Book of Paper

DLR at a glance

DLR is the Federal Republic of Germany's research centre for aeronautics and space. We conduct research and development activities in the fields of aeronautics, space, energy, transport, security and digitalisation. The German Space Agency at DLR plans and imple-ments the national space programme on behalf of the federal government. Two DLR project management agencies oversee funding programmes and support knowledge transfer.

Climate, mobility and technology are changing globally. DLR uses the expertise of its 55 re-search institutes and facilities to develop solutions to these challenges. Our 10,000 emplo-yees share a mission – to explore Earth and space and develop technologies for a sustainable future. In doing so, DLR contributes to strengthening Germany's position as a prime location for research and industry.

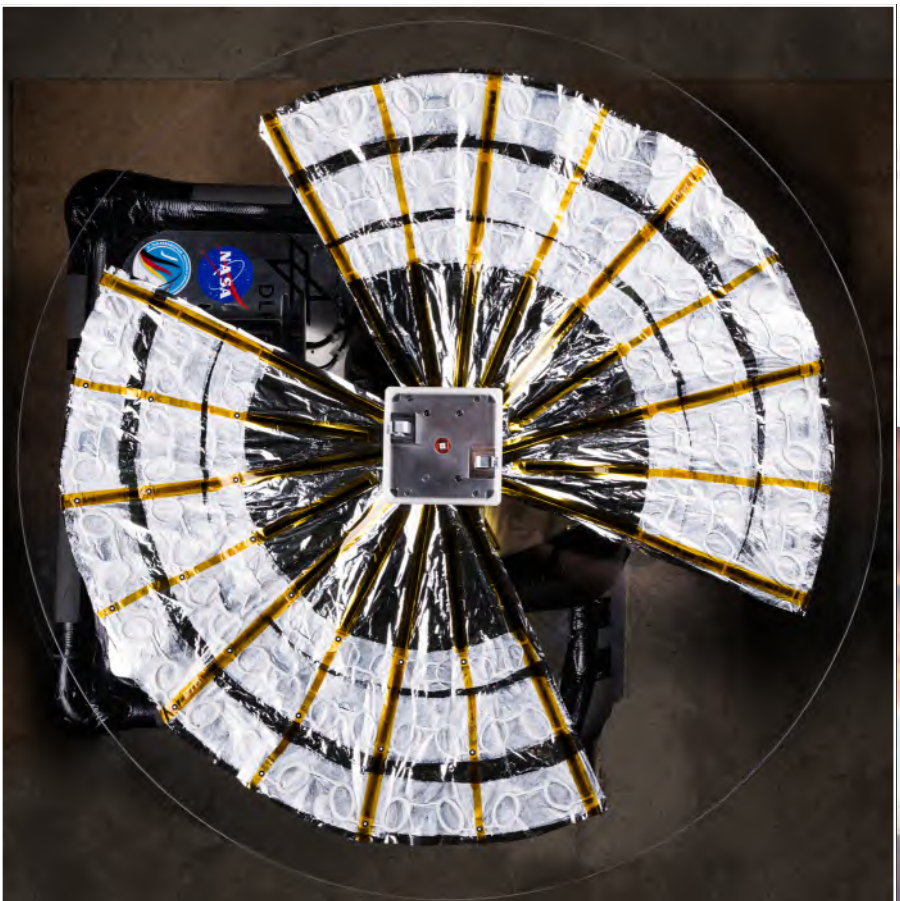
Topics at a Glance



The ECSSMET 2026 programme reflects the broad range of challenges involved in designing, manufacturing and verifying spacecraft structures. From mechanical architecture and structural design to materials, manufacturing and environmental testing, the sessions bring together established engineering approaches with emerging technologies and new application fields.

A particular focus is placed on the development and qualification of lightweight and composite structures, advanced materials and additive manufacturing. Contributions explore topics ranging from CFRP and thermoplastic structures to high-entropy alloys, ceramic components and novel manufacturing processes. Digital engineering is also gaining importance, with approaches such as digital twins, data-based modelling and machine learning opening up new possibilities for design and analysis.

The programme further covers the dynamic behaviour of spacecraft and launch vehicles, including vibration, shock, acoustic and coupled-load analysis, as well as the correlation of simulations with experimental results. Environmental testing and innovative measurement and instrumentation methods provide the link between numerical prediction and real-world performance.

Another important strand is the development of deployable and multifunctional structures, thermal-mechanical design and verification, and structural concepts for reusable and future missions. Sustainability is increasingly becoming part of structural engineering, with contributions addressing demisability, atmospheric impact, eco-design and the use of sustainable materials.

Together, these topics provide a view of a field that is evolving rapidly – from established spacecraft engineering practices to technologies and methodologies shaping the next generation of space structures.

Direct Field Acoustic Testing, Digital Twin, Pretest, Acoustic Simulation, Finite Element Method

ABSTRACT

This work presents use cases of pretest analysis of Direct Field Acoustic Testing/Noise (DFAT/DFAN). A Finite Element (FE) solver is used to simulate the acoustic field generated by a system of loudspeakers set up in a 6x6 configuration. To validate the proposed simulation framework, a dedicated experimental test campaign was conducted using a representative DFAN facility. Measured transfer functions, were systematically compared against model predictions. Good agreement between simulated and measured data confirmed the predictive capability of the model. The validated tool provides test engineers with a practical means to optimise DFAN system design parameters prior to test execution, ultimately improving acoustic field uniformity and control robustness for future spacecraft qualification campaigns.

1. INTRODUCTION

Direct Field Acoustic Testing/Noise (DFAT/DFAN) has emerged as a widely adopted method for performing environmental acoustic qualification of space hardware, offering significant advantages in cost, schedule, and risk management over traditional reverberant chamber testing [1]. In this approach, an electro-acoustic system comprising arrays of amplifiers and loudspeakers surrounds the test article, generating the required acoustic environments through direct sound radiation. Advanced Multiple-Input Multiple-Output (MIMO) control strategies are employed to achieve the spatially diffuse sound fields mandated by launcher authorities [2],[3].

There are two use-cases for creating a Digital Twin of a DFAN facility: First, predicting the performance of the electro-acoustic system – or else said, can we meet the reference profile with a given setup? Second, to look at a full pressure field – in addition to the 20-30 microphones we use in the test.

An add-on tool to the Simcenter 3D acoustics software was developed to facilitate the DFAN pretest simulation in acoustic Finite Element (FE) environment [4]. It automatically guides less experienced users through the various steps of most use cases, while allowing expert users to alter modelling and simulation steps as needed.

The workflow includes modelling of the speaker geometry, automatic placement of the speakers in stacks, import of the test structure geometric and/or structural FE representation, assigning speaker transfer functions of velocity over input voltage, assigning drives and solving the acoustic transfer functions to target microphones. Then, these transfer functions are coupled to a virtual MIMO controller working the same way as in test. The virtual pretest levels the responses to the targeted level and allows to select the most suitable control microphones. Moreover, the sound field can be visualised using microphone meshes.

2. SPEAKER CHARACTERISATION

The original development of the Pretest simulation tool [4] focused on representing the speaker diaphragm by a spring-mass damper system based on Thiele-Small Parameters [5]. High-performance Speaker systems frequently used in DFAN setups do not have their diaphragms exposed to the exterior but include a complex interior geometry to maximize the output of sound power evenly distributed over the frequency range. Therefore, the radiation of the speaker in the presented use cases was modelled based on scans of pressure and velocity using a PU probe. measurements. In a semi-anechoic environment, the front surface of the speaker is divided into small patches and each of these is scanned with a PU probe.

The velocity is processed as transfer function over input voltage. These are visualised by third octave band. Transfer functions are averaged over larger patches which in turn are used to define velocity and impedance boundary conditions in the FE model.

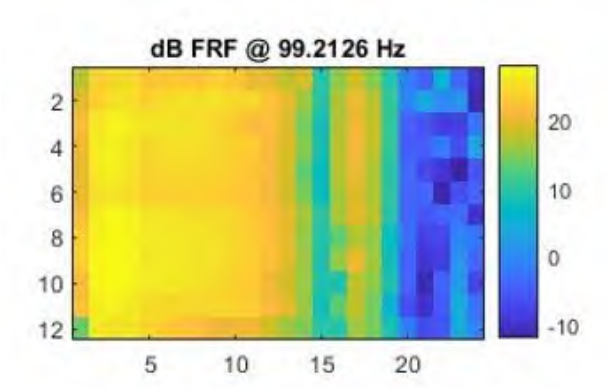

Figure 1: Post-processed velocity scan of MP-21 speaker

Within the same test campaign, also the response on a microphone array is measured on the reflecting ground. It has been demonstrated that the simulation replicates the directivity of the speaker with good accuracy.

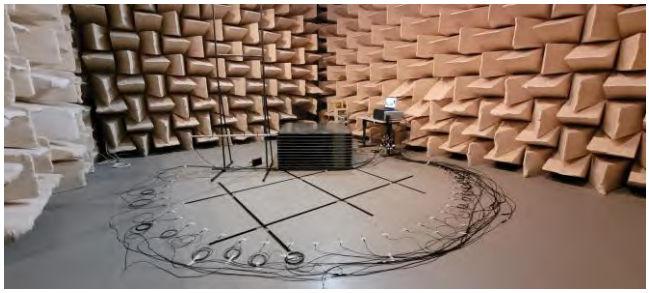

Figure 2: Validation measurement of MP-21 speaker: Sound field directivity

Pressure and velocity data from the probe is further process to generate the surface impedance to be used as a boundary condition in acoustic simulation.

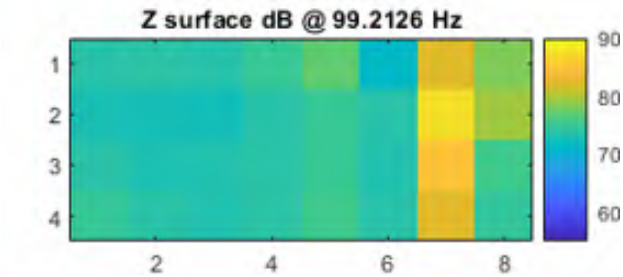

Figure 3: Processed surface impedance on MP-21 speaker

Replicating the test setup in acoustic FE environment, the directivity of the speaker could be predicted with good accuracy, see *Figure 4*.

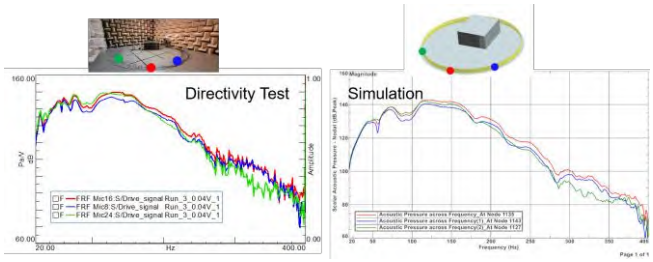

Figure 4: MP-21 speaker directivity from Test (left) and simulation (right)

The verified speaker models are available for future pretest activities of the same speaker type.

3. EMPTY TEST SETUP

As most applications of the pretest process concern confidential test objects, validation testing of a full speaker array has been performed on an empty setup.

Six MP21 woofers in double stacks and six single stacks of MP-150 mid/high frequency speakers are arranged at a radius of 10 ft. There are six drives with their own input voltage, controlled by a MIMO algorithm. Each drive is connected to one stack of each speaker type.

In the present work, the acoustic domain is modelled via an adaptive high-order finite element method (FEMAO) [6]. This solver, available in Simcenter 3D, reduces drastically the computational cost of the acoustic problem by automatically adjusting the polynomial order of the finite elements to the frequency requirements: The electro-dynamic actuators are modelled as rigid radiating surfaces with a prescribed acoustic normal velocity. Another important feature of the modelling approach is the application of free-field boundary conditions, which are imposed using the Automatically Matched Layer (AML) technology [7]. This simulation object, which may be defined on any convex shaped surface, efficiently absorbs outgoing acoustic waves regardless of their frequency and angle of incidence.

Using the validated speaker models from the previous step, the setup is modelled using the automatic DFAN tool.

It contains test microphone positions as well as a cylindrical and plane microphone mesh for visualisation of sound pressure distribution.

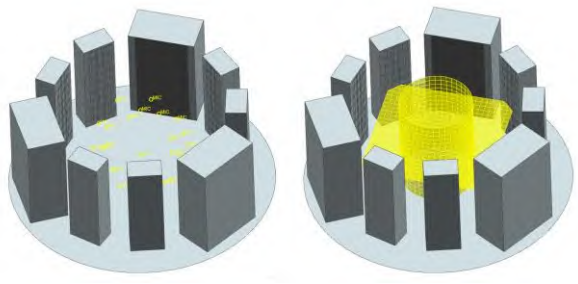

Figure 5: Model of empty test setup with test microphone positions (left) and microphone mesh for visualisation (right)

The transfer function from input voltage to microphone pressure has been validated against test data, as shown in *Figure 7*. In most frequency bands, good accuracy is obtained. In some lower frequency bands below 200 Hz, the difference between the two spectra is greater. Partly, this can be explained by the influence of the testing hall and its resonances, which are not included in the generated DFAN model.
Moreover, it was noted that different test runs yielded more variation in the results in this range than in others.

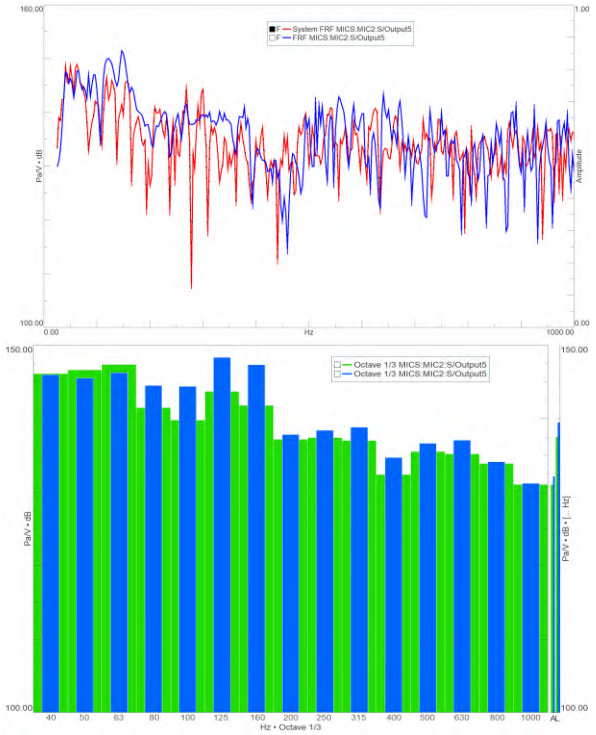

Figure 6: Example of pressure over voltage transfer function correlation, drive 5 to microphone 2. Top: Narrowband function, test: red, simulation: blue. Bottom: 3rd octave spectra test: green, simulation blue.

In the pretest analysis, the optimum set of control microphones is identified using predictions of the system responses achieved by the MIMO controller. The individual sound pressure levels by octave band are close to the target and to each other.

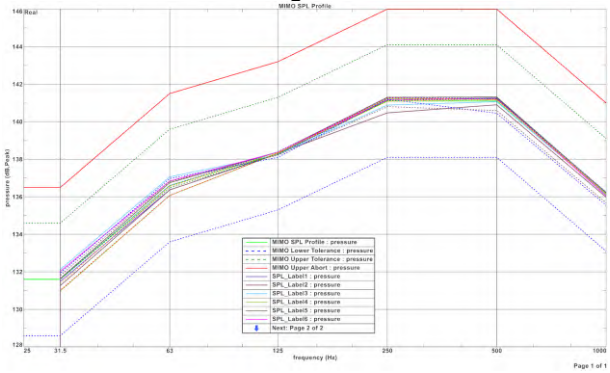

Figure 7: Predicted sound pressure levels in control microphones together with upper and lower tolerance bounds. Solid red line is abort pressure

The spatial distribution of sound pressures is relatively uniform in the central area of the setup. The test microphones – cubic blocks in *Figure 8* – have very similar pressure.

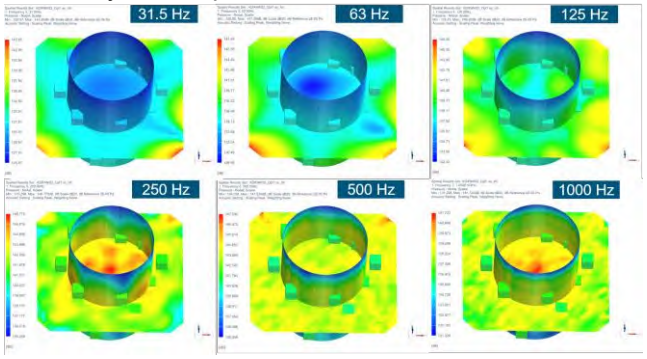

Figure 8: Predicted sound pressure levels in testing space and test microphones by octave band

4. SETUP WITH TEST OBJECT

A similar speaker setup of MP-21 and MS-25 speakers has been modelled to demonstrate the use of the tool in a typical pretest situation. Like in the empty case, velocity transfer functions from test have been assigned to patches of the speaker front faces and the speaker stacks connected virtually to drives.

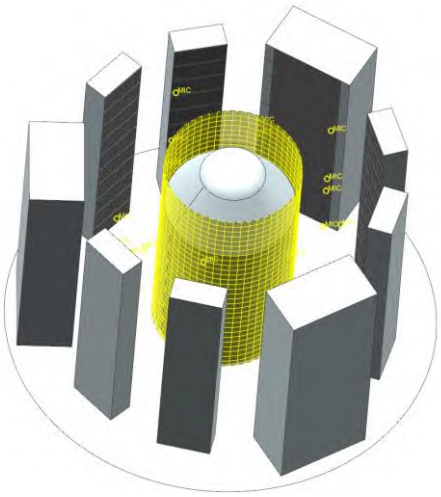

Figure 9: Model of test setup with spacecraft structure in the centre, candidate microphone points and a cylindrical visualisation mesh around the test object

For each patch on the faces, an individual transfer function is calculated using the acoustic FEM solver. As can be seen in *Figure 10*, the sound field from one single patch at a specific frequency shows a wave pattern similar to what typically results from a single point source.

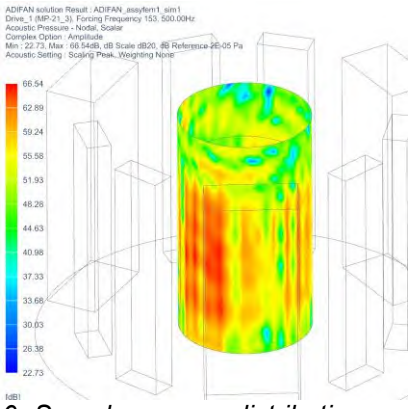

Figure 10: Sound pressure distribution around test object for discrete frequency 500 Hz and excitation from single patch on MS-21 woofer.

In a second step, the individual transfer functions are driven by the MIMO controller to generate the acoustic response in test condition. A randomly chosen combination of 12 control microphones results in most sound pressures being close to the target, whereas two of the microphone spectra fall out of the tolerance envelope.

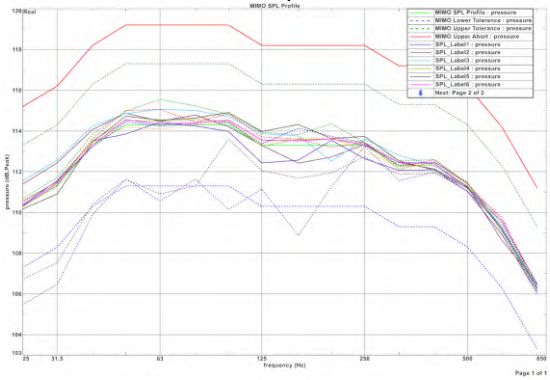

Figure 11: Control microphone response by 3rd octave band for randomly chosen set of 12 microphones.

Running the optimisation algorithm results in a better choice of control microphones, where all 3rd octave sound pressures are well within the tolerance band that was defined at the start of the simulation.

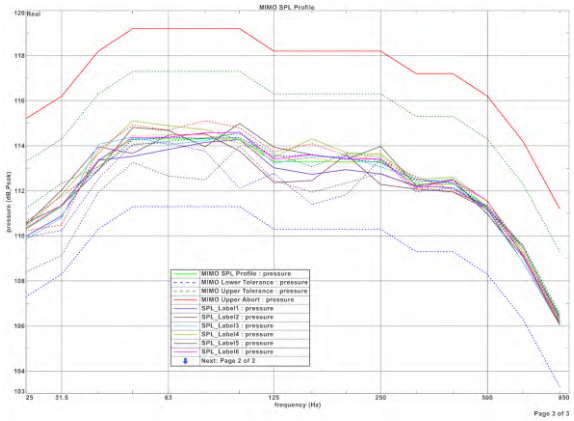

Figure 12: Control microphone response by 3rd octave band for optimised set of 12 microphones.

The pressure distribution around the test object is rather uniform with some interference in vertical direction at higher frequencies. The sound pressure in the top region of the microphone mesh is much lower for two reasons:
First, this region is at similar height as the top of the speaker arrays, so that a boundary effect occurs. Second, these microphones are farther away from the test structure that has a conical shape here. Therefore, the field pressure is not as much amplified by the reflection on the surface of the test object.

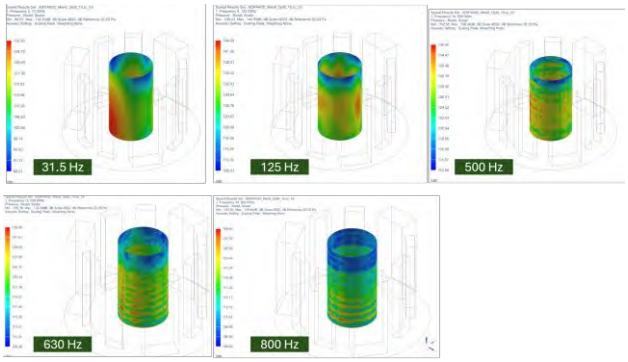

Figure 13: Sound pressure distribution around test object by 3rd octave band, controlled by optimised set of control microphones

5. OUTLOOK

The DFAN Pretest tool is now available for a commercially distributed and broadly used speaker system. After the validation and first applications, it can be fully used for pretest purposes. This can include prediction of vibration response and investigation of the room effect, like already presented in [4]. This is done to reduce the observed error when the room effects count.
Beside de-risking of test campaigns, also the layout of new test facilities can be supported.

6. CONCLUSION

The use of acoustic Finite Element simulation as pretest tool for Direct Field Acoustic Noise Testing has been demonstrated. Measured velocity fields at front faces of speakers have been implemented in the model. Validation with measured transfer functions shows good agreement. The use of the tool for the selection of control microphones has been demonstrated.

ABSTRACT

Accurate control-microphone coordinates are required in Direct Field Acoustic Noise (DFAN) testing for repeatability, traceable reporting, and Sinc Indicator Function (SIF) assessment of acoustic-field uniformity. This paper presents a localisation framework combining trilateration with electrical-reference-to-microphone delay estimation from logarithmic chirps. Sub-sample interpolation refines the correlation peak, while robust estimation limits the influence of inconsistent ranges. Following a preliminary laboratory trial, the method was deployed in an operational DFAN configuration using the existing speaker stacks. Speaker Equivalent Point Sources (EPS) were first identified by inverse localisation using microphones with known coordinates; the resulting source coordinates were then used to reconstruct 28 microphone positions. Comparison with Laser Radar coordinates yielded a mean three-dimensional discrepancy of 3.77 cm; 26 of 28 discrepancies were at or below 8 cm. These results support the feasibility of automated coordinate reconstruction within the calibrated DFAN configuration.

1. INTRODUCTION

During vibro-acoustic qualification, aerospace structures are subjected to extreme sound pressure levels (SPL) to simulate launch or operational conditions. Direct Field Acoustic Noise (DFAN) testing has become a standard alternative to traditional reverberant chambers for satellite qualification [1]. However, as noted in the NASA-HDBK-7010 handbook [2], it is of paramount importance to "make accurate measurements of the speaker and microphone locations" to guarantee the scientific and industrial validity of the test.

Precise control microphone localisation serves three fundamental purposes within the aerospace industry:

1. **Test repeatability:** Supporting consistent spatial reconstruction of the acoustic setup across testing campaigns and dry runs.
2. **Formal reporting:** Providing traceable, high-fidelity geometric data required for qualification certificates and mission assurance documentation.
3. **Field uniformity verification:** Enabling the robust calculation of sound field diffusivity through the Sinc Indicator Function (SIF) method [3], which maps the spatial cross-correlation of the pressure field against an ideal diffuse model.

Despite these strict requirements, standard industry practices still rely heavily on manual coordinate entries using tape measures or laser distance meters. This manual process is not only time-consuming but also introduces an additional positioning uncertainty due to human error, parallax effects, and the difficulty of precisely identifying the acoustic centres of complex transducers.

To overcome these limitations, this work presents the development, scaling, and operational deployment of an automated, high-resolution microphone localisation framework. While preliminary laboratory investigations verified the core algorithm using a small array of 8 dedicated acoustic anchors and 4 microphones, this paper focuses on scaling the method to an industrial DFAN configuration, where 28 control microphones are localised simultaneously.

The framework uses the high-power speaker stacks as localisation sources, avoiding a separate acoustic source array. Surveyed coordinates are still required for initial calibration and Equivalent Point Source (EPS) identification. Subsequent localisation runs use the calibrated sources to reconstruct microphone coordinates. The industrial

comparison with Laser Radar coordinates yielded a mean 3D discrepancy of 3.77 cm, with sub-centimetre discrepancies at selected positions.

2. EXPERIMENTAL CONFIGURATION

2.1. Hardware and instrumentation

Delay estimation depends on the signal-to-noise ratio (SNR), channel synchronisation and stability of the electro-acoustic chain. The hardware was evaluated in two experimental configurations:

1. **Laboratory-scale setup:** A Siemens SCADAS-Lab mainframe acquired signals from four GRAS 40BD ¼-inch prepolarised pressure microphones [4]. Eight acoustic anchors were arranged at staggered heights. Anchor and microphone coordinates were surveyed with a tape measure to provide a preliminary reference for algorithm development and evaluation.
2. **Industrial DFAN setup:** The reduced-scale operational configuration comprises 10 vertical speaker columns around the test volume: five subwoofer columns and five TOP columns, each containing three enclosures (Fig. 1). The TOP cabinets emitted the high-frequency localisation chirps (15 independent anchors). The receiver array comprised 28 control microphones. Laser Radar measurements of microphone positions and speaker cabinet faces provided the geometric reference for calibration and comparison with reconstructed coordinates.

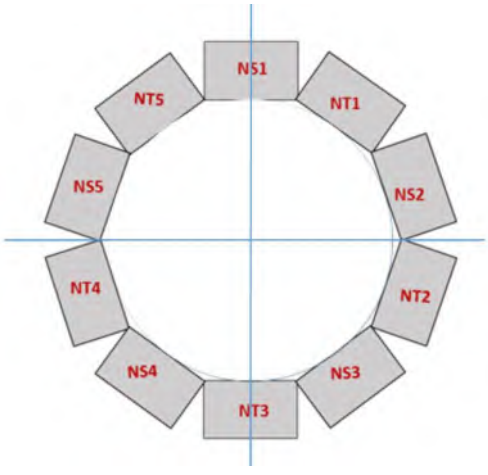

Figure 1: Top view of the reduced-scale DFAN setup. NT1–NT5 denote TOP columns; NS1–NS5 denote subwoofer columns.

2.2. Physical wiring and calibration layout

A dual-branch acquisition layout records an electrical reference and the microphone responses on a common acquisition clock.

As illustrated in Fig. 2, the analogue chirp signal $x(t)$ is split at the output of the digital-to-analogue converter (DAC) by an electrical Y-splitter:

- **Branch A (electrical reference):** The signal is routed directly to SCADAS input CH1, which records the electrical timing reference for each emission.
- **Branch B (acoustic path):** The signal drives the power amplifier and active speaker. Microphone responses are acquired on CH2 to CH$(M+1)$, where M is the number of microphones.

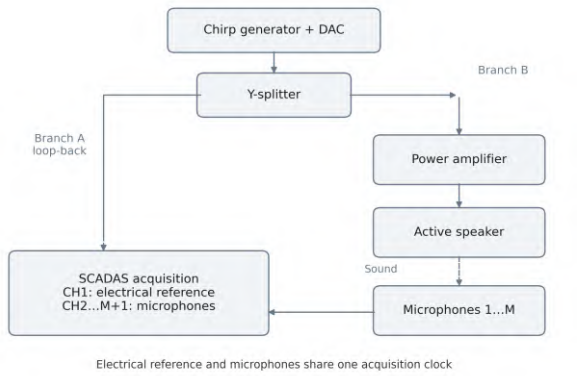

Figure 2: Electrical reference and acoustic acquisition paths. The DAC precedes the splitter; the power amplifier lies between the splitter and speaker.

Timing offsets upstream of the splitter are common to both paths and are rejected by the differential measurement [5]. The measured delay nevertheless retains the amplifier, speaker and receiver-chain delays, including any differential channel delay. These contributions require calibration; synchronous recording alone does not isolate the acoustic propagation time.

The preliminary calibration uses the surveyed distance $D_{\mathrm{cal},i}$ between the selected reference point on speaker i and a calibration microphone. The resulting effective timing bias depends on this geometric convention and on the electro-acoustic chain. Section 3.4 defines its subtraction before the EPS coordinates are used for localisation.

3. METHODOLOGY AND SIGNAL PROCESSING

3.1. Synchronous delay measurement and acoustic ranging

Each microphone recording is compared with the electrical reference from the same source emission. The observable is an electrical-to-acoustic delay. After bias correction it provides a source-to-microphone range, rather than the range difference used in conventional microphone-pair time-difference-of-arrival (TDOA) localisation [6]. Let i index the source and j the microphone. With both streams recorded on a common clock, the raw delay is:

$$\tau_{\mathrm{raw},ij} = t_{\mathrm{rec},ij} - t_{\mathrm{ref},i} \tag{1}$$

Here $t_{\mathrm{ref},i}$ is the electrical reference time and $t_{\mathrm{rec},ij}$ the corresponding microphone arrival time, both in seconds. Subtracting the effective source bias $\tau_{\mathrm{bias},i}$ gives the acoustic time of flight Δt_{ij} and range d_{ij}:

$$d_{ij} = c\,\Delta t_{ij} = c\left(\tau_{\mathrm{raw},ij} - \tau_{\mathrm{bias},i}\right) \tag{2}$$

The speed of sound c is in metres per second and d_{ij} in metres. This model assumes a stable calibrated chain and negligible or corrected receiver-channel delay differences. Temperature-dependent calibration and conversion are detailed in Section 3.4.

