment, its interactions with the stacks and interactions between stacks are computed with the network of heat capacitors linked by conductive and radiative transfers. Those heat transfer models are all finely tuned through external 3D Computational Fluid Dynamic (CFD) simulations.

Plant model had been implemented using Dymola software v2023x Refresh 1 (Dassault Systèmes 2025) as integrated development environment for Modelica Standard Library (MSLv3.2.3) and Modelon (MBLv3.7) - Fuel Cell Library (FCLv1.13) (Modelon AB 2021a; Modelon AB 2021b). The model is composed of:

- valves[1] with a quasi-static isenthalpic flow neglecting mass and energy storage, based on IEC 534/ISA S.75 standards for valve sizing.
- semi-empirical compressor models[2], implementing polytropic processes and quasi-static substance mass and energy balances are used. Both centrifugal and reciprocating compressors models have been chosen to best fit the experimental hardware.
- heat exchangers, for heat recovery from stack downstream fluid (Fig. 2 (A), (B) and (C)), represented

[1] Modelon.ThermoFluid.Valves.ValveCompressible
[2] Modelon.ThermoFluid.Compressors.DynamicCompressor and PositiveDisplacementCompressor

with dynamic NTU lumped exchanger using Modelon convective heat transfer model[3] and effectiveness functions[4] or value adapted to real components.
- heat exchangers[5], for cooling (Fig. 2 (a), (e) and (E)), represented with lumped model of indirect cooler using the logarithmic mean temperature difference for heat transfer calculation.
- friction models represented with static isenthalpic flow incorporating lumped pressure loss without energy or mass storage.

Valve parameters (opening flow characteristics and flow coefficient), compressor parameters (efficiency and flow maps) are set using components' data sheet and, in some models, based on experimental data.

The complete model once translated contains about 500 continuous time states. The hotbox thermal model dynamic being of paramount interest for HTE, it contains more than 300 continuous time states. The remaining states are distributed between the thermofluidic states of the fluids (~60 for the air loop, ~70 for the fuel loop and ~30 for the hotbox) and the stacks' electrochemistry.

This plant model has been encapsulated in FMU, v2.0, in co-simulation using implicit solver (Radau) which is stable for stiff thermofluidic models with a tolerance of 1e-4.

2.3 Control model on Simulink

The control of complex systems can be organized in two main parts:

- The low-level control corresponds to the signals applied directly to actuators. These signals could come from direct inputs (an opening value for a valve for example) or from set-point drived controllers, like the PID ones. This type of controllers compares a measured signal to a set-point and computes a correction signal to send to the actuator which impacts the measured variable.
- The high-level control corresponds to set-points definition. It can be as basic as direct values or more elaborate, with user-defined functions describing the logic to take into account, using a set of parameters, inputs, limitations, laws, etc.

For SOEL systems, the main goal is to produce a certain amount of H_2. To do this, the main variables to control are:

- the gases flow rates,
- the gases composition,
- the current density,
- the stacks' temperature.

In addition, other important variables need to be monitored in order to take into account the stacks limitations or users' requirements. Some are from direct measurements, as the cells voltage U, others are build from other variables. From this last category, the Steam Conversion (SC) is one of the most important and is defined as:

$$SC = \frac{j}{2F} * \frac{1}{\dot{n}_{H_2O}} \tag{1}$$

with the current j in A, F the Faraday's constant $(96485\, A \cdot s \cdot mol^{-1})$ and the molar flow rate of inlet steam $\dot{n}_{H_2O}$ in $mol \cdot s^{-1}$.

The nominal way of controlling the considered system for a constant H_2 production demand is to have the current density and the SC to the highest safe values possible. With these parameters fixed, Equation 1 leads to the flow rates values calculation. Then, the last parameter to determine is the stacks' operating temperature. In the current framework, it is controlled by the stacks' mean voltage value. The voltage target is the thermoneutral voltage (~1.287 V for one cell) where heat sources generated by the electrochemical process irreversibilities (such as omhic losses) are counterbalanced by the endothermicity of the electrolysis reaction. For a given flow rate and current density, only one temperature leads to operating the stacks at their thermoneutral mean voltage. The aim is to maintain the stacks voltage close to this value during their lifetime, by adjusting the temperature to compensate the voltage increase due to degradation phenomena.

It is expected that SOEL systems are operated in stationary mode, some punctual modulation of the production rate can be required. It could come from the final H_2 consumer or from inputs limitation as the electricity or steam availability.

Different strategies can be imagined to adapt the production rate of the system but they will all lead to modifications of the main parameters set-points (flow rates, current density and stacks' temperature). The way of applying these modifications can be critical for the stacks integrity and can cause irreversible damages. In order to limit the risks taken on the real system, the model-based control design approach is a pertinent solution for the test, the comparison and the validation of these strategies.

This study focuses on the comparison of two different strategies for an operating point transition:

- The slow transition, described by the state transition control diagram in Figure 3, aim to modulate the H_2 production with a constant SC. The first step

[3] Modelon.ThermoFluid.Volumes.HeatTransfer.LumpedHT_Dittus-Boelter and LumpedHT_constAlpha
[4] Modelon.ThermoFluid.HeatExchangers.Functions.parallelFlow and counterFlowEps
[5] FuelCell.HeatExchangers.GasWater.GasDryer

DOI 10.3384/ecp218425

is to start a ramp on the temperature (T ramp) to a higher or lower set-point (respectively for more or less H_2 production). The temperature evolution impacts the stacks' voltage value U and the current j can be increased or decreased by Δj to stay at the thermoneutral voltage U_{THN}. The current evolution would modify the SC value so the steam flow rate is adjusted to keep it constant. The last step corresponds to the stop of the temperature ramp. It is reached when the current is at its target value.

- The fast transition, as outlined in the state transition control diagram in Figure 4, enables the SC to adjust quickly by evolving the flow rate in order to reach the new current set-point as quickly as possible, while keeping the stacks at the thermoneutral voltage. To achieve this, a flow rate ramp (Q ramp) is initiated simultaneously with the temperature ramp (T ramp). It leads to a faster evolution of the voltage, compared to the temperature ramp only in the slow transition, that can be compensated by current variations. Once the new current set-point is reached, the flow rate ramp is halted, and the SC is gradually returned to its initial value by incrementing the flow rate, as the temperature change influences the voltage.

The described control model is based on the same logic and laws implemented in the real PLC of the test bench. These control laws were defined during the design phase of the multi-stacks testing equipment and aim to provide the desired conditions to the stacks, guaranteeing the safety of the installation and its components.

The control model has been developed using Simulink R2023b and the Stateflow library (The MathWorks Inc. 2025b). FMIKit v3.1 was used to to the plant's FMU integration instead of the native FMU integration block (Dassault Systèmes 2023). The FMU is co-simulated in Simulink and use its intern solver. Simulink model is simulated with a discrete fixed-step solver with a time-step of 1 s to be representative of real-PLC behavior. Communication time step between the FMU and the control model is inherited from Simulink solver (1 s).

These strategies have been tested on plant model presented in Section 2.2 in order to explore their limits before an implementation on the real system. The following section presents the simulation results obtained and a comparison with the corresponding experimental sequence.

3 Results

3.1 Initial conditions and results configuration

Before this study, the four stacks were operated in various conditions during several thousands of hours and as the degradation phenomena has impacted them differently, the temperature corresponding to the thermoneutral voltage (for a given set of operating conditions j and SC) is not the same for each stack. Because there is no individual temperature control implemented in this system, it was chosen to control the hotbox temperature on the stacks' mean voltage.

To assess the response of the multi-stack testing equipment to the two transition strategies and to ensure a significant variation in H_2 production (approximately 10 %), the operating condition changes outlined in Table 1 were selected for the experiments. These conditions take into account the limits on the real system such as the pressure or the maximal temperature allowed in the stacks and the maximum SC value. Moreover, the system efficiency is not in the scope of this study and regarding the level of degradation at the time of the test, the conditions are representative of a real system operation.

Table 1. Operating points of the study, normalized by cell's active area for the current density and the fuel flow rate

	OP71	*OP63*	*OP67*
Current density i $[A.cm^{-2}]$	0.71	0.63	0.67
Steam Conversion SC [%]	55	55	55
Inlet fuel flow rate $[NmL.min^{-1}.cm^{-2}]$	10.05	8.88	9.43
H_2O / H_2 [%] mol. frac.	90 / 10	90 / 10	90 / 10

3.2 Results description

The results shown in Figure 5 represent a succession of four transition sequences (two per strategy type). For each one, it starts from a nominal H_2 production, goes to a lower one before going back to the nominal. Two fast transition sequences are represented between 0 and 6 hours with variations from OP71 to OP63 to OP67 to OP71. Two slow transition sequences are represented between 6 and 18 hours with variations from OP71 to OP63 to OP71. Each sequence is highlighted with gray vertical area.

The current density is proportional to the H_2 production rate. In the transition from OP63 to OP71, a step at OP67 was needed because of pressure limitations on the system due to a high fuel flow rate value (low SC). All the changes on the parameters leading to a voltage evolution are done with the objective of maintaining the stacks' average voltage around the thermoneutral voltage, between 1.287 and 1.29 V (green area). The studied temperature is an average of fuel outlet temperature of the stacks. This average is displayed subtracting the initial temperature in

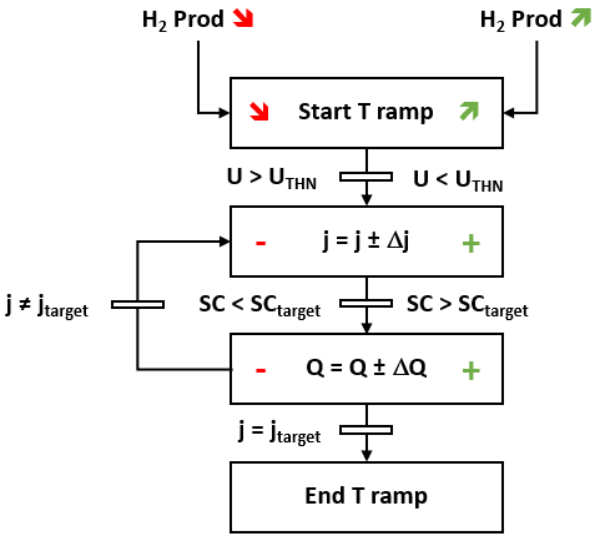

Figure 3. Slow operating point transition control state diagram

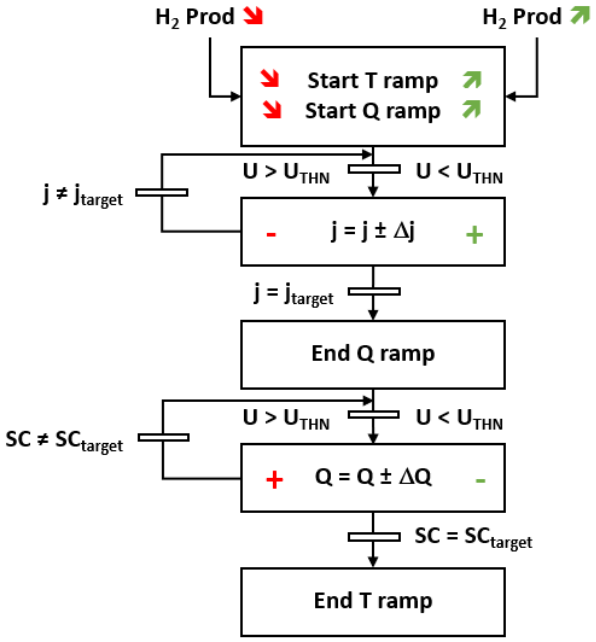

Figure 4. Fast operating point transition control state diagram

order to highlight the variation between the model and the real data, in which the absolute temperature initial values are different (degradation mechanisms are not all represented in the electrochemical model used). The fuel inlet flow rate is adjusted following the SC targeted at 55 %.

The described conditions have been reproduced in simulation (Figure 5). Computation time to simulate the sequences is about 10h20 with CPU 8th Gen Intel(R) Core(TM) i5-8365U 1.60 GHz and 16 Go RAM.

3.3 Comparison between experimental and model results

As a preliminary remark, it is important to mention that model is not fitted to real system. Main dynamics are represented by the model and it is used to test and debug control transitions. Model fitting using experimental data is a work in progress.

Overall, the model results are in accordance with the experimental data. One of the main difference between the model and real system is the thermal behavior. Even if the model describing the thermal phenomena occurring inside the hotbox, the stacks and between them is accurate comparing to 3D CFD simulations, some parameters are difficult to set precisely (as the thermal capacities for the conduction or the thermal emissivity of the materials for the radiation). It leads to differences, especially in term of dynamic behavior, which induce time shifts in the transitions, but also in term of absolute temperature value. However, it is worth noting that the main trends are represented and the order of magnitude of the temperature difference between an operating point to another is consistent (about 10 $°C$ for experimental data and about 7 $°C$ for simulation). Inertia phenomena are observed on temperatures between sequences and the inverse trends are also observed in voltages, which is the expected behavior as proved by the experimental data. Once more, trends and variation orders are consistent between model and experimental data. Another main difference is observed on SC and fuel inlet flow rate during the second sequence (fast transition from OP63 to OP67). This important difference, about 3 $NmL.min^{-1}.cm^{-2}$ for flow rate and 10 % for SC, can be explained by the cyclic pressure variations occurring on the test bench steam generator during the re-filling with cold water. The fuel flow rate, hence the SC, is directly impacted. These variations are not represented in the model which can also explain some time shift observed during transition phases. As these flow rate variations are periodic, it could be interesting to reproduce them in the model.

Despite these differences between the model and the real system, the model allows to validated the control behavior for the proposed transition strategies by pointing out the limits of these strategies.

3.4 Results analysis and transition methods comparison

The objective of the slow strategy is to reach the new production point by maintaining the steam conversion while the temperature ramp is affecting the voltage. As the overall dynamic is led by the temperature, the flow

DOI
10.3384/ecp218425

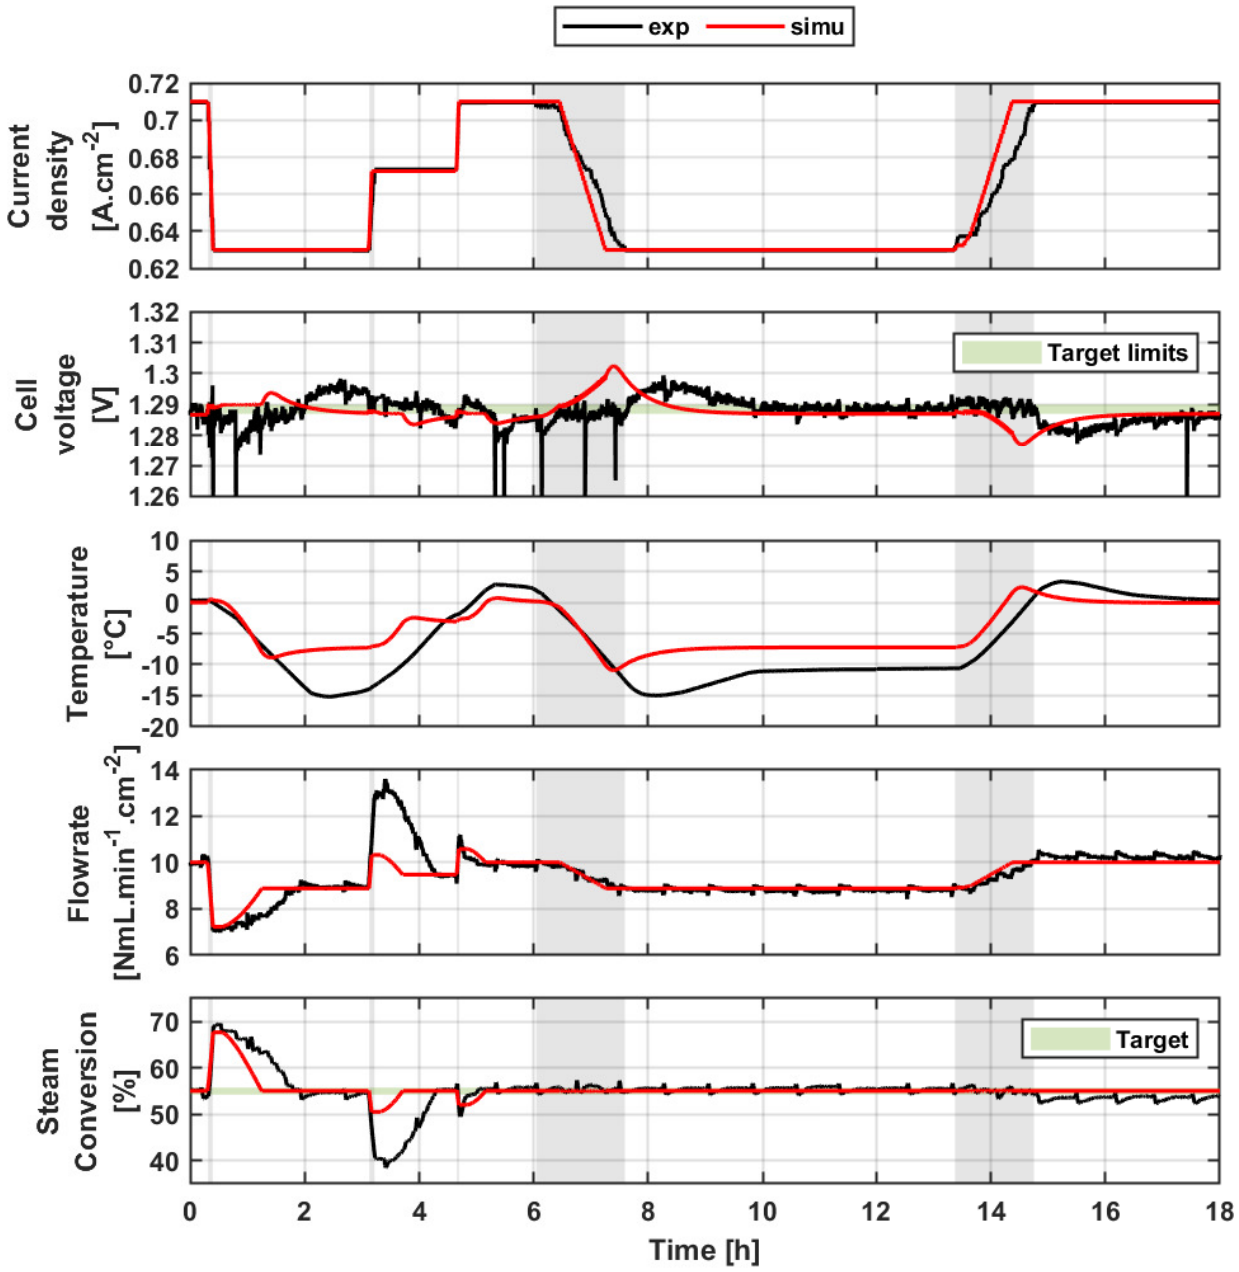

Figure 5. Experimental (black line) and simulated (red line) data for operating point transitions.

rate transition is smooth. It ensures safe conditions for the stacks.

The objective of the fast transition is to reach a new production point as soon as possible. To do so, and because the mean voltage is required to be maintained at its thermoneutral value, the only possible way is to allow variations on the flow rate (and so the SC).

The expected behavior for each strategy is clearly visible on the results. With the fast transition, the targeted production is reached ~20 time faster than with the slow one (5 minutes versus 1 hour 35 minutes).

In any case, both strategies led to a similar time for having the required operating point conditions (current density and SC). This is because the thermal dynamic is the slowest and therefore the one leading the system behavior.

To conclude this comparison, the advantages and drawbacks of each strategy can be sum-up in the following lists:

- Slow transition: The targeted production rate is reached slowly, but with a constant SC during the transition that limits the risks of having a critical value for the stacks (too high SC for less H_2 production and too high pressure due to a too low SC for more H_2 production).