3.2. Linearised trilateration and radical planes

For microphone j, let $\mathbf{m}_j = [x_j, y_j, z_j]^{\mathsf{T}}$ be its unknown position and $\mathbf{S}_i = [x_i, y_i, z_i]^{\mathsf{T}}$ the position of source i. All coordinates and ranges are in metres in a common Cartesian frame. With N available sources, the range constraints are:

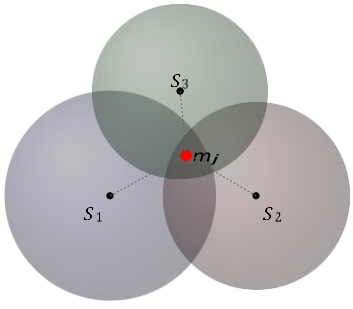

Figure 3: Spherical range constraints. Three sources are shown schematically; a unique unconstrained 3D solution requires additional geometric information.

$$\| \mathbf{m}_j - \mathbf{S}_i \|_2^2 = d_{ij}^2, \quad i = 1, \ldots, N \tag{3}$$

Subtracting the Nth sphere equation from each of the first $N-1$ equations eliminates the quadratic position terms and produces radical planes [7]. The resulting linear system is:

$$\mathbf{A}\mathbf{m}_j = \mathbf{b} \tag{4}$$

The Euclidean norm is denoted by $\|\cdot\|_2$ and transpose by T. For $i = 1, \ldots, N-1$, the rows of $\mathbf{A} \in \mathbb{R}^{(N-1)\times 3}$ and entries of $\mathbf{b} \in \mathbb{R}^{N-1}$ are:

$$\mathbf{A}_{i,:} = 2(\mathbf{S}_i - \mathbf{S}_N)^{\mathsf{T}} \tag{5}$$

$$b_i = \left(d_{Nj}^2 - d_{ij}^2\right) + \left(\| \mathbf{S}_i \|_2^2 - \| \mathbf{S}_N \|_2^2\right) \tag{6}$$

If $N \geq 4$ and $\mathrm{rank}(\mathbf{A}) = 3$, the least-squares estimate minimising $\| \mathbf{A}\mathbf{m}_j - \mathbf{b} \|_2^2$ is:

$$\hat{\mathbf{m}}_j = (\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}\mathbf{b} = \mathbf{A}^{+}\mathbf{b} \tag{7}$$

The symbol $\mathbf{A}^{+}$ denotes the Moore–Penrose pseudoinverse. This algebraic estimate minimises the linear-system residual, not directly the nonlinear range residual; the industrial robust refinement is described in Section 4.

3.3. Signal processing and sub-sample refinement

To quantify the acoustic time-of-flight (TOA), the excitation framework employs logarithmic chirp signals spanning from 2 kHz to 18 kHz with a burst duration of T = 100 ms. Acoustic sources are triggered sequentially via time-division multiplexing (TDM), emitting N = 5 consecutive bursts averaged in the time domain to maximize the signal-to-noise ratio. All channels are digitized at an industrial sampling rate of f_s = 51.2 kHz.

The raw microphone recordings and electrical reference signals are pre-filtered using a fourth-order Butterworth band-pass filter ($2\text{--}}18\text{ kHz}$) applied via zero-phase forward-backward filtering to prevent group delay distortion [8]. The coarse delay is found by correlating the electrical reference $x(t)$ with each microphone signal $y(t)$ from the same emission:

$$R_{xy}(\tau) = \int_{-\infty}^{\infty} x\,(t)y(t+\tau)\,\mathrm{d}t \tag{8}$$

Here t and τ are time and lag in seconds. A delayed microphone signal gives a positive lag with this convention. Correlation aligns the received chirp with the reference [9,10]; the peak includes chain delay as well as acoustic travel time. In sampled data, let $\hat{k}$ denote the discrete correlation at integer lag k samples and k_0 the selected peak of its

magnitude. Define $a_- = |R[k_0 - 1]|$, $a_0 = |R[k_0]|$ and $a_+ = |R[k_0 + 1]|$. Parabolic interpolation [11] yields:

$$\hat{k} = k_0 + \frac{a_- - a_+}{2(a_- - 2a_0 + a_+)}, \qquad \tau_{\text{raw}} = \frac{\hat{k}}{f_s} \tag{9}$$

The refined lag $\hat{k} = k_{\text{peak}} + \delta k$ is in samples; division by the sampling frequency f_s in samples per second gives t_{raw} in seconds. The interpolation requires an interior, non-flat peak and does not itself distinguish a direct arrival from a strong reflection.

The procedure is repeated for every source–microphone pair. Sub-sample interpolation reduces sampling quantisation; calibration then converts the raw delays into the ranges used by the localisation solver.

3.4. Electro-acoustic distance conversion and thermal compensation

Conversion to distance must separate the repeatable electro-acoustic timing bias from the temperature-dependent speed of sound.

For source i, let $\tau_{\text{raw,cal},i}$ be the raw calibration delay and $D_{\text{cal},i}$ the surveyed calibration distance. The effective bias is:

$$\tau_{\text{bias},i} = \tau_{\text{raw,cal},i} - \frac{D_{\text{cal},i}}{c_{\text{cal}}} \tag{10}$$

The calibration speed $c_{\text{cal}} = c(T_{\text{cal}})$ must correspond to the calibration temperature T_{cal}. Since the reference is taken after the DAC, its common upstream delay is already rejected. The bias represents the remaining chain delay under the chosen geometric reference convention.

For a later measurement of microphone j, the bias-corrected acoustic time of flight is:

$$\Delta t_{ij} = \tau_{\text{raw},ij} - \tau_{\text{bias},i} \tag{11}$$

The range uses the speed $c_{\text{meas}} = c(T_{\text{meas}})$ at the measurement temperature T_{meas}:

$$d_{ij} = c_{\text{meas}}\, \Delta t_{ij} \tag{12}$$

For temperature T expressed as a numerical value in degrees Celsius, the adopted dry-air approximation gives $c(T)$ in metres per second:

$$c(T) = 331.3\sqrt{1 + \frac{T}{273.15}} \tag{13}$$

Thus calibration and measurement may use different sound speeds. Each requires a representative ambient temperature; a single-temperature model neglects spatial temperature gradients and humidity effects. The effective timing bias is transferable only while the chain and source configuration remain stable However, since both the laboratory-scale and operational-scale measurements were conducted in a temperature-controlled environment (approximately 20 °C), the constant speed of sound at 20 °C was adopted.Robust localisation and experimental results

4. ROBUST LOCALISATION AND EXPERIMENTAL RESULTS

4.1. Multi-threshold random sample consensus outlier rejection

Wall, equipment and speaker-array reflections can produce secondary correlation peaks and inconsistent ranges in the industrial enclosure. The robust estimator reduces their influence but does not independently prove that every retained arrival is a direct path.

The industrial estimator applies Random Sample Consensus (RANSAC) with progressively relaxed range-residual tolerances:

$$\Theta = \{0.12,\ 0.25,\ 0.45\}\ \text{m}$$

These empirical thresholds accommodate increasing levels of range inconsistency caused by multipath.

Up to $K = 120$ random subsets are tested per threshold. Under the usual independent-trial approximation, with inlier fraction $\eta = 0.50$ and subset size $s = 4$, the probability of at least one all-inlier subset is $p = 1 - (1 - \eta^s)^K \approx 0.9996$. This is conditional on the assumed inlier fraction and non-degenerate geometry, rather than a guarantee for every dataset.

For each trial q, four anchors provide a candidate position $\mathbf{x}_q = [x_q, y_q, z_q]^{\mathsf{T}}$ using Sequential Quadratic Programming (SQP), within the test-volume bounds $-3 \le x_q, y_q \le 3$ m and $0.1 \le z_q \le 2.5$ m. The signed range residual for anchor i is:

$$e_i(\mathbf{x}_q) = \| \mathbf{S}_i - \mathbf{x}_q \|_2 - d_i \tag{14}$$

Here $d_i = d_{ij}$ for the microphone currently being solved; index j is suppressed in Section 4. The

range is calculated from the calibrated acoustic delay. Its calibration and the EPS anchor coordinates remain dependent on the initial metrology.

An anchor is an inlier when $\left|e_i(\mathbf{x}_q)\right| < \varepsilon$, where $\varepsilon \in \Theta$ is the current tolerance. Let $\mathcal{I}_q$ be the inlier-index set and $C_q = \left|\mathcal{I}_q\right|$ its cardinality. The tolerances are tested from 0.12 m to 0.45 m.Within each tolerance layer, the largest consensus size is:

$$C_{\max} = \max_q C_q \tag{15}$$

Among trials tied at $C_{\max}$, select $q^\star$ by the smallest sum of squared inlier residuals:

$$q^\star = \underset{q:C_q=C_{\max}}{\operatorname{argmin}} \sum_{i\in\mathcal{I}_q} e_i\left(\mathbf{x}_q\right)^2 \tag{16}$$

For the industrial configuration, the target is $C_{\max} \geq 12$ inlier anchors. This promotes redundancy but does not by itself ensure favourable source geometry. The target cannot be applied unchanged to the eight-anchor laboratory configuration.

If a layer does not reach 12 inliers, the tolerance is relaxed to the next value in Θ. If no layer reaches the target, the largest available consensus is retained with a lower-confidence flag. The final inlier set $\mathcal{I}$ is then fixed for refinement; rejected measurements receive no weight.

4.2. Iterative M-estimation via robust weighting

The final position is refined over eight iteratively reweighted least-squares (IRLS) iterations. This downweights residual outliers remaining in the RANSAC inlier set.

At iteration $\ell = 1, \ldots, 8$, the positive, dimensionless weight of inlier i is updated from the previous position:

$$w_i^{(\ell)} = \psi\left(\frac{\left|\left\|\boldsymbol{s}_i - \boldsymbol{x}^{(\ell-1)}\right\|_2 - d_i\right|}{\delta}\right) \tag{17}$$

where $\psi(\cdot)$ denotes the robust weighting function (e.g., Huber or Tukey bisquare [12]) and δ = 0.015 m is the residual scale parameter. With the RANSAC candidate as $\mathbf{x}^{(0)}$, the next estimate minimises the weighted sum of squared range residuals:

$$\mathbf{x}^{(\ell)} = \underset{\mathbf{x}\in\Omega}{\operatorname{argmin}} \sum_{i\in\mathcal{I}} w_i^{(\ell)} \left(\| \mathbf{S}_i - \mathbf{x} \|_2 - d_i\right)^2 \tag{18}$$

The admissible region Ω is the test volume defined in Section 4.1. SQP solves this constrained nonlinear objective. The final position is $\mathbf{x}_{\text{opt}} = \mathbf{x}^{(8)}$.

4.3. Geometric quality assessment

A weighted geometry indicator is evaluated at the final position. Relabel the $n = |\mathcal{I}|$ retained anchors locally as $i = 1, \ldots, n$. Let $r_i = \| \mathbf{x}_{\text{opt}} - \mathbf{S}_i \|_2$; the ith row of $\mathbf{G} \in \mathbb{R}^{n\times 3}$ is:

$$\mathbf{G}_{i,:} = \frac{\left(\mathbf{x}_{\text{opt}} - \mathbf{S}_i\right)^{\mathsf{T}}}{r_i} \tag{19}$$

Using the final robust weights, $\mathbf{W} = \operatorname{diag}\left(w_1^{(8)}, \ldots, w_n^{(8)}\right)$, the reported Geometric Dilution of Precision (GDOP) indicator is:

$$\text{GDOP} = \sqrt{\operatorname{tr}\left[\left(\mathbf{G}^{\mathsf{T}}\mathbf{W}\mathbf{G} + \lambda\mathbf{I}_3\right)^{-1}\right]} \tag{20}$$

Here $\lambda = 10^{-6}$ is dimensionless, $\mathbf{I}_3$ is the 3×3 identity matrix, and tr denotes the trace. This regularised, residual-weighted indicator is dimensionless; it is not a direct position-error estimate. Regularisation stabilises inversion but does not restore missing geometric information.

Internal range consistency is measured by $E_{\text{RMS}} = \sqrt{n^{-1}\sum_{i\in\mathcal{I}} e_i\left(\mathbf{x}_{\text{opt}}\right)^2}$. This quantity is distinct from the external coordinate discrepancy E_{TOT} reported against Laser Radar in Tab. 3. The internal review thresholds are GDOP > 4.0 or $E_{\text{RMS}} > 8$ cm. External coordinate discrepancies in Tab. 3 separately quantify agreement with Laser Radar.

4.4. Preliminary laboratory results

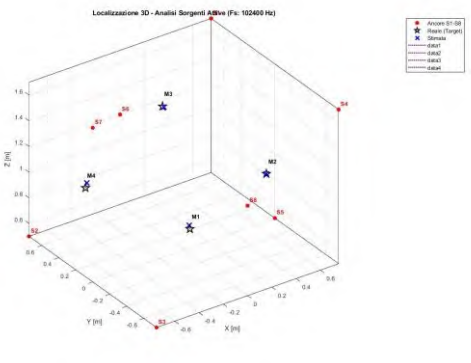

Figure 4: Laboratory source and microphone positions at $f_s = 102.4$ kHz. Surveyed and estimated microphone positions are compared.

Tabs. 1 and 2 summarise the preliminary laboratory comparison. Coordinates are rounded to two decimal places; error metrics are listed separately.

Table 1: Laboratory comparison. Coordinates are in metres and error magnitudes in centimetres.

ID	Real Z [m]	Est. Z [m]	Err Z [cm]	Err XY [cm]	Err Tot [cm]
1	1.00	1.00	0.27	4.38	4.39
2	1.15	1.16	1.49	2.35	2.78
3	1.50	1.50	0.29	1.78	1.80
4	0.90	0.91	1.14	4.60	4.74

Table 2: Mean laboratory error magnitudes.

Avg. Err Z [cm]	Avg. Err XY [cm]	Avg. Err Tot [cm]
0.80	3.28	3.43

The mean 3D discrepancy was 3.43 cm. The mean absolute Z discrepancy was 0.80 cm, versus a mean planar discrepancy of 3.28 cm. This is consistent with useful vertical constraints from the staggered anchors, but does not establish a causal advantage without a comparison layout. The tape-measure reference uncertainty limits the interpretation of absolute localisation accuracy.

4.5. Industrial DFAN deployment

Following preliminary validation, the framework was scaled up to an operational DFAN spacecraft testing enclosure. Ground-truth coordinates for all receivers and speaker cabinet faces were established using an industrial Laser Radar metrology system.

The industrial localisation was executed via a two-stage strategy:

1. **Inverse method (EPS characterisation):** A subset of primary control microphones with Laser Radar-verified coordinates was used as anchors to back-calculate the acoustic centres of the multi-driver speaker stacks, modelling them as Equivalent Point Sources (EPS).
2. **Direct localisation:** The identified EPS coordinates served as virtual acoustic anchors to localise the array of 28 control microphones distributed throughout the reverberant chamber.

Tab. 3 compares reconstructed positions with Laser Radar. X_{meas}, Y_{meas} and Z_{meas} denote the coordinates measured via TDOA algorithm . The axis errors are signed coordinate differences; the 3D discrepancy is:

$$E_{\mathrm{TOT}} = \sqrt{\mathrm{ErrX}^2 + \mathrm{ErrY}^2 + \mathrm{ErrZ}^2} \qquad (21)$$

Table 3: Industrial comparison with Laser Radar for 28 microphone entries. Coordinates are in metres; signed axis errors and 3D discrepancies are in centimetres. Status labels are as reported.

ID	Name	Xmeas [m]	Ymeas [m]	Zmeas [m]	ErrX [cm]	ErrY [cm]	ErrZ [cm]	ETOT [cm]	GDOP	Status

Table 4: Industrial summary across all 28 entries, including MC.

Metric	Value
Total Microphones Evaluated	28
Mean Absolute X Error ($\|Err_X\|$)	1.59 cm
Mean Absolute Y Error ($\|Err_Y\|$)	1.22 cm
Mean Absolute Z Error ($\|Err_Z\|$)	2.85 cm
Mean Planar Error ($\|Err_{XY}\|$)	2.10 cm
Mean 3D Total Error ($\bar{E}_{TOT}$)	**3.77 cm**
Median 3D Total Error	**3.05 cm**
Mean GDOP	2.53
3D discrepancy at or below 8 cm	92.9% (26/28)

4.6. Industrial performance analysis and error discussion

The industrial dataset provides a comparison within the calibrated DFAN configuration. Optical metrology was used for calibration and EPS identification; subsequent acoustic localisation used those identified source coordinates.

Key observations from the industrial dataset include:

1. **External coordinate agreement:** The mean 3D discrepancy was 3.77 cm and the median 3.05 cm. Twenty-six of 28 entries (92.9%) were at or below 8 cm. This count describes agreement with the surveyed coordinates and is distinct from an independently verified pass rate for the internal RMS criterion.
2. **Axis-specific discrepancies:** The mean absolute Z discrepancy was 2.85 cm, compared with 1.59 cm in X and 1.22 cm in Y; the mean planar discrepancy was 2.10 cm. The TOP cabinets are described as containing four vertically stacked compression drivers. Their extended radiating aperture may limit a single-EPS model in the vertical direction. The present data do not isolate that contribution from timing, geometry and calibration errors.
3. **Larger discrepancies:** MN1_3 and MN2_3 have external 3D discrepancies of 9.58 cm and 8.47 cm, respectively, and are reported as CHECK. Both lie above 1.69 m. Possible contributing factors include:
   - **Vertical source coverage:** The open-top source arrangement may give weaker vertical constraints at some locations. However, the two flagged entries have GDOP values of 2.58 and 1.50, so the reported geometry indicator alone does not explain their discrepancies.
   - **Speaker directivity:** Off-axis high-frequency radiation may reduce direct-arrival SNR and broaden or distort the correlation peak. Directivity and correlation data are needed to quantify this effect.
4. **Geometry indicator:** Mean GDOP was 2.53; all tabulated values were below the stated 4.0 review threshold. This describes the local weighted geometry, rather than an independent guarantee of position accuracy.

5. CONCLUSIONS

This paper presented a synchronous acoustic-ranging framework for microphone localisation in DFAN testing. The procedure combines an electrical timing reference, sub-sample correlation refinement, bias correction and temperature-dependent conversion to distance.

Following a preliminary laboratory trial, the method was applied to 28 industrial microphone entries. Existing TOP speaker cabinets were characterised as EPS anchors using surveyed microphone coordinates, then used for acoustic coordinate reconstruction. This reduces the need for additional localisation hardware during subsequent runs while retaining an initial metrology requirement.

The comparison with Laser Radar coordinates gave the following results:

- Mean and median 3D discrepancies were 3.77 cm and 3.05 cm; 26 of 28 entries (92.9%) were at or below 8 cm.
- The industrial solver combined multi-threshold RANSAC with robustly weighted nonlinear refinement. The mean weighted GDOP indicator was 2.53.
- The mean absolute vertical discrepancy was 2.85 cm. Extended source radiation and vertical coverage are possible contributors, requiring further investigation.

The results support further development for test-setup documentation and field-uniformity assessment. Independent validation with

microphones withheld from EPS calibration, quantified reference uncertainty and repeatability trials is needed to establish transferable accuracy. Future work will also examine temperature gradients and multi-driver source models.

ABSTRACT

RAL Space operates several major spacecraft environmental test facilities in Europe and recently expanded this infrastructure with the National Satellite Test Facility (NSTF). The NSTF is a large-scale test center, designed to bring a comprehensive suite of environmental test methods under one roof, including vibration and Direct Field Acoustic (DFAN) test methods within a shared floor space. Co-location offers considerable programmatic and logistical advantages, including elimination of inter-facility hardware transfers and the ability to schedule a battery of qualification tests within a single site visit.

Early in the design and procurement process, ARS and RAL identified that co-locating DFAN and vibration testing services in a fixed floor print of the Dynamics Lab presented several logistical challenges. The fixed vibration test interfaces which are flush with the floor are considered non-load bearing and could not accept the ground-supported loads of the DFAN acoustic system. Reconciling the completing structural and operational demands was paramount of the overall functionality of the multi-purpose testing space.

This paper documents the engineering assessment undertaken to resolve the conflict, from problem definition through concept selection and validation. A bespoke fiberglass reinforced plastic (FRP) platform system was ultimately selected to redistribute the weight of the DFAN system while preserving full reconfigurability of the floor space.

The paper concludes with a review of the commissioning for the integrated space which used a structural test model (STM) to demonstrate that the Dynamics Lab could be reconfigured between vibration and DFAN testing in an efficient manner. Selected results from commissioning tests are provided. This case study offers a practical reference for other facilities pursuing similar multi-modal test integration.

INTRODUCTION

Spacecraft environmental test facilities are increasingly being designed as multi-modal spaces; single rooms or buildings capable of hosting several distinct qualification test regimes rather than one dedicated capability per facility or space. Co-location of testing capabilities eliminates inter-facility hardware transfers, compresses schedule, and reduces the capital and footprint required to offer a full qualification campaign under one roof. The success of this approach depends on the thoughtfulness of the design and the flexibility of the final space, since requirements for different test methods are not always aligned.

In 2015, the UK Space Agency commissioned a gap study to review UK based aerospace support facilities [1]. The study concluded that the UK lacked a single facility of sufficient scale and comprehensiveness to test large, complex payloads. UK based programs that required full-scale environmental qualification often transported hardware and teams to mainland Europe, incurring significant logistical and programmatic cost.

RAL Space operates several major spacecraft environmental test facilities in the UK, with testing heritage across a wide spectrum of environmental test capabilities. In response to this study, RAL Space submitted a business case for the development of a large scale, environmental testing laboratory. The proposal was approved in June 2017 with an allocation of £99 million [2], later growing to a total investment of over £100 million as the project scope and construction timeline evolved [10]. The result of the investment was the National Satellite Test Facility (NSTF).

The NSTF is a large-scale environmental test center designed to consolidate a suite of environmental test methods under one roof. Thermal vacuum, vibration, acoustic, electromagnetic compatibility and antenna measurement, and mass properties testing capabilities are co-located in clean room conditions and sized to support spacecraft weighing up to 7 tonnes. Though originally planned to open in spring of 2020, construction progressed through a series of disruptions, including changes in government funding mechanisms and the COVID-19 pandemic, before reaching full customer readiness in early 2026.

Central to the NSTF design is shared infrastructure across test capabilities, rather than provisioning for each capability independently. Infrastructure for things like cleanrooms, cranes, chilled water distribution, reference earthing, and environmental monitoring are shared across test areas, following a precedent RAL Space had already established in its earlier R100 facility, operational since 2015 [3]. Sharing infrastructure this way reduces capital cost and facility footprint, echoing the same efficiencies that motivated the construction of a multi-modal testing facility.

This paper examines the NSTF design philosophy and implementation through a review of the multi-used Dynamics Lab, a single isolated space intended to host vibration, shock, and acoustic testing. Reconciling the spatial and operational requirements of vibration testing and acoustic testing within a shared room presented engineering challenges that, if left unaddressed, would have prevented the space from functioning as designed.

NSTF DYNAMICS LAB

The layout and test systems described below are directly relevant to the vibration and acoustic integration challenge addressed later in this paper.

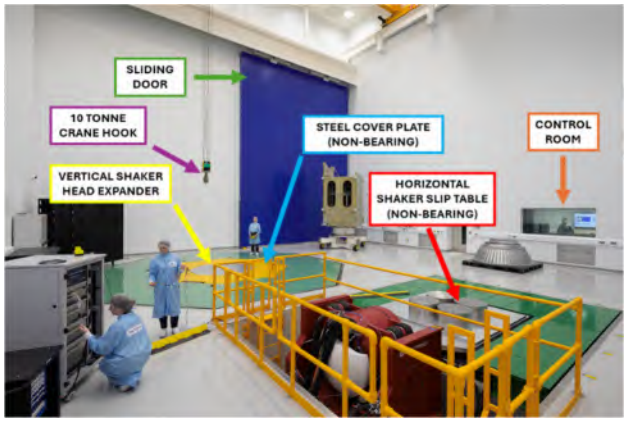

Figure 1 - Annotated Photograph of NSTF Dynamics Lab (courtesy of RAL Space)

The Dynamics (Vibration) Lab at the NSTF occupies a 16 m x 16 m x 16 m test room with an adjacent, acoustically isolated control room. The room and adjacent spaces are ISO class 8 cleanrooms, maintained at 20 °C. A large, sliding door on one wall provides equipment and spacecraft access.

An overhead crane rated for 10 tonnes provides coverage over the center portion of the floor print, with limited extents nearest the test area door. Fig. 2 shows a plan view of the lab with the crane coverage indicated with a hatch.

A unique, site-specific design requirement necessitated the recessing of shaker elements. The NSTF sits close to Diamond Light Source, the UK's national synchrotron, whose beam positions monitors that are sensitive enough to register ground vibration from seismic events on the other side of the globe [4]. Therefore, both shaker systems are mounted on recessed, 200 tonne seismic blocks that are raised on airbags during testing, fully isolating vibration tests from the surrounding environment.

The lab floor is a concrete slab on grade, load-rated to receive spacecraft, ground support equipment, and test hardware directly. Two recessed interfaces are built into the slab to service the shaker systems; an octagonal head expander for vertical testing and a rectangular slip table for horizontal testing, each set flush to the surrounding floor as shown in Fig. 1. Custom steel cover plates, green around the slip table and yellow around the head expander, are installed over the recesses allowing personnel and equipment to be moved across the room safely. The yellow cover plates surrounding the head expander are rated for foot traffic and light-weight ground support equipment only. The slip table at the horizontal shaker is also considered non-bearing floor area.

The lab can be configured to perform mass properties, vibration and shock deployment, and DFAN testing. Mass properties testing capabilities have been excluded for brevity.

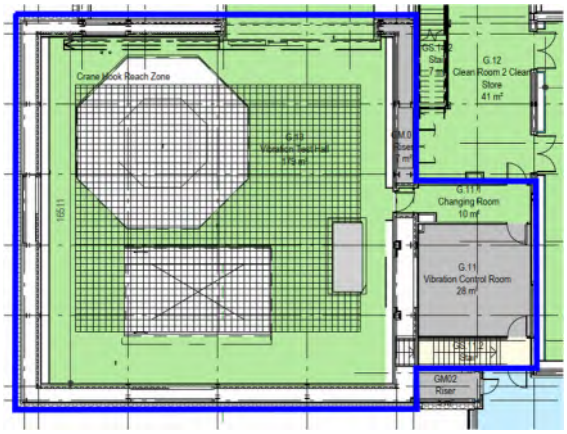

Figure 2 - Plan View of NSTF Dynamics Lab with Crane Coverage in Hatch

Vibration and Shock Deployment Testing

The vibration test system consists of a pair of Data Physics electro dynamic shakers, a guided head expander and slip table(s) supported by controllers and data acquisition systems. Each shaker can produce up to 222kN of thrust between 5-2000 Hz.

The facility can be arranged into three potential test

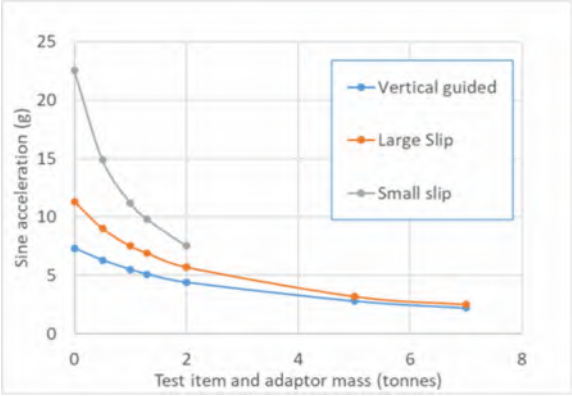

Figure 3 - NSTF Shaker Sine Capabilities g Level as Function of Test Item Mass & Test Configuration

configurations: 1) Vertical test in the guided head expander; 2) Horizontal test on the large slip table; 3) Horizontal test on the small slip table. The acceleration

limits in each configuration are a function of the moving mass of the shaker and/or slip tables/head expander with typical estimated performance shown in Fig. 3.

The shaker system is controlled using a 70 channel Data Physics 912 unit and SignalCalc software, supporting active control signals as well as acceleration, force, and moment limiting. This is supported by an independent 512 channel data acquisition system with a 100 kHz sample rate. The same data acquisition system is used across environmental test as DAQ racks can be moved with the spacecraft around the facility, allowing for a smoother transition between test types.

Direct Field Acoustic (DFAN) Testing

DFAN is an advantageous solution for integrating acoustic testing capabilities in a multi-purpose room, precisely because it is flexible, portable, and modular. The methodology has been used heavily in the United States since the late 1990s as it is a cost-effective solution for acoustic testing that can be performed in most facilities [5]. This removes the risk of transporting the test article to a suitable acoustic chamber. DFAN systems are designed to be deployed in various configurations and heights to provide adequate acoustic coverage of the test article. The methodology and test validity has been discussed thoroughly in industry publication and will not be expanded upon here.

The ARS Neutron acoustic testing solution was chosen in 2023 as the DFAN test solution through a competitive bidding process. The Neutron is a proprietary, full range (20 Hz to 10 kHz) acoustic device designed specifically for DFAN testing. It is manufactured by Acoustic Research Systems in conjunction with UK based EM Acoustics.

A system of forty-eight (48) Neutron devices, with associated amplifiers and cabling, was procured. The Neutron system was sized to accommodate a medium test-article envelope of up to 2.6 m x 2.6 m x 5.5 m in total height with the capability to expand the system for a large test-article envelope of up to 5 m in diameter and a maximum of 10.5 m in height. Both sizes were required to be capable of reproducing qualification-level acoustic environments spanning an envelope of launcher manuals requirements, as shown in Fig. 4. Additionally., the original tender also included an acoustic specification, in octave from 31.5 Hz to 8000 Hz, that required that the system be capable of achieving an OASPL of 147.3 dB

When not in use, the Neutron system can be broken down into modules that are stowed outside of the Dynamics Lab, freeing the room for other types of testing. The system was specified to be capable of full reconfiguration within 48 hours, a requirement set specifically to preserve the lab's ability to turn around between test regimes without extended downtime.

ENGINEERING CHALLENGE

Early in the design and procurement process, ARS and RAL identified that co-locating DFAN and vibration testing services in a fixed floor print presented several logistical challenges. Overcoming these challenges was paramount to the overall functionality of the multi-purpose testing space.

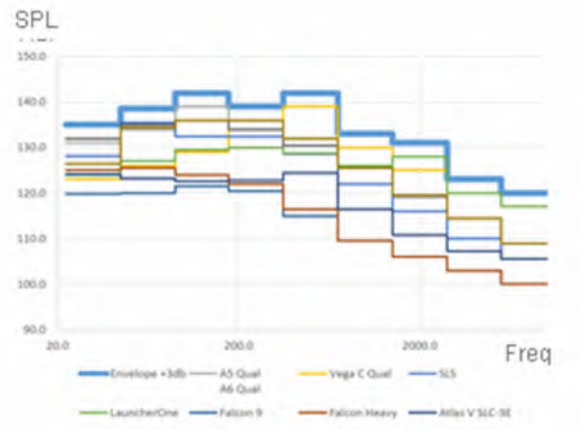

Figure 4 – DFAN Acoustic Spectrum Requirement

ARS provided a standard system outer diameter of 10.4 m, as shown in Fig. 5, with the ability to expand to an outer diameter of 11m. On paper, the 16 m x 16 m footprint of the room should have been of adequate size to support the extents of the largest proposed DFAN setup. However, two specific characteristics of the room, contrasted with the structural requirements of the Neutron, prevented the system from being assembled as required.

The Neutron is a ground supported structure, meaning the full weight of each stack must be carried by the floor structure beneath it. The bearing surface under the substantial footprint of each Neutron stack must be consistent, with adequate load capacity and levelness. As discussed above, the cover plates in the areas of floor around vertical and horizontal shakers do not have the capacity to support the weight of the Neutron acoustic devices and are therefore considered to be non-load bearing.

Neutrons are stacked and positioned within the room using the overhead crane. Stacks must be positioned so that the center of gravity of each stack falls within the crane extents. The crane coverage, as illustrated by the red line in Fig. 5, limits how far toward the room's perimeter any given stack can be placed. Combined with the non-bearing floor areas identified above, this reduced the number of positions in the room where a Neutron stack could be assembled without conflicting with either constraint.

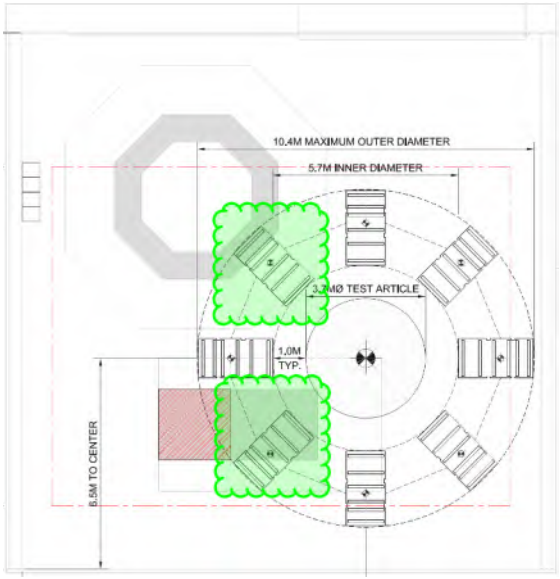

Figure 5 – Preliminary Plan Showing Configuration of Standard DFAN System Size in Dynamics Lab

Regardless of the system orientation, two (2) stacks of Neutrons must fall over designated non-bearing floor areas. A structural solution would be required to safely support the Neutron stacks without damaging existing, fixed infrastructure.

It should be noted that the architectural design of the NSTF was completed years before DFAN was considered as a testing capability. Therefore, the room was not sized with the capability in mind.

Engineering Design Methodology

Given the constraints identified above, ARS and RAL determined at the outset that a temporary structural solution, rather than a permanent modification to the room, was the only acceptable solution. A temporary structure could be installed only when needed and removed afterward, preserving the Dynamic Lab's flexibility to support other test regimes.

ARS and RAL performed an engineering assessment to determine how best to supplement the lab to accommodate larger acoustic tests. The assessment proceeded through a structured sequence: problem definition, development of design criteria, schematic design, concept selection, structural analysis and validation, and finalization of the selected technical solution. The highest priority when assessing potential solutions was maintaining the flexible nature of DFAN testing without hindering the vibration capabilities in the shared space.

Problem Definition

ARS went through an early drafting exercise to define the scope of the structure needed. This exercise included producing system layouts at a variety of inner diameters and configuring them within an as-built model of the lab. The lab model included overall room geometry, extents of the overhead crane, and exact placement of the head expander, slip plates, and other floor obstructions. Through careful and coordinated rotation and placement of the medium and large systems, the extent of the temporary structures required was determined.

The acoustic devices and associated kitting have significant weight that must be distributed out to the robust concrete slab on grade. To maintain the 48-hour reconfiguration requirement, it was determined that a portable, temporary structural solution was needed to maintain system flexibility.

Design Requirements & Evaluation Criteria

It was determined that the temporary structural solution had to meet the following requirements:

1. The temporary platform had to span the non-bearing areas of the floor, distributing the load of the acoustic devices out to the slab on grade.
2. The platform had to support a distributed load of 19.2 kN/m².
3. Deflection of the platform under the maximum applied load had to be less than 3.2 mm
4. The structural depth had to be minimized to reduce vertical offset between adjacent speaker stacks.
5. The structure had to be easy to assemble, place, and store, with minimal setup time.

This evaluation criteria, along with structural design standards were formalized in a Basis of Design document that was reviewed and approved by both RAL and ARS prior to schematic design.

Schematic Design & Concept Selection

Two primary structural solutions were explored as a part of the schematic design exercise.

Structural Steel Plinths

RAL contracted a fabricator to develop designs for bespoke structural steel frames or "plinths" for internal review. This concept used open rectangular hollow section (RHS) base frames in S355J mild steel to support each speaker stack as shown schematically in Fig. 6. Three distinct designs were developed: two separate frames to span over the horizontal and vertical shakers and a standard frame to elevate all other Neutron stacks to keep the bottom of stack elevations consistent.

While structurally straightforward, the steel concept was not carried forward for several reasons that emerged during the design review:

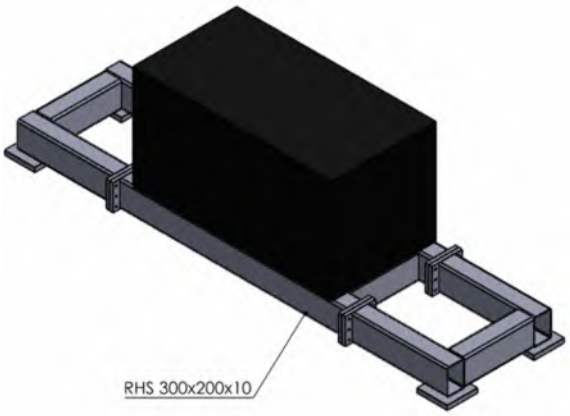

Figure 6 - Schematic Isometric of Steel Plinth at Slip Table

1. Excessive weight: The steel base frames alone added an estimated 4,215 kg of structure and would have required a dedicated transport and lifting solution for deployment.
2. Depth of structure: The RHS base frame depth added significant vertical offset between adjacent speaker stacks, which would compromise the design of the proposed lateral bracing elements between speaker stacks. To accommodate this, frames would be required under all stacks which added more equipment to the overall setup.
3. Limited flexibility: The steel frames were designed around fixed positions matched to a specific speaker layout, which offered less adaptability to the range of DFAN configurations the test facility needed to support. Fixed-position frames would have defeated the room's core purpose as a reconfigurable, multi-modal test space.

Taken together, the design issues associated with the steel concept made it a poor fit for governing design requirements. The limited flexibility presented by the steel frames led to the development of a second schematic structural solution. It was determined that if a solid platform could be provided, all configurations could be supported with the same structural solution.

FRP Temporary Platform System

ARS began exploring the design of a low-profile platform, like a temporary stage deck used in live entertainment events. Standard stage deck structures are composed of aluminium truss exterior members topped with a thin solid bearing surface and cannot support the weight of the Neutron devices regardless of span.

Fiberglass reinforced plastic (FRP) was selected as a candidate material for construction of a low-profile support platform. FRP is a structural composite in which continuous glass fibers reinforce a cured thermoset polymer resin. The glass fibers, which make up roughly 70% of the material's weight, provide tensile strength and stiffness, while the surrounding resin transfers load between fibers and protects them from environmental exposure [6]. This combination gives FRP a high strength-to-weight ratio relative to traditional structural materials like steel and concrete. FRP structures are also non-conductive, impact-resistant, and low-maintenance, reducing life-cycle cost.

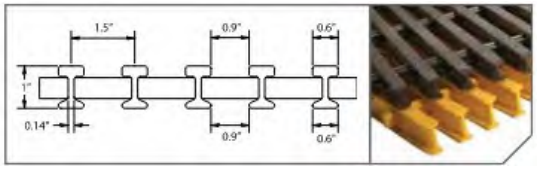

Figure 7 - Example of FRP Pultruded Grating (courtesy of Fibergrate Composite Structures)

Pultruded FRP grating was proposed as this was a high-capacity panel application, like those subject to vehicular loading. In the pultrusion process, continuous glass fiber reinforcement is pulled through a resin bath and heated die to form FRP profiles with controlled, consistent geometry. Grating panels are assembled from pultruded bearing bars, which carry the primary load, and cross-rods, which stabilize the panel and maintain consistent member spacing, as shown in Fig. 7. As a result, pultruded grating is designed to span in one direction [7].

BESPOKE FRP PLATFORM SOLUTION

Platform Construction

Covered pultruded FRP grating, manufactured by U.S.-based Fibergrate Composite Structures, was ultimately selected as the structural solution for the bearing platforms. A solid FRP plate was adhered to the top of high-capacity HI3730 grating [8], for a total material thickness of 85.7 mm. Four solid, full-length FRP runners of 50.8 mm depth were installed on the underside of the grating. The runners were aligned so that the grating spanned one-way over the non-bearing floor surfaces, distributing the load to areas of the floor capable of receiving the weight. Platform 1 is a three-span structure that is supported by the vertical head expander on one side and the concrete floor slab on the other. It is broken up into two (2) sections and has a maximum unsupported span of 1753 mm. Platform 2 is also a three-span structure that is supported entirely by the steel cover plate assembly around the horizontal shaker slip table. It is broken up into three (3) sections and has a maximum unsupported span of 2363 mm.

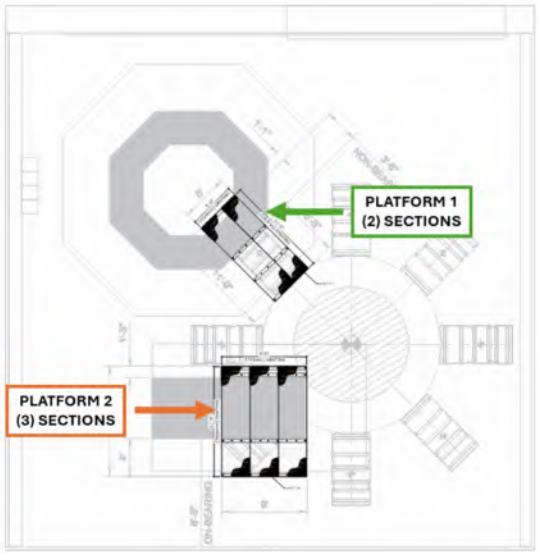

Figure 8 - Plan View of FRP Platform Locations

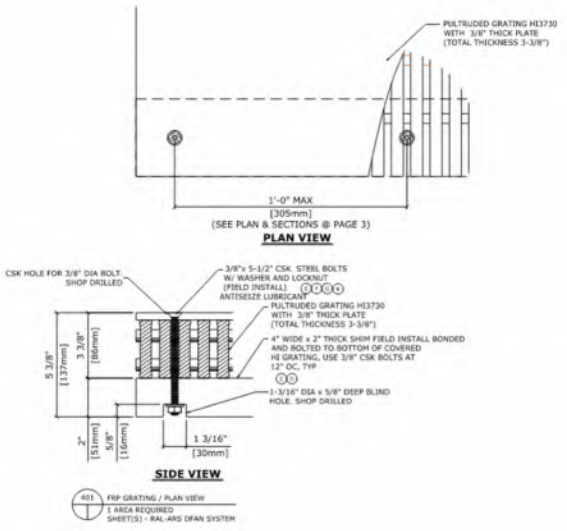

Figure 9 - Part Plan and Detail of FRP Platform Construction

The construction methodology is consistent across both platforms.

The final platform structures are rated for a live load of 19.2 kN/m², equivalent to the weight of seven Neutrons, while meeting the project's deflection criteria. The total depth of structure, 136.5 mm, is minimal enough that no redesign of the proprietary lateral bracing structure was required. To reduce component weight and simplify storage, the platform sections were broken into segments approximately 914–991 mm wide, with each section weighing between 338 kg and 345 kg. Each platform section was designed with four corner locations where an eyebolt and lifting shackle can be installed for lifting and placement.

Platform Analysis & Validation

Structural adequacy of the FRP platform was verified through two independent analyses. Analyses were performed in accordance with the load and resistance factor design (LRFD) recommendations made for FRP structures in the ASCE/SEI 74-23 design standard [9], evaluating the platforms against the applicable strength and serviceability limit states.

Fibergrate performed an independent hand calculation of the grating system, treating the platforms as multi-span structures under a uniform area load. The calculations consider a dead load (platform weight) of 1.1 kN/m², in addition to the live load of 19.2 kN/m². Deflection was calculated using standard static beam formulas for multi-span members, based on the average effective flexural stiffness (EI) of the grating panel derived from coupon testing of the pultruded material. The platform live load capacity was based on Fibergrate's published data for the HI3730 grating profile. The governing case for deflection under uniform load was found to be at the midspan of Platform 2 with a maximum predicted displacement of 5 mm, or L/476.

In parallel, ARS developed a finite element model of both platforms in RISA 3D to perform stress and strength checks as well as to calculate predicted deflection under a range of loading conditions. Because placement of the Neutron on the platform can vary, the analysis was performed for several representative loading conditions. Varying stack position within the model, rather than assuming a single uniformly distributed load, allowed the governing case for each span to be identified and checked against the design requirements. The model was built using Fibergrate's published section properties as well material coupon test results for the pultruded laminate. Grating was modelled as an equivalent orthotropic plate with properties matched to the manufacturer data. The governing deflection was also identified at the midspan of Platform 2 with a maximum predicted displacement of 3.9 mm, or L/606.

The hand calculation produced more conservative results, consistent with its simplified treatment of the platform as a uniformly loaded multi-span beam, whereas the FEA captures the actual distribution of the Neutron stack weight across the platform, allowing for a more refined prediction of deflection. Both governing predicted deflections exceed the initial design specification by between 0.7 mm and 1.8 mm however they meet the applicable strength requirements. ARS evaluated the additional deflection against the Neutron stack stability envelope and found that the additional deflection had no negative impact on the lateral stability of the structure.

Comparing the two approaches provided confidence that the platforms would perform to specification across the range of possible DFAN configurations, and both analyses showed good agreement that the structure would meet strength and serviceability requirements. On this basis, RAL did not require the platform structures to be proof tested prior to installation.

Platform Installation

The FRP structures were manufactured in the United States and shipped directly to RAL fully assembled. Upon receipt, the five (5) individual platform sections were unpacked and inspected. The visual inspection focused on material consistency, platform camber, and fastener installation. Visual inspection flagged one item for remediation. Bolts between the pultruded grating and the bearing strips were too long which prevented the platform from sitting flush with the floor. A representative of RAL cut the fasteners down and reinstalled rectifying the non-conformance.

The locations and extents of each platform were marked on the floor using known landmarks within the room. One by one, eyebolts and shackles were installed in the four (4) corner receivers on each platform, as shown in Fig. 10. Four slings were used to lift each platform, align it with its intended position, and lower it into place. Once placed, the lifting gear was removed and transferred to the next platform. This process took approximately ten (10) minutes per platform.

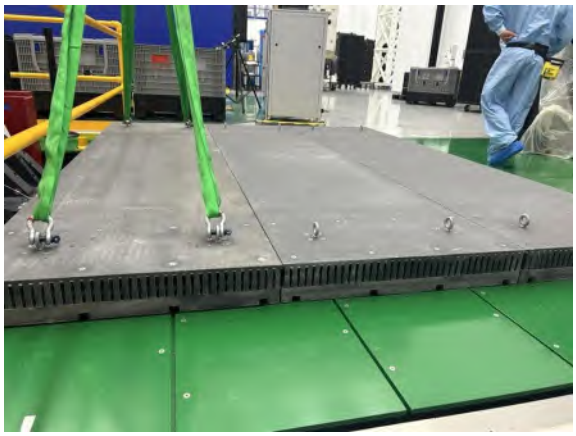

Figure 10 - Installation of Platform 2

Platform installation proceeded as planned with no major issues noted in the fabrication, geometry or placement methodology.

Once installed, a forty-eight (48) Neutron DFAN system, comprised of eight (8) stacks of six (6) devices was erected. Platforms were loaded as intended with no issue. While dial gauges were not installed to monitor deflection, no deflection of the long spans of the platform was noted visually when loaded.

The FRP platforms integrated smoothly with the balance of the Neutron system, adding little time or effort to the setup.

Figure 11 - Neutron Stack on Platform 1 at Head Expander

NSTF DYNAMICS LAB COMMISSIONING RESULTS

To commission the NSTF Dynamics lab each of the facilities were used to run tests using a Structural Tests Model (STM) lent to RAL by Surrey Satellite Technology Ltd (SSTL), which was nicknamed ORINOCO. These tests were designed to verify the technical performance of the different test facilities as well as the validation of test facility procedures. This was especially true moving between vibration testing and acoustic testing as the test hall needed to be reconfigured smoothly and efficiently. Reconfiguring the hall between tests, which included installation of floor platforms, setup of acoustic test system, as well as lifting of the spacecraft from shaker surface to acoustic trolley was performed in under a week.

Vibration Testing

ORINOCO first underwent vibration testing on the slip table (Fig. 13) and then head expander (Fig. 15).

Tab. 1 gives the applied vibration profiles, although notching was applied at key locations to both test the capabilities of the system and protect parts of the STM.

Table 1: Vibration Test Equalisation Sine Profile

Axis	Frequency Range Hz	Unnotched Levels g
Lateral	5-100	0.4
Axial	5-110	0.6

Results of the vibration test campaign confirmed that the shaker systems achieved the target control profiles. No anomalies were noted in the control signals shown in Fig. 12 and Fig. 14, and the system was cleared to proceed to acoustic testing.

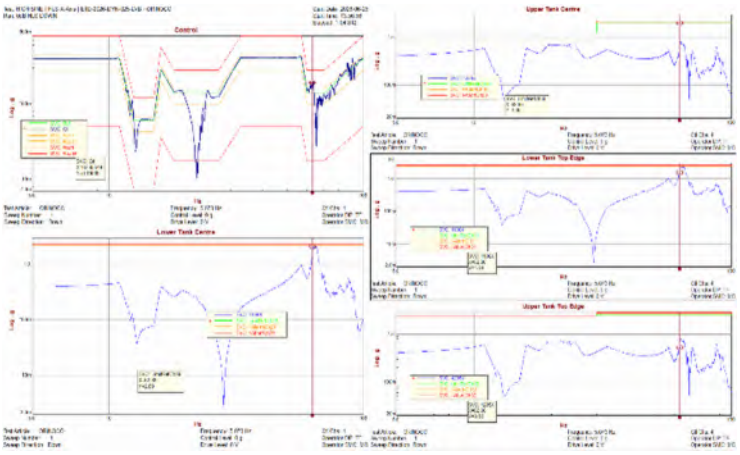

Figure 12 - Control Signals of Lateral Vibration Testing of ORINOCO

Figure 13 - ORINOCO on Slip Table ahead of Lateral Vibration Testing

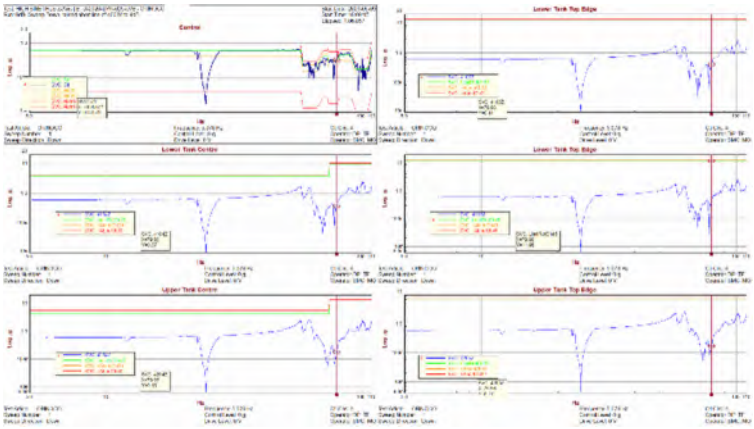

Figure 14 - Control Signals of Axial Vibration Testing of ORINOCO

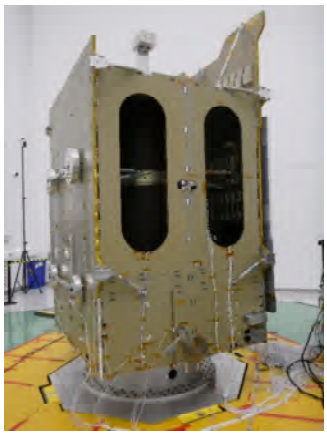

Figure 15 - ORINOCO on Head Expander ahead of Axial Vibration Testing

DFAN Testing

Once the vibration testing was completed the test hall was reconfigured to acoustic testing. This involved using the crane to remove ORINOCO from the head expander, place it on the acoustic trolley, and removing it from the hall. Once cleared, the team set out Platforms 1 and 2, built up eight (8) stacks of Neutron speakers, and placed them in the configuration shown in Fig. 5. Amplifiers were moved in, speakers were cabled, and control and monitor microphones were set out. Finally, ORINOCO was brought back into the centre of speakers, as shown in Fig. 16. The setup of the DFAN system and testing was done in just under a week by the NSTF team.

The Neutron stacks were arranged in a circle with an inner diameter of 5.7 m. The overall stack height was 6.7 m. Control and monitor microphones were supported using floor stands positioned in the space between the Neutrons and ORINOCO.

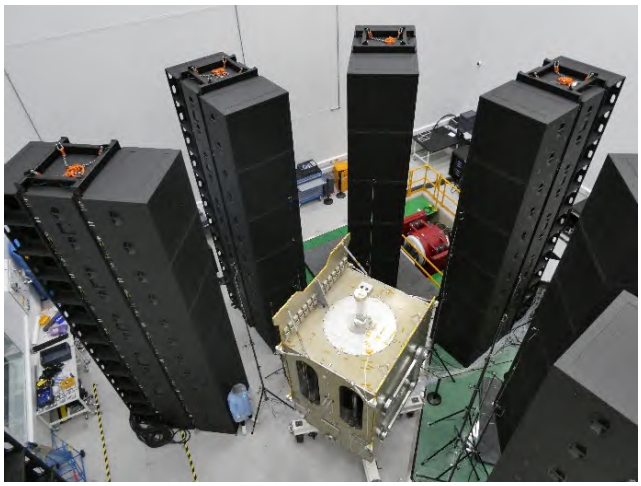

Figure 16 - Aerial View of ORINOCO Acoustic Testing Showing Platform 2 at Slip Table

For system commissioning, ORINOCO was subjected to acoustic loads as given in Tab. 2.

Table 2: ORINOCO Acoustic Test Profile in Octave

Centre Band (Hz)	Test Level (0dB)
31.5	125.4
63	127.7
125	129.1
250	128.2
500	123.1
1000	117.4
2000	113.8
4000	110.8
8000	107.8
OASPL	133.8

The average control and monitor microphone levels for the 0 dB run are shown in Fig. 17.

Results of the DFAN commissioning campaign confirmed that the Neutron achieved the target acoustic test profiles. System setup was achieved within the 48-hour reconfiguration tender requirement

RECOMMENDATIONS FOR FUTURE MULTI-MODALITY TESTING SPACES

The experience of integrating DFAN testing into the NSTF Dynamics Lab offers several lessons applicable to other facilities pursuing similar multi-modal test integration.

1. Where possible, consider all planned testing capabilities during the initial building design phases. When a facility's long-term roadmap includes capabilities that have not yet been defined in detail, reserving floor area, load paths, or crane coverage against a reasonable worst-case footprint can reduce complexity of later integration.
2. Evaluate fixed test-system interfaces, like slip tables, head expanders, and reaction masses, as permanent constraints on all capabilities sharing the space. Facilities planning multi-modal spaces should evaluate each fixed interface against the load, access, and clearance requirements of every test regime intended to share the room.
3. Favor temporary, removable structural solutions over permanent modifications when reconciling conflicting requirements. DFAN itself was an appropriate choice for acoustic test methodology because it is portable, allowing the lab to support other test regimes when not in use. This same concept extends to the FRP platform system which resolves the floor load conflict while preserving the flexibility of the space.

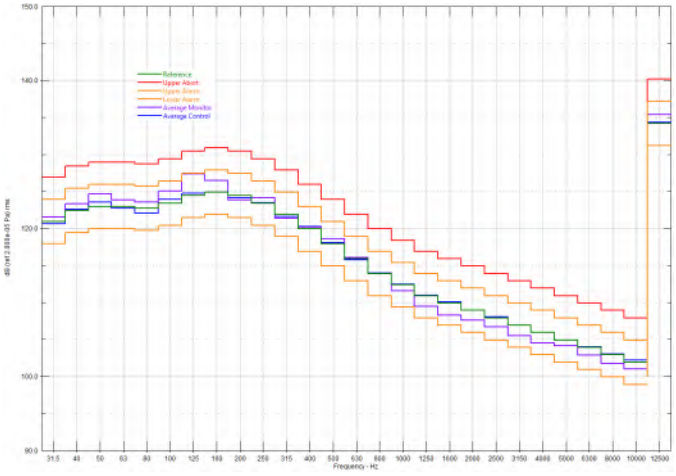

Figure 17 - Average Control and Monitor Microphone Levels Achieved Alongside Reference Lines

4. A structured engineering assessment can resolve conflicts a facility was not originally designed to accommodate. A structured review led to selection and validation of a solution that met all governing requirements without detrimentally impacting the functionality of the room or test system. Facilities facing a similar conflict between existing infrastructure and new capabilities should not view the conflict as disqualifying; assessment and solution implementation, as demonstrated here, can reconcile unintended conflicts between test system requirements.

CONCLUSION

This paper documented the engineering processes undertaken to integrate DFAN testing into the NSTF Dynamics Lab, a space designed and built prior to the acquisition of the Neutron system. The vibration test system's fixed, non-load bearing floor interfaces and the limited overhead crane coverage presented a structural and logistical conflict that, left unresolved, would have prevented the room from supporting DFAN testing at the scale required.

A structured engineering assessment, from problem definition through concept selection and validation selected a bespoke FRP platform system as the solution best suited to the competing system requirements. The platforms redistributed the load of the Neutron acoustic system away from the non-bearing floor areas and onto the surrounding slab, while remaining lightweight, modular, and fully removeable between test campaigns. Two independent analyses confirmed that the platform met the applicable strength requirements. While the selected structure is anticipated to deflect more than the original, conservative requirement, the additional deflection was not shown to affect the stability of the supported equipment.

Commissioning of the integrated Dynamics Lab, using the ORINOCO structural test model, demonstrated that the lab could be reconfigured between vibration and acoustic testing within the required timeframe, and that both test regimes could be performed to specification within a shared space.

The success of this integration shows that independent and conflicting design requirements can be reconciled without compromising either capability. Facilities facing similar challenges can look to this project for a practical reference on how to approach unique engineering challenges.

The authors would like to thank the RAL Space Environmental Test Division, Fibergrate Composite Structures, and Acoustic Research Systems teams for their support throughout the project.

CASE STUDY OF A LARGE SCALE DFAN TEST: PART TWO

Dann Hayes, Geoff Eckert, Kaileah Blazek-Freeman, Mitch Skinner

Acoustic Research Systems, Shepherdstown, WV, USA
Lockheed Martin, Kennedy Space Center, FL, USA

KEYWORDS

Direct Field Acoustic Noise (DFAN), large-scale acoustic testing, vertical control zones, discrete response limiting, spacecraft testing

ABSTRACT

Part One of this case study, presented at ECSSMET 2024, provided a holistic review of a Direct Field Acoustic Noise (DFAN) test campaign utilizing 48 full-range electrodynamic acoustic devices deployed to test a payload approximately 5 meters in height [1]. That work covered pre-test system design, structural stability analysis, installation procedures, safety considerations, and acoustic field qualification results, including a detailed comparison of bare chamber and spacecraft test runs. The conclusion of Part One identified the 48-device campaign as a critical stepping stone toward a significantly larger 90-device deployment to support taller payloads. This paper delivers on that objective by presenting a detailed case study of a test campaign that utilized 90 NEUTRON devices, nearly doubling the system size and introducing new technical and logistical challenges that required the development of novel approaches to system deployment, acoustic field control, and test article protection.

This campaign encompassed the acoustic testing of two test articles that were arranged in a stacked configuration. This required a 90 NEUTRON system deployed in 9 stacks of 10 NEUTRONs tall. A key technical contribution of this campaign was the development and deployment of multiple discrete vertical control zones. Additionally, discrete response limiting was introduced, enabling frequency-selective attenuation of specific 1/3-octave bands where structural response limits were approached, rather than applying broadband level reductions. This allowed the test to maintain full specification levels across most of the frequency range while protecting from over testing.

This test campaign required the introduction of a mobile crane as a critical operational asset for system assembly and reconfiguration. This, along with other challenges, necessitated developing detailed Concept of Operations (ConOps) for maintaining safety and schedule compliance. The paper presents the planning methodology and procedural documentation developed to support these operations.

This paper presents acoustic field measurements and key metrics. Comparisons are drawn between the 48-device and 90-device configurations to assess the scalability of acoustic field quality, operational efficiency, and system performance. Lessons learned are discussed, including recommendations for mobile crane integration, vertical zone implementation, and discrete response limiting, with the objective of supporting the continued development of industry best practices for large-scale DFAN testing.

1. INTRODUCTION

Part one of this case study presented an overview of a DFAN test campaign utilizing 48 ARS NEUTRON acoustic devices in an 8-stack by 6-tall arrangement. That paper covered the pre-test engineering including structural stability analysis, system installation and operation and test results. The payload tested was approximately 5 meters tall. The conclusion of part one noted that the 48-device test campaign was a stepping-stone towards the deployment of a 90-device configuration to support the testing of payloads approaching 10 meters in height.

This continuation references that forward-looking statement by presenting a detailed case study of a test campaign that utilized 90 NEUTRON acoustic devices. This campaign represents a substantial scaling of DFAN methodology, nearly doubling the number of acoustic devices and introducing new technical and logistical challenges.

The campaign, conducted at Lockheed Martin facilities in support of the Orion Multi-Purpose Crew Vehicle (MPCV) program, involved testing of an integrated Crew-Service Module (CSM) test article, comprised of the Environmental Test Article Crew Module (ETA CM) and the European Service Module Structural Test Article (ESTA). These tests required the development and deployment of dual-zone and triple-zone vertical configurations to address the differing acoustic requirements at various vertical positions along the test articles. This test was conducted at NASA's Kennedy Space Center (KSC).

Beyond the acoustic field performance data, this paper places an emphasis on the logistical and operational challenges that accompany large-scale DFAN deployments. Topics include the use of a

mobile crane for system assembly and disassembly, the development of ConOps for managing 90 NEUTRONs in a space constrained facility, and the implementation of novel acoustic control techniques including multiple discrete vertical zones each with discrete response limiting.

2. SCALING FROM 48 TO 90 DEVICES

2.1 System Configuration Overview

The transition from a 48-device configuration (8 columns of 6 devices) to a 90-device configuration (9 columns of 10 devices) required the scaling of multiple facets of the ARS system. The 10-tall NEUTRON configuration was designed to maintain adequate field uniformity and acoustic performance over the entire height of an article approaching 10-meters tall.

The increase from six to ten NEUTRON devices per stack introduced new structural stability considerations. The taller columns required updated structural analyses following the internal reference standards developed and discussed in Part One [1,2], with particular attention to the behavior of partially assembled configurations during the NEUTRON system build process.

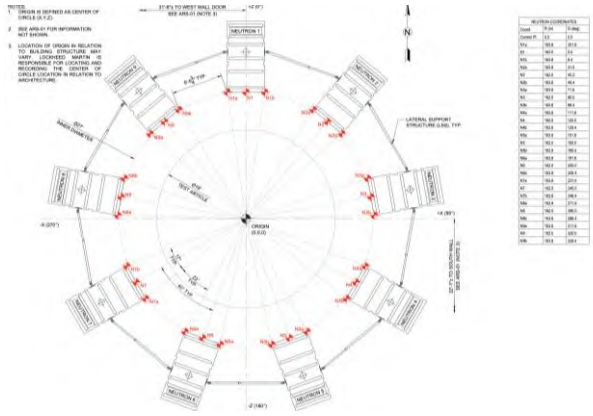

Figure 1: Overhead View of a 9-Stack NEUTRON System

2.2 Power and Signal Distribution

Scaling to 90 NEUTRONs required expanding both the power and signal distribution architecture that was discussed in Part One. Previously, ARS was able to assign 2 NEUTRONs to each drive which resulted in a total of 24 drives needed, with 24 corresponding control microphones. If this scaled linearly to the 90 NEUTRON configuration, it would have indicated use of 45 control microphones. For efficiency, the drive configuration was adjusted to use 4 drives per stack, leading to 36 drives and 36 control microphones overall. These drives are distributed to the NEUTRONs via the Dante Audio-Over-IP protocol. The increased drive count required additional audio processors that serve as the signal A-D and Dante distribution hub. The CORERACK amplifier rack count increased from 8 to 15, and the system power requirements were scaled to ensure an adequate mains power supply from the portable generator.