- Fast transition: The targeted production rate is reached quickly. The SC is variable during the transition so the system limits need to be carefully characterized, and the safety actions adapted to avoid critical damages to the stacks.

The fast transition allows a faster way to accommodate the production rate of the system and can be of interest for some applications where the load profile is not fully stable or in a scenario with variable current input such as in some renewable energy sources. On the other side, it is less smooth than the slow transition and could be the source of accelerating stacks' degradation.

4 Conclusions and discussions

This paper describes a Model in the Loop methodology to de-risk the implementation of new control strategies for a real SOEL system. A dynamic multi-physic model of the real system has been developed using Modelica language (supported by Dymola software). Then, this model has been exported as a FMU for being co-simulated in Simulink software where the control model was developed. This approach has been used to validate strategies of operating point transitions and corresponding results are discussed.

It is worth noting that this approach is sensitive to the level of implementation of the FMI standard of each software used. This is exemplified by its application to another SOEL system model, implemented in Modelica using another proprietary library and comprising more components. Even though the plant model run with its own control without errors in Dymola, trying to implement the same control in Simulink and applying it to the corresponding FMU of the Modelica plant model resulted in difficulties during simulation (extreme slowness and generally ending up with errors). Those difficulties have been observed and the identification of bottlenecks is non-trivial task. Future studies focused on model stability are considered.

Future objective for this model is Hardware in the Loop and/or Control Hardware in the Loop approach. Thus, many challenges can be addressed on the model such as fitting, adaptation and simplification to be compatible for real-time computer with a consistent representativeness. Concerning the control model, specific toolbox enabling a transfer of control developed in Simulink to real PLC can be tested. Moreover, in the present work, robust control has not been explored considering uncertainties in the model parameters. This aspect could be investigated to improve performance under such uncertainties.

Towards Integration of PeN-ODEs in a Modelica-based workflow

Andreas Hofmann[1] Lars Mikelsons[1]

[1]Chair of Mechatronics, University of Augsburg, Germany,
{andreas.hofmann,lars.mikelsons}@uni-augsburg.de

Abstract

Hybrid modeling – the combination of first-principle models and machine learning – offers the potential to increase model accuracy while reducing modeling effort. Although approaches for creating hybrid models from system simulation models exist, the unique characteristics of Modelica-based, object-oriented models – such as modularity and reusability – can, as of today, not be utilized. In this contribution, we explore approaches for bridging this gap to enable the use of hybrid models with Modelica. Key challenges of architecture definition, training environment and reintegration of the trained machine learning parts into a Modelica model are addressed. To illustrate our approach, we present a case study involving a SCARA robot. This example demonstrates a partially integrated workflow for hybrid modeling, intended to serve as a foundation and motivation for further research.

Keywords: hybrid modeling, PeN-ODE, SciML, NeuralFMU, Julia, machine learning

1 Introduction

1.1 Motivation

In recent years, data-driven models, i.e. machine learning (ML) models, and hybrid models, which combine first-principle modeling (FPM) and data-driven approaches, have gained wide attention in the field of system simulation. Data-driven models promise to eliminate efforts for traditional modeling tasks, while additionally increasing the fidelity of models based on real-world data. Alongside those benefits, however, data-driven models are limited by their high demand for data to approximate the underlying physics, their black-box nature, and limited extrapolation capabilities, thus restricting their application. While early architectures recurrently mapped states from a point in time to the next one, the more sophisticated approach of the NeuralODE paper (Chen et al. 2018), which gained a lot attention, confined data-driven models to the system dynamics and combined them with well-known numerical solvers.

Hybrid models, in contrast to their purely data-driven counterparts, try to incorporate ML-approaches into models that are built upon laws of physics and well-established empirical approaches. Since those models aim to only learn unmodelled physical effects, their data requirements are typically way more economic. Also, extrapolation capabilities and explainability of hybrid models are usually better compared to solely data-driven models due to the underlying FPM nature.

While the term NeuralODE is widely established in the field of data-driven approaches, various names and architectures for hybrid models abound, such as NeuralFMU (Thummerer, Kircher, and Mikelsons 2021), Universal Differential Equation (Rackauckas, Ma, et al. 2021), et cetera. Hence, since there is no common wording for hybrid models, their application, especially in industrial scope, is shortened. Therefore, a concise definition for hybrid models (for system simulation) has been developed in the the ITEA OpenSCALING project[1], based on earlier definitions by Thummerer and Mikelsons (2023), Thummerer, Kolesnikov, et al. (2023) and Kamp, Ultsch, and Brembeck (2023). The definition will be presented in the next section.

Modelica's object-oriented nature makes it especially well-suited for hybrid modeling, as it enables efficient reuse of models. On one hand, integrating machine learning models into component equations introduces a high degree of flexibility. This allows for modification of arbitrary mathematical relationships, like algebraic equations and state derivative expressions. Furthermore, a trained hybrid component can be reused across different modeling scenarios. For example, it is often advantageous to model an entire test rig, including both the device under test and the dynamic behavior of the testbed components. Using recorded data, a hybrid model of the device under test can be trained, subsequently extracted from the testbed model, and then embedded into a high-fidelity model of another system. This reusability helps justify the considerable effort involved in the training phase of hybrid modeling. On the other hand, object-oriented models retain information about algebraic relationships, which facilitates the direct integration of measurement data. As long as a relationship between the measured and augmented quantities exists, the model can be trained. This approach is particularly valuable when working with field data from systems in operation, where typically only a limited set of dedicated signals is available.

However, developing hybrid models from Modelica-based systems and reintegrating them into a Modelica-centered workflow presents several challenges. Key obstacles include the training process – typically performed

[1]project page: https://openscaling.org/

within machine learning frameworks developed in Python or Julia – and the integration of Neural Networks, which are among the most commonly used machine learning models, into the Modelica environment.

1.2 Outline

In the following section, a short overview of the PeN-ODE architecture and a further partitioning based on training strategies is provided. Following that, main challenges for building and training PeN-ODEs and utilizing those in a Modelica-based workflow are depicted. In the subsequent chapter, a workflow for PeN-ODEs is demonstrated, utilizing an object-oriented model of a Scara-Robot, however starting from the Julia programming language, avoiding the transfer of the model from a Modelica-based tool. Finally, the paper closes with an outlook on further developments and challenges.

2 Definition of PeN-ODE

As mentioned before, several methods for combining first principle models and machine learning have been available for many years. To make the concept of hybrid models accessible for wider industrial application, a common definition for hybrid models, or at least for the distinct class of system simulation, has been developed within the ITEA4 OpenSCALING project under the name PeN-ODE. Although this concise definition is limited to a model architecture, a further distinction, based on training strategies, can be made, which facilitates overall communication on required data, et cetera.

2.1 PeN-ODE Architecture

A PeN-ODE, short for Physics-enhanced Neural Ordinary Differential Equation, is an ODE[2] model that combines FPM and ML models, typically Neural Networks. As illustrated in Figure 1, no particular restrictions are imposed on the interaction between the FPM and ML subsystems, allowing maximum flexibility in tailoring the hybrid model to individual use cases.

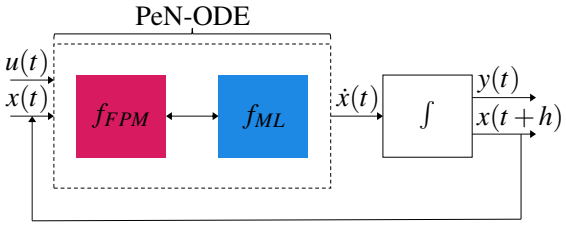

Figure 1. Architecture of a PeN-ODE with physical subsystem (f_{FPM}) and machine learning part (f_{ML}) within the solution process.
$x(t)$ - system states
$u(t)$ - inputs
$y(t)$ - outputs
h - solver step size

While this definition might seem arbitrary at first, it clearly differentiates the PeN-ODE from NeuralODEs and other data-driven approaches, where the complete dynamic of the system is represented using Neural Networks. Nonetheless, other common approaches for hybrid models are fully or partially incorporated: NeuralFMUs, the combination of Functional Mockup-Units and Neural Networks are a subset of the PeN-ODE, where the FPM is represented using the FMI standard. Universal Differential Equations (UDEs) describe a rich framework for ODEs, PDEs, SDEs, etc. and allow to build and train hybrid models but also models without any FPM (therefore similar to NeuralODEs). Also, training strategies such as Physics Informed Neural Networks are featured in the UDE framework. In this context, PeN-ODEs cover a dedicated subset of UDEs, focusing on the relevant parts for system simulation. There are far more approaches that fit into the PeN-ODE definition, though not necessarily from the field of technical system, such as Integrated Neural Network(Su et al. 1992) or methods without dedicated names (Quaghebeur, Nopens, and De Baets 2021), (Oliveira 2004). Sorourifar et al. (2023) also refer to their architecture as "Physics-Enhance Neural Ordinary Differential Equation", combining first-principle modelling and Neural Networks in chemical reaction systems.

Please note that in the PeN-ODE definition no training strategies, i.e. the training of the Neural Network, are explicitly defined. As a result, a pre-trained ML model augmenting an FPM is a valid PeN-ODE model.

2.2 Partitioning of PeN-ODE by training strategies

Although the PeN-ODE definition imposes no restrictions on the training process itself, different training strategies come with varying requirements for training data. Accordingly, alongside the definition of the PeN-ODE architecture, two distinct training strategies are delinated. It is important to note that, following successful training and integration, the specific training strategy used for the PeN-ODE becomes indistinguishable in the final model.

Closed-loop trained PeN-ODE

The first training strategy involves parameter optimization of the ML part by computing gradients through the solution of the ODE. Because this requires calculating gradients across the transient behavior of the system, aspects such as time and state events, as well as the numerical solution process itself, must be taken into account. For further details we refer to Thummerer, Olsson, et al. (2025), though focusing on NeuralFMUs.

In addition to the commonly used method of automatic differentiation, mathematical techniques, such as the Continuous Adjoint method or the Forward Sensitivity analysis for ODEs, have regained attention in recent years. The first approach performs the gradient calculation by tracing every operation on the discretized system, often referred to as "discretize-then-optimize". In contrast, the latter constructs an additional set of differential equations which are

[2]including DAEs and discretized PDEs

DOI 10.3384/ecp218435

solved alongside the original system. Since gradients are derived from the time-discrete solution values, it is often referred to as "optimize-then-discretize". A comprehensive review covering the details of gradient computation for ODEs can be found in (Sapienza et al. 2024).

The cost function of the optimization problem can aggregate any related quantity of the ODE system associated to the equations under consideration, i.e. alongside the states also algebraic quantities. Hence, considering the substantial effort for gradient computation, the constraints on available measurements from the (real-world) data are typically low. In Figure 2 the training strategy for closed-loop training is depicted.

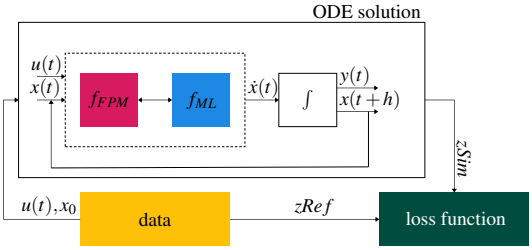

Figure 2. Closed-loop training procedure for loss calculation
$x(t)$ - system states
$u(t)$ - inputs
$y(t)$ - outputs
$zSim$ - relevant solution values from simulation
$zRef$ - reference solution values from data
x_0 - initial states
h - solver step size

Open-loop trained PeN-ODE

In contrast to the closed-loop training strategy, the open-loop procedure does not consider a transient cost function accumulating over the ODE solution. Instead, it uses state derivative quantities and algebraic variables to train the ML part based on the right-hand side (RHS) of the ODE, cf. Figure 3.

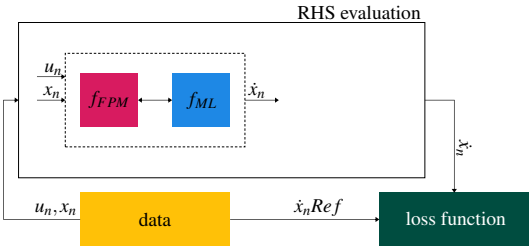

Figure 3. Open-loop training procedure for loss calculation, based on evaluation of the RHS of the ODE system
x_n - system states at time n
u_n - inputs at time n
$\dot{x}_n$ - state derivatives at time n
$\dot{x}_nRef$ - reference data at time n

As a result, the computational effort for gradient calculation is reduced and is typically handled via automatic differentiation. However, this approach places higher demands on the training data, as all relevant quantities must be explicitly available. Moreover, deviations during training on derivative level typically accumulate to increasing errors due to integration in the simulation of the trained PeN-ODE.

Although Figure 3 illustrates a joint evaluation, it is important to note that the machine learning component can also be trained independently. This corresponds to conventional data-driven approaches, as depicted in Figure 4.

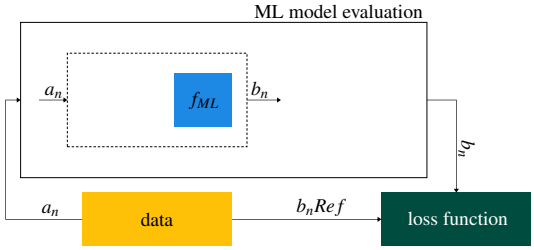

Figure 4. Open-loop training procedure for loss calculation, based on solely evaluating the ML model.
a_n - ML input at time n
b_n - ML output at time n
b_nRef - reference data at time n

3 Challenges for derivation and training of Modelica-based PeN-ODEs

As briefly mentioned in the introduction, utilizing PeN-ODEs in Modelica poses various challenges, which will be examined in more detail below. The primary challenges can be summarized as follows:

- **Training of the hybrid model:** Bridging the gap between Modelica-based modeling and common machine learning training frameworks, such as Julia
- **PeN-ODE architectures:** Limiting access to available signals and defining appropriate PeN-ODE architectures within the modular, object-oriented structure of Modelica.
- **Representation of hybrid architecture in Modelica:** Methods for incorporating trained ML components into Modelica models in a way that preserves their functionality and compatibility.

3.1 Training of the hybrid model

The first challenge in establishing an integrated workflow for PeN-ODEs in Modelica is bridging the gap to the ML training environment. Python and its extensive ecosystem of ML frameworks and libraries are indisputably the most common environment for machine learning tasks. Nevertheless, noting that many other suitable programming languages exist, we want to focus in the following passage on the Julia programming language. Julia offers a wide ecosystem for scientific machine learning (SciML) and does provide some initial approaches for bridging ML training environment and Modelica-based tools.

Tinnerholm et al. (2021) present a reimplementation of the OpenModelica compiler in Julia, called OM.jl, that can generate models for the Julia packages DifferentialEquations.jl (Rackauckas and Nie 2017), which provides methods for efficiently solving a wide range of differential equation problems, such as ODEs, DAEs, or SDEs. Additionally OM.jl can generate models for the Julia-specific environment for object-oriented modeling, ModelingToolkit.jl (Ma et al. 2021). In an additional step, similar to a Modelica compiler, ModelingToolkit symbolically processes the system to an executable set of differential-algebraic equations. Unfortunately, the corresponding Github-repositories (OM.jl, OMBackend.jl, ...) have not been maintained for years.

Similar to ModelingToolkit.jl, Modia (Elmqvist et al. 2021) offers capabilities of object-oriented modelling and simulation in Julia. Being strongly embedded into the Modelica community, the developers see Modia as an environment to test new algorithms and extensions towards further adaptions of Modelica. A translator has been developed by Otter, Elmqvist, et al. (2019), allowing to source-to-source translate a (subset) of the Modelica language to Modia. Unfortunately, the repository presented in their paper is no longer available. Bruder and Mikelsons (2021) utilized Modia to build an equation-based, hybrid non-linear single track model. However, like OM.jl, Modia is still based on an older version of Julia, released in Nov. 2021.

The Base Modelica initiative (Kurzbach et al. 2023) provides another approach for translating arbitrary, though only flattened, Modelica models to Julia. A dedicated package in the Julia SciML ecosystem exists, named BaseModelica.jl[3] , promising to parse and convert the Base Modelica model to the previously mentioned object-oriented modeling environment ModelingToolkit.jl. Please note that the initial Modelica change proposal for Base Modelica is currently in development. Once available, the pipeline could be an auspicious way of translating Modelica models to suitable simulation models for hybrid training in Julia. However, as of today, it remains unclear whether ModelingToolkit.jl is capable of supporting all relevant features of Modelica. Furthermore, in our experience, many Modelica models require specific numerical algorithms, which could cause further challenges.

Looking at the eFMI standard (Lenord et al. 2021), a representation reminiscent to the Algorithm Code, however without implemented solver arithmetic, could pose as a valid mutual baseline, for code generation to various languages and tools. From a Modelica compiler perspective, this would represent the hybrid[4] DAE system after the symbolic transformation. In contrast to Base Modelica, this representation would not require any additional transformation process. However, numerical challenges, as mentioned before, would still not be resolved by this intermediate representation.

Utilizing Julias' SciML ecosystem, while using the Functional Mockup Interface instead of Modelica directly, is possible through the packages FMIFlux.jl[5] and FMI.jl[6], which build the foundation of NeuralFMUs. FMI.jl allows to load and simulate FMUs in Julia, while FMIFlux.jl manages the gradient calculation through the FMU model. However, since all object-oriented information from a Modelica model is removed during FMU generation, it is not feasible to unroll the ML model of the trained NeuralFMU back to the object-oriented components.

Although we focused this section on model transfer from Modelica to Julia, the Enzyme project offers a solution to calculate the relevant gradients directly on LLVM level, see (Moses and Churavy 2020). LLVM supports a wide range of languages, however, changes to existing Modelica-based tools, that we cannot evaluate, might be needed. Furthermore, dedicated training frameworks, possibilities to define ML models, etc., within the Modelica tools would still be missing.

3.2 PeN-ODE architectures

Many hybrid model architectures, such as the NeuralFMU with its FMU foundation, grant access to the complete set of states, state derivatives, and algebraic quantities of the FPM. Consequently, hybrid models using arbitrary FPM signals in the ML model can be derived. Therefore, NeuralFMUs can be reused within other simulation models as a single component. However, separating the ML part from the physical model and re-introducing it in the original model and, therefore, also reusing partial models is not feasible. From an object-oriented modeling perspective, the use of arbitrary model quantities contradicts the paradigm of knowledge encapsulation, see (Cellier 1996). Consequently, the ML part of a hybrid component in an object-oriented model can only be supplied with internal quantities or existing interfaces of the model or additional signals must explicitly be exposed through model adaptions. Since encapsulation of knowledge enables the composition of hierarchical models, relying solely on available quantities renders reusing trained individual components possible.

As already stated in the PeN-ODE definition, arbitrary architectures for interaction between the FPM and ML part are applicable. Furthermore, ML models are adapted during their training phase and often optimized via hyperparameter optimization. Therefore, it is useful to only define the minimum necessary architectural parts, typically input and output features, within Modelica and shift all other architecture considerations to the ML side, where their optimization can take place. However, a Modelica compiler needs to know the relations of quantities to perform the symbolic transformation. The Modelica lan-

[3] https://github.com/SciML/BaseModelica.jl

[4] in this very case of this paper hybrid refers to continuous-discrete rather than to combination of FPM and ML

[5] https://github.com/ThummeTo/FMIFlux.jl

[6] https://github.com/ThummeTo/FMI.jl

DOI 10.3384/ecp218435

guage specification (Modelica Association 2023) provides the constructs of function inlining, which enables a placeholder functionality sufficient for the previously described considerations. Still, different types of augmenting the FPM equations exist.