A 500 kVA generator was used for the 48 NEUTRON campaign, while a 1500 kVA generator was used for the larger 90 NEUTRON campaign. Using prior test data to compare the proposed test configuration and profile levels, the test team estimates the maximum OASPL that can be achieved given the maximum allowable output by the amplifier limiters. It can be assumed that the amplifier is pulling its maximum peak power of 15 kVA at this point, though in practice it will be somewhat less depending on the profile. This number can then be scaled down to the actual OASPL of the test given that every 3 dB reduction is half the power. This gives us the expected peak power draw for each amplifier for the overall test level. Multiplying that by the number of amplifiers in the system will give you the peak power draw seen by the generator. A 2:1 conservatism factor is also typically used to account for any discrepancies in the generator performance. For this test configuration and acoustic spectrum, ARS would typically use around a 1000 kVA generator. Generator availability issues necessitated using the larger unit. Generator availability can be challenging in warmer climates during summer months, especially during hurricane season. No adverse issues were noted from using the larger generator.

The combined DFAN control and data acquisition system (DAS) architecture validated during the 48-device campaign [3,4] was scaled to accommodate the increased channel count that included additional inputs and outputs.

The fiber optic transport link between the test circle and a remote control area was maintained. A dedicated DAS rack was assembled and positioned near the speaker circle during testing. This rack handled instrumentation input from the test article, parallel or tee'd outputs to an external DAS, digitization and distribution of the drive signals via Dante, and discrete ground connections for instrumentation.

3. LOCKHEED MARTIN TEST CAMPAIGN

3.1 Test Article Description

The Lockheed Martin test campaign encompassed two distinct test articles that were combined to create a flight representative test article. The Environmental Test Article Crew Module (ETA CM) is the former Artemis I Crew Module built by Lockheed Martin, which was re-purposed post-flight as a test article for an abort-level campaign. The European Service Module Structural Test Article (ESTA) is a structural representation of the Orion European Service Module (ESM), developed by the European Space Agency (ESA) and Airbus for structural qualification of the ESM [5]. The ESTA includes a model of the Crew Module Adapter

(CMA), built by Lockheed Martin, that joins the CM and ESM. These modules were stacked to create a high-fidelity test article of the combined Crew-Service Module (CSM). This test campaign was conducted from November 10, 2025, to November 22, 2025. The test was completed 2 days ahead of schedule after all test objectives were successfully completed.

Figure 2: Orion CSM DFAN Testing at LASF

3.2 Mobile Crane Operations and Logistical Challenges

One of the most significant logistical challenges encountered during the Lockheed Martin campaign was the management of 90 acoustic devices within the physical constraints of the test facility. With 10 NEUTRONs per stack and 9 stacks surrounding the test article, the process of constructing, opening and restoring the DFAN configuration for test article installation required careful choreography.

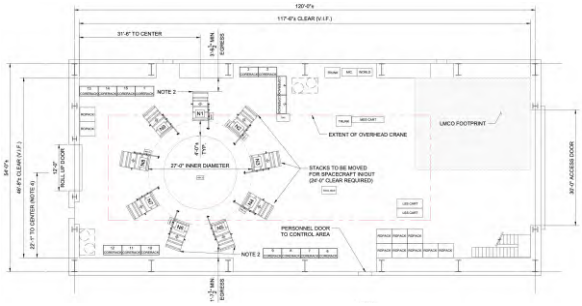

Figure 3: Overhead View of Speaker Circle Layout in the LASF

The main hurdle was the physical size of the specified test facility, the Launch Abort System Facility (LASF) at KSC. The diameter of the CSM test article and ground support equipment (GSE) was 19 ft, which necessitated an inner speaker circle diameter of 27 ft. The overhead crane at the LASF has a crane envelope width of just over 27 ft, leaving the rigging points of 3 NEUTRON stacks outside the crane footprint. If the diameter of the speaker circle was reduced to fit all speaker stack rigging points within the overhead crane envelope, the overall test performance would have been detrimentally impacted. ARS has developed best practices to keep the NEUTRON devices a minimum distance from the test article. Reducing the distance can affect the uniformity of the acoustic field and cause personnel and GSE access issues around the annulus of the speaker circle. Previous Orion testing was conducted using a full diameter speaker circle, so it was desired to have identical test configurations between the tests. Therefore, a different solution was pursued. An appropriately sized mobile crane for a 10-tall NEUTRON stack, weighing approximately 17,000 lbs, was introduced to handle the rigging and placement of the 3 NEUTRON stacks outside of the facility crane footprint. This applied to stacks N1, N5, and N6 depicted in Figure 3. The mobile crane became a critical path asset for the test campaign; its scheduling, positioning and operational constraints required integration into the overall ConOps.

Key considerations for mobile crane operations included: crane access pathways within the facility, floor loading limitations, minimum and maximum reach requirements for accessing the 3 NEUTRON stacks, coordination with the overhead bridge crane used for movement of the other 6 stacks, and development of a detailed schedule to accommodate mobile crane vendor availability.

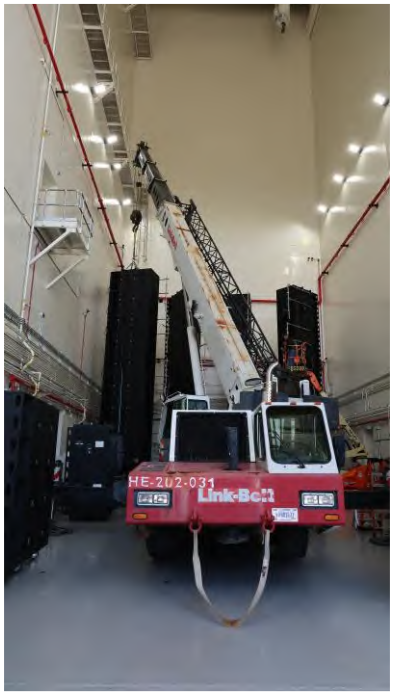

Figure 4: Mobile Crane Operations During Testing

At 10 NEUTRON units tall, the speaker stacks are in an unstable configuration until 4 stacks are supported in series by the Lateral Support System (LSS). Therefore, temporary ballasting was required during assembly of the speaker circle. A single standing stack utilized a ballast block support on either side of the stack. The ballast block could be removed once the LSS was connected to an adjacent speaker stack. Careful ConOps planning was performed to strategically erect NEUTRON

stacks, optimize ballast block usage, and minimize path interference for other assets, such as the mobile crane and personnel lifts. An example of a typical drawing for ballast deployment is depicted by Figure 5.

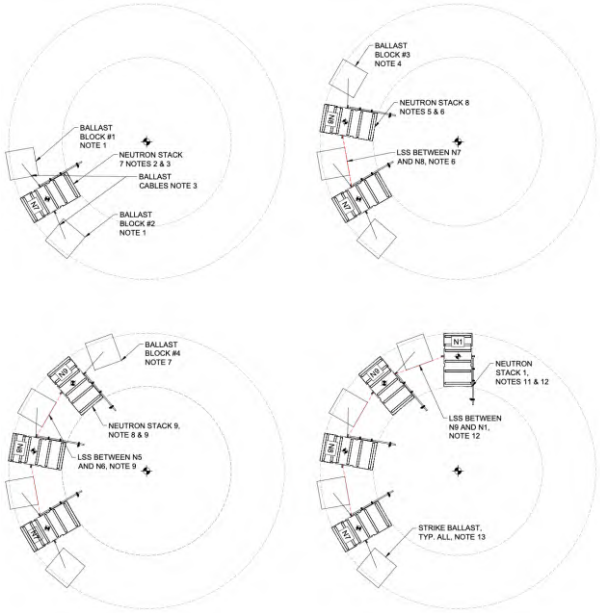

Figure 5: Ballast Block Deployment ConOps

An external generator was utilized for this test campaign. It was positioned on a concrete apron adjacent to the LASF, with the power feeder cabling run through building penetrations to the ARS CORERACK location. A power quality meter (PQM) was utilized on the generator to verify performance.

There were also other facility constraints to consider during the test operations. The LASF primarily supports activities for the Orion program that include the Launch Abort System (LAS) and working with vehicles fueled with hypergolics. Operating those systems require specialized fire detection hardware that could be sensitive to acoustic excitement. Due to the proximity of the LASF fire deluge system, the system was deactivated for the duration of the campaign by isolating the valves. The facility Infrared (IR) cameras were inspected for damage before and after the test. The overhead crane console was removed from the high bay for all test runs, since replacement parts for that console no longer exist. This required reinstallation of the console for any crane operations during the campaign. Lastly, a couple of crack gages were installed to monitor potential propagation of previous drywall damage in the high bay during acoustic test runs.

3.3 Multiple Discrete Vertical Zones

A significant technical advancement demonstrated during the Lockheed Martin campaign was the implementation of multiple discrete vertical zones within the DFAN system. In conventional DFAN testing, all acoustic devices in the system are controlled to achieve a single target spectrum across the entire acoustic field. Traditionally, the Orion Crew and Service modules have been DFAN tested independently before integrating the modules into the CSM configuration. Each module has its own acoustic spectrum that results from its position within the SLS rocket and its own acoustic cavities resulting from fairings and spacecraft architecture. The Service Module (SM) receives more low frequency excitation, while the Crew Module (CM) receives more high frequency noise. Testing the two modules simultaneously in the combined CSM configuration requires the application of at least 2 distinct vertical zones. For the primary campaign configuration, the top 4 devices in the NEUTRON stack were dedicated to the CM zone of the CSM, while the bottom 6 NEUTRONs targeted the SM zone.

Attached to the upper portion of the SM is the Crew Module Adapter (CMA). During launch, the CM is covered by the Launch Abort System (LAS) and its associated fairings and the ESM is enclosed by the Spacecraft Adapter Jettisonable (SAJ) fairings that jettison on orbit. The outer walls of the CMA are the only area of the Orion modules that are directly exposed to liftoff acoustics. As such, the expected flight environment on the CMA is higher than the bulk of the SM, which is covered by the SAJ fairings.

For this campaign, dual zone test runs were the emphasis. This is the most likely configuration to be used for a test on CSM flight hardware. Additionally, both single zone and triple zone configurations were explored. The single zone configuration involved leaving the bottom 6 NEUTRONs in the stack muted while only exercising the top 4. This is intended to simulate a CM only test but in the CSM configuration. Results for the single zone test are depicted by Figure 6.

The microphone configuration included 4 discrete rings of monitor microphones around the test article at varying heights. For all configurations, the monitor microphone averages were compared to the control mic averages for the given ring.

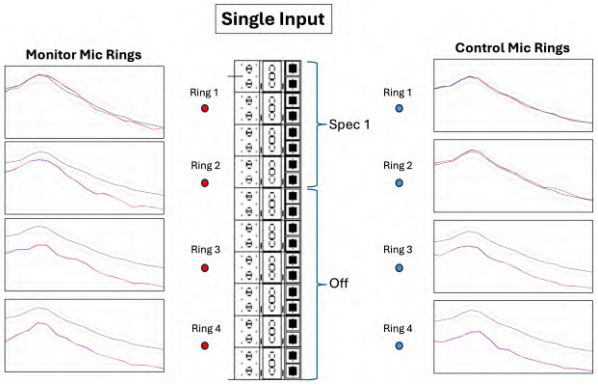

Figure 6: Schematic and Performance of Single-Zone Modified Vertical Configuration

Most of the test runs were conducted on the dual zone configuration. In this configuration, the top 4 speakers in the stack were dedicated to the CM spectrum and the bottom 6 speakers were dedicated to the SM spectrum. The influence of the zones on one another can be seen in Figure 7. Ring 2 was assigned the CM spectrum while the adjacent ring 3 was assigned the SM spectrum. Monitor microphone ring 2 shows somewhat elevated high frequency energy which more closely matches the SM spectrum. Even though the monitor microphones show the mixing of drive signals, the control microphones were responding nominally.

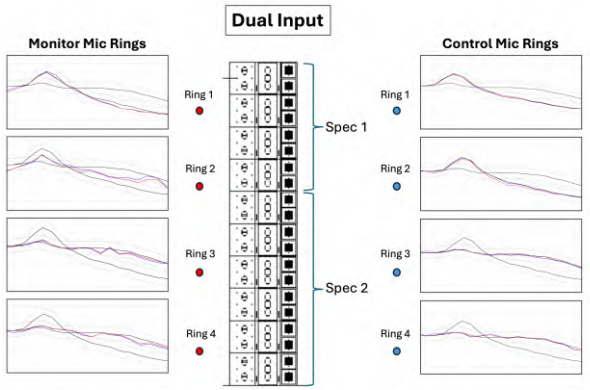

Figure 7: Schematic and Performance of Dual-Zone Vertical Configuration

A triple zone configuration was also demonstrated that added a discrete zone for the CMA. This allows the CMA to be driven harder than the remainder of the SM, with results depicted by Figure 8. As mentioned previously, the CMA is the only region of the Orion modules exposed directly to ascent acoustics, due to the lack of encompassing fairings.

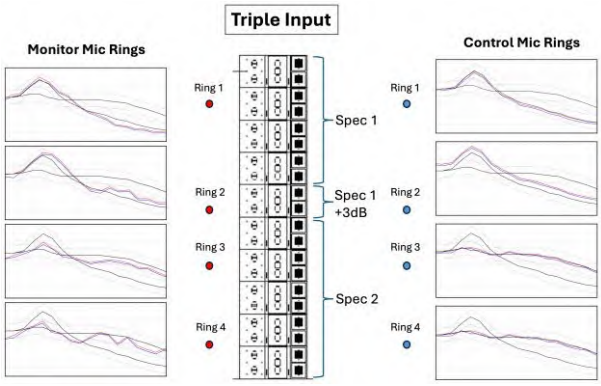

Figure 8: Schematic and Performance of Triple-Zone Vertical Configuration

The implementation of discrete vertical zones required modifications to the control system architecture. Each zone utilized its own set of control microphones positioned at the appropriate vertical height, and the 1/3-octave band Multiple Single Input, Single Output (SISO) controller was configured to manage each zone as an independent control. The uncorrelated drive signals within each zone ensured that spatial uniformity and sound pressure levels (SPL) were maintained within each controlled region.

Controllability between zones is highly dependent on the distance between microphones and the gradient of energy that exists between each zone. This can be characterized by measuring the response from all zones while activating only one at a time. For instance, in a two-zone system, if an output of 120 dB OASPL is driven into Zone 1, and the control microphone(s) for Zone 2 reads 114 dB OASPL, the difference between Zone 1 and 2 cannot exceed 6 dB OASPL. This example is a generalization, as the variation between 1/1 and 1/3 octave bands will depend on propagation of wavelengths, but studying the effects at higher resolutions can help predict the results with more detail.

3.4 Discrete Response Limiting

The traditional Orion module-level DFAN tests use a different configuration from that of flight. It also uses a test specific input acoustic spectrum that is not the same as the flight environment. Fairings add acoustic attenuation to the CM and SM during flight and add acoustic cavities. During DFAN testing, the vehicle fairings are not installed on the vehicle, so certain components respond higher (or differently) in the test environment than they would in flight. During the Structural Test Article (STA) program on Orion [5], an acoustic response limiting strategy was implemented to limit the response of specified components. This is achieved by specifying a do-not-exceed profile on a given sensor (i.e. accelerometer) [6]. By limiting components with less margin in the testing configuration, this enables other components to respond to a higher level. The goal is to reach the desired response (acceptance, qualification, etc.) on as much of the vehicle as possible without exceedances. This method of response limiting is preferred over input spectrum notching which causes a global reduction.

Before validating the discrete response limiting on the CSM test article, a test fixture comprised of 3 aluminum honeycomb panels mounted at different vertical levels on a support truss was used. One panel was located at the height of the CM, one at the height of the CMA, and one lower in the SM region. The 3 panels were instrumented with triaxial accelerometers. This fixture verified that discrete response limiting was effective on an easy-to-model analog. This also provided the opportunity to “tune” the notching capabilities of the response limits. Overly aggressive response limiting can cause test aborts or very reduced overall sound pressure levels.

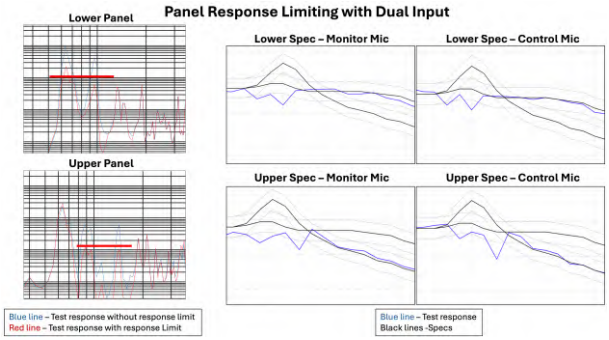

Figure 9: Orion CSM Pathfinder Demo Panel Response Limiting Results

During CSM DFAN pathfinder testing, components on both the CM and SM utilized response limiting. With separate acoustic input spectra applied to each module, discrete response limits were applied to each spectrum. This novel technique ensured vehicle protection and allowed for precise removal of energy. Limiting was seen on accelerometers on one side of the test article while the other side of the vehicle was minimally affected.

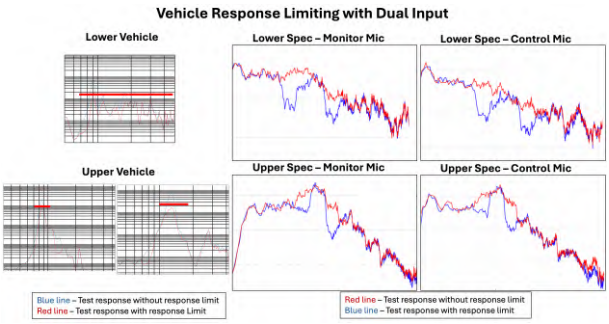

Figure 10: Orion CSM Pathfinder Demo Vehicle Response Limiting Results

4. COMPARISON AND DISCUSSION

4.1 Logistical Considerations at KSC

A previous DFAN capability demonstration was conducted for the Orion program at KSC's Space Systems Processing Facility (SSPF). This capability test featured the same 90-device NEUTRON configuration (9 columns of 10 devices). The logistical considerations for the original demonstration were distinct from the pathfinder campaign at the LASF that is the subject of this paper. The Orion pathfinder test campaign occurred at the LASF, which is a controlled facility only occupied by the Orion program. In contrast, the SSPF has many tenants that are all working on their own critical operations. The SSPF also directly supports missions to the ISS with extensive laboratory space and workstations. Time critical laboratory operations and the associated delays must be considered during initial scheduling. Even though the LASF and SSPF are only a ½ mile apart, different challenges were the main driver of ConOps changes.

For the original demonstration, a facility impact assessment followed the methodology described in Part One [1,8], utilizing inverse-square calculations and material Sound Transmission Class (STC) ratings to predict acoustic levels at key locations throughout the SSPF high bay and adjacent offices and laboratories. Given the proximity of other active spacecraft processing operations at KSC, these predictions were critical for establishing safe operating procedures and ensuring minimal disruption to neighboring programs.

Facility impact assessments for the testing at LASF focused on the impact to building systems such as fire detectors and operator safety. The Orion program was able to schedule and minimize parallel operations occurring inside the LASF which streamlined the testing schedule.

Similar power architectures can be utilized between test campaigns with some logistical differences. The external generator is placed outside of the test space and then has electrical feeder cable run into the test area to connect to the ARS system. Given that SSPF is an active secure integration facility, easily accessible external locations to place the generator were limited. The generator was set on an external ramp that leads to the airlock roll up door. This area is fenced and only accessible by badged NASA personnel. Access to the generator for operations and refuelling was limited as a result. Additionally, KSC rules forbade the operation of the generator outside during lightning warnings at KSC. Lightning is very common at KSC during certain times of the year. Strategies were implemented to negate the impact of generator access for all phases of the test campaign.

Generator operation at the LASF is more straightforward as the generator does not have to be placed in a secure area. In both cases, the generator was tied into an external ground connection on the testing buildings.

4.2 Scaling Effects on Acoustic Field Quality

A key question addressed by this campaign is whether the acoustic field quality demonstrated with 48 devices can be maintained when scaling to 90 devices. The results from this campaign indicate that the acoustic field characteristics – uniformity and diffusivity – are preserved at the larger scale [7].

4.3 Operational Efficiency at Scale

Despite the near-doubling of the device count, the operational procedures developed for the 48-device campaign scaled effectively to the 90-device configuration. The use of the ARS Microphone Support System (MSS) for pre-mounting instrumentation continued to reduce in-circle work time and trip hazards. The MSS allows microphone position to be fixed in 3D space relative to the

NEUTRON stack that it is mounted to. Each NEUTRON stack is then placed at a known position relative to a pre-determined location, typically the center of the speaker circle. This technique allows for the microphone-to-article relationship to be defined prior to test set up, rather than measuring in-situ for each microphone. It overcomes the hurdle of being able to accurately measure the location of a microphone in 3D space due to access limitations while the test article is located within the speaker circle. Custom laser cut jigs were also introduced to assist laying out the projection of the MSS from the front of a NEUTRON.

The primary area where operational complexity increased was in configuration changes requiring the mobile crane. These operations required more detailed planning, additional safety oversight, and tighter coordination between the DFAN team, facility operators, and mobile crane operators. The development of comprehensive lift procedures with clear signoff requirements was essential for maintaining safety and schedule compliance.

4.4 Key Metrics Summary

Parameter	48 Devices (Part One)	90 Devices (Orion)
Configuration	8 by 6	9 by 10
Drive Channels	24	36
Vertical Zones	Single	Dual / Triple
Response Limiting	Not Used	Yes, Discrete
Mobile Crane Required	No	Yes
Test Level Achieved	~141 dB OASPL	147 dB OASPL

5. LESSONS LEARNED

The execution of a 90-device DFAN campaign produced a few lessons learned that are relevant to the broader industry as DFAN testing continues to scale in size and complexity.

First, the importance of comprehensive ConOps cannot be overstated. A major example of this is the incorporation of a mobile crane in the testing flow. When device configurations grow beyond what can be handled within the footprint of the facility overhead crane, the mobile crane becomes a critical path resource. Early coordination with crane service providers, detailed pre-planning of access routes and lift sequences, and integration of crane operations into the test procedure documents are essential for maintaining schedule and safety.

Second, the development of multiple discrete vertical zones demonstrated that the DFAN methodology can be extended beyond uniform-field testing to provide spatially tailored acoustic environments. This capability opens new possibilities for testing tall, multi-element spacecraft assemblies where different sections may have different acoustic qualification requirements.

Third, discrete response limiting proved to be a valuable tool for protecting sensitive hardware while maximizing the qualification value of the test. By targeting level reductions to specific frequency bands rather than applying broadband reductions, the test team was able to maintain specification levels across a greater percentage of the frequency range (and test article).

Fourth, the successful deployment of the 90-device system at a facility that on paper was not ideal to use for a system of this size reinforces the portable and adaptable nature of the DFAN methodology. The facility impact assessment and acoustic propagation prediction techniques described in Part One [1,8] continue to provide reliable guidance for new deployment locations.

6. CONCLUSION AND FORWARD WORK

This paper has presented a detailed case study of a large-scale DFAN test campaign utilizing 90 ARS NEUTRON acoustic devices. The campaign conducted at NASA's Kennedy Space Center for the Lockheed Martin Orion program demonstrated that the methodology can be effectively scaled while maintaining acoustic field quality and operational safety and efficiency standards.

The introduction of multiple discrete vertical zones and discrete response limiting per zone represents a meaningful technical advancement in DFAN testing. These tools enable new testing configurations that could potentially reduce cost and schedule, while allowing for a test configuration that is more representative of the flight configuration.

The logistical and operational challenges encountered during this campaign reinforced the need for extensive pre-test planning and ConOps development. As tests grow, these operational considerations will become increasingly important to the overall outcome of the test.

Forward work includes the refinement of vertical zone control and discrete response limiting to support more complex multi module articles. The authors also plan to continue publishing operational and technical data from future campaigns to support the development of industry best practices for large-scale DFAN testing.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to the engineering and operational teams at Lockheed Martin for their collaboration and support during this test campaign.

KEYWORDS

Additive manufacturing, electrically functional structures, embedded conductors, multifunctional battery packaging, LPBF, spacecraft energy systems

ABSTRACT

Embedding electrical functions within metallic additively manufactured structures offers a promising pathway toward enhanced functional integration in spacecraft equipment. However, most reported demonstrations remain limited to the incorporation of commercial off-the-shelf components, such as wires, connectors, and sensors, rather than the true integration of these functionalities directly into the structural design.

This paper presents the BatmAM project, which extends CSEM's electrical functionalization approach [16] to a representative spacecraft battery-pack demonstrator. The proposed design combines structural support, embedded electrical distribution, cell interfaces, heat-dissipation paths and assembly features within a reduced number of additively manufactured components.

In close collaboration with Almatech, a 96-cell (8S12P) demonstrator was designed, manufactured and assembled using a process combining LPBF, epoxy insulation casting and machining. The resulting architecture distributes structural and electrical functions between a multifunctional frame, covers and compliant contact interfaces, while remaining compatible with commercial lithium-ion cells and conventional verification approaches.

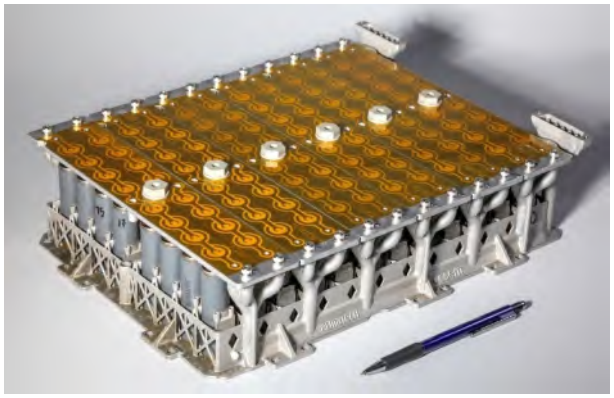

Figure 1: Final prototype of the battery pack

The demonstrator was subjected to electrical characterisation, vibration, shock and thermal-vacuum testing representative of space applications. The results confirmed that electrically functional metallic structures can be implemented at subsystem level while maintaining structural integrity and electrical continuity under representative environmental conditions. The approach also reduced packaging mass and manufacturing lead time compared with conventional battery-packaging solutions.

Beyond the battery application, the work contributes to the maturation of electrically functional additively manufactured structures. The packaging architecture reached TRL 5 and MRL 6, while the complete battery subsystem stands at TRL 4, confirming both the maturity of the demonstrated packaging concept and the remaining work required for full subsystem qualification.

1. INTRODUCTION

Electrical energy storage systems are critical elements of modern spacecraft, directly influencing mission lifetime, operational flexibility and overall system reliability [1,2]. While significant progress has been achieved at cell level, battery packaging architectures still rely largely on conventional mechanical integration approaches involving dedicated support structures, busbars and thermal interfaces [2,3].

While these solutions benefit from extensive flight heritage, they generally result in high part counts, significant assembly effort, and limited flexibility when adapting designs to mission-specific requirements. Future battery packs will require solutions that are simultaneously optimized, highly customized, and cost-effective. Achieving these objectives remains challenging with conventional manufacturing approaches, which constrain the achievable level of functional integration and limit opportunities for architectural simplification.

This work investigates Design for Additive Manufacturing (DfAM) as an enabling approach for enhanced system-level integration. Its potential is assessed through the development of a battery-

pack demonstrator within the BatmAM project, where structural support, electrical interconnections, and assembly interfaces are consolidated into a single additively manufactured platform. The objective is not to introduce a new electrochemical storage technology, but rather to demonstrate how electrically functional metallic structures can increase integration levels and contribute to the simplification of spacecraft equipment architectures.

2. STATE OF THE ART

2.1. Conventional Spacecraft Battery Packaging

Lithium-ion batteries have become the reference energy-storage technology for spacecraft due to their high specific energy, long cycle life and extensive operational heritage [2,8]. However, while cell technologies have evolved significantly, the packaging architectures surrounding them remain largely based on conventional mechanical and electrical integration principles [2,3].

A typical spacecraft battery is assembled from individual cells, integrated within a structural enclosure and interconnected through busbars, welded tabs, wire bonds or harness assemblies. Additional elements typically include fasteners, insulation materials, connectors, sensors, thermal-interface hardware and support structures. As a result, each engineering function is generally implemented through a dedicated set of components before being integrated into a complete battery assembly.

This design philosophy benefits from substantial flight heritage and mature qualification practices. However, the reliance on dedicated components and joining operations increases the number of parts, interfaces and manufacturing steps that must be designed, manufactured, procured, inspected and assembled. It also creates dependencies on external suppliers for COTS elements and reduces accessibility to individual cells and electrical interfaces when bonded or welded connections are used. Consequently, while conventional battery packaging remains robust and well understood, it still offers significant opportunities for architectural simplification and functional integration.

This motivates approaches that reconsider the battery package as an integrated engineering system rather than as a passive enclosure for electrochemical cells.

2.2. Additive Manufacturing for Electrically Functional Structures: Opportunities and Challenges

Over the last two decades, additive manufacturing has evolved from a prototyping technology into an established production method for aerospace and space applications [4,5]. LPBF is now routinely used to manufacture lightweight structural, thermal and fluidic hardware while enabling part consolidation and geometry optimisation through Design for Additive Manufacturing (DfAM) [5,8]. Beyond these established benefits, additive manufacturing also offers opportunities for integrating multiple engineering functions within a common architecture.

Several authors have explored the integration of electrical functions (*Figure 2*) into additively manufactured parts. Most early developments focused on structural electronics and relied on surface or near-surface integration of conductive tracks and electronic components on polymeric or dielectric substrates [9-13]. More recent work [14] extended these concepts towards multifunctional structures and metallic components through – among others – the integration of conductive pathways following CSEM's patented approach [16]. In parallel, additive approaches dedicated to spacecraft thermal-control hardware have demonstrated the direct printing of heating functions onto metallic tubing and other components [15].

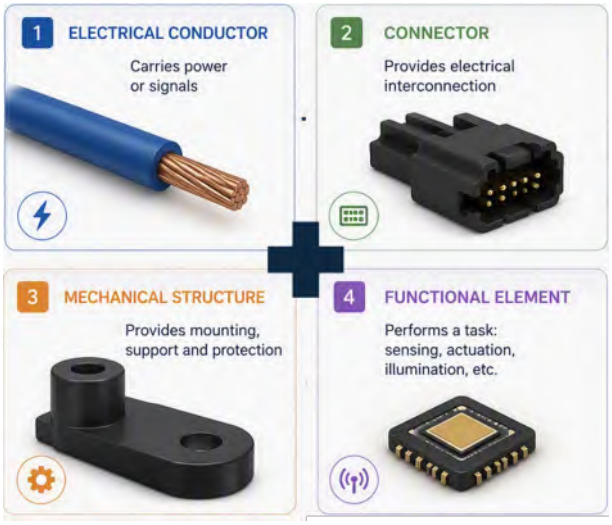

Figure 2: Key functional building blocks traditionally implemented as separate components and targeted for integration into a single structure.

These developments highlight the potential of additive manufacturing to reduce wiring complexity, interconnection hardware and assembly effort. However, implementing electrical functions within structural components remains challenging because conductive pathways, electrical insulation and load-bearing functions must coexist within the same architecture. Additional constraints arise from the manufacturing process itself, including feature resolution, material compatibility, dimensional tolerances, post-processing requirements and inspection capability. For metallic AM processes such as LPBF, these challenges are further compounded by support strategies, powder removal, surface roughness and machining requirements, all of which can directly influence electrical performance, insulation integrity, structural behaviour and overall manufacturability.

To address these limitations, CSEM developed the patented EP3740382 technology [16]. The concept, illustrated in Figure 3, relies on a manufacturing sequence in which an electrically conductive structure is produced by additive manufacturing with future electrical pathways temporarily connected to the surrounding material through sacrificial bridges or skins. Following the casting and solidification of the insulation material, these sacrificial elements are removed by conventional machining, thereby electrically isolating the conductive pathways from the surrounding metallic structure. When an epoxy resin is used as the insulation material, solidification is achieved through a polymerisation process.