The easiest way for setting up a hybrid architecture by place holder in a Modelica models is parallel execution on equation level, see Listing 1. Missing information in the equation is compensated by adding the function *fun_1*, which will later be replaced by some ML architecture. Only relevant inputs and outputs are provided in the Modelica model. Through the annotation "Inline=false" the function is not symbolically processed in the compiler and can be replaced during code generation.

Listing 1. parallel architecture on equation level

```
model SimpleParallelArchitecture
    function fun_1 "dummy function"
        input Real b, c, d;
        output Real dx;

    algorithm
        dx = b*c+d; // some operations that
        // will be replaced
    annotation(Inline=false);
    end fun_1;

    Real x "state variable";
    Real a,b,c,d;
    ...

equation
    ...
    // adding missing parts of the equation
    // by a Neural Network
    der(x) = a * x +  fun_1(b,c,d);
    ...
end SimpleParallelArchitecture;
```

The parallel architecture offers a coherent augmentation of a physical equation. However, to enable arbitrary architectures on ML side, further adaptions to existing model equations are required. This is done by splitting the relation of interest into two parts, as shown in Listing 2.

Listing 2. universal architecture on equation level

```
model UniversalArchitecture
    Real a "some algebraic qoi";
    Real a_fpm "the known relation of the
        qoi";
    Real b,c,d,x; // some additional
        variables
    ...
equation
    ...
    // a = b*x; // original equation
    a_fpm = b*x;
    a = fun_2(a_fpm, c,d);
    a = sin(time);
end UniversalArchitecture;
```

A detailed discussion on combination of FPM and ML, though in the context of NeuralFMUs, can be found in (Thummerer and Mikelsons 2025).

The relation between the algebraic variable a and the quantities b and x in Listing 2 shall be enhanced by some data-driven approach. Therefore, the first principle knowledge is rearranged into a new variable *a_fpm*. The original equation is replaced by the place holder function *fun_2*, that utilizes the existing knowledge of *a_fpm* and further employs the information from variables c and d. On ML side arbitrary combinations for interaction of the variables are possible, including the parallel architecture described before. Since the augmentation takes place on equation level rather than variable level, non-linear systems can arise from the function inline annotation during the symbolic transformation of the model. This is depicted in Listing 2 by explicitly providing a value to variable a, since time is the independent variable of a Modelica model. Solving the nonlinear system introduces additional evaluations during simulation. This is necessary because the placeholders used at this stage do not yet contain the actual relationships, which are only incorporated at a later point in the workflow. Obviously, on the machine learning side, the training framework must be capable of solving the nonlinear system and computing the corresponding gradients. To our current understanding, there are no further limitations imposed by Modelica itself, since the language specification has a rich extensiveness, like providing derivative annotations for the place holder function, et cetera.

If the architecture of the ML model is known before training, an implementation in Modelica could be possible. Some approaches will be discussed in the next section. However, since all equations from the ML model are processed by a Modelica compiler, additional effort is added to the symbolic transformation. Furthermore, the benefit of the symbolic representation of the ML model within Modelica remains unclear.

With experience, at least with ModelingToolkit.jl, we would recommend to only define the minimum required interfaces in Modelica and process all other parts in the ML environment. Having trainable parameters available as arrays, contrary to current Modelica compiler implementations, provides a convenient workflow in combination with hyperparameter optimization.

3.3 Representation of hybrid architecture in Modelica

As stated before, the final ML model is typically derived throughout the training in a hyperparameter optimization. Once the final structure has been established, the ML model and parameters must be reintegrated to the Modelica environment. Since Neural Network are today's dominating approach, we will limit approaches to this ML model type.

The most naive approach is implementing the corresponding tensor operations directly as a Modelica model, since the Modelica language provides features for multidimensional arrays. However, this is typically limited to simple architectures such as multilayer perceptions

(MLPs). A more sophisticated approach, while keeping Modelica language features, is provided in the NeuralNetwork Library[7] developed at Hochschule Bielefeld , that allows to automatically generate a model from Tensorflow. However, since array equations are, as of today, scalarized throughout the model transformation in a Modelica compiler, large Neural Networks might cause high compilation times or even overstrain available computer memory. Certainly, algorithms for keeping array structures throughout the symbolic pipeline of a Modelica compiler have been developed and will mitigate those issues, e.g. (Abdelhak, Casella, and Bachmann 2023), (Otter and Elmqvist 2017), (Fioravanti et al. 2023). Nonetheless, as stated before, the benefit of symbolic neural network representation in a Modelica model remains unclear.

Alternatively, standardized formats for exchanging deep learning models among tools, such as the Open Neural Network Exchange (ONNX) or the Neural Network Exchange Format (NNEF), could be utilized, for example the SmartInt Library[8] , which provides ONNX support using Modelica's "external C" feature. Therefore, Neural Networks with high number of parameters are be applicable, without any impact on a Modelica compiler.

3.4 Summary on Findings

There exist a wide range of different solution approaches which, in combination, help to prepare, create, and implement PeN-ODEs in Modelica. Modelica language features can be used to define interfaces in a convenient way and libraries and tools are available to embed ML models in Modelica. Nonetheless, the transfer of the (processed) Modelica model to a training environment such as Julia, poses an unsolved challenge. Once Base Modelica, is available, its application with ModelingToolkit.jl should be further investigated. Having a new implementation, positioned between Base Modelica (flattened) and the Algorithm Code from eFMI (including solver arithmetic) could pose a useful new representation, also for other applications. Further experiments with Modia or OM.jl might enable a first integrated workflow bridging the gap between Modelica and Julia, at the cost of limitations from the machine learning environment, due to their dependency on an old version of the Julia language.

We are confident, once PeN-ODEs have proven their usefulness, even against the current issues, a joint solution for bridging the gap can be achieved, suitable for users and tool vendors at the same time.

4 Scara-Robot Example

Based on the previously described solution approaches for integration PeN-ODEs in a Modelica workflow, we implemented an example application featuring a SCARA robot. However, since there exists no up-to-date solution for bridging the gap from Modelica to Julia while preserving the object-oriented structure of the model, we bypass this step in that we start from an object-oriented model within ModelingToolkit.jl. We hope that this example will encourage people to approach the findings from the previous chapter and to apply the idea of Modelica-based PeN-ODEs.

4.1 Overview on the SCARA Robot Example

The example is a modification of the NeuralFMU workshop (Thummerer and Mikelsons 2024) adapted for object-oriented application. A SCARA robot is used to write text on a sheet of paper by actuating its two revolute joints. A marker pen is mounted at the end effector, which can be pressed against the paper for writing or lifted for non-writing movements. The joints are actuated by DC motors and controlled using simple proportional controllers. An inverse kinematics model converts tabular end-effector position data – linearly interpolated between setpoints – into the corresponding joint angles.

The SCARA robot is modeled as 2D mechanical system and the writing process is modeled by applying a defined normal force, rather than implementing actual pen movement and collision considerations. Most importantly, no friction between the paper and the pen is model, but is supposed to be learned within the PeN-ODE. An equivalent Modelica model is illustrated in Figure 5. As reference data, simulation results from the robot containing Stribeck friction between end effector and paper, writing the words "train" and "validate" are available. To render a realistic scenario, we will only use motor currents as the available measurement outputs, since those signals are commonly available quantities and most importantly contain the friction force resp. acceleration information.

4.2 Model generation

As already mentioned at the beginning of this section, we employ ModelingToolkit.jl, to actually start from an object-oriented simulation model of the SCARA robot. Apart from own model implementations, models from the Modeling Toolkit Standard Library[9] were employed. Utilizing the Modelica PlanarMechanics library (Zimmer 2012) as a blueprint, necessary components for the mechanical system were implemented in ModelingToolkit.jl. All files reproducing the example can be found in the corresponding github repository[10]

As proposed previously, we insert a place holder function in the end effector model and consider only the known quantities within the component, i.e. end effector velocity in x- and y-direction and the normal force to the paper plane, to allow for the reuse of the trained subsystem, see Listing 3. Please note that "$\sim$" is used as the equality sign in ModelingToolkit.jl and the Modelica "der()"-operator corresponds to the "D()"-operator in the listing. NN_dummy refers to the place holder function that will be replaced after code generation. Its implementation is

similar to the previously mentioned workflow with annotation "Inline=false" from the Modelica specification.

ModelingToolkit.jl does generate an ODE system for models that can be represented by a structure incidence matrix with lower triangular form after transformation and a DAE system in mass matrix form otherwise. For the SCARA robot model a DAE system is generated, whose code is further adapted by us. The mass matrix, parameter information, and modified right-hand side functions are exported to a new Julia file, that will later be used within our training pipeline.

4.3 ML model and PeN-ODE training

For learning the friction forces from the applied normal force and the velocities at the end effector, a Neural Network is employed as ML model. It is built using an MLP with three hidden layers, 32 neurons and tanh as the activation function. To scale input features (velocity in x- and y-direction, normal force onto the paper) as well as the output features (friction forces in x- and y-direction), a layer adding z-score standardization resp. another layer providing inverse transformation for the output features are added. However, those layers do not contain fixed values for means and standard deviations but are rather trainable parameters as well. As a last measure, a trainable gate, initialized with start value of zero is added. This guarantees that the randomly initialized network does provide stable output during the first training steps. The complete architecture is depicted in Figure 6.

The model is trained using a single trajectory, with the word "train" written by the SCARA robot, cf. Figure 7

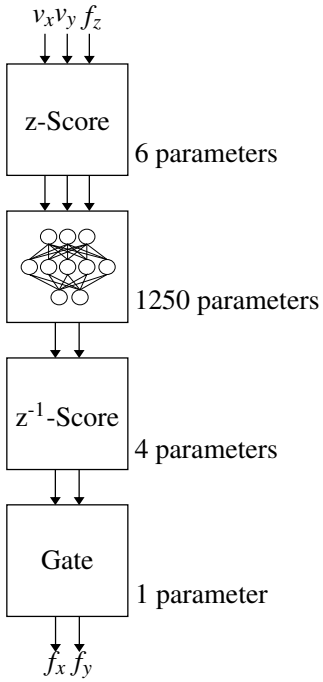

Figure 6. Employed ML model for the SCARA robot and the individual number of trainable parameters for the individual parts

Currently, only single-step solvers can be employed for the hybrid DAE of the SCARA during gradient calculation[11]. Therefore, we use Rodas5P, a fifth order Rosenbrock method from within DifferentialEquations.jl, as numerical method.

The trajectory is split into samples of 50 ms length and gradients are calculated over the solution of randomly selected single samples. The sampling is done for various reasons. On the one side, it helps to increase training speed, since gradients over a short elapsed time can be calculated faster and have lower requirements for computer hardware. Additionally, using stochastic examples helps to better progress in the beginning of the optimization, while calculating only gradients for a few examples, cf. (Goodfellow, Bengio, and Courville 2016). On the other side, since the calculated gradients combine all deviations across the simulated period, shorter time spans support capturing highly dynamic details. The Adam optimizer (Kingma and Ba 2015) with default settings was used for updating parameters. For loss accumulating Mean Absolute Error (MAE) aggregation was chosen, considering motor currents as quantities as available signals, as stated above. As algorithm for deriving the gradients of the DAE ReverseDiffAdjoint from the package SciMLSensitivity.jl (Rackauckas, Ma, et al. 2021) was selected.

The system was trained for 5000 steps on a laptop with i7-11850H CPU, 32 GB RAM and Win11 as OS, which took about two hours. Details on the used Julia packages can be found in the corresponding GitHub repository.

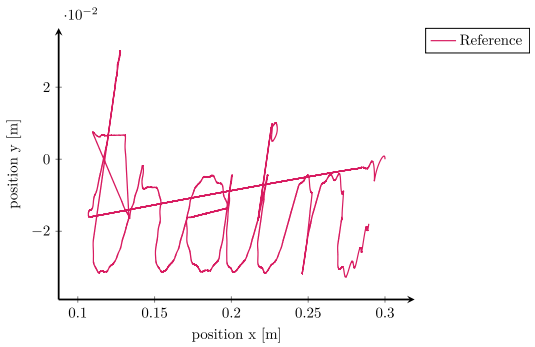

Figure 7. Training trajectory (end effector) for the SCARA robot (without distinguishing actually applied forces for writing)

4.4 Training results

Please note that no extensive effort, e.g. through hyperparameter analysis, was spent on the model. The results are purely derived to motivate and validate a PeN-ODE workflow, rather than to provide the best possible model outcome. Nonetheless, to anticipate some results of the trained model, the MAE for the combined model states is reduced by a factor greater than 4, while the Mean Squared Error (MSE) is reduced by a factor larger than 11, each for the chosen test trajectory.

As test data for the SCARA robot application, the word "validate" has been selected. In Figure 8, the model with and without training are compared to the reference data for the end effector position. The further the SCARA arms is extended, the more impact from friction is visible. The common error metrics MAE and MSE show a significant reduction in deviations. An overview for the aggregated model and individual states is collected in Table 1.

Table 1. Error metrics of the trained PeN-ODE compared to the original model (in brackets) for the test data trajectory.

state	MAE	MSE
complete model	7.76e-03	4.47e-04
$[-]$	(3.61e-02)	(5.19e-03)
$motor1.\varphi$	1.69e-04	1.17e-07
$[rad]$	(1.26e-03)	(2.87e-06)
$motor1.i$	1.40e-02	1.04e-03
$[A]$	(9.39e-02)	(1.61e-02)
$motor1.\omega$	5.59e-03	2.34e-04
$[rad/s]$	(1.62e-02)	(1.27e-03)
$motor2.\varphi$	3.40e-04	3.92e-07
$[rad]$	(1.67e-03)	(5.31e-06)
$motor2.i$	1.63e-02	9.58e-04
$[A]$	(7.60e-02)	(1.11e-02)
$motor2.\omega$	1.01e-02	4.55e-04
$[rad/s]$	(2.76e-02)	(2.70e-03)

A more detailed insight on the expressiveness of the PeN-ODE can be gained from the plots of the motor currents, see Figure 9 and Figure 10, as well as from the applied friction forces in the model, cf. Figure 11 and Figure 12. The model still holds some limitation w.r.t. force in x-direction, probably limited by the scalar gate. Furthermore, the friction forces during the start of the simulation, although no normal force is present, would require some further investigation on the training. Also, no further study on the impact of partly implementing physical effects, such as explicitly providing Coloumb friction, was conducted. This remains to be investigated in detail in the future. Yet, a first study on partially modelling friction, based on NeuralFMUs, was executed by Thummerer, Kolesnikov, et al. (2023).

From an object-oriented modeling perspective, the machine learning component can be seamlessly reintegrated into the end effector by replacing the placeholder function with the actual implementation containing the trained parameters. As previously noted, keeping these parameters independent of the compiler contributes to maintaining fast compilation times. Since only internal variables and inputs of the end effector component were utilized within the hybrid architecture, the component remains fully reusable in other applications – such as robots with different mechanical structures – without requiring further modifications.

[11] this is due to the discontinuous setpoint data and a bug during initialization of the DAE

5 Summary and Outlook

Although Modelica and the corresponding tools are natively incompatible with ML training environments such as the Julia programming language, many solution approaches for bridging the gap towards creating, training and applying of PeN-ODEs exist. Once a model is made available in Julia, all necessary steps can be applied, which was shown for the SCARA robot.

From the interfacing point of view, having an intermediate representation of the derived DAE system from a Modelica compiler, reminiscent of Base Modelica, would allow a universal starting point for arbitrary ML environments in Julia, Python or other languages but also for other applications. Furthermore, Base Modelica, once available, could offer a convenient way from Modelica to Julia, though it needs to be investigated if ModelingToolkit.jl is capable of supporting all relevant Modelica language features. Nonetheless, also tool vendor-specific implementations of Modelica compilers and simulation capabilities and particularities of their individual simulation runtimes might still pose challenges.

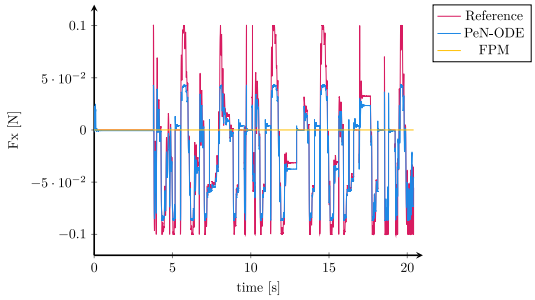

Figure 11. Comparison of friction force in x-direction

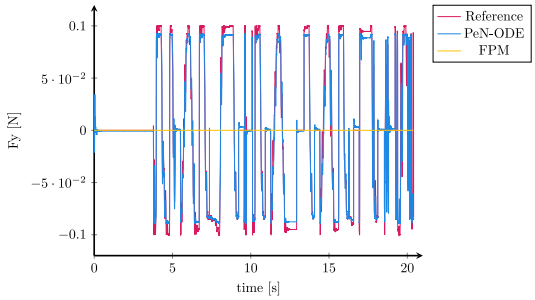

Figure 12. Comparison of friction force in y-direction

Apart from interfacing, new challenges, such as appropriate training strategies and best suitable ML models arise. While the example model was trained on a random selection of data samples, more sophisticated approaches such as dedicated scheduling algorithms for picking worst elements from the training set or different strategies, such as multiple shooting, growing horizon, et cetera, might accelerate and improve training.

In particular, the aspects of reusability of PeN-ODE components can facilitate the object-oriented approach from methods such as NeuralFMU, which in contrast does benefit from tool independence and bypasses the interfacing issues. A Modelica-based approach would allow to easily compose hierarchical systems of high fidelity PeN-ODEs.

Furthermore, the appropriate ratio of embedded physically-based white box models, such as known parts of friction, is an open research question for all hybrid models. Further studies are required to provide some indication, especially based on real-world problems.

Efficient Training of Physics-enhanced Neural ODEs via Direct Collocation and Nonlinear Programming

Linus Langenkamp [1] Philip Hannebohm [1] Bernhard Bachmann [1]

[1]Institute for Data Science Solutions, Bielefeld University of Applied Sciences and Arts, Germany,
{first.last}@hsbi.de

Abstract

We propose a novel approach for training Physics-enhanced Neural ODEs (PeN-ODEs) by expressing the training process as a dynamic optimization problem. The full model, including neural components, is discretized using a high-order implicit Runge-Kutta method with flipped Legendre-Gauss-Radau points, resulting in a large-scale nonlinear program (NLP) efficiently solved by state-of-the-art NLP solvers such as Ipopt. This formulation enables simultaneous optimization of network parameters and state trajectories, addressing key limitations of ODE solver-based training in terms of stability, runtime, and accuracy. Extending on a recent direct collocation-based method for Neural ODEs, we generalize to PeN-ODEs, incorporate physical constraints, and present a custom, parallelized, open-source implementation. Benchmarks on a Quarter Vehicle Model and a Van-der-Pol oscillator demonstrate superior accuracy, speed, generalization with smaller networks compared to other training techniques. We also outline a planned integration into OpenModelica to enable accessible training of Neural DAEs.

Keywords: Physics-enhanced Neural ODEs, Dynamic Optimization, Nonlinear Programming, Modelica, Neural ODEs, Universal Differential Equations

1 Introduction

Growing access to real-world data and advances in computational modeling have opened new possibilities for combining measured data with physics-based models. Neural Ordinary Differential Equations (NODEs) (Chen et al. 2018) represent a significant advancement in merging data-driven machine learning with physics-based modeling. By replacing the dynamics of an ODE with a neural network

$$\dot{\boldsymbol{x}}(t) = NN_{\boldsymbol{p}}(\boldsymbol{x}(t), \boldsymbol{u}(t), t), \tag{1}$$

where $\boldsymbol{x}(t)$ are states, $\boldsymbol{u}(t)$ is a fixed input vector, and $\boldsymbol{p}$ are the neural network parameters, NODEs bridge the gap between traditional differential equations and modern deep learning. After obtaining a NODE and given an initial condition $\boldsymbol{x}(t_0) = \boldsymbol{x}_0$, the state trajectory is reconstructed by simulation with an arbitrary ODE solver

$$\boldsymbol{x}(t) := \text{ODESolve}\left(NN_{\boldsymbol{p}}(\boldsymbol{x}(t), \boldsymbol{u}(t), t), \boldsymbol{x}_0\right). \tag{2}$$

However, learning the full dynamics can be unstable, requires a lot of data, and can suffer from poor extrapolation (Kamp, Ultsch, and Brembeck 2023). As a result, hybrid modeling is an emerging field that combines the flexibility of neural networks with known physics and first principle models. Extensions like Universal Differential Equations (UDEs) (Rackauckas et al. 2020) or Physics-enhanced Neural ODEs (PeN-ODEs) (Kamp, Ultsch, and Brembeck 2023; Sorourifar et al. 2023) generalize this paradigm, allowing domain-specific knowledge to be incorporated into the model while still learning observable but unresolved effects. These approaches have demonstrated great success in various fields, including vehicle dynamics (Bruder and Mikelsons 2021; Thummerer, Stoljar, and Mikelsons 2022), chemistry (Thebelt et al. 2022), climate modeling (Ramadhan et al. 2023), and process optimization (Misener and L. Biegler 2023).

Training neural components typically involves simulating (2) for some initial parameters $\boldsymbol{p}$ and then propagating sensitivities of the ODE solver backward in each iteration. Afterward, the parameters are updated via gradient descent. This process is computationally expensive and results in long training times (Lehtimäki, Paunonen, and Linne 2024; Roesch, Rackauckas, and Stumpf 2021; Shapovalova and Tsay 2025), as explicit integrators are low-order and unstable, requiring small step sizes, while stable, implicit integrators involve solving nonlinear systems at each step, thus being computationally demanding.

To address these enormous training times several alternative procedures have been proposed: in (Roesch, Rackauckas, and Stumpf 2021) a collocation technique is introduced, which approximates the right hand side (RHS) of an ODE from data. The NN is then trained on the approximations with standard training frameworks. Further, in (Lehtimäki, Paunonen, and Linne 2024) model order reduction is used to accurately simulate the dynamics in low-dimensional subspaces. Very recent work presented in (Shapovalova and Tsay 2025) introduced global direct collocation with Chebyshev nodes, a method originating from dynamic optimization for optimal control and parameter optimization, for training Neural ODEs. The approach reduces the continuous training problem to a large finite dimensional nonlinear program (NLP) and shows fast and stable convergence, demonstrated on a typical problem, the Van-der-Pol oscillator.

In Modelica-based workflows, the training of Neural ODEs is typically performed externally by exporting a Functional Mock-Up Unit (FMU), subsequently training it in Python or Julia using standard machine learning frameworks and ODE solvers, and finally re-importing the hybrid model. While this approach introduces external dependencies and additional transformation steps, the *NeuralFMU* workflow (Thummerer, Stoljar, and Mikelsons 2022) demonstrates a practical method for integrating hybrid models into real-world applications.

Building on recent advances in direct collocation-based training of Neural ODEs (Shapovalova and Tsay 2025), we significantly extend the approach to PeN-ODEs. We formulate the training process as a dynamic optimization problem and discretize both neural and physical components using a stable, high-order implicit collocation scheme at flipped Legendre-Gauss-Radau (fLGR) points. This results in a large but structured NLP, allowing efficient, simultaneous optimization of states and parameters. Our custom, parallelized implementation leverages second-order information and the open-source NLP solver Ipopt (Wächter and L. T. Biegler 2006). It is designed for a future integration into the open-source modeling and simulation environment OpenModelica (Fritzson, Pop, Abdelhak, et al. 2020), thus providing an accessible training environment independent of external tools.

2 Dynamic Optimization for NODEs

In this section, we introduce a general class of dynamic optimization problems (DOPs) and formulate training for both NODEs and PeN-ODEs as instances of this class. We then discuss the transcription of the continuous problem into a large-scale nonlinear optimization problem (NLP). Finally, necessary considerations and key challenges are presented.

2.1 Generic Problem Formulation

Consider the DOP

$$\min_{\boldsymbol{p}} M(\boldsymbol{x}(t_0),\boldsymbol{x}(t_f),\boldsymbol{p}) + \int_{t_0}^{t_f} L(\boldsymbol{x}(t),\boldsymbol{p},t)\,\mathrm{d}t \tag{3a}$$

s.t.

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x}(t),\boldsymbol{p},t) \qquad \forall t \in T \tag{3b}$$

$$\boldsymbol{g}^L \le \boldsymbol{g}(\boldsymbol{x}(t),\boldsymbol{p},t) \le \boldsymbol{g}^U \qquad \forall t \in T \tag{3c}$$

$$\boldsymbol{r}^L \le \boldsymbol{r}(\boldsymbol{x}(t_0),\boldsymbol{x}(t_f),\boldsymbol{p}) \le \boldsymbol{r}^U \tag{3d}$$

for a fixed time horizon $T = [t_0, t_f]$ with time variable $t \in T$. The states of the system are given by $\boldsymbol{x} : T \to \mathbb{R}^{d_x}$ and the goal is to find optimal time-invariant parameters $\boldsymbol{p} \in \mathbb{R}^{d_p}$, such that the objective (3a) becomes minimal and the constraints (3b)–(3d) are satisfied. These constraints are divided into the ODE (3b) and *path constraints* (3c), which both must be satisfied at all times on time horizon T, as well as *boundary constraints* (3d), which must only hold at the initial and final time points t_0, t_f. The objective is composed of a *Mayer* term M, that defines a cost at the boundary of T, and a *Lagrange* term L, that penalizes an accumulated cost over the entire time horizon. To ensure compatibility with typical nonlinear optimizers, all model functions must be twice continuously differentiable. This includes neural networks, their activation functions, and error measures. For completeness, the bounds of the constraints are given as $\boldsymbol{g}^L, \boldsymbol{g}^U \in (\mathbb{R} \cup \{-\infty, \infty\})^{d_g}$ and $\boldsymbol{r}^L, \boldsymbol{r}^U \in (\mathbb{R} \cup \{-\infty, \infty\})^{d_r}$.

2.2 Reformulation of PeN-ODE Training

PeN-ODEs embed one or more NNs with parameters $\boldsymbol{p}$ into known, possibly equation-based, dynamics $\dot{\boldsymbol{x}}(t) = \hat{\boldsymbol{\phi}}(\boldsymbol{x},\boldsymbol{u},t)$. The resulting differential equation has the form

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{\phi}(\boldsymbol{x},\boldsymbol{u},t,NN_{\boldsymbol{p}}(\boldsymbol{x},\boldsymbol{u},t)), \tag{4}$$

where $\boldsymbol{u} : T \to \mathbb{R}^{d_u}$ is a fixed input vector and $NN_{\boldsymbol{p}}$ are enhancing NNs. This formalism aims to enhance systems that already express dynamics based on first principles, by further incorporating data-driven observables in form of neural components. Clearly, these components need not be NNs in general, and can be any parameter dependent expression. With additional information about the problem, one could use a polynomial, rational function, sum of radial basis functions or Fourier series.

The subsequent considerations also apply to the training of NODEs, where the goal is to learn the full dynamics without relying on a first principle model. This is evident from the fact that NODEs are a subclass of PeN-ODEs with

$$\dot{\boldsymbol{x}}(t) = NN_{\boldsymbol{p}}(\boldsymbol{x},\boldsymbol{u},t) = \boldsymbol{\phi}(\boldsymbol{x},\boldsymbol{u},t,NN_{\boldsymbol{p}}(\boldsymbol{x},\boldsymbol{u},t)). \tag{5}$$

In this paper, we propose a formulation for training PeN-ODEs as a DOP (3a)–(3d), using known data trajectories $\hat{\boldsymbol{q}}$ and the corresponding predicted quantity $\boldsymbol{q}$. The DOP takes the form

$$\min_{\boldsymbol{p}} \int_{t_0}^{t_f} E\left(\boldsymbol{q}(\boldsymbol{x},\boldsymbol{u},t,NN_{\boldsymbol{p}}(\boldsymbol{x},\boldsymbol{u},t)),\hat{\boldsymbol{q}}(t)\right)\,\mathrm{d}t \tag{6a}$$

s.t.

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{\phi}(\boldsymbol{x},\boldsymbol{u},t,NN_{\boldsymbol{p}}(\boldsymbol{x},\boldsymbol{u},t)) \quad \forall t \in T \tag{6b}$$

for some smooth error measure E, e.g. the squared 2-norm $E(\boldsymbol{q},\hat{\boldsymbol{q}}) = \|\boldsymbol{q} - \hat{\boldsymbol{q}}\|_2^2$. This formulation represents the minimal setup.

By further incorporating the generic constraints (3c) and (3d), it is possible to impose an initial or final condition on the states as well as enforce desired behavior. For example, consider a NN approximation of a force element NN_F, with no force acting in its resting position. Therefore, the NN should have a zero crossing, i.e. $NN_F(0) = 0$. This can be trivially formulated as a constraint, without introducing a penalty term that may distort the optimization as in standard unconstrained approaches like (Kamp,

DOI 10.3384/ecp218445

Ultsch, and Brembeck 2023). Thus, the optimizer can handle the constraint appropriately.

As the loss in (6a) is a continuous-time integral, it enables an accurate and stable approximation using the same discretization employed for the system dynamics. In contrast to MSE loss as in (Shapovalova and Tsay 2025), which effectively corresponds to a first-order approximation of the integral, our formulation benefits from high-order quadrature, potentially preserving the accuracy of the underlying discretization.

2.3 Transcription with Direct Collocation

In the following, the general DOP (3a)–(3d) is reduced to a NLP using orthogonal direct collocation. Direct collocation approaches have proven to be highly efficient in solving DOPs and are implemented in a variety of free and commercial tools, such as PSOPT (Becerra 2010), CasADi (Andersson et al. 2019) or GPOPS-II (Patterson and A. V. Rao 2014), as well as in Modelica-based environments like OpenModelica (Ruge et al. 2014) or JModelica (Magnusson and Åkesson 2015). While OpenModelica only supports optimal control problems, the other frameworks allow for simultaneous optimization of static parameters. Recent work in the field of NODEs (Shapovalova and Tsay 2025) shows that learning the right hand side of small differential equations can be performed stably and efficiently using global collocation with Chebyshev nodes.

In direct collocation the states are approximated by piecewise polynomials, that satisfy the differential equation at so-called *collocation nodes*, usually chosen as roots of certain orthogonal polynomials. If the problem is smooth and with increasing number of collocation nodes, these methods achieve *spectral*, i.e. exponential, convergence to the exact solution. In this paper, the collocation nodes are chosen as the *flipped Legendre-Gauss-Radau points (fLGR)* rescaled from $[-1,1]$ to $[0,1]$. This rescaling is performed, so that the corresponding collocation method is equivalent to the Radau IIA Runge-Kutta method. Radau IIA has excellent properties, since it is A-, B- and L-stable and achieves order $2m-1$ for m stages or collocation nodes. These nodes c_j for $j = 1,\dots,m$ are given as the m roots of the polynomial $(1-t)P^{(1,0)}_{m-1}(2t-1)$, where $P^{(1,0)}_{m-1}$ is the $(m-1)$-th Jacobi polynomial with $\alpha = 1$ and $\beta = 0$. A detailed explanation of the method's construction based on quadrature rules is given in (Langenkamp 2024).

First, we divide the time horizon $[t_0, t_f]$ into $n+1$ intervals $[t_i, t_{i+1}]$ for $i = 0,\dots,n$ with length $\Delta t_i := t_{i+1} - t_i$. In each interval $[t_i, t_{i+1}]$ the collocation nodes $t_{ij} := t_i + c_j \Delta t_i$ for $j = 1,\dots,m_i$ as well as the first grid point $t_{i0} := t_i + c_j \Delta t_i$ with $c_0 = 0$ are added. Since the last node $c_{m_i} = 1$ is contained in any Radau IIA scheme, the last grid point of interval $i-1$ exactly matches the first grid point of interval i, i.e. $t_{i-1,m_{i-1}} = t_{i0}$. Furthermore, the states are approximated as $\boldsymbol{x}(t_{ij}) \approx \boldsymbol{x}_{ij}$ and for each interval i replaced by a Lagrange interpolating polynomial $\boldsymbol{x}_i(t) = \sum_{j=0}^{m_i} \boldsymbol{x}_{ij}\, l_j(t)$ of degree m_i, where

$$l_j(t) := \prod_{\substack{k=0 \\ k\neq j}}^{m_i} \frac{t - t_{ik}}{t_{ij} - t_{ik}} \quad \forall j = 0,\dots,m_i \tag{7}$$

are the Lagrange basis polynomials. Note that the parameters $\boldsymbol{p}$ are time-invariant and thus, need not be discretized. Each $\boldsymbol{x}_i$ must satisfy the differential equation (3b) at the collocation nodes t_{ij} and also match the initial condition $\boldsymbol{x}_{i0}$, which is given from the previous interval $i-1$. By differentiating we get the collocated dynamics

$$\mathbf{0} = \begin{bmatrix} D^{(1)}_{10} I & \dots & D^{(1)}_{1m_i} I \\ \vdots & \ddots & \vdots \\ D^{(1)}_{m_i 0} I & \dots & D^{(1)}_{m_i m_i} I \end{bmatrix} \begin{bmatrix} \boldsymbol{x}_{i0} \\ \vdots \\ \boldsymbol{x}_{im_i} \end{bmatrix} - \Delta t_i \begin{bmatrix} \boldsymbol{f}_{i1} \\ \vdots \\ \boldsymbol{f}_{im_i} \end{bmatrix} \tag{8}$$

with identity matrix $I \in \mathbb{R}^{d_x \times d_x}$, entries of the first differentiation matrix $D^{(1)}_{jk} := \frac{\mathrm{d}\tilde{l}_k}{\mathrm{d}\tau}(c_j)$, where

$$\tilde{l}_k(\tau) := \prod_{\substack{r=0 \\ r\neq k}}^{m_i} \frac{\tau - c_r}{c_k - c_r} \; \forall k = 0,\dots,m_i, \tag{9}$$

and the RHS of the ODE $\boldsymbol{f}_{ij} := \boldsymbol{f}(\boldsymbol{x}_{ij}, \boldsymbol{p}, t_{ij})$. The numerical values of $D^{(1)}_{jk}$ can be calculated very efficiently with formulas provided in (Schneider and Werner 1986).

Approximating L is analogous to discretizing the differential equation. This is done by replacing the integral with a Radau quadrature rule of the form

$$\int_{t_0}^{t_f} L(\boldsymbol{x}(t), \boldsymbol{p}, t)\,\mathrm{d}t \approx \sum_{i=0}^{n} \Delta t_i \sum_{j=1}^{m_i} b_j L(\boldsymbol{x}_{ij}, \boldsymbol{p}, t_{ij}), \tag{10}$$

where the quadrature weights are given by

$$b_j = \int_0^1 \prod_{\substack{k=1 \\ k\neq j}}^{m_i} \frac{\tau - c_k}{c_j - c_k}\,\mathrm{d}\tau \quad \forall j = 1,\dots,m_i. \tag{11}$$

M and the boundary constraints (3d) are approximated by replacing the values on the boundary with their discretized equivalents, i.e. $M(\boldsymbol{x}(t_0), \boldsymbol{x}(t_f), \boldsymbol{p}) \approx M(\boldsymbol{x}_{00}, \boldsymbol{x}_{nm_n}, \boldsymbol{p})$ and $\boldsymbol{r}(\boldsymbol{x}(t_0), \boldsymbol{x}(t_f), \boldsymbol{p}) \approx \boldsymbol{r}(\boldsymbol{x}_{00}, \boldsymbol{x}_{nm_n}, \boldsymbol{p})$, while the path constraints (3c) are evaluated at all nodes, i.e. $\boldsymbol{g}(\boldsymbol{x}(t_{ij}), \boldsymbol{p}, t_{ij}) \approx \boldsymbol{g}(\boldsymbol{x}_{ij}, \boldsymbol{p}, t_{ij})$.

2.4 Training with Nonlinear Programming

By flattening the collocated dynamics (8), we obtain the discretized DOP (3a)–(3d) of the form

$$\min_{\boldsymbol{x}_{ij}, \boldsymbol{p}} M(\boldsymbol{x}_{00}, \boldsymbol{x}_{nm_n}, \boldsymbol{p}) + \sum_{i=0}^{n} \Delta t_i \sum_{j=1}^{m_i} b_j L(\boldsymbol{x}_{ij}, \boldsymbol{p}, t_{ij}) \tag{12a}$$

s.t.

$$\mathbf{0} = \sum_{k=0}^{m_i} D_{jk}^{(1)} \boldsymbol{x}_{ik} - \Delta t_i \boldsymbol{f}(\boldsymbol{x}_{ij}, \boldsymbol{p}, t_{ij}) \quad \forall i, \forall j \geq 1 \quad (12b)$$

$$\boldsymbol{g}^L \leq \boldsymbol{g}(\boldsymbol{x}_{ij}, \boldsymbol{p}, t_{ij}) \quad \leq \boldsymbol{g}^U \quad \forall i, \forall j \geq 1 \quad (12c)$$

$$\boldsymbol{r}^L \leq \boldsymbol{r}(\boldsymbol{x}_{00}, \boldsymbol{x}_{nm_n}, \boldsymbol{p}) \leq \boldsymbol{r}^U \quad (12d)$$

This large-scale NLP (12a)–(12d) can be implemented and solved efficiently in nonlinear optimizers such as Ipopt (Wächter and L. T. Biegler 2006), SNOPT (P. E. Gill et al. 2007; Philip E. Gill, Murray, and Saunders 2005) or KNITRO (Byrd, Nocedal, and Waltz 2006). These NLP solvers exploit the sparsity of the problem as well as the first and second order derivatives of the constraint vector and objective function to converge quickly to a suitable local optimum.

The open-source interior-point method Ipopt requires the already mentioned first derivatives and, in addition, the Hessian of the augmented Lagrangian at every iteration. Since the derivatives only need to be evaluated at the collocation nodes, there is no need to propagate them as in traditional ODE solver-based training. Furthermore, training with ODE solvers usually limits itself to first order derivatives and therefore, does not utilize higher order information as in the proposed approach.

The resulting so-called *primal-dual* system is then solved using a linear solver for symmetric indefinite systems, such as the open-source solver MUMPS (Amestoy et al. 2001) or a proprietary solver from the HSL suite (HSL 2013), after which an optimization step is performed. This step updates all variables $\boldsymbol{x}_{ij}, \boldsymbol{p}$ simultaneously, allowing for direct observation and adjustment of intermediate values. In contrast, ODE solver training only captures the final result after integrating the dynamics over time, without the ability to directly influence intermediate states during the optimization process. Because this linear system must be solved in every iteration anyway, high order, stable, implicit Runge-Kutta collocation methods, e.g. Radau IIA, can be embedded with only limited overhead. As a result, the NLP formulation overcomes key limitations of explicit ODE solvers in terms of order, stability, and allowable step size. Moreover, since the solver performs primal and dual updates, the solution does not need to remain feasible during the optimization, in contrast to ODE solver approaches where the dynamics (3b) are enforced at all times through forward simulation. This results in both advantages and disadvantages: On the one hand, it enables more flexible and aggressive updates, potentially accelerating convergence. On the other hand, it may lead to intermediate solutions that temporarily violate physical consistency or produce invalid function evaluations, which require careful handling.

For a comprehensive overview of nonlinear programming, interior-point methods, and their application to collocation-based dynamic optimization, we refer interested readers to (L. T. Biegler 2010) and the Ipopt implementation paper (Wächter and L. T. Biegler 2006).