This approach has already been demonstrated through applications such as an additively manufactured slip ring rotor [17] and a multifunctional pipe segment integrating built-in heating, sensing interfaces and connector [18] (see *Figure 4* & *Figure 5*).

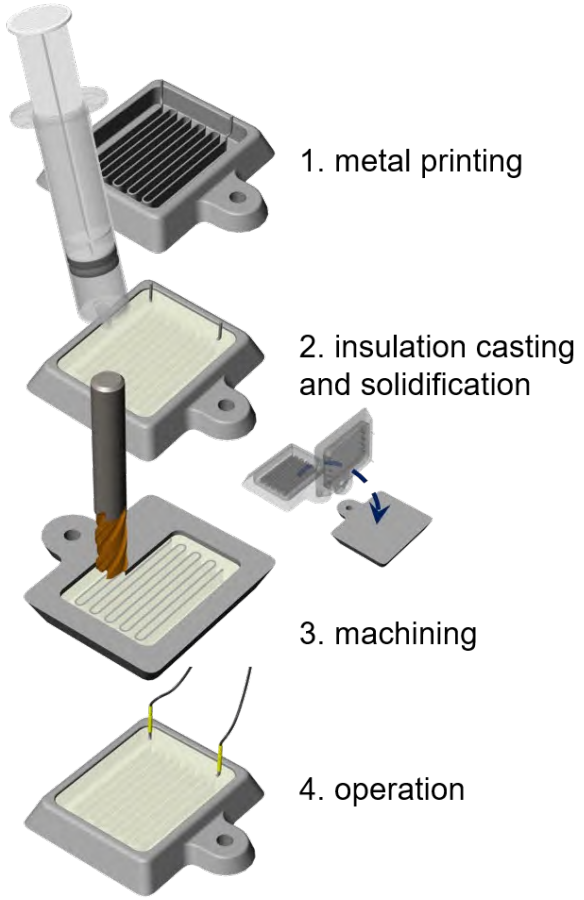

Figure 3: DfAM concept [16] for integrating electrically insulated conductive features within LPBF-manufactured metallic structures.

The BatmAM project extends this concept from component-level functionality to subsystem-level integration by investigating how electrically functional metallic structures can support structural functions and electrical distribution within a spacecraft battery pack.

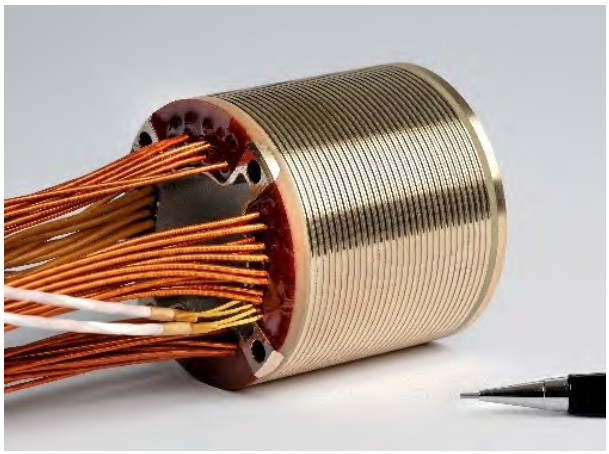

Figure 4: Slip ring rotor re-designed for AM [17]. For 30 tracks, the new design reduces the number of parts from > 60 to one single part.

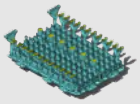
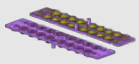
Figure 5: Pipe segment with heater, temperature sensor and connector embedded in one part [18]. An animation of the manufacturing sequence is available here.





3. MULTIFUNCTIONAL DESIGN CONCEPT

In the BatmAM project, the objective was to simplify the pack architecture, reduce packaging mass and integration effort. The concept was therefore developed around a limited number of multifunctional structural elements designed to preserve compatibility with commercially available lithium-ion cells and established verification practices. This concept provides the basis for the function allocation described below and for the representative prototype presented in Section 4.

The proposed architecture applies the electrically functional LPBF approach introduced in Section 2.2 to battery packaging. Unlike conventional AM components, where electrical functions are typically provided by external wires, busbars or connectors, this approach allows conductive pathways to become part of the structural component itself. The same component can therefore contribute to mechanical support, electrical routing and thermal roles. This capability allows the battery package to be treated as an electrically functional mechanical component rather than as a passive enclosure

carrying separate wiring and busbar elements. The architecture was organised around a limited number of integrated elements, each carrying a defined subset of functions summarised in Table 1.

Table 1: Functional allocation overview

Function	Frame 	Covers 	Spring contacts 
Primary structure	X	X	
Mechanical interfaces to spacecraft	X		
Cell positioning	Radial	Axial	Axial compliance
Parallel electrical distribution	X		
Series electrical interconnection		X	
Cell-to-network electrical interface			X
Electrical connectors	X		
Tolerance and thermal-expansion accommodation	Cells - radial		Cells - axial
Thermal management	Cell heat dissipation path through the frame	Heaters glued on the covers	Thermal link between covers and cells

4. PROTOTYPE DETAIL DESIGN, MANUFACTURING AND ASSEMBLY

4.1. Design

The multifunctional architecture described in Section 3 was implemented through a representative 96-cell battery-pack prototype arranged in an 8S12P configuration (i.e. 12 parallel strings of 8 cells each). The multifunctional frame illustrated in *Figure 7* provides the primary load path while integrating the cell-positioning features. Each cell is held by a dedicated compliant bracket integrated into the frame. The geometry was defined to ensure controlled cell positioning, efficient load transfer and heat dissipation by conduction through the frame. Electrically conductive paths are embedded in the frame to implement the parallel cell interconnections (see *Figure 7* and *Figure 9*), while series interconnections were implemented within the covers (see *Figure 8* and *Figure 9*).

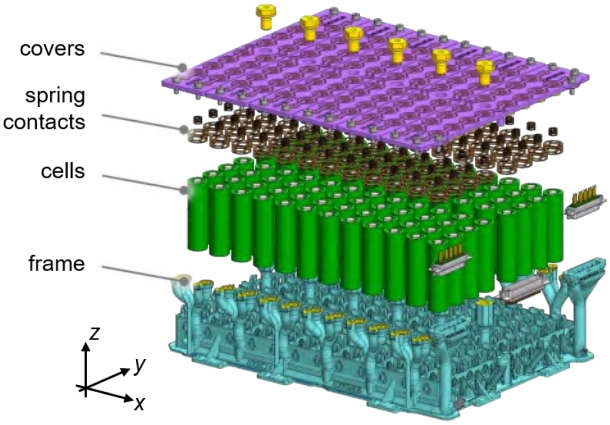


Figure 6: exploded CAD view of the battery pack

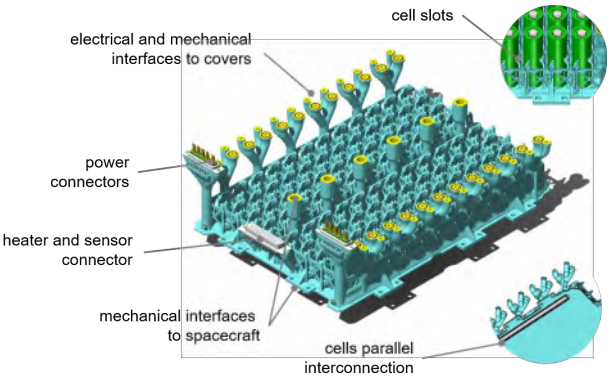

Figure 7: CAD view of the battery frame

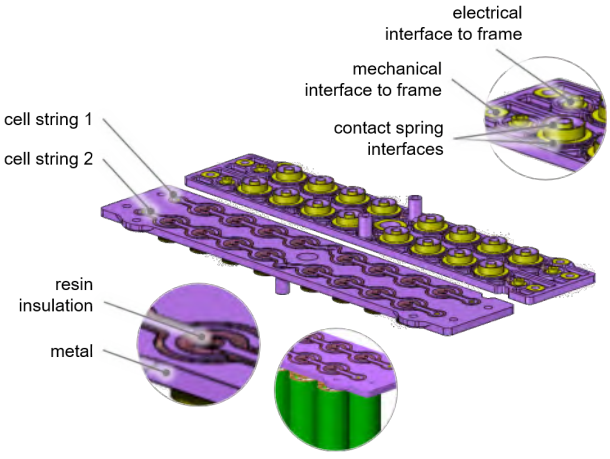

Figure 8: CAD view of the battery covers

Electrical contact between the cells and the integrated conductive network is achieved through compliant spring interfaces. These contacts accommodate dimensional tolerances and differential thermal expansion while avoiding welded or soldered joints at cell level.

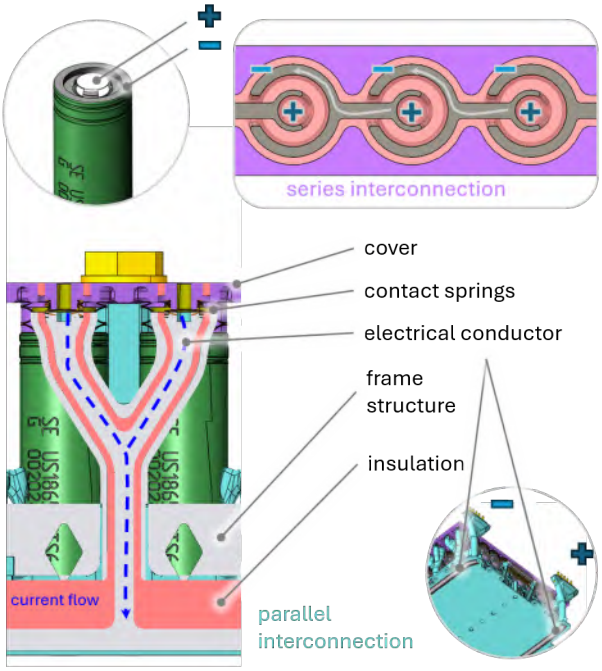

Figure 9: Electrical pathway implementation

The electrical interface to spacecraft uses male D-Sub connector geometries printed with the frame (*Figure 10*). During assembly, commercial female connectors are mounted on these printed interfaces and used as the nominal harness connection points (*Figure 6*). This avoids repeated mating/de-mating cycles directly on the printed connector features which, unlike the commercial female connectors, are not qualified COTS interfaces.

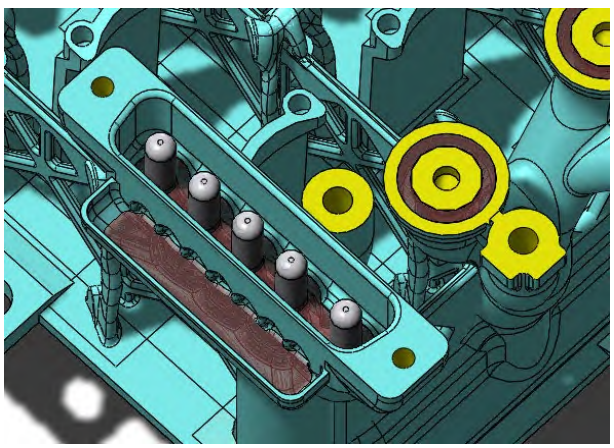

Figure 10: Detailed view of the male D-Sub connector

4.2. Design Benefits

By integrating electrical connections, connectors and routing features directly within the structural components, the proposed architecture significantly reduces the amount of dedicated wiring, interconnection hardware and assembly operations required to realise the battery pack. The architecture also enables a maintenance-oriented approach through mechanically clamped and demountable cells, making inspection, replacement and future servicing operations possible without modifying the overall packaging concept. In addition, the simplified architecture facilitates the development of representative multiphysics models by reducing the number of components and interfaces that need to be represented in the simulations.

From a manufacturing perspective, the combination of LPBF and electrically functional structures demonstrated an approximately 30% reduction in packaging mass, corresponding to about 15% reduction at complete battery-pack level. Manufacturing, assembly and cell-integration lead time were reduced from approximately 11 weeks to about 2 weeks. Finally, the architecture is inherently scalable and can be adapted to different electrical configurations and form factors while preserving the same integration principles.

Table 2: *comparison between conventional packaging and the BatmAM demonstrator.*

Aspect	Conventional battery packaging	BatmAM demonstrator
Electrical features	Assembled busbars, wires, connectors	Embedded conductive paths and connectors
Cell electrical interface	Welding or wire bonding	Compliant spring contacts
Cell mechanical interface	Individually glued in mechanical slots	Compliant radial and axial mounting.
Maintenance and repair	Challenging because of welded / bonded / glued components	Straightforward: remove the covers, replace cells, reinstall the covers
Packaging mass	Reference conventional packaging	~ 30% reduction at packaging level
Manufacturing and assembly time	~ 11 weeks	~ 2 weeks

4.3. Manufacturing

The frame and covers were produced by LPBF using AlSi10Mg alloy, followed by de-powdering and cleaning of internal features and cavities. An epoxy resin with space heritage was then cast and cured to provide electrical insulation between the conductive paths and the surrounding metallic structure. Final machining removed sacrificial material linking the electrical pathways to the structure and provided the dimensional accuracy required for the mechanical interfaces.

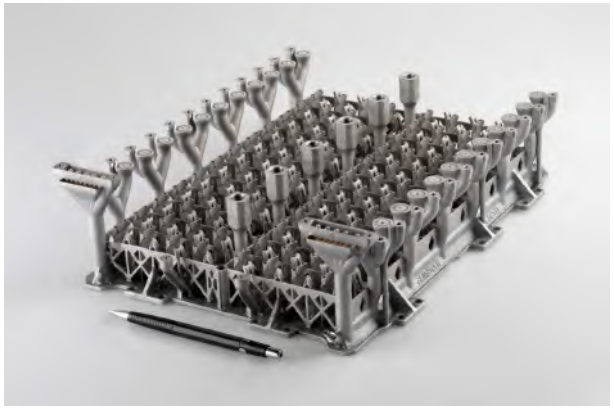

Figure 11: Battery pack frame ready for assembly

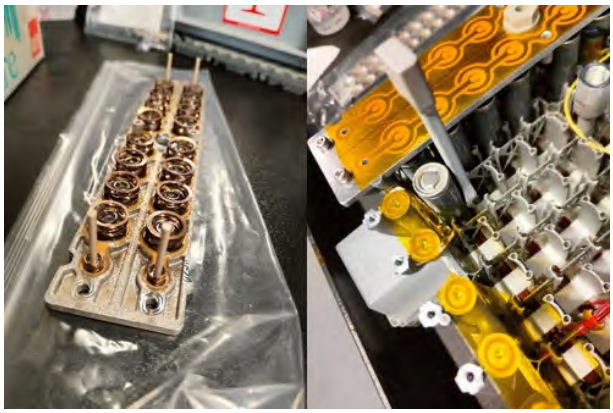
Figure 12: Battery pack cover ready for assembly

4.3 Assembly

The cells were inserted into their respective locations, as shown in *Figure 13*. The contact springs and covers were then installed to complete the mechanical closure and the electrical interconnections of the pack. External connectors, heaters and temperature sensors were subsequently integrated. The assembly sequence was concluded with electrical verification and functional checks before environmental testing.



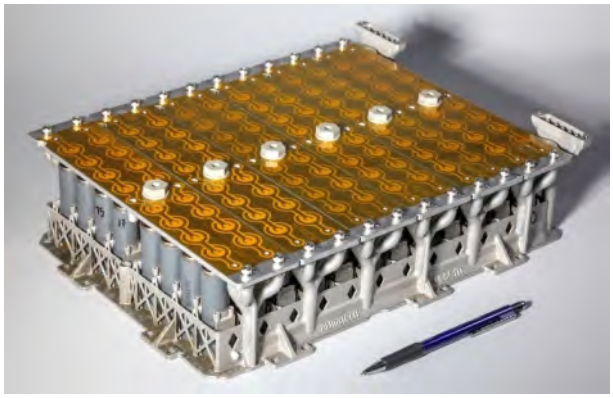


Figure 13: Left picture: cover with contact springs and fasteners. Right picture: integration of a cell. Click on this link to access a video showing the assembly sequence of the BatmAM prototype.

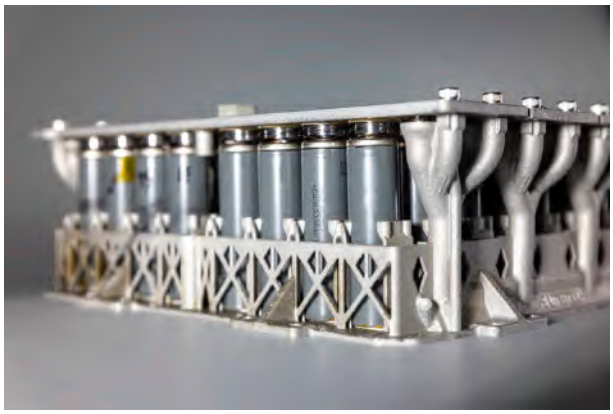

Figure 14: Final prototype ready for tests.

5. EXPERIMENTAL VALIDATION

The proposed multifunctional battery packaging architecture was validated through a comprehensive environmental and electrical verification campaign performed on two engineering model battery packs. The campaign included dimensional inspections, electrical characterisation, vibration, shock, thermal-vacuum testing and post-test electrical characterisation following an ECSS-inspired qualification philosophy. The qualification sequence is summarised in Tab. 3. It includes intermediate electrical health checks after each environmental phase, allowing potential degradation mechanisms to be isolated throughout the campaign.

Table 3: *Qualification campaign summary*

Test phase	Main activities	Objective
Initial conformity	Visual inspection, dimensions, insulation, continuity, heater verification	Manufacturing verification
Initial electrical characterisation	Cell voltages, Electro Impedance Spectroscopy (EIS)	Electrical reference
Mechanical qualification	Resonance search, sine vibration, random vibration, shock	Structural verification
Intermediate electrical characterisation	Voltage, EIS, capacity	Damage assessment
Thermal vacuum qualification	LEO cycles, GEO cycles, heater tests, thermal cycling	Thermal verification
Final electrical characterisation	Voltage, EIS, capacity	Performance verification
Final conformity	Visual inspection and functional checks	Final acceptance

5.1. Mechanical Qualification

Mechanical verification included resonance searches, sine vibration, random vibration and shock tests. Resonance searches performed before and after each test and visual inspections confirmed the absence of structural damage after vibration and shock testing.

[1] LEO & GEO electrical cycling tests were shortened due to cell imbalance in one string.

Table 4: *Mechanical qualification summary.*

Test	Qualification level	Result
Resonance search	Before/after each run	No significant modal shift
Sine vibration	Qualification level (25 g design case)	No amplification observed; first mode at 515 Hz
Random vibration	up to 17.39 g RMS equivalent qualification	Successful
Shock	Three shocks per axis (plateau at 2200 g)	Successful
Electrical health check	After each axis	No significant degradation

5.2. Thermal Vacuum Qualification

Thermal verification reproduced representative orbital environment including functional and non-functional operating conditions. During thermal testing, battery voltage, current, embedded temperature sensors and delivered capacity were continuously monitored.

Table 5: *Thermal-vacuum campaign summary*

Test	Description
Functional heater verification	Battery heaters operation
LEO cycling [1]	8 functional thermal cycles planned but only 4 performed (3 cold and 1 nominal)
GEO cycling [1]	3 functional thermal cycles planned but only 1 performed at nominal temperature
Thermal cycling	8 cycles between 0 °C and 30 °C
Continuous monitoring	Voltage, current, temperatures, capacity and energy

5.3. Electrical Performance

Electrical characterisation was performed before mechanical testing, after mechanical testing and after completion of the thermal-vacuum campaign.

Following mechanical qualification, electrical measurements showed negligible deviations from the reference values, with a battery capacity of approximately 35 Ah and an impedance of approximately 70 mΩ. These results confirm that

the multifunctional package maintained both structural integrity and electrical continuity during the mechanical test campaign.

After thermal-vacuum exposure, the estimated battery capacity decreased from the reference value of approximately 35 Ah to 27.3 Ah. Electrochemical impedance spectroscopy revealed an increase of approximately 35 mΩ in the real component of the pack impedance. Preliminary de-risking activities on cells from the same batch exposed to vacuum conditions support the hypothesis that the observed degradation originated from the commercial cells rather than from the multifunctional packaging architecture itself; the exact degradation mechanisms were not investigated in the project.

Table 6: *Electrical performance summary.*

Parameter	Result
Battery architecture	8S12P (96 × 18650 cells)
Measured capacity after TVAC	27.3 Ah
Reference capacity before TVAC	~35 Ah
Capacity degradation	Observed after thermal-vacuum exposure
Impedance evolution	~35 mΩ increase
Cell voltages after mechanical tests	No significant variation
Visual inspection	No structural damage

6. CONCLUSIONS

This paper presented the BatmAM multifunctional battery packaging architecture, a new approach to spacecraft battery integration that combines structural support, electrical interconnections and thermal management within a limited number of additively manufactured components. The proposed concept exploits commercially available cylindrical Li-ion cells and focuses on optimizing the surrounding packaging architecture through Design for Additive Manufacturing (DfAM) principles.
The proposed architecture demonstrates how additive manufacturing can be effectively leveraged to consolidate multiple subsystem functions into a lightweight, compact and highly integrated battery package. The multifunctional frame and covers simultaneously provide structural support, compliant cell retention, embedded electrical routing, and assembly interfaces while significantly reducing part count, mechanical interfaces and assembly complexity. Compared with conventional spacecraft battery designs, the new concept leads to approximately 30% reduction of the packaging mass and to a reduction of the manufacturing and assembly time from approximately 11 to approximately 2 weeks. The modular and parametric architecture also facilitates adaptation to different battery capacities, cell configurations and mission requirements, making it suitable for a wide range of future spacecraft platforms.

A comprehensive validation test campaign including mechanical, thermal-vacuum and electrical testing confirmed the feasibility and robustness of the proposed concept. Throughout the environmental qualification campaign, the multifunctional battery package successfully maintained its structural integrity, electrical continuity and thermal functionality under representative launch and space environmental conditions. Although electrical characterisation after thermal-vacuum testing revealed a reduction in battery capacity and an increase in internal impedance, the probable cause is a leakage of electrolyte at cell level. Indeed, the increase in impedance and loss of capacity were also observed in cells from the same batch that had been exposed to vacuum but had not undergone electrical cycling. The results therefore demonstrate that the proposed architecture effectively fulfils its intended structural, electrical and thermal functions while showing significant measurable impacts on mass reduction and production time reduction.

The manufacturing and successful environmental validation of the multifunctional battery packaging design in a representative environment advance supports the assessment of the packaging technology at TRL 5 and MRL 6. The complete battery subsystem is currently assessed at approximately TRL 4, as full system-level qualification, operational validation and long-duration performance assessment remain to be completed. This distinction appropriately reflects the maturity of the validated packaging technology relative to the overall battery subsystem and establishes a clear roadmap for its further development.

Future work will focus on advancing the complete battery subsystem toward higher technology readiness through optimisation and flight-representative qualification of the integrated thermal management strategy, extension to alternative cell formats and chemistries, and further exploitation of additive manufacturing (see *Figure 15*) to embed additional sensing and structural health-monitoring functions. The battery package design will also evolve to be compatible with state-of-the-art BMS (Battery Management System).

Beyond the BatmAM demonstrator, this work demonstrates how additive manufacturing can change the design philosophy of spacecraft energy systems by enabling true multifunctional integration

rather than simply replacing conventionally manufactured components. The methodology presented here is applicable to a broad range of spacecraft energy systems, including small satellites, telecommunication satellites, scientific missions and exploration platforms, particularly where reductions in mass, volume, interface count, and integration effort represent major system-level design drivers.

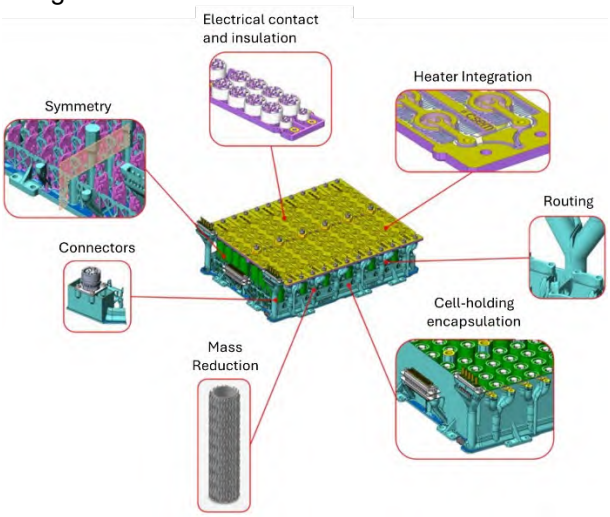

Figure 15: Design upgrades foreseen in future development steps

ACKNOWLEDGEMENTS

This work was performed within the BatmAM (Additive Manufacturing for Multifunctional Battery Packaging) project funded by the European Space Agency (ESA) under the ARTES, Contract No. 4000139904/22/NL/AF. The authors sincerely thank the ESA technical officers for their continuous technical support, constructive feedback and valuable guidance throughout the project.

Large-Scale Additive Manufacturing, Continuous Fibre Reinforcement, Recycled Carbon Fibre, High-Performance Thermoplastics, Path Planning, Aerospace Structures

ABSTRACT

Large-scale additive manufacturing (LSAM) of continuous fibre-reinforced thermoplastics offers significant potential for lightweight aerospace structures but remains limited by sustainable feedstock availability and restricted deposition strategies.

This work presents an integrated manufacturing approach combining the development of continuous 12K carbon fibre filaments manufactured from both virgin carbon fibres and recycled fibres originating from industrial production waste with advanced deposition strategies for uninterrupted structural additive manufacturing. High-performance thermoplastic matrices, including polyphenylene sulfide (PPS) and polyaryletherketone (PAEK), were processed using a co-extrusion process to produce continuous fibre filaments suitable for LSAM. Their processability, microstructure, and mechanical performance were evaluated to assess the suitability of recycled fibres for structural applications.

In addition, localized trajectory adaptations for continuous fibre crossings and support-free three-dimensional deposition strategies were developed and experimentally validated using representative demonstrator structures.

The results demonstrate that recycled continuous fibre feedstocks can be successfully combined with advanced toolpath strategies, preserving continuous load paths while extending the geometric design space of large-scale additive manufacturing.

The presented approach provides a promising pathway towards sustainable, load-path-oriented composite structures for future aerospace and space applications.

1. INTRODUCTION

The increasing demand for lightweight, resource-efficient and mission-adapted structures continues to drive the development of advanced manufacturing technologies for aerospace and space applications. Besides achieving high specific mechanical properties, future manufacturing processes must enable rapid design adaptation, efficient material utilisation and economically viable production of highly individualised structural components. Large-scale additive manufacturing (LSAM) has therefore emerged as a promising technology, combining the geometric freedom of additive manufacturing with the processing of engineering thermoplastics and fibre-reinforced composite materials. Compared with conventional manufacturing technologies, LSAM enables the direct fabrication of large and highly customised structures while significantly reducing tooling effort and material waste [1].

Among the various reinforcement concepts, continuous carbon fibres offer the greatest potential for enhancing the mechanical performance of additively manufactured thermoplastic structures. In contrast to short-fibre reinforced polymers, continuous fibres provide uninterrupted load paths that enable efficient stress transfer along the fibre direction, resulting in substantially increased stiffness, strength and damage tolerance. Consequently, continuous fibre reinforced additive manufacturing has attracted considerable attention for structural aerospace applications, where lightweight design and load-path-oriented reinforcement concepts are of central importance [2-4].

Despite these advantages, current continuous fibre additive manufacturing technologies still exhibit several fundamental limitations. Most existing systems remain restricted to planar layer-by-layer deposition, limiting the fabrication of spatial reinforcement architectures that efficiently follow three-dimensional load paths. Furthermore, intersecting toolpaths generally require interruption of the continuous reinforcement, introducing discontinuities that reduce structural efficiency. In addition, support-free deposition of spatial reinforcement structures remains a major

technological challenge [3,4].
Besides these process-related limitations, sustainability has become an equally important challenge for future composite manufacturing. Carbon fibre production is associated with high energy consumption and considerable material losses during industrial processing. Continuous fibre production waste is frequently discarded because local defects prevent its use in conventional high-performance laminate manufacturing, although a large proportion of the intrinsic mechanical properties of the fibres remains unaffected. Preserving these continuous fibres for structural applications therefore represents an attractive opportunity to improve resource efficiency while simultaneously reducing the environmental footprint of composite manufacturing [5].
Previous work at the German Aerospace Center (DLR) established a co-extrusion process for manufacturing continuous fibre thermoplastic filaments from both virgin and recycled 12K carbon fibre tows. These investigations demonstrated the feasibility of producing printable continuous fibre filaments based on high-performance thermoplastics and provided the technological foundation for recycled continuous fibre feedstocks in large-scale additive manufacturing [6,7]. Building upon these developments, further advances are required to fully exploit the structural potential of continuous fibre LSAM. In particular, reliable processing of recycled feedstocks, uninterrupted fibre deposition across intersecting toolpaths and support-free three-dimensional deposition remain key challenges for manufacturing highly load-adapted composite structures.
To address these challenges, this work presents an integrated manufacturing framework combining sustainable feedstock development with advanced deposition strategies for continuous fibre large-scale additive manufacturing. Continuous fibre filaments manufactured from virgin and recycled carbon fibre tows are comparatively evaluated regarding processability, microstructure and structural performance. Building upon these feedstocks, localized toolpath adaptations enabling uninterrupted fibre crossings and support-free spatial deposition strategies are developed and experimentally validated using representative demonstrator structures. The overall workflow of the presented research is illustrated in Figure 1. It highlights the two main contributions of this work: (i) the development of sustainable continuous fibre filaments from recycled carbon fibre production waste and (ii) the development of advanced deposition strategies for uninterrupted, load-path-oriented large-scale additive manufacturing. By combining these complementary developments within a single manufacturing framework, the presented approach extends both the material basis and the geometric design space of continuous fibre large-scale additive manufacturing for future aerospace and space structures.

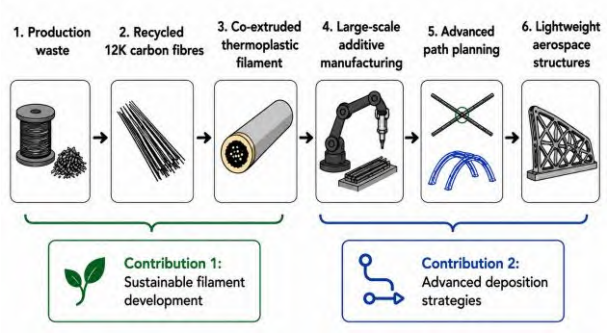

Figure 1: Overview of the presented workflow illustrating the two main contributions of this work: (1) the development of sustainable continuous fibre filaments from recycled carbon fibre production waste and (2) advanced deposition strategies for uninterrupted large-scale additive manufacturing of lightweight aerospace structures.

2. MATERIALS AND EXPERIMENTAL METHODS

This chapter describes the materials, filament manufacturing process, large-scale additive manufacturing system, and experimental procedures employed throughout this study. The experimental programme comprised the development and characterization of continuous fibre thermoplastic filaments manufactured from both virgin and recycled carbon fibres, followed by the experimental validation of advanced deposition strategies for uninterrupted continuous fibre placement and support-free three-dimensional printing. The overall methodology is structured to evaluate both the suitability of recycled continuous fibre feedstocks for structural large-scale additive manufacturing and the feasibility of the proposed process innovations.