2.5 Challenges and Practical Aspects

We identify four main challenges in training PeN-ODEs using the proposed direct collocation and nonlinear programming approach. These challenges are closely related to those encountered in conventional PeN-ODE or general NN training.

2.5.1 Grid Selection

The choice of time grid $\{t_0, \ldots, t_{n+1}\}$ and the number of collocation nodes per interval m_i are crucial for both the accuracy and efficiency of the training process. In practice, the grid can either be chosen equidistant or tailored to the specific problem. While equidistant grids are straightforward to implement and often sufficient for well-behaved systems, non-equidistant grids may reduce computational costs while capturing the dynamics more efficiently. Placing more intervals with low degree collocation polynomials in regions of rapid state change can improve approximation quality without unnecessarily increasing the problem size. Similarly, in well-behaved regions, it is feasible to perform larger steps with more collocation nodes. Because the collocation scheme and grid are embedded into the NLP, these must be given *a-priori*. This leaves room for future developments of adaptive mesh refinement methods with effective mesh size reduction, which have already shown great success for optimal control problems (Zhao and Shang 2018; Liu, Hager, and A. Rao 2015).

2.5.2 Initial Guesses

Due to the size and possible nonlinearity of the resulting NLP, the choice of initial guesses has a strong influence on convergence behavior. Unlike classical NN training, where poor initialization primarily affects convergence speed, the constrained nature of the transcribed dynamic optimization problem can lead to poor local optima or even solver failure. It is therefore of high importance to perform informed initializations for the states $\boldsymbol{x}_{ij}$ and, if possible, for the NN parameters $\boldsymbol{p}$.

One practical approach to obtain the required parameter guesses is to first train the network on a small, representative subset of the full dataset using constant initial values for both the states and parameters. The optimized parameters resulting from this reduced problem then serve as informed initial guesses for the full training problem. Consequently, the states are obtained by simulation, i.e. $\boldsymbol{x}(t) := \text{ODESolve}\left(\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{u}, t, NN_{\boldsymbol{p}}(\boldsymbol{x}, \boldsymbol{u}, t), \boldsymbol{x}_0)\right)$ and $\boldsymbol{x}_{ij} := \boldsymbol{x}(t_{ij})$ for a given initial condition $\boldsymbol{x}(t_0) = \boldsymbol{x}_0$. By construction, the collocated dynamic constraints (12b) are satisfied, leading to improved convergence and stability in the full NLP.

Clearly, this strategy does not work in general. However, in simple cases where the model can be decomposed and the NN's input-output behavior is observable, e.g. if model components should be replaced by a neural surrogate, the NN can be pre-trained using standard gradient descent. This yields reasonable initial guesses

DOI 10.3384/ecp218445

for the parameters and states by simulation, which can then be integrated into the constrained optimization problem. Another pre-training strategy could be the *collocation technique* proposed in (Roesch, Rackauckas, and Stumpf 2021). Still, developing general, effective strategies to obtain reasonable initial guesses is one of the key challenges and limiting factors we identify for the general application of this approach.

2.5.3 Batch-wise Training

Standard ML frameworks employ batch learning to efficiently split up data. This is not as straightforward when training with the approach described here. One might assume that the entire dataset must be included in a single discretized DOP. However, recent work (Shapovalova and Tsay 2025) demonstrates that batch-wise training is possible and promises significant potential. The Alternating Direction Method of Multipliers (ADMM) (Boyd et al. 2011) allows decomposing the optimization problem into smaller subproblems that can be trained independently, while enforcing consensus between them. This allows for memory-efficient training and opens up the possibility of handling larger models or learning from multiple data trajectories simultaneously.

2.5.4 Training of Larger Networks

While computing Hessians of NNs is generally expensive, it is tractable for small networks. To reduce computational effort for larger networks, it might be reasonable to use partial Quasi-Newton approximations such as SR1, BFGS or DFP (L. T. Biegler 2010) to approximate the dense parts of the augmented Lagrangian Hessian H, e.g. the blocks $H_{\boldsymbol{x}_{ij},\boldsymbol{p}}$ and $H_{\boldsymbol{pp}}$, or solely $H_{\boldsymbol{pp}}$. These blocks, which contain derivatives with respect to the NN parameters, are computationally expensive, while the block $H_{\boldsymbol{x}_{ij},\boldsymbol{x}_{ij}}$, which contains second derivatives with respect to the collocated states, is extremely sparse and comparably cheap. A Quasi-Newton approximation of the block $H_{\boldsymbol{x}_{ij},\boldsymbol{x}_{ij}}$ is therefore disadvantageous. The sparsity can be exploited by computing this block analytically and using it directly in the Quasi-Newton update. An implementation of this partial update using the SR1 Quasi-Newton method is straightforward. Instead of one expensive symmetric rank-one update for the entire Hessian H, one cheap symmetric rank-one update for $H_{\boldsymbol{pp}}$ and one general rank-one update for $H_{\boldsymbol{x}_{ij},\boldsymbol{p}}$ are needed.

This procedure significantly reduces the cost of the Hessian, while still providing fairly detailed derivative information. SR1 is particularly advantageous here, as it can represent indefinite Hessians, which is favorable when dealing with highly nonlinear functions.

Since our current examples perform well with small NNs, we do not explore larger networks in this paper. However, we anticipate that such Quasi-Newton strategies will be necessary in future work with larger networks. Very recent work (Lueg et al. 2025) independently expresses similar ideas, highlighting the potential of the approach.

3 Implementation

The generic DOP (3a)–(3d) and its corresponding NLP formulation (12a)–(12d) are implemented in the custom open-source framework GDOPT (Langenkamp 2024), which is publicly available.[1] For neural network training the code has been extended, including predefined parametric blocks such as neural networks, support for data trajectories and parallelized optimizations. This extended, experimental version is also publicly available.[2]

3.1 GDOPT

GDOPT (General Dynamic Optimizer) consists of two main components: an expressive Python-based package *gdopt* and an efficient C++ library *libgdopt*. The Python interface provides an user-friendly modeling environment and performs symbolic differentiation and code generation. Symbolic expressions are optimized using common subexpression elimination via SymEngine[3], and the resulting expressions together with first and second derivatives are translated into efficient C++ callback functions for runtime evaluation. In the present implementation, all expressions are flattened, resulting in large code, especially for the Hessian. Note that keeping NNs vectorized and employing symbolic differentiation rules with predefined NN functions offers significant advantages.

The library *libgdopt* implements a generalized version of the NLP (12a)–(12d) using Radau IIA collocation schemes, while also supporting optimal control problems. It is interfaced with Ipopt to solve the resulting nonlinear programs. Both symbolic Jacobian and Hessian rely on exact sparsity patterns discovered in the Python interface. Additional functionality includes support for nominal values, initial guesses, runtime parameters, mesh refinements, plotting utilities, and special functions. A detailed overview of features and modeling is provided in the GDOPT User's Guide[4].

Nevertheless, GDOPT lacks important capabilities that established modeling languages and tools offer, such as object-oriented, component-based modeling and support for differential-algebraic equation (DAE) systems. It is possible to model DAEs by introducing control variables for algebraic variables. However, this approach increases the workload and size of the NLP and may lead to instabilities.

3.2 Parallel Callback Evaluations

Since in every optimization step, the function evaluations as well as first and second derivatives of all NLP components (12a)–(12d) must be provided to Ipopt, an efficient callback evaluation is crucial to accelerate the training.

[1] https://github.com/linuslangenkamp/GDOPT
[2] https://github.com/linuslangenkamp/GDOPT_DEV
[3] https://github.com/symengine/symengine
[4] https://github.com/linuslangenkamp/GDOPT/blob/master/usersguide/usersguide.pdf

Note that these callbacks themselves consist of the continuous functions evaluated at all collocation nodes. For simplicity we write $\boldsymbol{z}_{ij} := [\boldsymbol{x}_{ij}, \boldsymbol{p}]^T$ for the variables at a given collocation node and, in addition,

$$\boldsymbol{\psi}(\boldsymbol{x}, \boldsymbol{p}, t) := [L(\cdot), \boldsymbol{f}(\cdot), \boldsymbol{g}(\cdot)]^T \tag{13}$$

for the vector of functions that are evaluated at all nodes. Clearly, the required callbacks

$$\boldsymbol{\psi}\big|_{z_{ij}} \quad \nabla\boldsymbol{\psi}\big|_{z_{ij}} \quad \nabla^2\boldsymbol{\psi}\big|_{z_{ij}} \quad \forall i\, \forall j \geq 1$$

are independent with respect to the given collocation nodes t_{ij} and thus, allow for a straightforward parallelization. In the extension of GDOPT, we use OpenMP (Chandra et al. 2001) to parallelize the callback evaluations required by Ipopt. Depending on the specific callback, i.e. objective function, constraint violation, gradient, Jacobian, or Hessian of the augmented Lagrangian, a separate `omp parallel for` loop is used to evaluate the corresponding components at all collocation nodes. This design results in a significant reduction in computation time, especially for the comparably expensive dense derivatives of neural components.

4 Performance

In order to test the proposed training method and parallel implementation, two example problems are considered. The first example is the Quarter Vehicle Model (QVM) from (Kamp, Ultsch, and Brembeck 2023), where an equation-based model is enhanced with small neural components, such that physical behavior is represented more accurately. The second example is a standard NODE, where the dynamics of a Van-der-Pol oscillator (Roesch, Rackauckas, and Stumpf 2021) are learned purely from data. In both cases, the experimental setup closely follows the configurations used in the respective paper. Training is performed on a laptop running Ubuntu 24.04.2 with Intel Core i7-12800H (20 threads), 32 GB RAM and using GCC v13.3.0 with flags `-O3 -ffast-math` for compilation, while MUMPS (Amestoy et al. 2001) is used to solve linear systems arising from Ipopt (Wächter and L. T. Biegler 2006). All dependencies are free to use and open-source.

4.1 Quarter Vehicle Model

We follow the presentation in (Kamp, Ultsch, and Brembeck 2023) for an overview of the model and the data generation process. The Quarter Vehicle Model (QVM) captures the vertical dynamics of a road vehicle by modeling one wheel and the corresponding quarter of the vehicle body. It consists of two masses connected by spring-damper elements representing the suspension and tire dynamics. The linear base model is described by the differential equations $\dot{z}_r = u$, $\dot{z}_b = v_b$, $\dot{z}_w = v_w$, and

$$\dot{v}_b := a_b = m_b^{-1}\left(c_s \Delta z_s + d_s \Delta v_s\right) \tag{14a}$$

$$\dot{v}_w := a_w = m_w^{-1}\left(c_t \Delta z_t + d_t \Delta v_t - c_s \Delta z_s - d_s \Delta v_s\right) \tag{14b}$$

where $\Delta z_s = z_w - z_b$, $\Delta v_s = v_w - v_b$, $\Delta z_t = z_r - z_w$, $\Delta v_t = u - v_w$. In addition, m_w is the mass of the wheel, m_b is mass of the quarter body, and c_s and d_s are the coefficients of the linear spring-damper pair between these masses, modeling the suspension. Furthermore, c_t and d_t define an additional linear spring-damper pair between the tire and ground. The state vector $\boldsymbol{x} = [z_b, z_w, v_b, v_w, z_r]^T$ contains the positions of the body z_b and wheel z_w, their velocities v_b and v_w, and the road height z_r. The differential road height $\dot{z}_r = u$ is given as an input and the observable outputs $y = [a_w, a_b]$ measure the wheel and body accelerations. A corresponding Modelica model of the linear QVM is depicted in Figure 1. (Kamp, Ultsch, and Brembeck 2023)

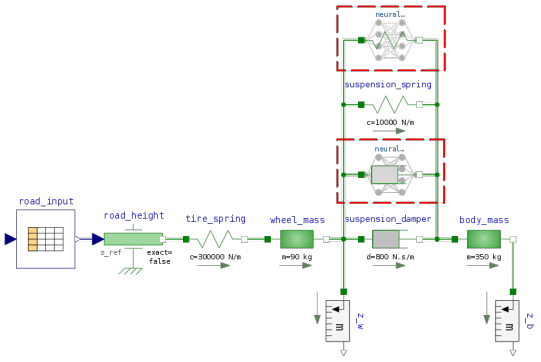

Figure 1. Modelica Models of the Linear (without boxes) and Neural (with boxes) QVM. Modified from T. Kamp.

4.1.1 Data Generation

The linear model is extended by introducing two additional nonlinear forces between both masses, a translational friction force F_{fr} and a progressive spring characteristic F_{pr}. These nonlinear components are introduced only for data generation, creating a more complicated, nonlinear model whose behavior deviates from the known base dynamics. Therefore, the differential equations (14a) and (14b) become

$$\dot{v}_b = m_b^{-1}\left(c_s \Delta z_s + d_s \Delta v_s + F_{pr}(\Delta z_s) + F_{fr}(\Delta v_s)\right) \tag{15a}$$

$$\dot{v}_w = m_w^{-1}\left(c_t \Delta z_t + d_t \Delta v_t - c_s \Delta z_s - d_s \Delta v_s - F_{pr}(\Delta z_s) - F_{fr}(\Delta v_s)\right) \tag{15b}$$

To generate data, a simulation of the nonlinear model for an imitation of a realistic, rough road (ISO8608, Type D (Múčka, Peter 2018)) is performed. The observables a_b and a_w as well as the states are disturbed by random Gaussian noise and sampled with 1000 Hz for a 42 s trajectory as in (Kamp, Ultsch, and Brembeck 2023).

4.1.2 Training Setup

The nonlinear components $F_{fr}(\Delta v_s)$ and $F_{pr}(\Delta z_s)$ introduced for data generation are replaced by two neural network surrogates $F_{fr}^{NN}(\Delta v_s)$ and $F_{pr}^{NN}(\Delta z_s)$, illustrated in Figure 1. The goal is to find suitable replacements that minimize the mismatch between the simulated, disturbed

DOI 10.3384/ecp218445

outputs $\hat{a}_b$ and $\hat{a}_w$ of the nonlinear model and the observed data during the optimization. As discussed before, we write this objective as an integral over the entire time horizon, i.e.

$$\min \int_{t_0}^{t_f} \left(\frac{\hat{a}_b - a_b}{\sigma_{\hat{a}_b}} \right)^2 + \left(\frac{\hat{a}_w - a_w}{\sigma_{\hat{a}_w}} \right)^2 \mathrm{d}t, \tag{16}$$

where $\sigma_{\hat{a}_b}$ and $\sigma_{\hat{a}_w}$ are corresponding standard deviations of the data, ensuring that both accelerations contribute equally to the objective. Furthermore, it is known that both force elements have a zero crossing and therefore, the additional constraints

$$F_{fr}^{NN}(0) = 0 \quad \text{and} \quad F_{pr}^{NN}(0) = 0 \tag{17}$$

are simply added to the optimization problem.

We employ three different training strategies. At first, both feedforward neural networks are trained directly on the full trajectory using randomly initialized parameters, while the initial state guesses are obtained from a simulation of the linear model (I). Each network has the structure $1 \times 5 \rightarrow 5 \times 5 \rightarrow 5 \times 1$ and therefore, both nets contain just 92 parameters in total. We use the smooth squareplus activation function

$$\text{squareplus}(x) := \frac{x + \sqrt{1 + x^2}}{2} \tag{18}$$

to ensure a twice continuously differentiable NN as required for Ipopt. In the second strategy (II), described in Section 2.5.2, first an acceleration scheme is employed, where the same networks are trained on a short segment one eighth of the entire trajectory. After that, a simulation of the neural QVM with the obtained parameters is performed. The resulting states are used as initial guesses in the subsequent optimization with full data. To show that the surrogates need not be NNs and training can be performed efficiently with other parameter-dependent expressions, the third strategy (III) uses rational functions to model the unknown behavior. For instance, F_{fr} is replaced by

$$F_{fr}^{RC}(\Delta v_s) := \frac{\sum_{k=0}^{N} \omega_k T_k(\Delta v_s)}{\sum_{k=0}^{D} \theta_k T_k(\Delta v_s)}, \tag{19}$$

where T_k is the k-th Chebyshev polynomial, ω_k and θ_k are parameters to be optimized, and N and D are the numerator and denominator degrees. For both rational functions we choose $N = D = 7$, resulting in a total of merely 32 learnable parameters.

Since the QVM contains very fast dynamics due to high-frequency excitations, in all cases the time horizon is divided into a tightly spaced, equidistant grid of 2500 intervals and using a constant 5-step Radau IIA collocation scheme of order 9. This leads to a total of 12500 collocation nodes and more than 2.7×10^6 nonzeros in the Jacobian and roughly 4.73×10^6 nonzeros in the Hessian of the large-scale NLP.

4.1.3 Results

Table 1 presents the training times for all strategies. Each optimization was run for a maximum of 150 NLP iterations and was automatically terminated early if no further significant improvement in objective could be achieved. We want to stress that all trainings, performed on a laptop, are executed in under 7 minutes, compared to 4.5 hours for the fastest optimization in (Kamp, Ultsch, and Brembeck 2023) using ODE solver-based training. Clearly, this is also due to the fact that smaller neural components are used. Furthermore, Figure 2 depicts the objective value with respect to training time, where both the first and second optimizations of (II) are concatenated.

Strategy	Total	Ipopt	Callbacks
(I)	394.43	284.18	110.25
(II) - initial	26.75	15.08	11.67
(II) - final	173.06	124.65	48.41
(II)	199.81	139.73	60.07
(III)	34.96	27.10	7.85

Table 1. Training Times in Seconds

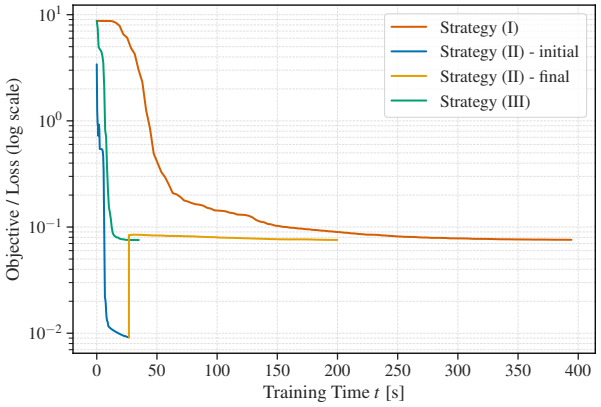

Figure 2. Objective History with Respect to Training Time

Even though a poor initialization has been used and thus the optimization required more time, the naive strategy (I) converged stably to a suitable optimum with a similar objective as strategies (II) and (III). For this example, the acceleration scheme (II) proves effective, since the initial optimization for a shorter data trajectory takes just 26.75 s in total, and the subsequent initial guesses for states and parameters become very good approximations of the real solution. This can be observed in Figure 3 and Figure 4, where the resulting neural surrogates are depicted. By performing the second optimization, (II) effectively halves the time required by strategy (I), i.e. less than 3.5 minutes, and furthermore results in indistinguishable neural components.

Moreover, as seen in Figure 3 and Figure 4, the resulting very small NNs match the reference in almost perfect

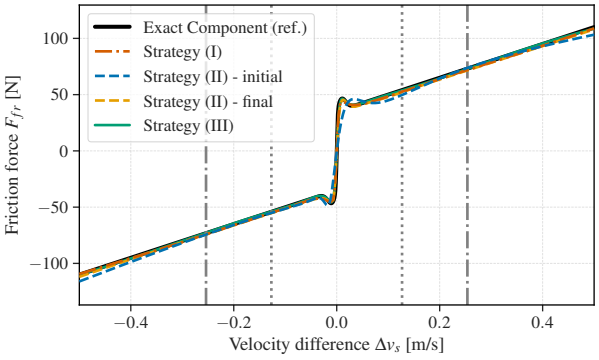

Figure 3. Neural and Reference Damper Characteristics

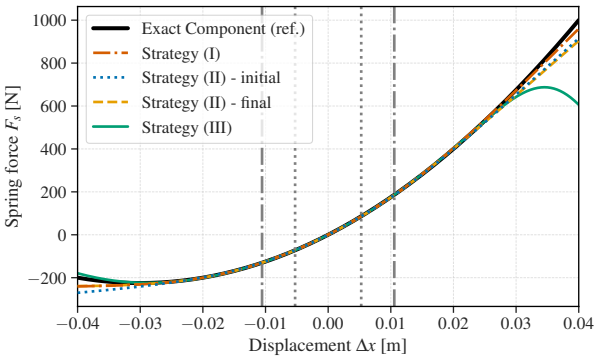

Figure 4. Neural and Reference Spring Characteristics

accordance, correctly representing highly nonlinear parts of the damper. These also generalize in a very natural way, as can be seen from the behavior outside the vertical dotted lines, which represent the first and second standard deviations of the inputs to the nets. Performing simulations on a new, unknown input road shows that the obtained PeNODE from (II) matches the nonlinear reference model perfectly, as illustrated in Figure 5. Note that, our characteristics of the damper and spring serve as even better surrogates than those reported in (Kamp, Ultsch, and Brembeck 2023), despite using significantly smaller networks and requiring considerably shorter training times. While (Kamp, Ultsch, and Brembeck 2023) relied on larger models with longer ODE solver-based training, our approach yields more accurate and better-generalizing results.

By having principal knowledge of the underlying characteristics shown in Figure 3 and Figure 4, it is possible to model observed behavior with minimal parameters. Since the number of Hessian nonzeros grows quadratically with the number of parameters, such knowledge of the procedure can greatly benefit both training time and surrogate quality. Therefore, consider simple rational functions as an educated guess for both missing components. This optimization, with 32 instead of 92 free parameters, is performed in under 35 seconds without any acceleration strategy. Moreover, the obtained surrogates are of mostly equal quality to the NN components from (II), although

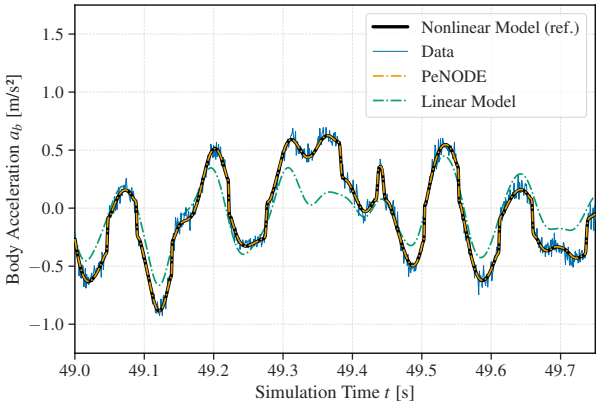

Figure 5. Body Accelerations a_b for Simulations of PeNODE and Standard Models on a Type C Road (Múčka, Peter 2018)

Figure 4 shows that the rational function does not generalize as well. Nevertheless, these results demonstrate that unknown behavior may be expressed with fewer parameters and yield equivalent quality.

4.1.4 Parallel Implementation

Finally, it is stressed that the parallel implementation, described in Section 3.2, leads to 5.44 times less time taken in the generated function callbacks. This yields a total training time that is more than halved and clearly shows that the implementation efficiently exploits the independence of collocation nodes.

Method	Total	Ipopt	Callbacks
GDOPT (default)	385.90	122.52	263.38
GDOPT (parallel)	173.06	124.65	48.41

Table 2. Comparison of Parallel and Sequential Optimization Times in Seconds of (II) - final

4.2 Van-der-Pol Oscillator

To illustrate the ability of learning a full NODE, we follow an example from (Roesch, Rackauckas, and Stumpf 2021), where a different kind of collocation method was proposed. This method approximates the RHS of the ODE with data, thus enabling faster, unconstrained training without the need for ODE solvers. Consider the Van-der-Pol (VdP) oscillator

$$\dot{x} = y \tag{20a}$$

$$\dot{y} = \mu y \left(1 - x^2\right) - x \tag{20b}$$

with $\mu = 1$ and initial conditions $x(t_0) = 2$ and $y(t_0) = 0$. Data generation is performed by simulating the dynamics with OpenModelica (Fritzson, Pop, Abdelhak, et al. 2020) on an equidistant grid with 200 intervals and artificially perturbing the observed states by additive Gaussian noise. To test sensitivities of the approach, we use 3 different

DOI
10.3384/ecp218445

levels of noise $\mathcal{N}(0,\sigma)$ to disturb the observable states, i.e. no noise ($\sigma = 0$), low noise ($\sigma = 0.1$) and high noise ($\sigma = 0.5$).

The continuous DOP has the form

$$\min_{\boldsymbol{p}_x,\boldsymbol{p}_y} \int_{t_0}^{t_f} (\hat{x}_\sigma - x)^2 + (\hat{y}_\sigma - y)^2 \,\mathrm{d}t + \lambda \|\boldsymbol{p}\|_2^2 \tag{21a}$$

s.t.

$$\dot{x} = NN^x_{\boldsymbol{p}_x}(x,y) \tag{21b}$$

$$\dot{y} = NN^y_{\boldsymbol{p}_y}(x,y) \tag{21c}$$

$$x(t_0) = 2,\ y(t_0) = 0, \tag{21d}$$

where $\hat{x}_\sigma, \hat{y}_\sigma$ is the disturbed state data, $NN^x_{\boldsymbol{p}_x}(x,y)$, $NN^y_{\boldsymbol{p}_y}(x,y)$ are neural networks of the architecture $2 \times 5 \to 5 \times 5 \to 5 \times 1$ with sigmoid activation function, $\boldsymbol{p} = [\boldsymbol{p}_x, \boldsymbol{p}_y]^T$ are 102 learnable parameters, while $\lambda > 0$ is a regularization factor to enhance stability.

As in (Roesch, Rackauckas, and Stumpf 2021), the training is performed on a 7 second time horizon, thus including a little over one period of the oscillator. Furthermore, 500 intervals and the 5-step Radau IIA method of order 9 are used. The initial guesses for the state variables are trivially chosen as the constant initial condition and the NN parameters are initialized randomly. No acceleration strategy or simulation is used for educated initial guesses. We set a maximum number of Ipopt iterations / epochs of 200 and an optimality tolerance of 10^{-7}.

4.2.1 Results

In almost all cases, the optimization terminates prematurely, since the optimality tolerance is fulfilled and thus, a local optimum was found. The corresponding training times are displayed in Table 3. Note that, because the high noise ($\sigma = 0.5$) leads to larger objective values, the regularization λ is increased in this case. Nevertheless, the optimization with a total of 2500 discrete nodes is very rapid and terminates in several seconds from an extremely poor initial guess, while in some instances runs settle in poor local optima. Clearly, more reasonable initial guesses and sophisticated initialization strategies will further enhance these times and stability.

σ	λ	Total	Ipopt	Callbacks	#Epochs
0	10^{-4}	8.17	5.95	2.22	80
0.1	10^{-4}	7.69	5.60	2.09	76
0.5	10^{-3}	13.49	9.79	3.70	134

Table 3. Training Times (in seconds) and Number of Ipopt Iterations / Epochs of the Van-der-Pol Oscillator NNs

Figure 6 presents the simulation results and training data for various levels of noise. It is evident that for no or low noise, the solution obtained is virtually indistinguishable from the reference, which is quite impressive. Even with high noise ($\sigma = 0.5$), the Neural ODE remains close to the true solution, showing significantly better performance compared to the results reported in (Roesch, Rackauckas, and Stumpf 2021), where NODE and reference do not align for $\sigma \geq 0.2$. While smaller neural networks are employed here, these compact models still demonstrate exemplary performance and fast training, highlighting the effectiveness of the approach under severe noise.

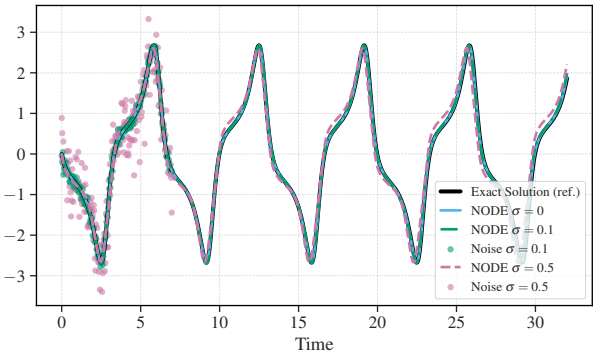

Figure 6. Simulation Results of the Neural and Reference Models as well as the Data for $y(t)$

To verify the robustness of the training procedure, a comprehensive sensitivity analysis, consisting of 100 training runs for each noise level, was conducted. The results, detailed in the Appendix and Figure 10, demonstrate that while all runs converge perfectly for the no-noise case ($\sigma = 0$) and approximately 95% show excellent agreement under low noise ($\sigma = 0.1$), as expected the robustness diminishes with high noise ($\sigma = 0.5$). In these cases, several runs converge to poor local optima or fail to converge, leading to solutions with noticeable period and amplitude mismatches or an outright collapse of the trajectory.

To further illustrate the obtained NODEs, we compare the learned and true vector fields of the ODE

$$\begin{bmatrix} x \\ y \end{bmatrix} \mapsto \begin{bmatrix} NN^x_{\boldsymbol{p}_x}(x,y) \\ NN^y_{\boldsymbol{p}_y}(x,y) \end{bmatrix}, \quad \begin{bmatrix} x \\ y \end{bmatrix} \mapsto \begin{bmatrix} y \\ \mu y\left(1-x^2\right) - x \end{bmatrix}. \tag{22}$$

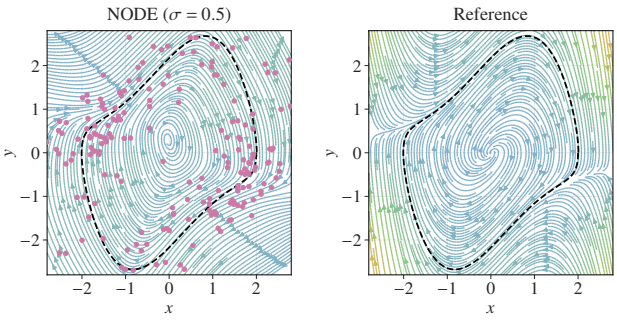

Figure 7. Neural ($\sigma = 0.5$) and Reference Vector Fields of the ODE and the Exact VdP Trajectory (dashed)

In Figure 7, we show the high-noise NODE, its training data, and the true vector field. Despite the heavily

scattered observable states, the NODE still manages to recover a vector field that aligns well with the true dynamics in the vicinity of the solution trajectory.

Further comparison is given in Figure 8, where the scalar fields visualize the 2-norm error between the neural and reference vector fields. The low-noise NODE ($\sigma = 0.1$) yields way smaller error values along the trajectory, but even the high-noise model produces a fairly accurate vector field in regions close to available training data. As expected, generalization outside this domain remains limited, but within the training region, the results demonstrate strong consistency.

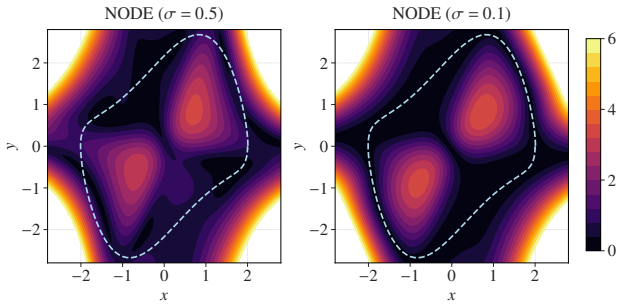

Figure 8. Scalar Fields Representing the 2-Norm Error Between the Neural ($\sigma = 0.5$, $\sigma = 0.1$) and Reference Vector Fields (Values > 6 are white)

In addition to the local collocation approach with 500 intervals, we also reproduce the results in (Shapovalova and Tsay 2025) using a global, *spectral* collocation method. We employ a single interval with 70 fLGR nodes, corresponding to Radau IIA of order 139. This high-order global formulation yields an approximation of equal quality to the figures above, even under high noise ($\sigma = 0.5$). Furthermore, the optimization terminates in outstandingly fast time, i.e. under 1.2 seconds. This demonstrates the remarkable efficiency and accuracy of spectral methods for such smooth problems.

5 Future Work

Although OpenModelica currently includes an optimization runtime implementing direct collocation (Ruge et al. 2014), it remains limited to basic features: it supports only 1- or 3-step Radau IIA collocation, does not allow parameter optimization, lacks analytic Hessians, and does not perform parallel callbacks. To overcome these limitations, work is underway to embed an extended version of *libgdopt* into OpenModelica. This integration combines recent developments from GDOPT with the existing strengths of OpenModelica, particularly its native ability to handle DAEs. The extended framework enables expressive Modelica-based modeling, native support of neural components via the NeuralNetwork Modelica library and incorporates recent advancements in mesh refinement for optimal control problems (Langenkamp 2024).

5.1 NeuralNetwork Modelica Library

The NeuralNetwork library, originally developed in (Codecà and Casella 2006), is an open-source Modelica library[5] modeling ML architectures with pure Modelica. Neural components can be constructed by connecting dense feedforward layers of arbitrary size with layers for PCA, standardizing, or scaling. These blocks contain all equations and parameters as pure Modelica code, which makes seamless integration of neural components into existing Modelica models straightforward. Together with this library, OpenModelica will enable modeling and training of PeN-ODEs within a single development environment.

5.2 Workflow

The workflow presented in Figure 9 illustrates the intended process for native Modelica-based modeling and training of PeN-ODEs. While some components of the workflow are operational, the full integration is still under active development. Users model physical systems and NN components with free parameters directly in Modelica and provide corresponding data. Both the model

[5] https://github.com/AMIT-HSBI/NeuralNetwork

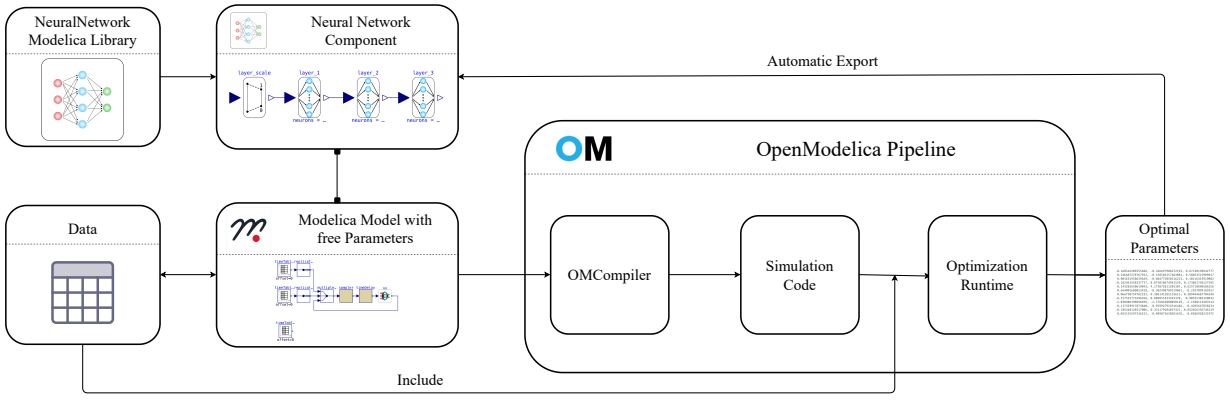

Figure 9. OpenModelica Workflow for PeN-ODE Training (under development)

DOI 10.3384/ecp218445

and data are processed by the standard OpenModelica pipeline, while the OpenModelica Compiler (OMC) generates fast C code. The new backend of OMC introduces efficient array-size-independent symbolic manipulation (Abdelhak, Casella, and Bachmann 2023). Ongoing work further targets resizability of components after compilation (Abdelhak and Bachmann 2025), offering significant benefits for array-based components such as NNs.

Furthermore, current work focuses on leveraging the generated simulation code to enable fast callback functions for a new optimization runtime. After training, the optimal parameters are directly inserted into a NN block, enabling immediate simulations by swapping connectors.

This workflow removes the need for export and import steps for neural components and models, e.g. in the form of a Functional Mock-up Unit (FMU). It also eliminates reliance on external training routines in Julia or Python and avoids external C functions in the model, since the neural components are pure Modelica blocks. This integrated workflow unifies modeling, training, and simulation within a single toolchain, enabling free and accessible optimizations.

5.3 Neural DAEs

One of the main advantages of the integration into OpenModelica is the native ability to handle DAEs. Modelica compilers such as OpenModelica systematically apply index reduction and block-lower triangular (BLT) transformations to restructure DAEs into semi-explicit ODE form with index 1 (Ruge et al. 2014; Åkesson et al. 2012). As the simulation code already resolves algebraic variables during evaluations, no additional handling, e.g. inclusion of algebraic variables in the NLP, is needed on the optimization side. This allows the new training workflow to seamlessly extend from ODEs to DAEs, far surpassing the current range of applications.

6 Conclusion

This paper proposes a formulation of PeN-ODE training as a collocation-based NLP, simultaneously optimizing states and NN parameters. The approach overcomes key limitations of ODE solver-based training in terms of order, stability, accuracy, and allowable step size. The NLP uses high order quadrature for the NN loss, potentially preserving the accuracy of the discretization. We demonstrate that known physical behavior can be trivially enforced.

We provide an open-source parallelized extension to GDOPT and on two example problems demonstrate exemplary accuracy, training times, and generalization with smaller NNs compared to other training techniques, even under significant noise. Furthermore, we show that the approach allows for efficient optimization of other parameter dependent surrogates.

Key limitations and challenges of the proposed method, including grid selection and general initialization strategies to increase stability, as well as training with larger datasets and networks are identified. Addressing and evaluating these issues in future work is essential to support broader applicability. To enable accessible training of Neural DAEs, without relying on external tools, work is underway to implement the method in OpenModelica.

Acknowledgements

This work was conducted as part of the OpenSCALING project (Grant No. 01IS23062E) at the University of Applied Sciences and Arts Bielefeld, in collaboration with Linköping University. The authors would like to express their sincere appreciation to both the OpenSCALING project and the Open Source Modelica Consortium (OSMC) for their support, collaboration, and shared commitment to advancing open-source modeling and simulation technologies.

Appendix: Sensitivity Analysis and Robustness of VdP Neural ODEs

(a) No noise: $\sigma = 0$ **(b)** Low noise: $\sigma = 0.1$ **(c)** High noise: $\sigma = 0.5$

Figure 10. Sensitivity analysis of the learned Van-der-Pol (VdP) Neural ODEs to different levels of Gaussian noise. For each noise level, 100 training sessions were performed with random initial guesses for the neural network parameters and a random seed for the data perturbation. The plots show the simulation results for the observable state y(t) over an extended time horizon of 32 seconds. Each subplot consists of two panels: The top panel visualizes the reference solution (dashed black line), the median of the 100 learned solutions, and the 25-75% and 10-90% percentile bands. The bottom panel shows all 100 individual learned trajectories (faint lines). **(a) No noise** ($\sigma = 0$)**:** The method demonstrates full robustness and perfect convergence, with all 100 solutions converging to the exact reference solution. **(b) Low noise** ($\sigma = 0.1$)**:** The method remains highly robust. A vast majority of the solutions (approximately 95%) form a tight band around the reference, showing excellent agreement. **(c) High noise** ($\sigma = 0.5$)**:** As expected under severe noise, the robustness is reduced. While many solutions remain relatively close to the reference, some diverge significantly, indicating a failure to find a good local optimum during training. The solutions that do converge often show a period mismatch or diverge after a few periods, but still capture the general oscillatory behavior. The combined effects of reduced solution quality and an inaccurate period are reflected in the median and percentile bands, which exhibit a noticeable deviation in amplitude and phase after three periods compared to the true trajectory.