2.1 Raw Materials

Two continuous carbon fibre reinforcement systems were investigated: a commercial 12K virgin carbon fibre tow and a recycled 12K carbon fibre tow recovered from industrial production waste. In contrast to conventional recycling approaches based on discontinuous fibres, the original continuous fibre architecture was preserved, enabling the recycled material to be processed directly as continuous reinforcement for extrusion-based additive manufacturing.
Three continuous fibre reinforced filament systems were investigated throughout this study. Two filament systems were manufactured at DLR using the ENDLOS-Effekt co-extrusion process and polyphenylene sulfide (PPS) as matrix material, reinforced with either virgin or recycled continuous carbon fibres. In addition to the in-house manufactured filament, a commercially available continuous carbon fibre reinforced polyaryletherketone (PAEK) filament was included

in the printing experiments as a reference material. All three filament systems were processed using the same large-scale additive manufacturing platform to evaluate the developed deposition strategies under comparable processing conditions. An overview of the investigated material systems is provided in Table 1.

Table 1: used material systems

Mat.-Sys-	Reinforc.	Matrix	Application
Dev. filament	Virgin continuous carbon fibre (12K)-AS7	PPS	Filament character. and printing
Dev. filament	Recycled continuous carbon fibre (12K)-T700	PPS	Filament character. and printing
Com. filament	Continuous carbon fibre	PAEK	Printing experiments

2.2 Continuous Fibre Filament Manufacturing

Continuous fibre reinforced thermoplastic filaments were manufactured using the DLR ENDLOS-Effekt co-extrusion process, which was developed for the continuous production of structural composite filaments for large-scale additive manufacturing [6,7]. The process integrates continuous fibre impregnation, filament consolidation, dimensional calibration and spool winding within a single continuous manufacturing route, resulting in printable composite feedstocks with homogeneous fibre distribution and stable filament geometry.

A major challenge in manufacturing continuous fibre thermoplastic filaments is the impregnation of densely packed carbon fibre bundles with highly viscous engineering thermoplastics. Since only a limited residence time is available within the processing zone, sufficient matrix infiltration must be achieved while maintaining continuous fibre alignment and a constant filament geometry. The resulting impregnation quality directly influences filament handling, extrusion stability and the mechanical performance of the printed components [7].

During manufacturing, the continuous carbon fibre tow is guided through the co-extrusion die, where the molten thermoplastic matrix is introduced under controlled thermal conditions. Ultrasonic excitation is applied within the impregnation zone to improve matrix infiltration and enhance process stability during continuous production [7]. After impregnation, the composite strand passes through a consolidation and cooling section before being calibrated to the target filament diameter and wound onto spools for subsequent additive manufacturing experiments. A schematic illustration of the manufacturing process is shown in Figure 2.

Both virgin and recycled 12K carbon fibre tows were processed using the same manufacturing route. Although the recycled fibres exhibited minor local variations resulting from their previous industrial processing history, only small adjustments to the fibre guidance were required. No modifications of the underlying co-extrusion concept were necessary, demonstrating the compatibility of recycled continuous carbon fibre production waste with the established filament manufacturing process.

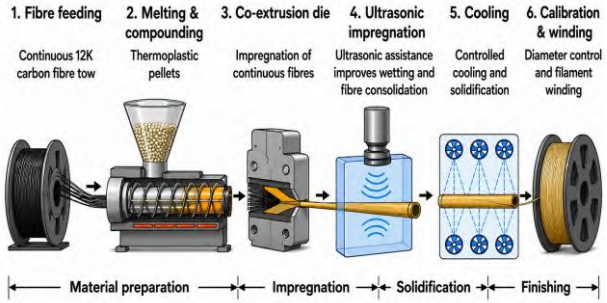

Figure 2: Schematic illustration of the DLR co-extrusion process for manufacturing continuous fibre thermoplastic filaments.

2.3 Large-Scale Additive Manufacturing System

Printing experiments were performed using a custom-developed large-scale additive manufacturing (LSAM) platform equipped with a high-temperature extrusion unit specifically designed for processing continuous fibre reinforced thermoplastic filaments. The system comprises a six-axis industrial robot, a heated extrusion unit and a temperature-controlled build platform to ensure reliable processing of high-performance thermoplastic materials.

The print head was developed to process continuous fibre reinforced filaments while maintaining homogeneous heating of the thermoplastic matrix and minimizing mechanical loading of the continuous fibre bundle during feeding. Stable processing requires a balanced interaction between material feed, extrusion rate and machine motion, as variations in fibre tension directly affect strand geometry, deposition accuracy and fibre alignment.

All printing experiments were performed using the same manufacturing platform. Process parameters, including nozzle temperature, printing speed and layer height, were adapted to the respective filament system and experimental objective. The investigated parameter ranges are summarized in Table 2. The parameter ranges cover all experimental investigations presented in this work and were adapted to the respective material system and demonstrator geometry.

Figure 3 shows the robotic LSAM platform used for the experimental investigations, while Figure 4 illustrates the custom-developed continuous fibre print head during the processing of continuous fibre reinforced thermoplastic filaments.

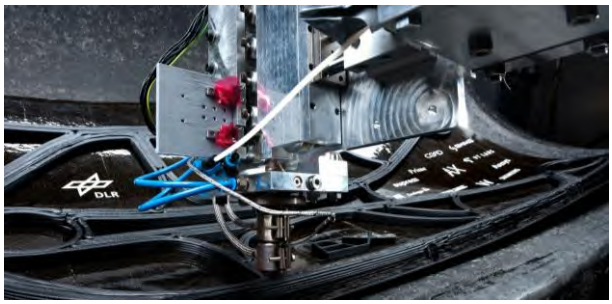

Figure 4. The custom-developed continuous fiber print head printing continuous CF/PAEK filament

Table 2: Parametersetup

Parameter	Value
Fibre	Virgin CF/ recycled CF
Matrix	PPS /PAEK
Filament diameter	1.2 mm
Nozzle diameter	1.3 mm
Nozzle temperature	350°C-490°C
Printing speed	30 – 3000 mm/min
Layer height	0.5 mm
Notch height	0.25 mm
Inclination angle	30° -90°

2.4 Experimental Methods

The experimental programme comprised both feedstock characterization and process validation experiments. Initially, the developed continuous fibre filaments were characterized with respect to their manufacturing quality, microstructure and mechanical performance. Optical microscopy was employed to evaluate fibre distribution and impregnation quality. Mechanical characterization was performed by tensile testing using a test procedure adapted from ASTM D638 [8]. A minimum of five specimens was tested for each material condition to compare the mechanical performance of filaments manufactured from virgin and recycled continuous carbon fibres.
Subsequently, the developed deposition strategies were investigated using representative demonstrator geometries addressing three key challenges of continuous fibre large-scale additive manufacturing. First, continuous fibre crossings were analysed to evaluate localized toolpath modifications designed to reduce material accumulation while preserving uninterrupted fibre continuity. Second, infrared thermography was employed to identify suitable thermal process windows for support-free deposition. Finally, progressively more complex demonstrator structures, including standing triangles, pyramid geometries and spatial lattice structures, were manufactured to validate uninterrupted free-space deposition under representative processing conditions.
The overall experimental workflow is illustrated in Figure 5.

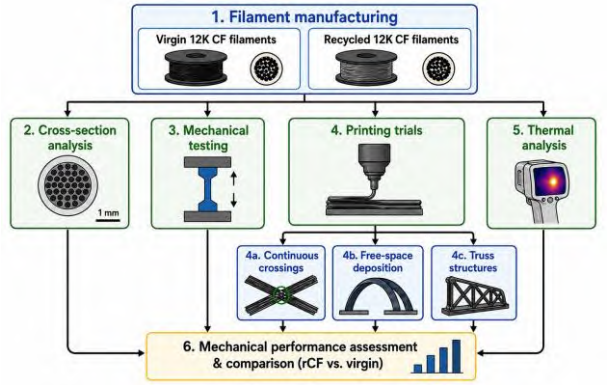

Figure 5: Overview of the experimental methodology employed for filament characterization and continuous fibre deposition investigations.

3. DEVELOPMENT AND CHARACTERIZATION OF CONTINUOUS FIBRE FILAMENTS

The successful implementation of continuous fibre reinforced large-scale additive manufacturing depends fundamentally on the quality of the employed feedstock material. Besides providing high mechanical performance, continuous fibre reinforced filaments must exhibit homogeneous fibre impregnation, stable geometry and reliable feeding behaviour during extrusion. Consequently, the development of robust filament feedstocks represents a prerequisite for the advanced deposition strategies presented in the following sections.
To evaluate the suitability of recycled continuous carbon fibres for structural additive manufacturing, continuous fibre reinforced PPS filaments were manufactured. The resulting filaments were subsequently characterized with respect to their manufacturing quality, microstructure and mechanical performance.

3.1 Filament Manufacturing

Continuous fibre reinforced thermoplastic filaments were successfully manufactured from both virgin and recycled 12K carbon fibre tows using the DLR ENDLOS-Effekt co-extrusion process described in

previous work [6,7]. Stable processing conditions were achieved throughout the manufacturing campaign, enabling continuous filament production without significant interruptions, fibre breakage or filament collapse. The manufactured filaments exhibited sufficient flexibility for spool winding while maintaining the stiffness required for reliable feeding during large-scale additive manufacturing.
Although the same manufacturing principle was applied to both fibre systems, slight differences in handling behaviour were observed. Owing to their previous industrial processing history, the recycled fibre bundles exhibited locally varying bundle morphologies, requiring minor adjustments to the fibre guiding system during manufacturing. These adaptations neither affected process stability nor required modifications to the underlying co-extrusion concept. As a result, both virgin and recycled continuous carbon fibre tows were successfully processed into continuous fibre reinforced thermoplastic filaments using the same manufacturing route, demonstrating the robustness and transferability of the developed process.
Representative cross-sections of the manufactured filaments are shown in Figure 6. Both filament systems exhibited continuous fibre bundles embedded within the thermoplastic matrix, confirming successful impregnation and providing the basis for the subsequent microstructural and mechanical characterization.

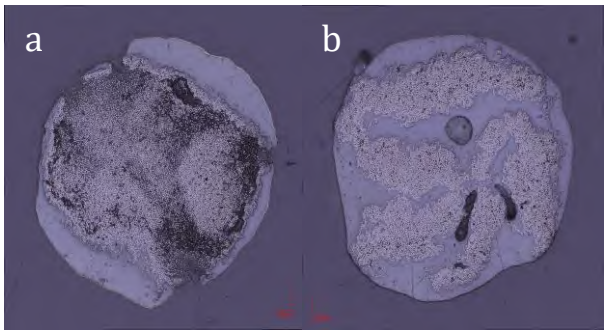

Figure 6: Cross-sectional optical micrographs of continuous fibre reinforced PPS filaments manufactured from (a) virgin and (b) recycled 12K carbon fibre tows. Both filament systems exhibit continuous fibre bundles embedded within the thermoplastic matrix. The recycled fibre filament shows locally increased variations in bundle morphology and matrix distribution resulting from the previous industrial processing history of the reinforcement.

3.2 Filament Microstructure

Representative polished cross-sections of the manufactured continuous fibre reinforced PPS filaments were analysed by optical microscopy to evaluate fibre distribution and impregnation quality.
Both filament systems exhibited continuous fibre bundles fully embedded within the thermoplastic matrix, confirming successful impregnation during the co-extrusion process [6,7]. The virgin fibre filaments displayed a comparatively homogeneous fibre distribution across the cross-section. In contrast, the recycled fibre filaments exhibited slightly larger local variations in bundle morphology and matrix distribution, which are attributed to the previous industrial processing history of the recovered carbon fibres.
Despite these local differences, no pronounced impregnation defects, extensive void formation or discontinuities of the continuous fibre reinforcement were observed. The matrix provided continuous encapsulation of the fibre bundles, indicating a sufficiently high impregnation quality for subsequent additive manufacturing.
Overall, the microstructural analysis demonstrates that the developed co-extrusion process is capable of producing structurally sound continuous fibre reinforced filaments from both virgin and recycled carbon fibre feedstocks. While the recycled material exhibits greater local variability, its overall microstructural quality is comparable to that of the virgin reference material and is suitable for the subsequent mechanical characterization and printing experiments.

3.3 Mechanical Performance

The mechanical performance of the developed continuous fibre reinforced PPS filaments was evaluated by tensile testing using specimens manufactured from both virgin and recycled continuous carbon fibre feedstocks. The corresponding results are presented in Figure 7.

Both filament systems exhibited high load-bearing capacities, confirming the successful manufacture of mechanically robust continuous fibre reinforced filaments. Under the investigated processing conditions, the recycled continuous fibre filaments achieved an average failure load of approximately 1.4 kN, compared with approximately 0.93 kN for the virgin reference material, corresponding to an increase of approximately 50%. Although both material systems exhibited a certain scatter in the measured values, the recycled filament consistently demonstrated excellent mechanical performance.

The unexpectedly high load-bearing capacity of the recycled filament indicates that continuous carbon fibres recovered from industrial production waste can be processed into structurally efficient thermoplastic composite filaments without compromising their mechanical performance. Combined with the stable manufacturing behaviour and homogeneous impregnation observed in the previous sections, these findings demonstrate that recycled continuous carbon fibre feedstocks represent a technically viable and resource-efficient alternative to virgin reinforcement for extrusion based large-scale additive manufacturing [5].

The recycled T700 production waste retained an excellent load-bearing capacity comparable to, and under the investigated conditions exceeding, that of

the virgin AS7 reference. These results indicate that the previous industrial processing history does not preclude the structural use of recycled continuous carbon fibres. A direct comparison using identical fibre grades will be the subject of future work.

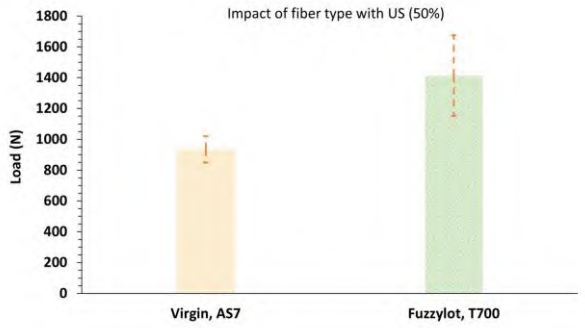

FIGURE 7: Average failure load of continuous fibre reinforced PPS filaments manufactured from virgin (AS7) and recycled (T700) 12K carbon fibre tows. The results represent the average of a minimum of five specimens per material condition tested using a tensile procedure adapted from ASTM D638 [8]. Error bars indicate the minimum and maximum measured values.

3.4 Discussion

The presented investigations demonstrate that continuous carbon fibre coming from production waste can be successfully transformed into continuous fibre reinforced thermoplastic filaments suitable for structural large-scale additive manufacturing. In contrast to conventional carbon fibre recycling approaches, which typically produce discontinuous or short fibre reinforcement with reduced structural efficiency [5], the developed manufacturing route preserves the original continuous fibre architecture and thus maintains uninterrupted load paths within the final composite.

The microstructural characterization confirmed that both virgin and recycled filament systems exhibited homogeneous impregnation without critical defects, despite the slightly greater local variability observed for the recycled reinforcement. Furthermore, the mechanical investigations demonstrated that the recycled filament system achieved a load-bearing capacity comparable to, and under the investigated conditions exceeding, that of the virgin reference material. These findings indicate that the previous industrial processing history of the recycled fibres does not preclude their use in structurally demanding additive manufacturing applications.

Overall, the combination of stable filament production, homogeneous microstructure and excellent mechanical performance demonstrates that recycled continuous carbon fibres represent a technically viable and resource-efficient feedstock for extrusion-based large-scale additive manufacturing. These results establish the material foundation for the advanced deposition strategies presented in the following section, where uninterrupted fibre crossings and support-free three-dimensional printing are investigated.

4. ADVANCED CONTINUOUS FIBRE DEPOSITION STRATEGIES

Having demonstrated the successful manufacturing and characterization of continuous fibre reinforced thermoplastic filaments from both virgin and recycled carbon fibre feedstocks, the next step is to evaluate their applicability in large-scale additive manufacturing. This section presents the development and experimental validation of advanced deposition strategies addressing two key challenges of continuous fibre printing: the realization of uninterrupted fibre crossings and the support-free deposition of three-dimensional continuous fibre reinforced structures.

4.1 Motivation

Continuous fibre reinforced thermoplastic composites are well established for the manufacture of lightweight structures using Automated Tape Placement (ATP) and Automated Fibre Placement (AFP). These technologies enable the efficient production of planar and moderately curved laminate structures with excellent mechanical performance. In contrast, comparatively little research has addressed the additive manufacturing of spatial continuous fibre reinforced structures, although such approaches offer considerable potential for realizing lightweight load-bearing components with increased geometric freedom [3,4].

Unlike conventional laminate manufacturing, extrusion-based large-scale additive manufacturing enables reinforcement paths to follow complex three-dimensional load paths rather than being restricted to stacked planar layers. This capability is particularly attractive for truss- and lattice-like structures, where continuous fibre reinforcement can efficiently carry tensile loads while maintaining a low structural weight. Consequently, support-free deposition of continuous fibre reinforced thermoplastics offers the potential to manufacture highly material-efficient lightweight structures without the need for sacrificial support material or subsequent post-processing.

Despite this potential, two major technological challenges currently limit the wider application of continuous fibre large-scale additive manufacturing. First, intersecting deposition paths typically require interruption of the continuous reinforcement or lead to localized material accumulation at crossing points. Second, successful support-free deposition requires the extruded filament to achieve sufficient mechanical stability immediately after extrusion, making the thermal behaviour of the thermoplastic matrix a critical process parameter.

The following investigations therefore focus on the development of localized toolpath strategies for

uninterrupted continuous fibre crossings and on the experimental validation of support-free three-dimensional deposition concepts for continuous fibre reinforced large-scale additive manufacturing.

4.2 Challenges of Continuous Fibre Crossings

Intersections between continuous fibre reinforcement paths represent one of the principal challenges in continuous fibre large-scale additive manufacturing. When two continuous fibre strands intersect, material is deposited twice within the same local region, resulting in increased bead height and a locally modified cross-sectional geometry. Conventional approaches typically avoid this problem by interrupting the continuous reinforcement prior to the intersection, thereby simplifying the deposition process at the expense of structural fibre continuity.
To overcome this limitation, a dedicated crossing strategy was developed that enables uninterrupted continuous fibre intersections. Instead of cutting the reinforcement, localized modifications of the deposition path are introduced to compensate for the additional deposited material while maintaining continuous fibre paths through the intersection.
A representative polished cross-section of an unoptimized fibre crossing is shown in Figure 8. The micrograph reveals pronounced local bead accumulation caused by the superposition of two deposited strands. This results in an increased bead height, localized porosity and insufficient consolidation beneath the upper strand. Such geometric irregularities impair the deposition of subsequent layers and may reduce the dimensional accuracy and structural quality of printed components [9].

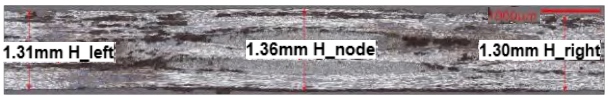

Figure 8: Cross-sectional micrograph of a baseline continuous fibre intersection without local toolpath optimization. Double deposition within the crossing region results in localized bead accumulation, increased bead height, localized porosity and insufficient consolidation beneath the upper continuous fibre strand [9].

Based on these observations, several localized notch geometries were investigated to compensate for the excess material deposited within the crossing region. The objective was to minimize local bead accumulation while preserving uninterrupted fibre continuity and ensuring stable deposition conditions. The resulting optimized crossing concept forms the basis for the deposition strategies presented in the following sections.

4.3 Continuous Fibre Crossing Strategy

Rather than interrupting the reinforcement at each intersection, a continuous crossing strategy was developed to preserve uninterrupted fibre paths throughout the printed structure. The proposed approach combines synchronized extrusion control with localized nozzle trajectory modifications, enabling intersecting continuous fibre strands while minimizing material accumulation at the node.
Based on the microstructural observations presented in section 4.2, the intersection defect was identified as a consequence of localized volumetric overload caused by the superposition of two deposited strands. To compensate for this effect, a tunnel-shaped notch is introduced into the lower strand by applying a localized vertical nozzle offset immediately before the intersection [9]. This additional volume accommodates the intersecting strand and promotes improved consolidation without requiring interruption of the continuous reinforcement. The localized notch inevitably introduces a minor geometric deviation at the crossing. However, the resulting increase in contact area between the intersecting strands improves consolidation and contributes to a stronger node connection, representing a favourable trade-off between geometric accuracy and structural integrity.
The developed crossing concept is illustrated in Figure 9. After generating the notch, the intersecting strand is deposited into the prepared cavity before the nozzle returns to the nominal deposition height. Consequently, uninterrupted continuous fibre reinforcement is maintained throughout the complete toolpath while reducing the local increase in bead height.

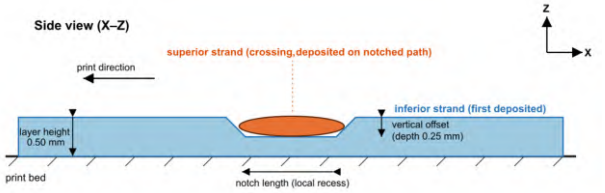

Figure 9: *Schematic illustration of the Notch Method for continuous fiber crossings.*

Several notch geometries were evaluated experimentally to identify a suitable balance between bead height reduction and consolidation quality. Particular attention was paid to preserving continuous fibre integrity while avoiding excessive local compression, which may promote fibre waviness, porosity or insufficient matrix consolidation. In contrast to conventional fibre interruption approaches, the proposed strategy relies exclusively on software-based toolpath adaptation and can therefore be implemented on existing robotic additive manufacturing systems without additional hardware modifications [9].

4.4 Thermal Behaviour During Free-Space Deposition

Following the analysis of continuous fibre crossings, the thermal conditions during deposition were

investigated to evaluate the feasibility of support-free continuous fibre printing. In contrast to conventional layer-based additive manufacturing, unsupported deposition requires the extruded filament to maintain its geometry immediately after leaving the nozzle. Since the continuous carbon fibres themselves provide only limited bending stiffness during deposition, the temporary structural stability is governed primarily by the cooling and solidification of the surrounding thermoplastic matrix. Consequently, the thermal behaviour of the deposited filament defines the process window for successful free-space manufacturing.

Infrared thermography was employed to characterize the temperature distribution of the extruded filament directly below the nozzle under representative processing conditions. A representative thermographic image is shown in Figure 10. The measurements revealed a pronounced temperature gradient, with the highest temperatures occurring immediately at the nozzle exit, followed by rapid cooling during deposition. Infrared thermography was therefore used to quantify the maximum unsupported deposition length prior to sufficient matrix solidification, which was approximately 8 mm during continuous printing and 6 mm under stationary conditions. The transition from non-self-supporting to self-supporting behaviour is gradual and therefore represents a transition zone rather than a discrete location.

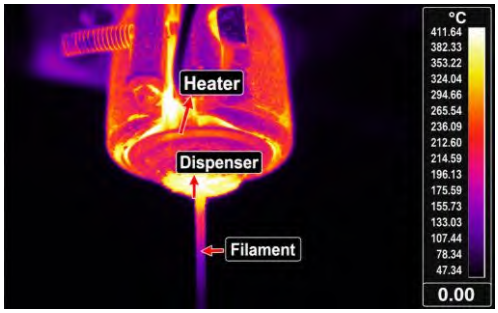

Figure 10: Infrared thermographic image of the continuous fibre deposition process showing the temperature distribution of the extruded filament directly below the nozzle under representative processing conditions.

The thermographic analysis demonstrates that the extruded filament remains highly deformable directly beneath the nozzle before progressively solidifying as its temperature decreases. Consequently, only a limited region adjacent to the nozzle lacks sufficient mechanical stability, whereas the deposited filament rapidly develops the stiffness required to maintain unsupported geometries. The identified cooling behaviour therefore defines the effective processing window for free-space deposition and determines the achievable combination of nozzle temperature, deposition speed and unsupported span length.

These observations provide the thermal foundation for the support-free deposition strategies presented in the following sections. By identifying the process window in which sufficient bonding and rapid solidification occur simultaneously, the subsequent manufacturing experiments could be performed with stable unsupported deposition while preserving continuous fibre reinforcement

4.5 Development of Support-Free Continuous Fibre Structures

Following the identification of a suitable thermal process window, the next objective was to investigate whether continuous fibre reinforced thermoplastic filaments could be deposited without sacrificial support structures. Rather than directly manufacturing complex lattice geometries, the experimental investigations followed an iterative development strategy in which the geometric complexity was progressively increased while continuously evaluating the resulting process limitations.

The initial experiments focused on the deposition of individual unsupported members in order to evaluate whether the extruded filament could maintain its geometry solely through the cooling and solidification of the thermoplastic matrix. These preliminary investigations confirmed the feasibility of unsupported deposition and provided important insight into the influence of thermal behaviour, deposition sequence and nozzle motion on the stability of the printed strand. Based on these findings, progressively more complex demonstrators comprising vertical members, inclined struts and node connections were manufactured using uninterrupted continuous fibre paths.

Figure 11. Standing triangular demonstrators manufactured without sacrificial support material. The structures served as the first benchmark for evaluating unsupported continuous fibre deposition under increasing geometric complexity.

The standing triangular demonstrators shown in Figure 11 represent the first stable support-free structures manufactured with the developed process. Their successful fabrication confirmed that continuous fibre reinforced thermoplastic filaments can be deposited without sacrificial support material while preserving uninterrupted fibre reinforcement. At the same time, the experiments revealed important process limitations. Stable manufacturing proved to be highly dependent on the selected thermal process parameters, while the continuously changing stiffness of the growing structure made the deposition sequence an essential process parameter alongside nozzle temperature and

printing speed.

Building upon these results, the developed manufacturing strategy was transferred to pyramid-shaped demonstrators introducing multiple unsupported inclined members and node intersections within a single continuous fibre path. Compared with the triangular benchmark, these geometries represent a substantially more demanding validation of the developed deposition strategy.

The successful manufacture of the pyramid structures confirmed that the identified thermal process window and optimized deposition sequence can be transferred to increasingly complex three-dimensional reinforcement architectures. Nevertheless, the larger geometries also revealed additional process limitations. Geometric deviations occurred primarily at the transitions between inclined and vertical members, where the deposited filament occasionally deflected before sufficient solidification of the thermoplastic matrix had occurred. These observations demonstrate that manufacturing stability is governed not only by thermal process control but also by nozzle accessibility, deposition sequence and the continuously increasing stiffness of the evolving structure.

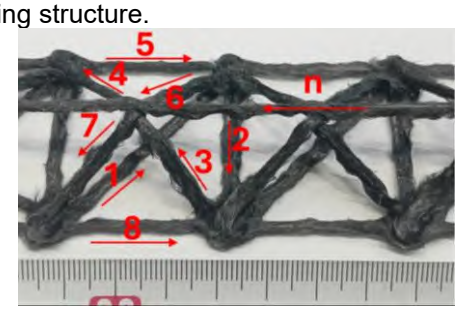

Figure 12. Evolution of the support-free deposition strategy from standing triangular demonstrators to pyramid-shaped lattice structures. The refined deposition sequence significantly improved geometric accuracy, process stability and manufacturing reproducibility.

Through iterative refinement of the deposition strategy, including optimized deposition sequencing and improved stabilization of unsupported members, the geometric accuracy and manufacturing reproducibility were significantly improved. The resulting evolution from simple unsupported members to standing triangles and finally pyramid structures is illustrated in Figure 12, demonstrating that support-free continuous fibre deposition can be systematically extended towards increasingly complex spatial reinforcement architectures. The pyramid-shaped demonstrators were selected because they combine unsupported inclined members (e.g. 3, 4, 6 and 7), vertical struts (e.g. 5, 8 and *n*), multiple node intersections (e.g. between members 3–4 and 6–7), and changes in deposition direction (e.g. member 6) within a single uninterrupted continuous fibre path, thereby representing a demanding validation geometry.

4.6 Overall Process Evaluation

The successful implementation of continuous fibre large-scale additive manufacturing relies not only on advanced deposition strategies but also on the availability of robust and reproducible feedstock materials. While the previous sections demonstrated the feasibility of uninterrupted fibre crossings and support-free three-dimensional deposition, these process developments fundamentally depend on the consistent manufacturing quality of the continuous fibre reinforced thermoplastic filaments.

Figure 13 summarizes the influence of the developed co-extrusion process on the mechanical performance of the manufactured filaments over the investigated processing conditions. In contrast to the material comparison presented in Figure 7, which evaluates representative filament systems processed under their respective optimized manufacturing conditions, Figure 13 isolates the influence of filament production speed by comparing specimens manufactured under identical process conditions (0% ultrasonic assistance and an impregnation pressure of 10 bar). The results demonstrate stable failure loads for both virgin and recycled continuous carbon fibre feedstocks, indicating that the manufacturing process provides a high degree of reproducibility despite variations in production speed. The absence of a significant reduction in mechanical performance confirms that the impregnation quality and fibre integrity are maintained throughout the investigated processing window.

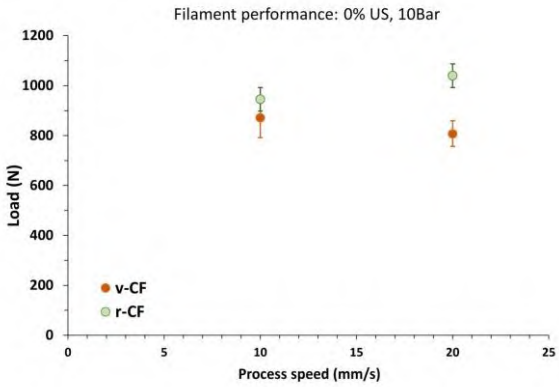

Figure 13. Influence of filament production speed on the failure load of continuous fibre reinforced thermoplastic filaments manufactured from virgin and recycled carbon fibre tows under identical processing conditions (0% ultrasonic assistance, 10 bar impregnation pressure).

These observations are particularly relevant for large-scale additive manufacturing, where continuous production of several hundred metres of reinforced filament is required for manufacturing structural components. The demonstrated process

stability therefore represents an essential prerequisite for reliable robotic deposition and validates the developed co-extrusion approach as a suitable manufacturing route for continuous fibre reinforced thermoplastic feedstocks.

The combination of stable filament manufacturing and the mechanical performance presented in section 3 establishes the material foundation for the deposition strategies introduced in the previous sections. Together, these results demonstrate that recycled continuous carbon fibres can be processed into structurally efficient feedstocks suitable for large-scale additive manufacturing without compromising manufacturing robustness.

4.7 Validation of the Continuous Fibre Crossing Strategy

Following the successful validation of the developed filament manufacturing process, the effectiveness of the tunnel-notch crossing strategy was assessed by comparing optimized intersections with the baseline deposition approach. The objective was to evaluate whether localized toolpath adaptation could improve the geometric quality of fibre crossings while maintaining uninterrupted reinforcement throughout the deposited structure.
Representative crossing geometries are presented in Figure 14. Compared with the unmodified deposition strategy, the optimized tunnel-notch approach significantly reduces local bead accumulation at the intersection. The additional cavity created within the lower strand accommodates the intersecting filament, resulting in a more uniform bead profile and improved consolidation of the crossing region. Consequently, the local increase in layer height is substantially reduced, facilitating the deposition of subsequent layers and improving the dimensional consistency of the printed structure. In the optimized configuration, the relative height increase at the intersection was reduced from 4.41 % (for the unmodified reference) to 0.73 % [9].
Beyond the geometric improvements, the developed strategy preserves continuous fibre reinforcement across the complete intersection without requiring fibre interruption or additional joining operations. This represents a key advantage over conventional continuous fibre deposition approaches, where reinforcement paths are frequently terminated prior to intersecting toolpaths to avoid local material accumulation.

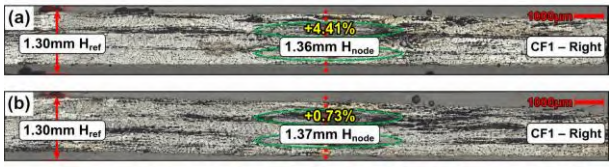

Figure 14. Microscopic comparison of continuous fibre intersections. (a) Conventional crossing showing localized material accumulation and increased bead height. (b) Optimized intersection manufactured using the Notch Method. The localized trajectory modification reduces bead accumulation while maintaining uninterrupted continuous fiber reinforcement and improving the geometric accuracy of subsequent deposition paths. (Orthogonal fiber strands are highlighted by green circles.)

The presented results demonstrate that localized software-based toolpath adaptation provides an effective solution for one of the principal geometric limitations of continuous fibre large-scale additive manufacturing. The developed strategy can be implemented without modifications to the deposition hardware and therefore offers a practical route towards manufacturing increasingly complex continuous fibre reinforced structures.

4.8 Scalable Support-Free Manufacturing of Three-Dimensional Structures

Having validated both the developed filament system and the optimized continuous fibre crossing strategy, the final stage of the experimental programme investigated the scalability of the manufacturing concept towards increasingly complex three-dimensional reinforcement structures. The objective was to assess whether the developed deposition strategies remain applicable as structural complexity and the number of unsupported members increase.

The representative demonstrators shown in Figure 15 illustrate the progression from simple unsupported geometries to increasingly sophisticated spatial reinforcement architectures manufactured along a single uninterrupted continuous fibre path. The successful fabrication of these demonstrators confirms that the developed process is not limited to isolated proof-of-concept specimens but can be extended to structures incorporating multiple inclined members, repeated node intersections, and complex three-dimensional load paths.

Stable support-free deposition was achieved only within a limited processing window. Insufficient thermal input (below 420 °C) resulted in inadequate interlayer bonding, whereas excessive thermal input (approximately 490 °C) at low printing speeds (<100 mm min^{-1}) delayed matrix solidification and promoted geometric deformation. As printing speed increased, higher nozzle temperatures were required to ensure complete filament heating. Printing speeds exceeding 1000 mm min^{-1} were only achievable at nozzle temperatures of approximately 490 °C, whereas lower speeds (<100 mm min^{-1}) could be processed below 450 °C provided that no fibre intersections were present. Conversely, excessively low nozzle temperatures resulting in poorly consolidated bead surfaces with locally exposed fibres. At fibre crossing locations,

substantially lower deposition speeds (<30 mm min^{-1}) were necessary to achieve reliable bonding while preventing fibre damage. Furthermore, unsupported node connections required an absolute positioning accuracy better than 0.1 mm to ensure reproducible node formation.

Manufacturing stability was governed by the interaction between thermal management, deposition sequence, print head accessibility, and the continuously evolving stiffness of the growing structure. During the initial deposition stages, unsupported members were susceptible to gravitational deflection before sufficient matrix solidification had occurred. As the structure developed, however, the increasing global stiffness progressively stabilised subsequent deposition, improving dimensional accuracy. The largest geometric deviations, reaching up to 2 mm, occurred at transitions between inclined and vertical members, where elevated temperatures and insufficient structural stiffness temporarily reduced positional stability.

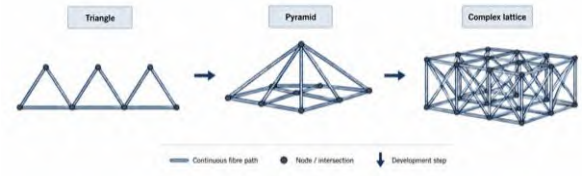

Figure 15. Progressive development of support-free continuous fibre demonstrator structures from standing triangles to pyramid geometries and complex lattice architectures.

Based on these observations, the toolpaths were iteratively refined by adapting the deposition sequence to the structural growth of the component. Previously deposited members were intentionally utilized as intermediate supports to increase the stiffness of the evolving structure, while unsupported deposition lengths were reduced to approximately 70 mm, which proved sufficient to ensure stable unsupported deposition under the investigated process conditions, resulting in significantly improved process stability and geometric accuracy.

The experimental validation demonstrates that the combination of optimized filament quality, localized fibre crossing strategies, and controlled thermal processing enables the reliable manufacture of complex continuous fibre reinforced structures without sacrificial support material. These results considerably expand the geometric design space of continuous fibre large-scale additive manufacturing and provide the technological foundation for future lightweight structural applications requiring continuous reinforcement along three-dimensional load paths.

4.9 Integrated Manufacturing Concept

The investigations presented in this chapter demonstrate that the successful realization of continuous fibre reinforced large-scale additive manufacturing requires the simultaneous optimization of both the feedstock material and the deposition process. Neither high-quality continuous fibre reinforced filaments nor advanced deposition strategies alone are sufficient to manufacture complex structural components. Instead, reliable processing is achieved through the interaction of reproducible filament manufacturing, controlled thermal management and dedicated toolpath planning.
The developed co-extrusion process enables the production of continuous fibre reinforced thermoplastic filaments from both virgin and recycled carbon fibre feedstocks with stable processing behavior and high mechanical performance. Building upon this material basis, the notch strategy overcomes one of the principal limitations of continuous fibre additive manufacturing by allowing uninterrupted fibre crossings while reducing local bead accumulation and improving geometric consistency. Furthermore, the experimental validation of support-free deposition demonstrates that increasingly complex three-dimensional reinforcement architectures can be manufactured without sacrificial support structures while maintaining continuous fibre paths throughout the complete component.
large-scale additive manufacturing technologies.

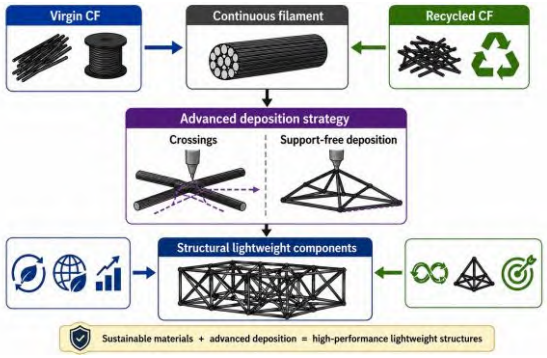

Figure 16. Integrated manufacturing concept combining continuous fibre filament production, optimized robotic deposition strategies and support-free manufacturing of three-dimensional continuous fibre reinforced structures.

The integrated manufacturing concept is summarized in Figure 16, illustrating the relationship between material development, filament production and robotic deposition. The presented process chain establishes a continuous workflow from recycled carbon fibre feedstocks to complex three-dimensional continuous fibre reinforced structures, demonstrating the feasibility of combining sustainable materials with advanced Overall, the presented approach significantly extends the manufacturing capabilities of

continuous fibre large-scale additive manufacturing by combining sustainable feedstock materials with software-based process innovations. The developed process chain provides a scalable foundation for the production of lightweight structural components with uninterrupted reinforcement and offers considerable potential for future aerospace and space applications, where both structural efficiency and resource sustainability are becoming increasingly important design requirements.

5 CONCLUSION AND OUTLOOK

This work presented an integrated approach for sustainable continuous fibre large-scale additive manufacturing by combining recycled continuous fibre reinforced filaments with novel deposition strategies for uninterrupted fibre paths and support-free three-dimensional printing. The proposed process chain demonstrates that sustainable feedstock materials can be successfully processed while simultaneously expanding the geometric capabilities of extrusion-based continuous fibre additive manufacturing.
Mechanical characterization showed that recycled continuous fibre reinforced PPS filaments exhibit a substantially higher failure load than virgin filaments, confirming their suitability as structural feedstock for large-scale additive manufacturing. In parallel, the developed continuous fibre crossing strategy successfully eliminated fibre interruptions at intersecting toolpaths without requiring additional hardware modifications. This software-based solution enables continuous reinforcement across complex deposition paths while preserving process efficiency.

To further extend the manufacturing capabilities, the thermal behaviour of the deposited filament was experimentally investigated to identify the process window required for support-free deposition. Based on these investigations, stable unsupported continuous fibre structures were successfully manufactured, progressing from simple unsupported members to increasingly complex three-dimensional lattice demonstrators. The experiments demonstrate that the rapid solidification of the thermoplastic matrix provides sufficient temporary structural stability to enable free-space deposition without sacrificial support structures. At the same time, the investigations revealed that process stability is governed by the interaction of thermal conditions, deposition sequence, nozzle accessibility and the continuously evolving stiffness of the growing structure.
Overall, the presented manufacturing concept combines sustainable material utilization, uninterrupted continuous fibre reinforcement and support-free spatial deposition within a unified process chain. The proposed approach therefore represents an important step towards the production of lightweight, resource-efficient composite structures with significantly increased design freedom for future aerospace and space applications.
Future work will focus on improving the robustness and industrial applicability of the process. In particular, optimized nozzle concepts are required to enable higher deposition speeds while maintaining adequate thermal control of the continuous fibre filament. Furthermore, strengthening fibre intersections, improving the dimensional reproducibility of unsupported structures and developing automated topology-optimized toolpath generation will further enhance process reliability and enable the efficient manufacture of increasingly complex lightweight structures. Additionally, future work should investigate improved nozzle concepts to reduce the limitations imposed by the thermal inertia of the print head and the limited heat transfer to the continuous fiber filament.

ABSTRACT

This work investigates the predictive capability of two modelling strategies for an AlSi7Mg0.6 sandwich panel with a micro-lattice core, manufactured via L-PBF and used as a stiffener in a satellite platform. Using additive manufacturing to produce this stiffening panel resulted in a mass saving higher than 20%, compared to that of integrally machined aluminium stiffeners. Low-level swept-sine vibration tests were performed to identify the first six natural frequencies, providing a benchmark for validating an equivalent homogenised model (EHM) and a detailed full solid three-dimensional model (FS3D). The FS3D model reproduced the experimental modal response with good accuracy, with errors generally below 8% and an almost exact prediction of the fourth mode (0.1%), whereas the EHM systematically overestimated the natural frequencies by 22% to 85%, revealing an overly stiff representation of the lattice core. Despite this lower accuracy, the EHM preserved the global modal behaviour while reducing the computational cost dramatically, requiring 44 times fewer degrees of freedom and 339 times less CPU time than the FS3D model. The comparison also shows the influence of manufacturing-induced geometric deviations and defects on the dynamic response of as-built structures. Finally, the study proposes a model improvement strategy combining X-ray computed tomography-based geometry reconstruction and modal correlation to recalibrate homogenised models, enabling improved predictive capability while maintaining computational efficiency for industrial-scale structural analyses.

1. CONTEXT

Extensive research has long been conducted on lattice structures, especially aluminium lattices made via Laser Powder Bed Fusion (L-PBF), covering design, modelling, manufacturing, testing, and validation [1-3].

From an industrial point of view, substantial mass saving and cost gain for recurring parts have been identified a long time ago. The savings in cost and time-to-delivery lead time compared to bonded-core aluminium sandwich structures are easy to understand, given the economic advantages offered by bonding processes, particularly in terms of surface treatment, manufacturing lead times and inspection of several materials. Anyway, the current inability of L-PBF technology to produce large-scale structures (of around 1 m) drastically limits the range of applications of industrial interest.

In the frame of a telecom satellite project, an improved structural design imposed the implementation of six stiffeners between two large aluminium sandwich panels, as shown in Fig. 1.

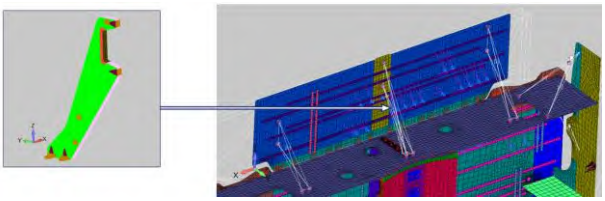

Figure 1: View of the location of three of the six stiffeners

The advantage of this application case was that the dimensions were compatible with existing L-PBF machines, making it possible to manufacture several parts in a single batch. In addition, the elementary bricks developed and tested in previous studies (up to TRL 6), such as interface designs and lattice pattern ideas, are proving useful for the design of this type of component.

This qualification process will enable the L-PBF lattice sandwich structure to be rapidly brought up to TRL 9. Given that these parts mainly require stiffness and strength at the interfaces, the qualification plan must be based on good correlations with the results of modal and static FE analyses. This article focuses on the dynamic vibration testing of the stiffener, and more specifically on its modal behaviour, albeit in a non-representative configuration. A forthcoming article will address the analyses and static tests in the representative configuration.

Another key industrial challenge is the inability to handle the extremely large number of finite elements needed to model each small lattice strut (a few millimetres thick) in large-scale satellite structures.

This paper furthers previous work led or followed by Thales Alenia Space (TAS-F) on lattice structures [4-7] in which several cellular solids were investigated in terms of thermal and mechanical performances, design, fabrication and experimental tests.

2. DESCRIPTION OF THE SPECIMEN

2.1. Geometrical Description

The specimen illustrated in Fig. 2 is a sandwich panel with overall dimensions of approximately 500 × 120 × 20 mm³ (length × width × thickness), consisting of two outer skins and a lattice core in between, featuring zones locally reinforced with solid material, *i.e.* the load introduction areas and fastening inserts.

The skins have a nominal thickness of 0.3 mm in standard areas and 0.6 mm in reinforced areas.

Figure 2: Photograph of the specimen

The specific geometry of the lattice unit cells is proprietary to Thales Alenia Space France (TAS-F) and will not be described for reasons of confidentiality. Nevertheless, the design of the unit cells was constrained by standard L-PBF manufacturability rules, including minimum strut diameter, overhang angles, and residual powder drainage requirements. What can be disclosed is the mass saving, higher than 20%, compared to that of integrally machined aluminium stiffeners.

2.2. Design, Manufacturing and Post-Treatment

The complex geometry of the panel reflects a Design for Additive Manufacturing (DfAM)-driven compromise between build orientation, self-supporting requirements, and process-specific tolerances inherent to L-PBF process. The fabrication of such a large and relatively thin aluminium panel is challenging because of the potential for thermal distortions, residual stress generation, and local deviations from the nominal CAD geometry. Consequently, the manufacturing strategy was defined to ensure both the manufacturability of the lattice core and the dimensional stability of the skins and mounting features.

The specimen was printed by LISI Aerospace Additive Manufacturing (LAAM), one of the major partners of TAS-F in Metallic Additive Manufacturing (MAM). The part was produced from AlSi7Mg0.6 aluminium alloy powder using a COLIBRIUM (Concept Laser) X-Line 2000R system, which has a large build volume of 400 × 800 × 500 mm³. This machine is qualified by TAS-F for the production of AlSi7Mg0.6 flight hardware.

The specimen was manufactured with the skins oriented vertically and parallel to the build direction. This orientation was selected to accommodate the overall dimensions of the panel and to ensure the manufacturability of the lattice core. A powder layer thickness of 50 µm was used, with a new powder layer being deposited before each laser-scanning operation.

After completion of the build, the specimen underwent a post-fabrication heat treatment for 6 h at 170°C in an air atmosphere while remaining attached to the build plate. The part was subsequently removed from the base plate using wire electrical discharge machining. The inserts and mounting lugs were then finish-machined by surface milling to obtain the required interface geometry and dimensional accuracy.

2.3. Geometry Control

Particular attention was paid to the dimensional control of the skins, lattice struts, inserts, and mounting lugs, as these features directly influence the mass, stiffness, and dynamic response of the panel. The inspection strategy therefore combined a visual examination, local dimensional measurements, and metrological X-ray computed tomography. These investigations were used to identify deviations from the nominal CAD geometry and to provide representative geometrical data for the subsequent finite element analyses.

A metrological micro X-ray computed tomography (µCT) scan was carried out by ELEMCA at CNES. The observations indicated higher skin-thickness values and provided additional information on the morphology of the lattice struts. 88% of the deviations fall between 0.3 and 0.5 mm, with an average of 0.39 mm (Fig. 3).

The µCT results were therefore used to characterise the as-built geometry more accurately than was possible from local manual measurements alone.

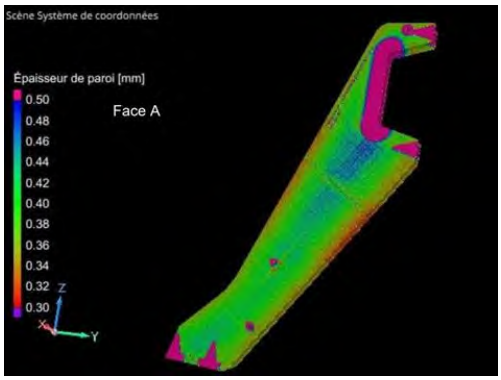

Figure 3: 3D visualisation of the measured thicknesses

3. VIBRATION TESTS

3.1. Test Setup

Dynamic tests were performed by the Mechanical Testing Lab of Icam in Toulouse (F) using a LDS V650 electrodynamic shaker. The specimen was mounted on the shaker via 4 CHc M6 screws. A low-level swept-sine test (0.1 'g', 2 oct / min) was carried out in order to obtain natural frequencies and damping. The frequency range of interest was from 10 Hz up to 1000 Hz.

Swept-sine excitation is applied along the vertical axis (X-axis) (Fig. 4).

Figure 4: Sine test shaker setup

Acceleration was measured using single-axis accelerometers along the X, Y, and Z axes (Fig. 5).

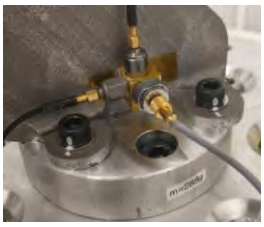

Figure 5: Photograph of 3 single-axis accelerometers

Data acquisition and post-processing were performed using BK Connect software.

3.2. Results

As the specimen was excited in the plane parallel to the skins, *i.e.* the XY plane, determining the natural frequencies of the out-of-plane modes is not easy. The excitation force has a very low modal participation factor for out-of-plane bending modes, resulting in weak resonance amplitudes that are either buried in noise or masked by in-plane modes (see Fig. 6). However, given that the test specimen is not symmetrical wrt the XY plane and that real structures are never perfectly decoupled, the modes remain detectable under such testing conditions.

To facilitate analysis, the test was repeated several times with the positions of certain accelerometers modified. Furthermore, to confirm the results, a rapid impact test (tap test) was also performed in the Z and Y directions. The interpretation of the measurements was also facilitated by the results of FE analyses (section 4).

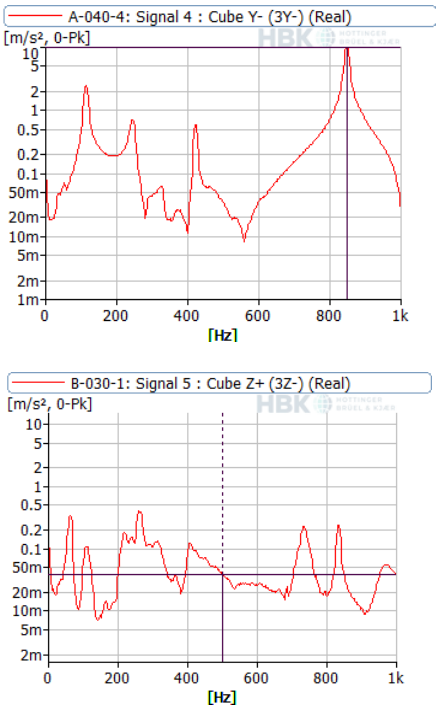

Figure 6: FFT measured for an accelerometer oriented along the Y-axis in-plane (top) and for an accelerometer oriented along the Z-axis out-of-plane (bottom)

Although the in-plane swept-sine excitation limited the excitation and identification of out-of-plane modes, the combination of repeated measurements, complementary tap tests, and FE analysis provided sufficient confidence to identify the first six natural modes within the investigated frequency range (10–1000 Hz), as presented in Tab. 1.

Table 1: Results of the sine vibration test

Mode	*Freq. [Hz]*	*Mode description*
1	63. (±8%)	1st out-of-plane bending mode
2	109. (±4%)	1st in-plane bending mode
3	244. (±3%)	1st torsion mode
4	422. (±0%)	2nd torsion mode
5	732. (±3%)	2nd out-of-plane bending mode
6	837. (±1%)	2nd in-plane bending mode

4. NUMERICAL ANALYSES

4.1. Finite Element Analyses (FEA)

The FEA objective is to assess the modal behaviour of the panel for the load case that have been experimentally tested (section 3). All the simulations were carried out using Msc.Nastran software v2024.1 in the linear elastic domain.

Two FE modelling approaches are proposed:

1. The use of an equivalent 3D-anisotropic metal foam with homogenised mechanical properties allowing the actual lattice core to be replaced by an equivalent material. This alternative is naturally the one privileged by industrial companies due to its low computational cost and the relative simplicity of mesh generation.

2. All geometric and property details of the structure are modelled with a full solid 3D mesh. This approach is technically difficult and time-consuming due to the huge amount of degrees of freedom (DOF) it generates. The main interest of this model for the present study lies in the possibility of comparing its results with those of the homogenised model.

These two approaches are fundamentally different. The choice depends on the design stage, the quantities of interest, and the required level of accuracy. It is obvious that a properly calibrated homogenised model is well-suited to large industrial components and enables good prediction of global behaviour, such as overall stiffness, global deformation, or natural frequencies. The full solid 3D model is useful for evaluating local behaviours, such as local stresses, stress concentrations, and the bending and/or torsion of the struts. It will be very useful for the subsequent work sizing the panel for static conditions and for conducting a future static test.

Initially, all input data were set to the nominal values of the CAD design, *i.e.* the geometrical dimensions correspond to a perfect defect-free structure. In a second step, once the specimen had been manufactured, the equivalent homogenized model was updated based on measured values (average skin thicknesses and mass).

As previously indicated, the panel is made of an AlSi7Mg0.6 aluminium alloy, the properties of which are as follows: E_s = 65 GPa for Young's modulus, ν_s = 0.3 for Poisson's ratio, and ρ_s = 2 675 kg/m^3 for density.

4.1.1. Equivalent Homogenised Model (EHM)

The mesh (Fig. 7) of the equivalent homogenised model EHM consists of three connected parts: (1) the solid zones (inserts and fixing areas), (2) the skins, and (3) the lattice core, modelled with an equivalent anisotropic continuum. Given the highly complex geometry of the inserts (Fig. 8), the entire mesh was generated using 10-node parabolic tetrahedral elements (CTETRA10).

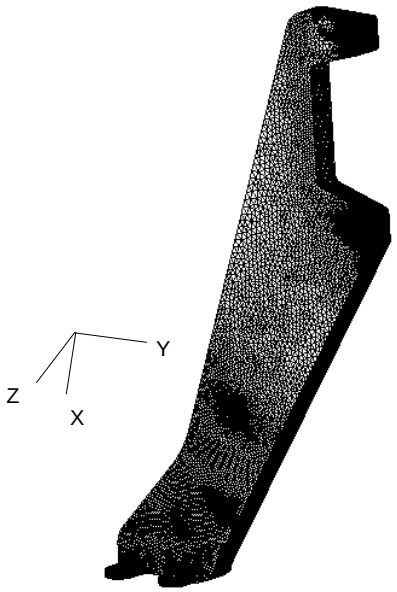

Figure 7: View of the mesh for the entire structure

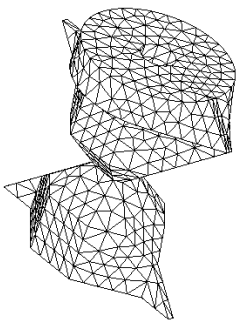

Figure 8: View of the mesh of an insert

The upper and lower skins are modelled using 6-node triangular 2D shell elements (CTRIA6) to ensure proper connection with the tetrahedral elements (CTETRA10) (Fig. 8).

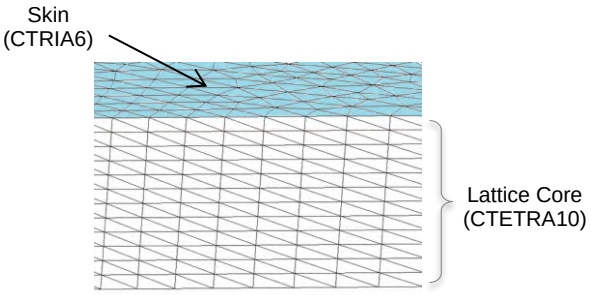

Figure 9: View of the skin and core mesh

The lattice core is represented as a homogenised 3D material possessing equivalent anisotropic elastic properties. This implies a predetermination by FE analysis of the stiffness matrix (Eq. 1) representative of the lattice pattern.

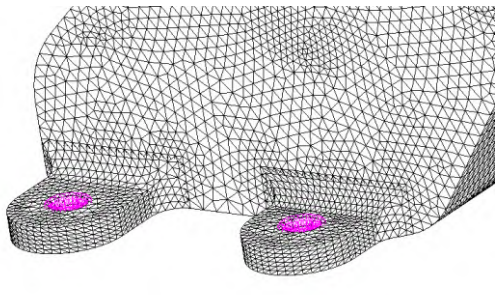
$$\underset{\sim}{\sigma} = \underline{\underline{C}}\,\underset{\sim}{\varepsilon} \qquad (1)$$

This was performed using the multi-scale material modelling platform Digimat developed by Hexagon and led to the stiffness matrix depicted in Fig.6 where: $G_{11} = G_{22} = 2580$ MPa, $G_{12} = 849$ MPa, $G_{13} = G_{23} = 142$ MPa, $G_{33} = 183$ MPa, $G_{44} = 969$ MPa, and $G_{55} = G_{66} = 138$ MPa (see the MAT9 Nastran matrix in Fig. 10).

$$\begin{pmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{xy} \\ \tau_{yz} \\ \tau_{zx} \end{pmatrix} = \begin{bmatrix} G_{11} & G_{12} & G_{13} & 0 & 0 & 0 \\ & G_{22} & G_{23} & 0 & 0 & 0 \\ & & G_{33} & 0 & 0 & 0 \\ & & & G_{44} & 0 & 0 \\ & sym. & & & G_{55} & 0 \\ & & & & & G_{66} \end{bmatrix} \begin{pmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{xy} \\ \gamma_{yz} \\ \gamma_{zx} \end{pmatrix}$$

Figure 10: Stiffness matrix of the elastic anisotropic material equivalent to the lattice core

Boundary conditions applied to the model: the structure is fixed at the base at the four mounting holes (M6 screws) (Fig. 11).



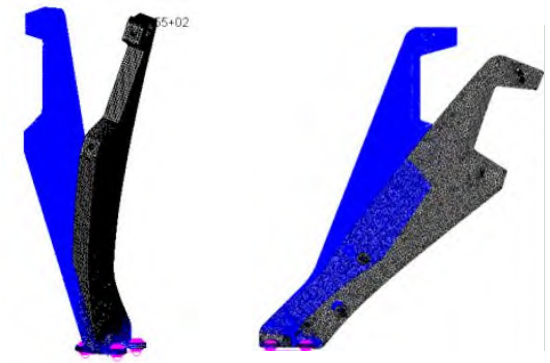


Figure 11: Boundary conditions: fixed at the 4 mounting holes (via RBE2 elements)

The results of the modal analysis are presented in Tab. 2 in terms of the first six natural frequencies and the corresponding effective masses. The mode shapes are shown and described in Fig. 12.

4.1.2. Full Solid 3D Model (FS3D)

One of the principal challenges encountered during the generation of this FE model was the quality of the imported CAD geometry. The original geometry, provided as a STEP file, contained topological inconsistencies, such as disconnected or poorly connected surfaces, small gaps, and overlapping faces. These defects prevented the automatic generation of a conforming volumetric mesh and resulted in meshing failures. This is a common issue when importing lattice geometries from CAD software. The STEP file was imported into Abaqus/CAE v2020 software and automatically repaired. Next, the Tetra10 mesh was generated using Abaqus and converted to Nastran format in order to utilize its effective mass calculation capability and enable a comparison with the homogenised model. Due primarily to limitations in available computing resources and time, it was not possible to vary the mesh density across different zones of the specimen. The mesh was created by selecting a specific element size, and Abaqus/CAE generated the mesh automatically. Fig. 13 shows a view of the mesh generated in this way. A finer mesh was not possible.

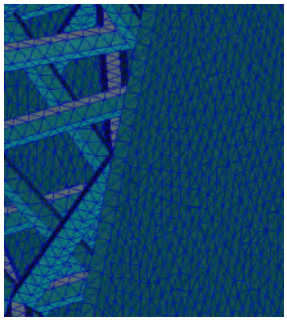

Figure 13: Zoomed-in view of the mesh of the full solid 3D model

The results of the modal analysis are presented in Tab. 3 in terms of the first six natural frequencies and the corresponding effective masses. The mode shapes remain identical to those of the homogenised model EHM (see in Fig. 11).

Table 3: FE modal analysis results (FS3D Model)

Mode	Freq. [Hz]	Effective masses [kg] X	Y	Z
1	67.2	-	-	0.085
2	146.9	0.019	0.068	-
3	299.4	-	-	0.013
4	422.0	-	-	-
5	751.2	-	-	0.013
6	807.2	-	0.014	-

FE model mass = 0.194 kg

4.1.3. Comparison of the EHM and FS3D models

The frequency results of the EHM and FS3D models are summarized in Tab. 4.

Table 4: Comparison of natural frequencies for the EHM and FS3D FE models

Mode	FS3D [Hz]	EHM [Hz]	Relative Error wrt FS3D model
1	67.2	77.0	+14,6%
2	146.9	201.2	+37,0%
3	299.4	358.2	+19,6%
4	422.0	514.0	+21,8%
5	751.2	916.9	+22,1%
6	807.2	1078.4	+33,6%

The homogenized model systematically shows higher natural frequencies than the detailed full-solid model. The overestimation ranges from approximately 15% to 37%, indicating that the equivalent model is globally stiffer than the full 3D solid model. It is noteworthy that the effective modal masses are similar for both models (Tab. 3 and Tab. 4). The FEM masses are also very close, 0.203 kg for the EHM model, and 0.194 kg for the FS3D model. The difference is approximately +4.6%, which is relatively small and cannot explain the differences in natural frequencies. These results suggest that the homogenized anisotropic material cannot fully capture all deformation mechanisms present in the actual lattice structure. In the full solid 3D model, the lattice struts deform through a combination of axial stretching, bending, torsion and local joint compliance, unlike in the homogenised model. The close agreement in effective modal masses indicates that the homogenisation preserves the global mode shapes and energy distribution, confirming that the equivalent model captures the overall dynamic behaviour of the sandwich panel even though its dynamic stiffness is somewhat overestimated.

The FS3D model has 163,340,700 DOFs, making it 44.4 times larger than the EHM model at 3,675,438 DOFs. Both models were solved on an Intel Xeon Gold 6246R processor with 32 physical cores (64 threads) and 512 GB of RAM. In terms of total CPU time, the FS3D model required 624,560 CPU seconds (approximately 173.5 hours), which is 339 times more CPU processing resources than the EHM model, which required 1,842 seconds (approximately 30.7 minutes). Unsurprisingly, the ratio of computation times is enormous, not to mention the pre- and post-processing times, which are also huge.

The objective of the full solid 3D model was to identify and quantify the differences compared to the equivalent homogenised model. The homogenised model clearly remains the preferred and appropriate tool for industrial structural sizing, enabling rapid assessment of large-scale spacecraft components. The full solid model is useful during research phases for understanding the mechanical behaviour of new lattice architectures, calibrating the homogenisation method, and investigating local phenomena.

5. RESULTS AND DISCUSSION

5.1. Comparison of experimental and numerical responses

The comparison of natural frequencies between the measurements and the numerical results from the two models, EHM and FS3D, is presented in Tab.5.