Status of the SMArtInt Library: Simple Modelica Artificial Intelligence Interface

T. Hanke[1] J. Brunnemann[1] R. Flesch[1] J. Eiden[1]

[1]XRG Simulation GmbH, Hamburg, Germany, {hanke,brunnemann,flesch,eiden}@xrg-simulation.de

Abstract

This paper presents the current status of the open-source Modelica library SMArtInt (**S**imple **M**odelica **Art**ificial **I**ntelligence **Int**erface) (SMArtInt 2025), which offers users a straightforward and efficient approach of integrating artificial intelligence via neural networks directly into Modelica models. We provide a detailed overview of the library's features, area of application, and development process. The primary focus is on the diverse use cases of SMArtInt. The new version 0.5.1 brings an exciting feature with the support of the ONNX (ONNX 2025) format. ONNX (Open Neural Network Exchange) is an open, cross-platform format for the representation and exchange of deep learning models. This means that in addition to TensorFlow (TensorFlow 2025) models (TFLite), many other models, such as PyTorch (PyTorch 2025) can now also run in SMArtInt via the ONNX format.

Keywords: AI, SMArtInt library, Artificial Intelligence, Neural Network, TensorFlowLite, ONNX, BNODE

1 Introduction

1.1 Context of Paper

In recent years, machine learning techniques have successfully established themselves in various areas of science and technology, often summarized under the term "artificial intelligence" (AI). These methods have proven to be particularly effective in processing large amounts of data and enable an automatic recognition of correlations, patterns and classifications within the data (Lam et al. 2023; Kong et al. 2025).

Time series models, in which AI techniques such as neural networks can be used to predict and analyze temporal data, are more and more integrated into physical simulations. Such hybrid systems (see figure 1) combine data-driven insights with traditional physical models (Matei 2018; Kurz et al. 2022; Rudolph, Kurz, and Rakitsch 2024; Quarteroni, Gervasio, and Regazzoni 2025). This integration enables more accurate and flexible system modeling, especially for complex, non-linear or unknown processes , see for instance (Von Krannichfeldt, Orehounig, and Fink 2025), (Gijon et al. 2025) or (Markovic et al. 2018) as example with Modelica context. It also improves the ability to simulate and optimize dynamic systems, see e.g. (Singgraval, Suykens, and Geyer 2018), (Aka, Brunnemann, Freund, et al. 2023).

In the Modelica context of state space models, described by a system of ordinary differential equations (ODE), the hybrid model architecture (figure 1) leads to the concept of a Neural ODE (Chen et al. 2018): time derivatives of the states are computed from a combination of equations and neural networks.

There are different possibilities for integrating neural networks into physical system simulations. On the one hand, software manufacturers may develop tool-specific AI interfaces for integrating neural networks into their Modelica simulation environments. On the other hand, there are already different tool-independent, open-source approaches available in the Modelica community, such as the NeuralNetwork (NeuralNetwork 2025) library, which maps neural layers using Modelica blocks, whereby the associated weights and biases are obtained from a read-in matrix, or the SMArtInt library, which implements neural networks directly via external C-functions.

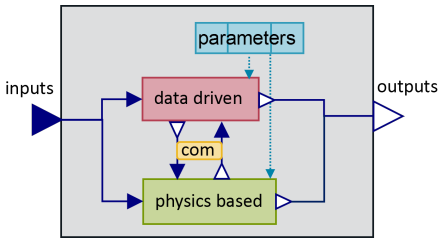

Figure 1. Concept of hybrid modeling: data driven and physics based model parts integrated into a single system model. Internal data exchange via interface variables (com).

The aim of SMArtInt is to create a library that allows integration of trained neural networks directly into Modelica very much in the fashion of input-output blocks. The library is explicitly intended to enable Modelica users to create hybrid models in a simple way while staying inside their preferred Modelica development tool, hence strengthening Modelicas position as multi physics engineering modeling language. Additionally, usage of external C-functions makes the Modelica equation system independent of the size of inferred neural networks, which may in practice contain several thousand parameters. Moreover this approach allows for exchanging the inferred neural network without re-translating the Modelica model, as

long as the input-output structure stays the same.

SMArtInt was developed within a German research collaboration (DIZPROVI 2021-2024)[1] (Brunnemann, Flesch, and Hanke 2024) under the name *SMArtIInt*. The first official release of version 0.1.0 dates back to March 2023.

1.2 Outline of Paper

This paper is structured as follows: Section 2 provides the scope and structure of the library as well as an insight into the functionality of SMArtInt. Section 3 discusses the innovations introduced in version 0.5.1, with a particular focus on the support of the ONNX format. Section 4 presents three different application cases for the library: the integration of a simple feed-forward neural network within a discretized pipe, replacing a heat transfer correlation; a hybrid superheater model trained on measurement data from a coal-fired power plant, developed as part of the DIZPROVI project; and a Balanced Neural ODE used to create a surrogate model of an entire steam cycle. Section 5 presents the SMArtInt funding concept and outlines the additional content of the SMArtInt+ commercial version. Finally, a summary and outlook is given in section 6.

2 Overview of the Library SMArtInt

2.1 Scope of Library

SMArtInt enables the integration of trained artificial intelligence (AI) models into Modelica tools. SMArtInt currently supports TensorFlow models (exported in TFLite format), as well as ONNX models. LiteRT (formerly TensorFlow Lite) (Shuangfeng 2020) was initially selected as the core inference runtime due to its optimizations for embedded systems and edge computing environments, offering a small binary size, high execution efficiency, and support for low-latency inference, while ONNX support was added in the latest version (see section 3) to improve SMArtInt's framework compatibility. For integration, users need to specify the path to the AI model, as well as the input and output dimensions of the neural network within the interface block. The network structure, including layers and neurons, does not need to be defined, allowing neural networks to be easily exchanged as long as the input/output structure remains unchanged. This flexibility enables repeated training with different datasets, hyperparameters, or internal architectures (e.g., layer configurations) without requiring modifications to the Modelica model in which the neural network is used. Inputs and outputs are accessible in Modelica as arrays via the interface blocks, ensuring a simple and flexible integration process.

In hybrid modeling, different levels of hybridization can be distinguished (see figure 2 for illustration). On the top level, entire models can be replaced by data driven surrogates. On the system level, individual submodels and replaceable models can be substituted to implement physical correlations directly from data. Additionally AI models can be used to model detailed physical effects that are usually not accessible at the level of system simulation: thanks to acausality of Modelica a simplified physics based system model may be inverted in order to 'subtract' its result from measurement data. For example the effect of heat exchanger fouling, represented in a simple manner by a model parameter in the original model, may be extracted in more detail as a time series by imposing the measured heat flow and extracting the effective time depending fouling as output of the inverted model. The generated time series may then be used in order to train a detailed data driven fouling model.

The approaches described above were investigated and implemented as part of the DIZPROVI research project.

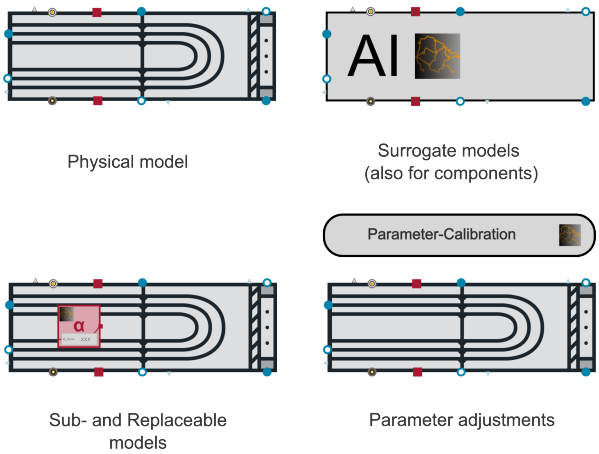

Figure 2. Different levels of hybridization

In the construction of hybrid models care has to be taken, when combining AI models based on measurements of the real system with an abstract physics based system model, subject to several simplifying model assumptions. In practice a thorough investigation is recommended in order to determine the 'best' level of hybridization as well as interface variables between physics and data based mode parts (figure 1). For example it may happen that certain spatially resolved sensor positions are not available in the 1D system model or vice versa certain system variables are not accessible for measurement. Moreover validity of data based model parts is limited to the input range of measurement data. It is also important to realize that AI models usually expect a causal input-output structure, while physics based Modelica models are equation based and acausal. A more detailed discussion of these issues can be found in the DIZPROVI project report (Brunnemann, Flesch, and Hanke 2024).

2.2 Structure of Library

The SMArtInt library is designed to be as simple and user-friendly as possible. Table 1 provides an overview of its top-level structure. The library consists of four packages and a *UsersGuide*, which offers essential information for getting started and effectively using the

[1] funded by the German Federal Ministry of Education and Research under reference number FKZ 03WIR0105E

DOI 10.3384/ecp218459

library.
The *Blocks* package contains interface blocks (as shown in Figure 3) necessary for integrating neural networks into Modelica models. The *Tester* package includes various examples demonstrating the correct usage of these interfaces and their integration into different models.

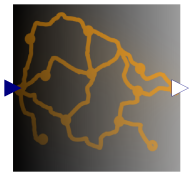

Figure 3. SMartInt's interface block for neural networks

For advanced users, the *BaseClasses* package provides direct access to the core functionalities of the library. Finally, the *Internal* package contains the underlying external C functions that build the base of SMArtInt.

Table 1. SMartInt library structure

SMArtInt	
UsersGuide	Basic information on usage and licenses
Tester	Examples to introduce new users to the library
BaseClasses	Basic models/templates for integrating different types of neural networks in Modelica
Blocks	Blocks to integrate different types of neural networks into Modelica models (based on the *BaseClasses*)
Internal	Internal functions for integrating/interacting with the neural networks

2.2.1 Technical realization

A large part of the functionality of SMArtInt is located outside of Modelica in external C functions, which are integrated into SMArtInt as dynamic libraries (.dll and .so). SMArtInt supports three different neural network types, each of which has its own interface block:

1. Feed-forward neural networks (**FFNNs**): Output depends only on the current input.
2. Recurrent neural networks (**RNNs**): Use previous inputs (time series) to compute the current output.
3. Stateful recurrent neural networks (**sRNNs**): Preserve their hidden state across inference steps to capture long-term dependencies.

SMArtInt operates as a real-time application, processing only the input variables provided by the solver at the current time step. This creates particular challenges regarding the input management of RNNs. This is addressed by the input management system, which supports RNNs as well as stateful RNNs in combination with solvers that utilize variable time step sizes, ensuring seamless integration within Modelica simulations.
Since RNNs must operate at the same temporal resolution as their training data, SMArtInt uses an external C-based container to store input values. If the time step of the Modelica solver exceeds the trained step size of the RNN, the required values are interpolated to maintain consistency. In addition, this input storage mechanism ensures robustness by allowing retrieval of the last accepted values in cases where solver steps are rejected.

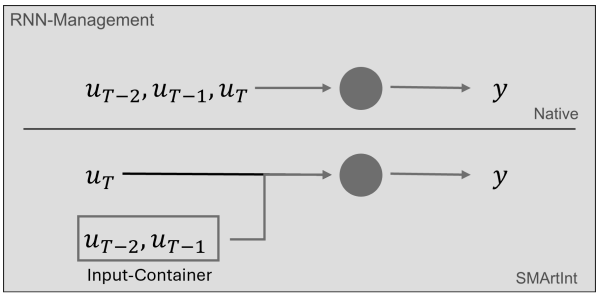

Figure 4. RNN input management

Stateful RNNs are not natively supported in TFLite and have limited functionality in ONNX (ONNX 2025), where network states can only be stored internally for batched inputs. Stateful RNNs must be explicitly restructured by representing layer states as outputs and defining corresponding state inputs. These states are managed externally by the SMArtInt input management system in a special state container, which enables seamless integration while maintaining time dependencies.

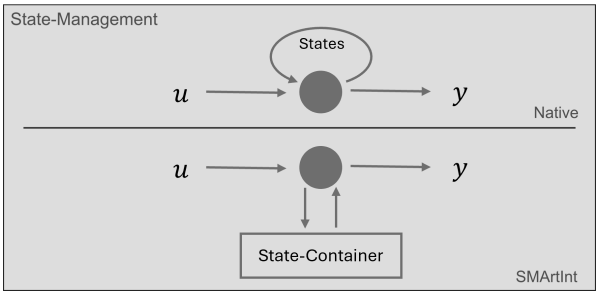

Figure 5. State input management

3 Latest Features of SMArtInt

Version 0.5.1 introduces support for the ONNX format. The Open Neural Network Exchange (ONNX 2025) is an open-source, cross-platform format designed for the exchange of deep learning models. It serves as an interface between various machine learning frameworks, en-

abling model conversion across different formats. The integration of ONNX extends SMArtInt's compatibility beyond TensorFlow (TensorFlow 2025) to include frameworks such as PyTorch (PyTorch 2025), NeoML (NeoML 2025), and many others. A comprehensive list of supported frameworks is available on the ONNX website[2]. SMArtInt automatically detects whether the specified model path corresponds to a TFLite or ONNX model and processes it accordingly. This ensures that Modelica users can work with a unified interface without requiring any additional configuration, simplifying the integration of neural networks into Modelica simulations.

4 Example use cases

In this chapter, three different examples are presented that illustrate different use cases of SMArtInt. Both feed-forward neural networks and recurrent neural networks (RNNs) are integrated into Modelica models. Finally, a complex architecture of neural networks (BNODE) (Aka, Brunnemann, Eiden, et al. 2024) is presented, which can also be implemented with SMArtInt in Modelica.

4.1 FFNN: Nusselt-Correlation

The first example model is a simple, trained feed-forward neural network integrated into Modelica as a TFLite model. It replaces the physical calculation of the Nusselt number with a neural network. The underlying correlation is given by the following relation:

$$\mathrm{Nu} = f\left(\mathrm{Re}, \mathrm{Pr}, \frac{\mathrm{L}}{\mathrm{d}}\right) \tag{1}$$

Figure 6 illustrates the model and the exchangeable heat transfer model used in the pipe. The pipe is discretized into ten segments, resulting in inference being performed ten times per time step on the same instance of the neural network.

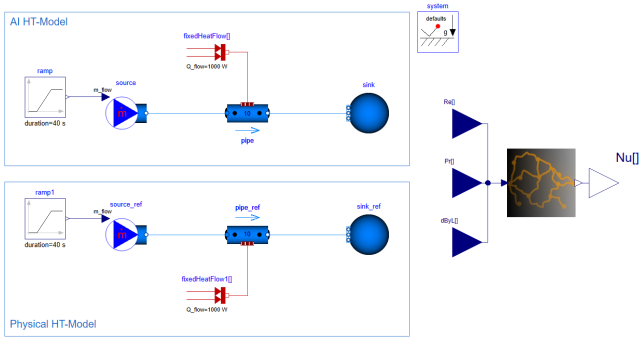

Figure 6. Left: Pipe model with AI Nusselt correlation and physical refernce model. Right: Diagram of the build in data based heat transfer correlation.

The model is primarily based on the SMArtInt example *Tester.PipeHeatTransferExample.TFLite.TestPipe_tflite* and has been extended with a reference pipe and a dynamic mass flow input. During the simulation, a constant heat flow is applied to the pipe, while the mass flow is defined by a ramp function. Figure 7 shows the variation of mass flow rates through the pipe. Initially, the mass flow is constant at 0.2 kg/s, and after 20 seconds, it is linearly increased to 0.9 kg/s over a period of 40 seconds. This dynamic change also impacts the heat transfer, as a higher mass flow with a constant heat flow results in a decrease in temperature within the pipe (as shown in Figure 8). When comparing the resulting temperatures of the pipe segments in Figure 8, no significant difference is observed between the physical and data-driven correlations.

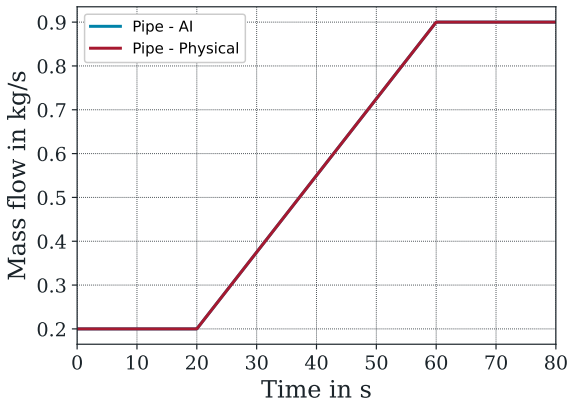

Figure 7. Mass flow in the pipe and the reference pipe

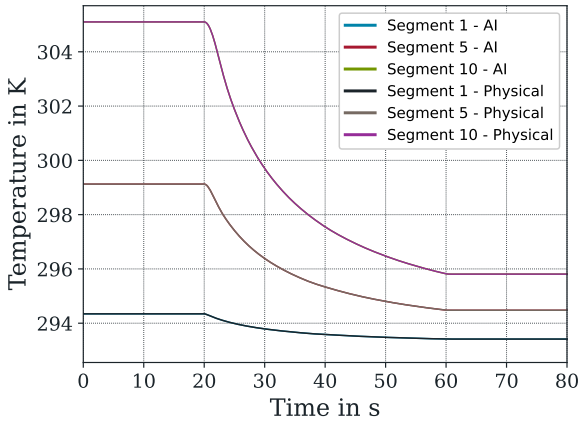

Figure 8. Temperature in the different pipe segments

4.2 sRNN: Superheater heat transfer model

The second example is based on a model (Brunnemann, Koltermann, et al. 2022) that comes from the DIZPROVI (Brunnemann, Flesch, and Hanke 2024) research project, in which SMArtInt also was developed. The project's primary focus was the replacement of physically modeled components with data-driven neural networks as part of a digital power plant twin (illustrated in Figure 9). In this example, the physics-based heat transfer model for

[2]ONNX, supported frameworks and converters: `https://onnx.ai/supported-tools.html#buildModel`

DOI 10.3384/ecp218459

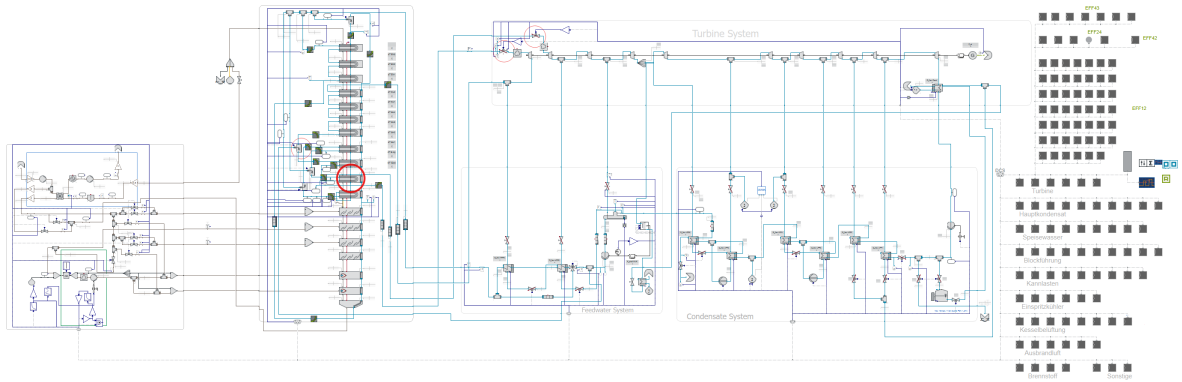

Figure 9. Digital twin of the investigated coal fire power plant, taken from (Brunnemann, Koltermann, et al. 2022)

one of the superheaters (SH4), which relies on energy balance, a Nusselt number correlation, and thermal radiation exchange, was replaced by a recurrent neural network (RNN). Using the inputs of flue gas and steam mass flow, as well as steam enthalpy and flue gas temperature at the superheater inlet, the neural network predicts the transferred heat flow as output. Figure 10 illustrates the predicted heat flow for both the physical and AI-based models within a validation scenario. The detailed control of the model presents a particular challenge for AI-based modeling, as the neural network must produce stable and reliable predictions even in regions outside the training distribution. Due to the mutual dependency between prediction and control, initial inference errors can cause the control logic to drive the system further into areas of low model confidence. This, in turn, degrades prediction quality and may ultimately lead to instability or simulation failure. This leads to two different integration approaches for the AI model:

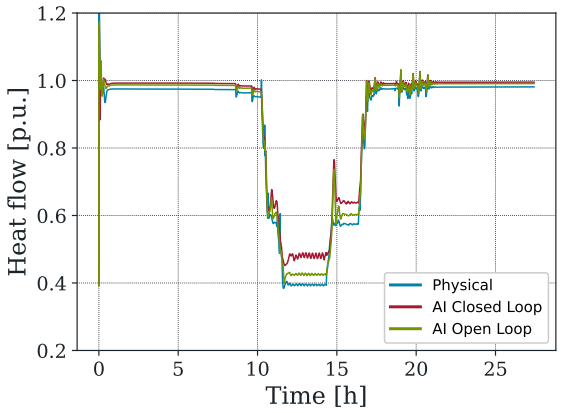

Figure 10. Heat flow SH4 (replaced heat transfer model)

1. Closed-loop integration, where the neural network is directly embedded into the superheater model, allowing interaction with the power plant's control system.

2. Open-loop integration, where the neural network operates independently of the overall model, serving primarily as a performance test for the trained neural network.

The AI-based heat transfer model was trained using data sets derived from measurement data. During data preparation, the spatial distribution of the sensors as well as the four-pass configuration of the evaporator area in the actual system were taken into account. In addition, the measurement data contains information on the degree of fouling and other relevant factors that influence the heat transfer surfaces. Therefore, in contrast to the physically based model, no further model calibration is required.
Figure 10 shows that both the open-loop and closed-loop models align well with the calibrated physical model in the steady-state full-load range. In the partial-load range, however, the heat flow predicted by both AI models exceeds the physically computed heat flow. This discrepancy does not necessarily indicate poor prediction accuracy of the AI model but may instead result from the calibration process of the physical model. For the physical model, the heat flow was adjusted via the fouling factor (CF) of the heat transfer surfaces under steady-state full-load conditions. Consequently, the actual heat flow in the partial-load range of SH4 may deviate from the physically computed and calibrated heat flow. Additionally, certain assumptions made during data processing may have led to lower-quality training data in the partial-load range, further affecting prediction accuracy. More details can be found in the DIZPROVI final report. The comparison of open-loop and closed-loop integration highlights the impact of control. The cooling regulation (CoolerSH3) stabilizes the steam outlet temperature of SH4, reducing thermal stress on the turbines. If heat transfer in SH4 increases, more cooling water is injected, lowering the outlet temperature and improving overall heat transfer. This effect is particularly evident in partial load operation. More detailed insight into the example and the research project can be found in the final report (Brunnemann, Flesch, and Hanke 2024).

4.3 BNODE: Steam-Cycle

The third example builds on the concept of a Balanced Neural ODE (BNODE), introduced by (Aka, Brunnemann, Eiden, et al. 2024). This approach employs a complex architecture composed of multiple interacting neural networks and can be used as a surrogate model for simulating the behavior of complex Modelica systems.
Balanced Neural ODEs combine Neural Ordinary Differential Equations (NODEs) (Chen et al. 2018) with Variational Autoencoders (VAEs) (Kingma and Welling 2019). Instead of approximating the original terms of the ODE directly by a neural network, the state space is mapped into a latent space and the neural network describes an ODE in the latent space. The latent states are then decoded back into the physical space to generate predictions that can be compared to the actual solutions of the ODE. By combining variational autoencoders with state space models, the generalization capability induced by the information bottleneck of VAEs can be used effectively. The information bottleneck created by the numerically defined latent space enforces a compressed, abstract representation of the data and promotes both data locality and the orthogonality of latent dimensions.
The term Balanced Neural ODE (BNODE) refers to the trade-off between state space compression and reconstruction quality, which is established during training and can be controlled via the β parameter. A detailed description of the BNODE concept is provided in the work of (Aka, Brunnemann, Eiden, et al. 2024).

Figure 11 illustrates the concept of the BNODE. The encoders (for state and control) map the input signals and initial system states into the latent space. The state encoder is only required for initialization, as the subsequent latent states are computed by the Neural ODE (NODE). The NODE is a neural network that estimates the state derivatives, from which the next latent states are determined using an ODE solver. These latent states can then be transformed back into the state space using the decoder.

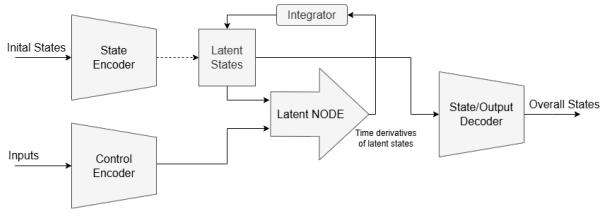

Figure 11. BNODE Concept

For this example, a BNODE was developed for a steam cycle of a coal-fired power plant, based on the concept proposed by (Aka, Brunnemann, Eiden, et al. 2024) and using a training process similar to that described in (Aka 2025). The model replaced by the BNODE originates from the Modelica library ClaRa (ClaRa 2025) (*Examples.SteamCycle_01*) and describes a steam cycle of a coal power plant, considering both mass and energy balances. The original physical model, consisting of 134 states, 29,775 variables, and 8,522 equations, is shown in Figure 12.

Out of the 134 states, the surrogate model approximates 102 states along with 7 additional outputs. Only states related to control elements (e.g., PI controllers), which do not carry essential information about the systems physical state, are omitted. The key parameters of the BNODE surrogate model are listed in the tables 2 and 3.

Table 2. Basic parameters of the BNODE model

Parameter	Value
States	102
Outputs	7
Control inputs	1
Latent states	128
β	0.1

Table 3. Hyperparameter of Encoders, Decoder and Latent ODE

Hyperparameter (for all NNs)	Value
Layers	4
Hidden dimension	64
Activation	ELU

After completion of the training process, the individual neural networks that constitute the BNODE architecture can be exported from the PyTorch format to the ONNX format, which can in turn be integrated into Modelica environments using SMArtInt. The Neural ODE solver employed during training is replaced by the native solver of the Modelica tool, by defining the output of the NODE network as the time derivative of the latent states (see code listing 1).

```
for i in 1:n_lat_states loop
        der(lat_states[i]) =
            LNODE_func.y[i];
end for;
```

Listing 1. Modelica loop of BNODE state derivatives

In addition to the trained networks, the initial states must be provided for model initialization and mapped into the latent space using the state encoder. It is essential that, along with the initial states, the corresponding control input is also specified. After initialization, the control input can be varied within the bounds defined during the training data generation. Figure 13 shows the BNODE brought back to Modelica. The initial states are stored in the *states_tab* table, while the control input is provided in the *P_Target* table. The neural networks that form the BNODE architecture are implemented as individual SMArtInt blocks within the model, and their inputs and outputs are processed at the equation level.

If the same power target (*P_Target*) time series is applied to both the physical model and the surrogate BNODE model, their simulation results can be directly compared. In this example, the control input is initially set to

DOI 10.3384/ecp218459

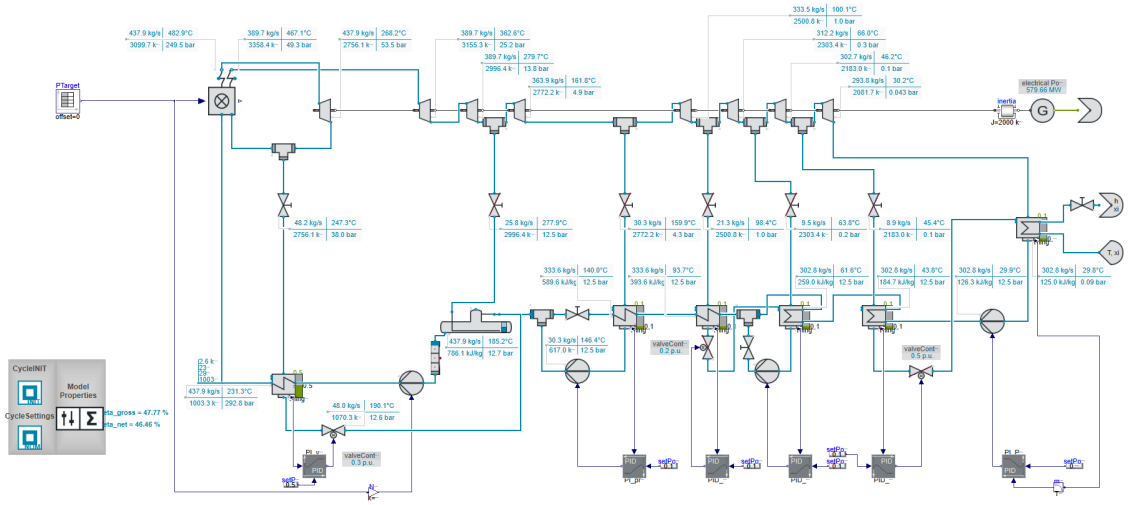

Figure 12. ClaRa: Steam cycle example

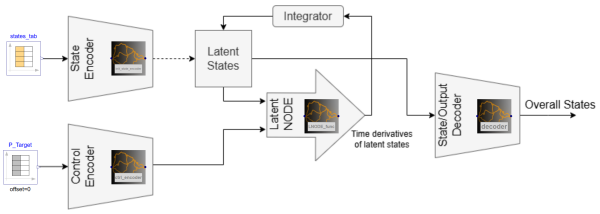

Figure 13. BNODE brought back to Modelica

the BNODE's starting value. After 1000 seconds of simulation time, it is linearly ramped up to 100% (full load) over the course of 100 seconds. Following an additional 900 seconds at full load, the power target of the steam generator is decreased to 70% (partial load), before being increased back to full load at 3000 seconds.
Therefore, the steam cycle displayed by both the BNODE and the physical model experiences a load change. Figure 14 shows the comparison results, including the power target and the seven additional outputs for both the physical model (in red) and the BNODE model (in blue).

The BNODE approximates the results of the physical model quite well, while performing state reduction at the same time. Only 116 of the 128 possible latent state dimensions are utilized. By adjusting the β value, the number of utilized latent state dimensions could be further reduced, although this might result in a decrease in the prediction accuracy of the BNODE. Figure 15 additionally presents a comparison of the computation times of both models. It becomes evident that, especially during dynamic operation, the BNODE requires significantly less computation time compared to the physical model. In this example scenario, the simulation computation time can be reduced by almost a factor of 10 using the BNODE concept. The speed-up factor can increase further in more complex scenarios involving additional load changes, as these have a significant impact on the computation time of the physical model, while leaving the BNODE largely unaffected.

5 The SMArtInt Funding Scheme: Sustaining Open-Source Development

SMArtInt is and will remain an open-source project, continuously evolving with regular updates and releases. To ensure the long-term financial sustainability of its development, it is complemented by a commercial companion version: SMArtInt+ (SMArtIntPlus 2025).
SMArtInt+ extends the functionality of the open-source SMArtInt library by further simplifying its use while also enhancing the quality of the results. The key features of the premium version are listed below:

- Extrapolation Warning
- Modelica Model Generator
- Network Generator (in development)
- Advanced Interfaces
- Tensorflow-Converter (Python)
- Tensorflow-Dedimensionalization-Layer (Python)

As previously mentioned, the individual features of SMArtInt+ are designed to address different aspects of model improvement. One such feature is the **Extrapolation Warning**, which helps ensure the reliability of neural network predictions. Neural networks are highly effective at interpolating within the range of their training data. However, their behavior can get unpredictable when making inferences on unseen data outside that range. In order to identify an extrapolation, SMArtInt+ includes an *Extrapolation Warning* based on three alternative methods: convex hull, kernel density estimation, and a simplified density estimation. These techniques monitor inputs in real time and detect whether the neural network is operating outside its training data.

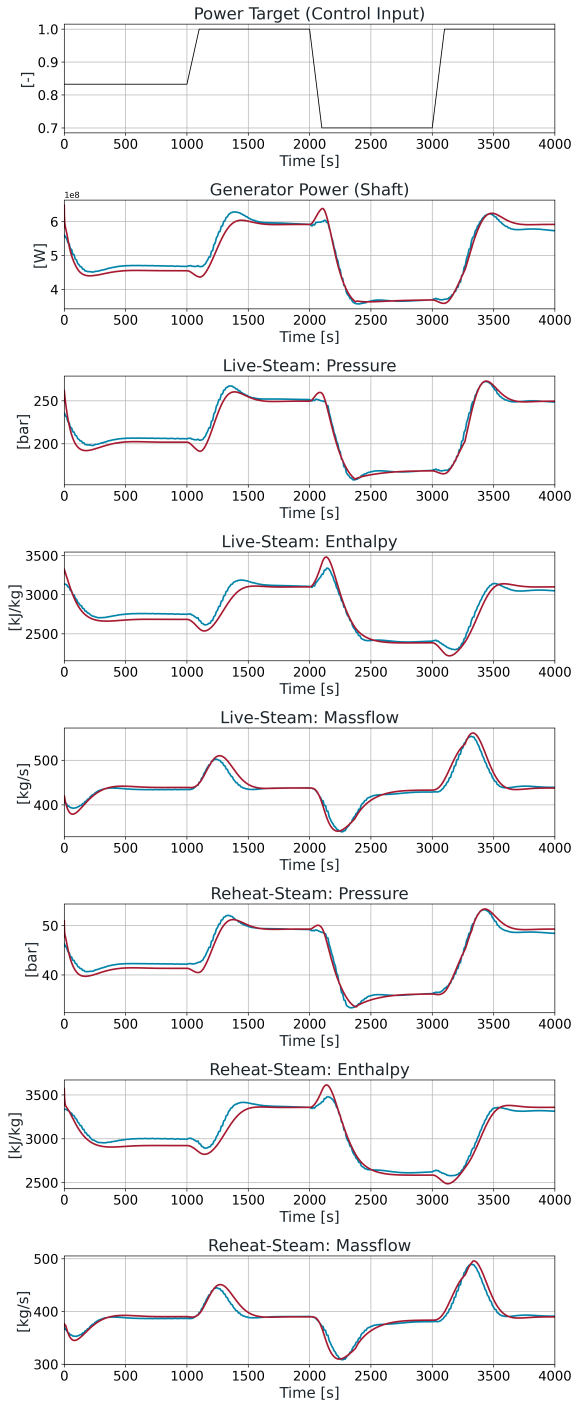

Figure 14. Comparison of different states between physical model (red) and the BNODE surrogate model (blue)

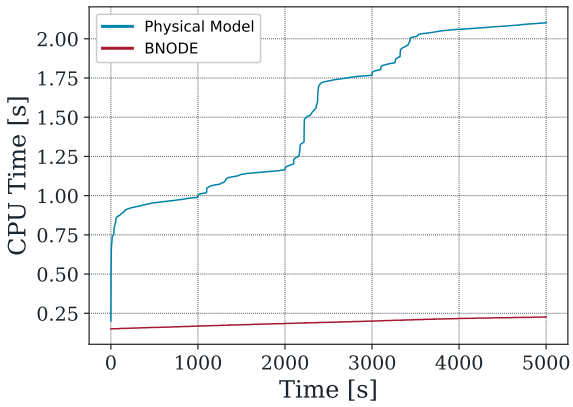

Figure 15. CPU times of the physical model (Dassl-Solver) and the BNODE surrogate model (Euler-Solver)

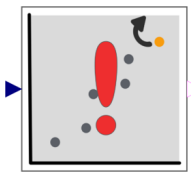

Figure 16. Icon of the ExtrapolationWarning Block

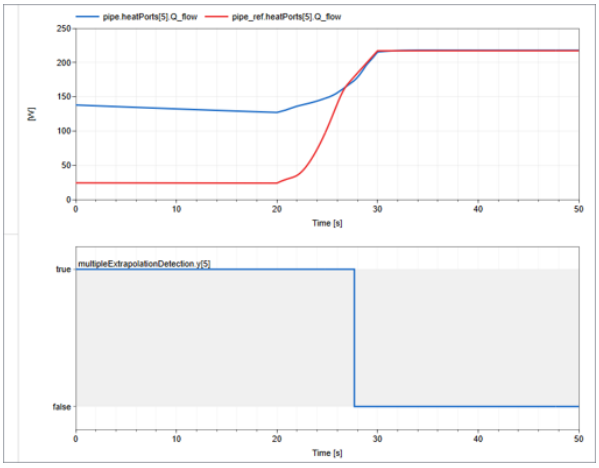

Figure 17. Extrapolation example of a neural network (network prediction and extrapolation curve)

Figure 16 illustrates the extrapolation warning icon triggered during an extrapolation event.
While Figure 17 presents a plot showing its status throughout the entire simulation.

The Modelica **Model Generator** automates the integration of pre-trained neural networks (in TFLite and ONNX format), enabling users to incorporate their models into Modelica with minimal effort. Especially when used in combination with the Network Generator (currently under development) which will allow users to define and train sequential feed-forward and recurrent neural networks with TensorFlow directly in Modelica, the Model Generator becomes a useful tool. SMArtInt+ also features enhanced **interface blocks** equipped with input/output smoothing, integrated scaling, and extrapolation monitoring.

The Modelica library also comes with a **Python-based converter** specifically designed for TensorFlow models with internal states (such as sRNNs), enabling their conversion to TFLite format for seamless integration into SMArtInt (see Section 2.2.1). In addition to the converter, SMArtInt+ includes **dedimensionalization layers (PI-Layer)** (Bakarji et al. 2022), which are custom TensorFlow layers that allow dimensionless quantities to be

DOI
10.3384/ecp218459

used as inputs to neural networks, either automatically or manually. This approach reduces the dimensionality of the underlying problem, enabling the use of smaller neural network architectures with fewer layers or units for the same application. Additionally, dedimensionalization improves the generalization capability of AI models. Figure 18 shows the structure of a neural network wrapped with a PI-layer.

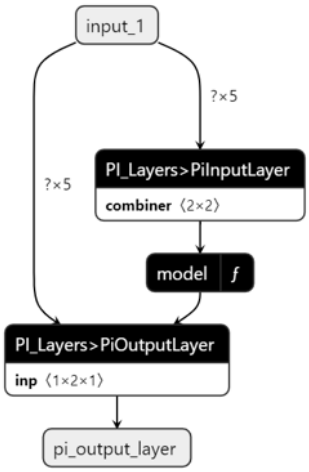

Figure 18. Structure of a neural network wrapped in a dedimensionalization layer

Further information on SMArtInt+ can be found in (SMArtIntPlus 2025).

6 Summary & Outlook

In this paper we have introduced the status of the open-source Modelica library SMArtInt, which enables Modelica users to combine physics based Modelica code with data driven neural networks in a Modelica-based workflow.

With its latest release, users of SMArtInt can now integrate ONNX models into the field of physical Modelica simulations. This enables users to utilize machine learning, deep learning, and other AI techniques from various ONNX-compatible frameworks, thus enhancing the modeling of complex physical systems. The capabilities of SMArtInt are illustrated by examples given in section 4.

SMArtInt is open source and intended to become a Modelica community project and we warmly invite the Modelica community to participate in the libraries improvement by providing user feedback, feature requests and discussing / coding new ideas in order to further enhance Modelicas hybrid modeling capabilities.

The SMArtInt development team will continue development in ongoing and planned research projects.