Table 5: Comparison between the measured and FEM natural frequencies

Mode	*Meas. [Hz]*	*FS3D [Hz]*	*Relative Error*	*EHM [Hz]*	*Relative Error*
1	63.	67.2	+7.5%	77.0	+23.2%
2	109.	146.9	+35.1%	201.2	+85.2%
3	244.	299.4	+22.6%	358.2	+46.6%
4	422.	422.0	+0.1%	514.0	+21.9%
5	732.	751.2	+2.6%	916.9	+25.2%
6	837.	807.2	-3.5%	1078.4	+28.9%

The L-PBF manufacturing process introduces inherent imperfections, such as deviations in strut diameter and cross-sectional shape, geometric distortions, internal porosity, and localised defects at the lattice junctions. These imperfections reduce the effective stiffness of the lattice sandwich structure. Consequently, and as observed, the as-built specimen exhibits natural frequencies lower than those predicted by finite element models based on the nominal CAD geometry, assuming a geometrically perfect, defect-free lattice structure.

The FS3D model reproduces the experimental dynamic behaviour with significantly greater accuracy than the homogenised model. Except for the second and third modes - respectively the first in-plane bending mode and the first torsion mode - the prediction error remains below 8%, with excellent prediction of the fourth mode (+0.1%). In contrast, the EHM model systematically overestimates all frequencies by approximately 22% to 85%, indicating that the equivalent model is significantly stiffer than the real structure.

As previously identified in Tab.1, 2, and 3, the first and fifth modes correspond to the first out-of-plane bending modes, the second and sixth modes represent the first in-plane bending modes, whereas the third and fourth modes are associated with the first torsional modes.

The FS3D model accurately reproduces out-of-plane bending behaviour. The first bending mode is predicted with an error of 7.5%, while the fifth mode differs from the experimental measurement by just 2.6%. This model captures the global flexural stiffness of the sandwich structure in the transverse direction. In contrast, the homogenised model overestimates out-of-plane bending frequencies by approximately 23% to 25%, suggesting that the equivalent material properties provide an overly stiff representation of the lattice core.

A different trend is observed for in-plane bending modes. The first in-plane mode (mode 2) shows the largest discrepancy for both numerical models, with errors of 35.1% for the FS3D model and 85.2% for the homogenised EHM model, whereas the second in-plane mode (mode 6) is accurately predicted by the FS3D model (−3.5%) but remains significantly overestimated by the homogenised model (+28.9%). This poorer correlation is difficult to interpret without an in-depth study of the overall in-plane stiffness, which could involve modelling the interaction between the lattice structure struts, the skins, and the solid regions.

The torsional response is reproduced more or less satisfactorily by the FS3D model. The second torsion mode (mode 4) is almost perfectly predicted, with an error of only 0.1%, while the first torsional mode (mode 3) shows a moderate overestimation of 22.6%. Conversely, the homogenised model overestimates both torsional frequencies by 21.9% and 46.6%, indicating that the homogenisation procedure does not fully capture the torsional compliance resulting from local deformation of the lattice members and their junctions.

5.2. Future Investigation for FE Model Improvement

The first and most important step in improving the predictive capability of FE models would be to account for the actual as-built geometry, rather than the nominal geometry derived from CAD. FE models should be updated by reconstructing them from the geometry obtained via X-ray computed tomography (work to be carried out).

A second important step for improving the FE models will be to incorporate material properties identified from dedicated test coupons manufactured in the same L-PBF build as the lattice sandwich panel. To this end, the TAS-F Mechanical Lab has already conducted tensile tests on printed coupons, together with edgewise and flatwise compression tests on specimens representative of the lattice sandwich panel. Although the results of these tests have not yet been analysed, they will provide valuable experimental data for calibrating the material properties of the numerical models.

The full 3D solid model (FS3D) shows much better agreement with experimental natural frequencies than the equivalent homogenised model (EHM), but it cannot be used in an industrial design phase. However, it can serve as a high-fidelity reference for recalibrating the homogenised model. Since the equivalent model must reproduce dynamic behaviour, the recalibration process would be guided by modal correlation. Starting from the equivalent elastic properties obtained via homogenisation, the stiffness parameters of the anisotropic material would be iteratively updated to

minimize discrepancies in natural frequencies and mode shapes. The objective would be to maximize the Modal Assurance Criterion (MAC) while minimizing the relative frequency difference.

6. CONCLUDING REMARKS AND OUTLOOK

This work presented the modelling and experimental validation of a Laser Powder Bed Fusion (L-PBF) manufactured aluminium lattice sandwich panel representative of lightweight space structures. Low-level swept-sine vibration tests enabled the identification of the first six natural modes of the structure, providing a reliable experimental basis for assessing the predictive capability of two finite element modelling strategies: an equivalent homogenised model (EHM) and a detailed full solid three-dimensional model (FS3D).

The comparison demonstrated that the FS3D model reproduces the measured dynamic behaviour with significantly greater accuracy than the homogenised model. The detailed representation of the lattice members captures local deformation mechanisms that cannot be fully represented by an equivalent anisotropic continuum. Conversely, although the EHM systematically overestimates the natural frequencies, it preserves the global modal behaviour while drastically reducing the computational cost, making it the most appropriate solution for the design of industrial structures and large-scale spacecraft analyses.

The comparison with the experimental results also highlights the importance of considering the as-built characteristics of L-PBF structures. Manufacturing-induced deviations from the nominal CAD geometry, including increased skin thickness, geometric imperfections and material defects, reduce the effective stiffness of the structure and therefore have a significant influence on its dynamic response.

Future work will therefore focus on improving the correlation between numerical predictions and experimental measurements. The first priority will be to reconstruct the FE models directly from X-ray computed tomography data. In parallel, the FS3D model will be used as a high-fidelity reference for recalibrating the homogenised model through modal correlation techniques. Such a methodology preserves the computational efficiency of the equivalent model while improving its predictive capability. Beyond the present modal analysis, the validated modelling framework will be extended to static and buckling analyses.

7. ACKNOWLEDGEMENTS

The authors wish to acknowledge and convey their appreciation to those individuals, Erasmus+ students, and corporations, in particular Thales Alenia Space - France (TAS-F) in Cannes, and LISI Aerospace Additive Manufacturing (LAAM) for the manufacturing of the test specimen. We also thank ELEMCA for carrying out the X-ray micro-computed tomography of the sample.

thermoplastic composites, automated fiber placement, press thermoforming, resistance welding, satellite

ABSTRACT

Within the ESA ARTES program, the Łukasiewicz – Institute of Aviation (Ł-ILOT) and Creotech Instruments (CTI) used weldable, high performance thermoplastic composite for fast fabrication of Engineering Model (EM) of a telecommunication satellite. The aim of the project was to build an EM of telecommunication satellite made entirely of thermoplastics materials with use of methods and technologies suitable for automation for future medium/large scale production. The Engineering Model (EM) passed required TVAC (Thermal-Vacuum) and vibration tests and have proven validity of used technologies reaching TRL 5.

1. INTRODUCTION

The small-satellite market is driven by trends such as miniaturization of payloads, deployment of large constellations and demand for faster time-to-orbit. At the same time, developers face challenges: tight mass/volume budgets, thermal and radiation management.
Therefore market is looking for new methods of fabrication of satellite structures, which will increase production speed and lower the costs. One of commonly used approach is to use 3D printing. This method however is limited to not very large geometries and material is used without additional reinforcements like e.g. carbon fibers [1][2]. The reasonable approach seems to be use of fiber composites with thermoplastic matrices. The thermoplastic composites utilizes remelting of thermoplastic matrix for impregnation or fibers, thermoforming in shapes and joining by welding. All of those processes are fast and do not require chemical reactions at any stages. The technologies used for thermoplastic composites are commonly Automated Fiber Placement (AFP) and press consolidation [3][4][5]. Those are fast technologies realized in highly automated processes. Those materials can be also joined by welding. Welding is also fast process of joining using fusion bonding of melted matrix [6][7].
One of the solutions for faster stiffeners fabrication is application of rib grids, which were tested in cylindrical satellite structures fabricated by winding [8][9]. This approach can be applied to thermoplastic composites with use of automated tape lay-up.
Therefore, to achieve rapid and scalable manufacturing the following approach was taken to:

- use thermoplastic composite technologies with potential for automation,
- simplify the design geometry (solid laminates with rib grids stiffeners),
- reduce number of parts and joining steps,
- use minimal amount of tooling,
- fabricate as many features as possible, such as walls, joining interfaces and stiffeners in one process.

In the task, full development of fabrication and joining technologies was carried out, with validation at the specimens level and up to full structure of Engineering Model. The research included development of in situ AFP fabrication using tapes, press thermoforming using fabric, characterization of materials, design of the platform, fabrication of parts, development of inserting technology, development of resistance welding, fabrication of tooling for machining and joining, joining of the structure (welding and screws), integration with instruments.

2. MATERIALS AND METHODS

2.1. Material

Material selected for the satellite structure is carbon fiber composite with semicrystalline Low Melt Polyaryletherketone (LM-PAEK) as matrix. The material has high service temperature up to 250 °C in short term, with processing temperatures around 340 °C [10]. In comparison, polyether ether ketone

(PEEK) has processing temperatures of 385 °C [11]. The lower processing temperature was one of the main factors of material selection. Material was used in two forms: UD tapes Victrex AE250 for AFP application and fabric Toray TC 1225 5HS for press thermoforming. The material was tested for outgassing compliance, with Total Mass Loss = 0,04% and Collected Volatile Condensable Material = 0.03%.
In resistance welding processes the Victrex LM-PAEK APTIV AE™ 250 foils were used.

2.2. Design

The aim of the EM of satellite was to be suitable for automated fabrication allowing for production in series with relatively short lead times. Those assumptions are reflected in EM design. The design was aiming to simplify the geometry, reduce number of parts and joining processes. Therefore the joining interfaces were designed to be fabricated in one process with satellite walls. Similarly simple solution for stiffeners in form of rib grids was introduced.
The joining interfaces in form of 45° degrees flanges allow to join walls without additional joining element like L-shape, and reduces joining processes from two to one.
The rib grid solution replaces solution in form of e.g. L-shapes or hat-shapes, which will be probably lighter solution but in would add parts and joining interfaces.

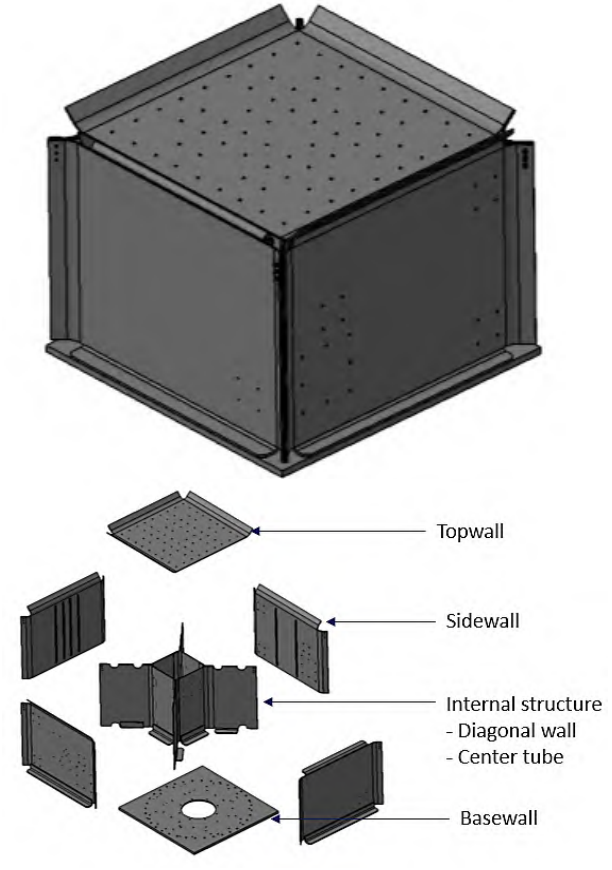

Figure 1: Composite structure exploded view

The design of the structure aimed to enable various manufacturing methods with either a press or AFP. The side walls, top wall and internal walls of structure were made on one tool. The base wall was made separately as a flat panel. The number of parts and joining steps were reduced by fabrication of walls, joining interfaces and rib grid stiffeners in one process.
The minimum external wall thickness of the spacecraft is set at 3,5 mm to ensure adequate radiation protection for the internal electronic units [12]. This decision is based on the assumption of utilizing Commercial-Off-the-Shelf (COTS) electronics, which are not inherently radiation-hardened. A density of 1.52 g/cm3 was used for the wall thickness calculations, representing the least dense composite material under consideration for the project.

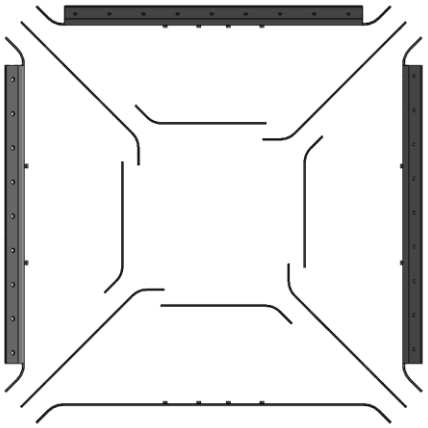

Figure 2: Exploded view of interal structure showing the strategy of joining (welidng)

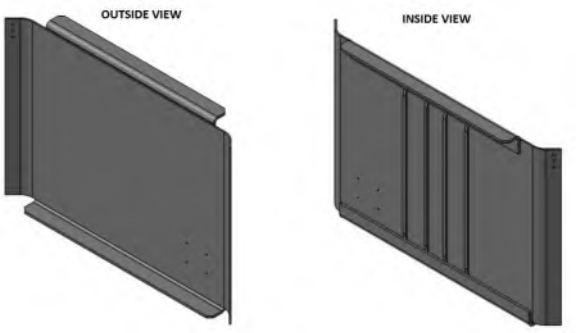

Figure 3: Sidewall design with joining interfaces and rib grid stiffeners

2.3. AFP

The Automated Fiber Placement is a technology where fabrication is performed by programmed robotic arm. It requires dedicated and process specific tooling, which often requires heating.
The technology can produce flat panels, curved shapes, grid stiffeners, which makes it highly versatile and can produce components with additional features like stiffeners.
The AFP can fabricate panels or elements directly on site without further processing,

which is called in situ process. This process was used for fabrication of side walls and base wall of the EM. The panels for side walls, top walls and for internal structure were fabricated with joining interfaces in forms of 45° flanges. In the same process the grid stiffeners were manufactured directly on the panels.

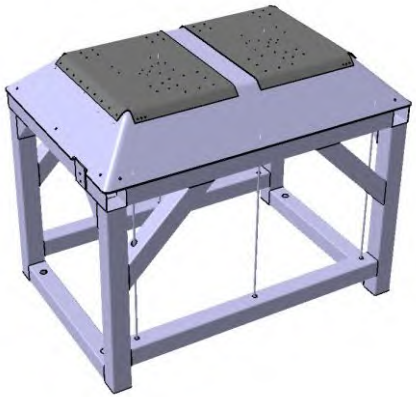

Figure 4: AFP tool design for fabrication of satellite walls

All above mentioned operations reduce number of fabrication steps, tools and machines and contribute to reduction of fabrication time. The fabrication time can be also shortened if multiple elements are joined and manufactured as a one piece to be cut and trimmed after layup.

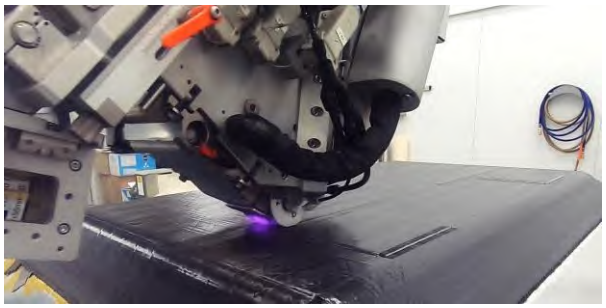

Figure 5: AFP sidewalls manufacturing

Actual layup time of 600x600mm 25 ply panel takes about 60 minutes. Straight section of 5 mm high rib is manufactured in minutes. Production rate expressed in kilograms of structure manufactured per hour is case specific.

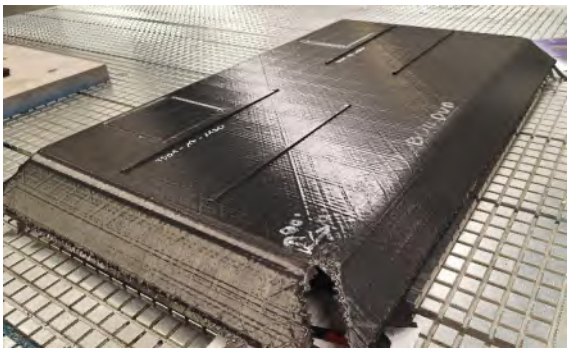

Figure 6: Two sidewalls with 45° joining flanges and rib grid stiffeners fabricated in one process ready for trimming.

2.4. Press thermoforming

Press is automated process which requires specially prepared moulds for fabrication of shapes. The thermoforming of profiles like L-shapes, trapezoid-shapes etc is highly efficient and fast - 20 min or less for one shape.

The procedure for thermoforming structures using thermoplastic composites consists of two elementary technological processes:

- Consolidation of prefabricated flat composite panels.
- Shaping (thermoforming) of previously consolidated flat composite panels into the desired part.

The press technology has high versatility in use of raw material in form of semipreg, prepreg or consolidated panel used for thermoforming. The higher level of raw material (e.g. panel) the smaller number of fabrication processes (e.g. only thermoforming), but higher cost of material.

The thermoforming process is usually combined of four steps: heating panel by Infrared (IR) heaters, fast transport in press, shaping using moulds and demoulding of shaped element (Figure 7).

Press is potentially more efficient for fabrication of simple, less complex shapes. Additionally, those parts can be produced even faster, when number of elements (panels, shapes) can be done in one process.

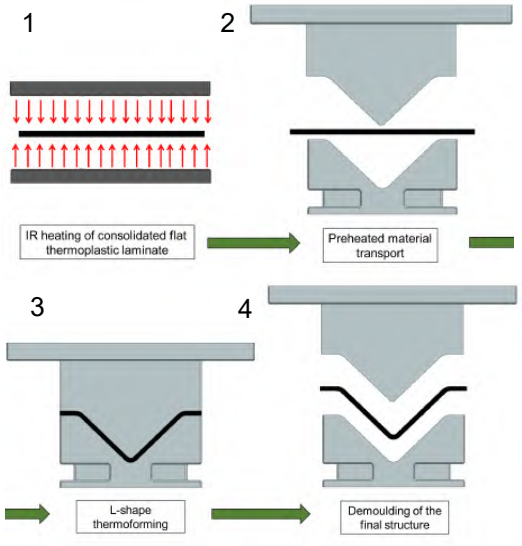

Figure 7: Thermoforming process workflow: 1 - IR heating of consolidated laminate, 2 – material transport, 3 – thermoforming, 4 - demoulding

The press consolidation of semipregs into panels takes up to 2 hours. Multiple panels (depends on thickness) can be consolidated in one process. The consolidated panels can be thermoformed in desired shape in 20 minutes, which is highly effective. Prior to that process the sheets for thermoforming should be cut from panels into desired shapes. Thermoforming can be performed also on AFP sheets. Process time is similar.

Figure 8: Moulds for thermoforming

The process parameters used were validated through quality control by non-destructive testing and through characterization of the material's mechanical properties.

The design of the satellite allows for versatility of the fabrication. The walls can be manufactured using press technology where panels with 45° flanges using thermoforming in fast processes. Grid stiffeners can be added after thermoforming or joined with panel during thermoforming.

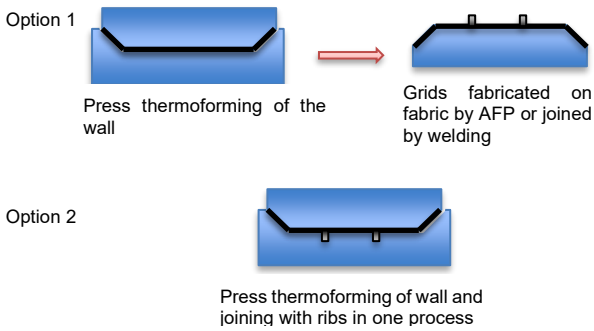

Figure 9: Alternative methods of walls fabrication using press

2.5. Joining

Resistance welding is the process where resistive heating element (metallic mesh or carbon fibres) is placed between joined thermoplastic surfaces. When electrical current passing through the metallic element, it heats up according to the Joule's law. The temperature rises at the interface, causing the polymer around the implant to melt and form a weld under pressure.

Resistance welding is a separate process which is done outside press or AFP. The process itself takes less than 10 minutes. Additional operations are preparation of welding element and electrical isolators, assembly of weld, applying pressure, placing electrical connectors. All of this steps can be accelerated by using highly automated welding rigs specific to certain application.

Unlike ultrasonic welding, the resistance welding is not limited by laminate thickness and is therefore suitable for the 3.5 mm thick walls of the satellite structure. Ultrasonic and conduction welding were excluded due to technological limitations, such as incomplete fusion, poor energy transfer, and limited process control in thicker laminates.

The drawback of resistance welding is current leakage phenomenon. During process the current can flow from heating element to conductive carbon fibres in welded materials. It causes local overheating and burning of the welded parts. Therefore the isolating material is placed between welded part and heating element. The most popular solution is glass fabric impregnated by polymer similar to matrices of a welded parts. It adds additional layer and mass to a weld, but prevents catastrophic current leakage.

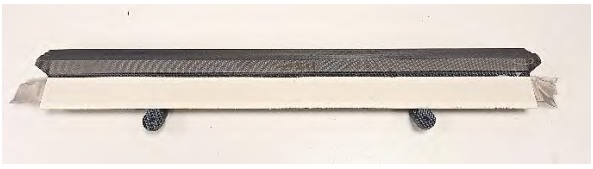

Figure 10: Thermoformed L-shape prepared for resistance welding with heating mesh and isolating layer

The solution with glass fabric was implemented in welds of the satellite EM. The welds were tested in

static lap-shear standard tests including elevated and lowered temperatures.

The welding was used on all vertical joints of the EM. Also all L-shapes were welded to vertical walls of the EM. In total 32 weld were performed. Welds have passed the vibration tests of the whole structure of the Engineering Model.

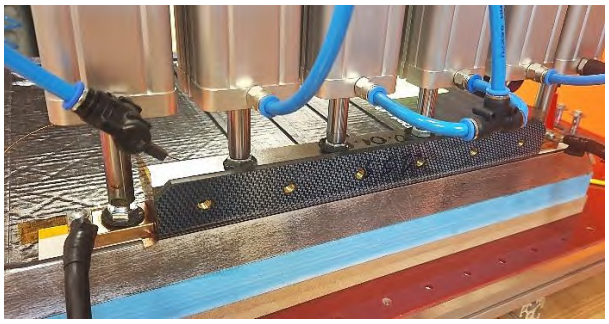

Figure 11: L-shape welding to side wall of EM.

Resistance welding has high potential for automation, and is suitable for production of joints in series. Resistance welding has limitation in case of complexity, where curved welds can pose problems and might require special design of heating element.

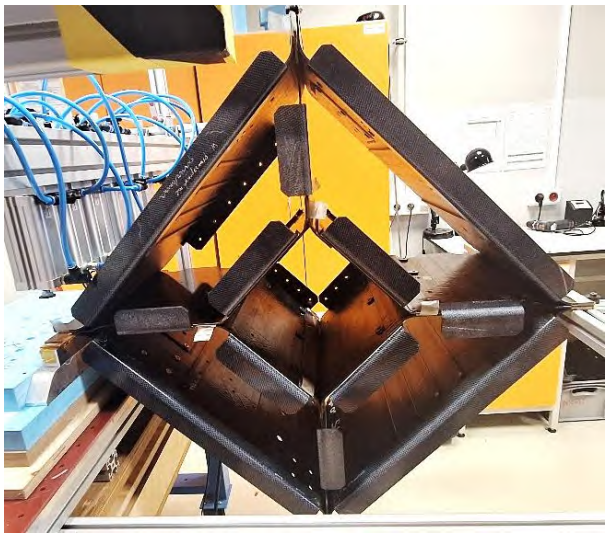

Figure 12: Welding of final joints of the EM of a satellite. All joint in the figure were made using resistance welding.

For detachable joints the metallic inserts technology was chosen. The heated inserts were pushed in the composite material with holes. The technology is fast and effective. The processes takes up to one minute per insert.

Figure 13: Fully inserted basewall

The inserts were also used in all fixing points for electronic instruments. Most inserts where put in basewall of the EM of telecommunication satellite. There were in total 254 inserts, 178 in basewall and 76 in walls.

2.6. Integration

Prior to integration of structure with instruments preliminary assembly was performed for confirmation of proper positioning of all parts. In this form structure was transported to Creotech Instruments for full integration.

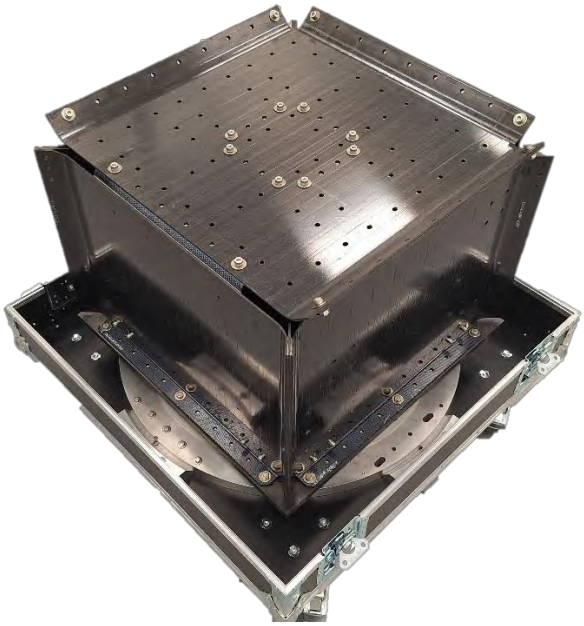

Figure 14: Composite structure of the Engineering Model in transport case prepared for instruments integration.

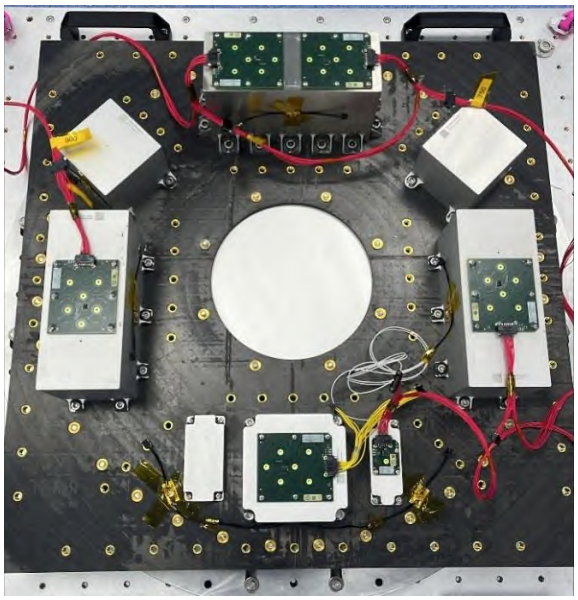

Figure 15: Basewall during integration, photo courtesy of Creotech Instruments

In the structure vertical walls were already joined (welded) which significantly reduced integration time – in the understanding of the last step of integration of the spacecraft with equipment. Thermoplastic structure allowed for distinction between integration of mechanical parts into bigger modules and much quicker integration with other components.

Practical experience shows that integrating the complete Structural Thermal Model (STM) model (including payload) took only ~2 weeks, which is lower than for traditional aluminum structures.

Such performance is rarely achievable with traditional aluminum structures, where panel mating requires more alignment and additional brackets and supporters are required.

Fully developed thermoplastic structures therefore may appear particularly beneficial for small satellite manufacturers facing rapid production cycles. Similar for projects which, by their very nature, require urgent and rapid integration.

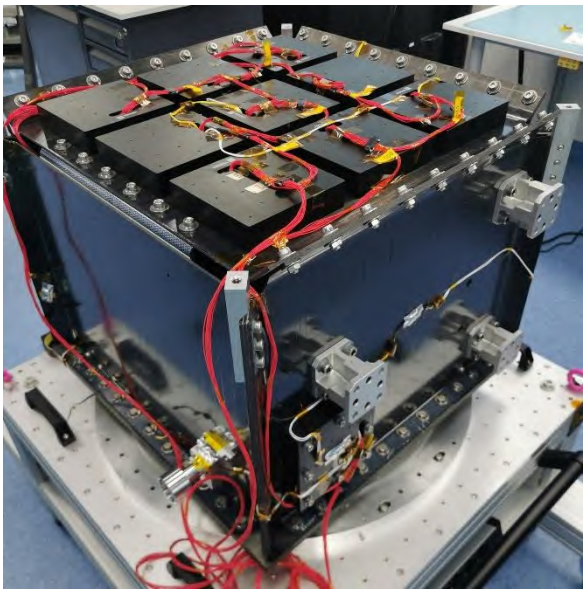

Figure 16: Fully integrated Engineering Model prepared for testing, photo courtesy of Creotech Instruments

2.7. Benefits

The full thermoplastic engineering model of a telecommunication satellite, measuring 655×655×506 mm with instrumentation was built.

In the project the strengths of thermoplastic composite technology was explored for application in satellite structures. The Engineering Model was designed to test wide scope of solutions utilized for those materials: AFP fabrication, press thermoforming, welding and inserting used on high performance thermoplastic composite. Some of the benefits of this approach are listed below.

1. Use of high performance resins with stability in temperatures temperature above 150 deg. C and thermal survivability above 200 deg. C, with high chemical and UV radiation resistance.
2. Materials have unlimited shelf life and do not require special infrastructure like freezers.
3. Utilization of in situ (on site) AFP fabrication, which do not require additional steps like post-consolidation in press or autoclave, which results in reduction of fabrication steps.
4. Utilization of simple rib grids, which can be fabricated with the panel in one process.
5. Utilization of press thermoforming, which is possibly the fastest method of composite material shaping. Technology was used for L-shapes for structural walls joining. Method highly suitable for medium/large scale production.
6. Utilization of welding technology. This is the fast technology of joining, where process takes less than 10 minutes and the weld does not require foreign materials like adhesives, which makes homogenous joint and ensures the same thermal properties of joint and joined parts.

7. Utilization of inserting technology for thermoplastic materials. Inserting methods for those materials use heated inserts which is fast and efficient.

All mentioned technologies are suitable for automation and application in medium/large scale production.

Unused material or production waste can be recycled or reused for other elements like secondary structures or used in out of space applications.

3. SUMMARY

The paper summarizes the overall approach to manufacture the EM of a telecommunication satellite.

The suggested approach was tailored to meet main requirement, which is increasing the fabrication rate due to:

- design simplification,
- reduction of fabrication steps and using fast fabrication methods distinctive to thermoplastic materials like:
    - AFP in situ fabrication,
    - press thermoforming,
    - welding,
    - inserting using heat.

The proposed solution supports fabrication optimization approach:

- one AFP tool for multiple elements fabrication: side walls, top wall and internal structure walls,
- one set of tooling for L-shape thermoforming,
- fabrication of walls with joining interfaces (45 degrees flanges), resulting in reduction of joining steps,
- fast joining methods like inserts and welding – methods with fast processes and suitable for automation.

The thermoplastic composites technology enable high-speed, repeatable production while maintaining structural integrity and performance. This approach marks a significant step toward redefining how future satellite platforms can be built – in a faster and more efficient way with scalability to medium/large scale production.

ABSTRACT

The very stringent performance requirements for the telescope of the Copernicus Sentinel 2 next generation mission, require mirror surfaces with a strong freeform shape and materials with outstanding thermo-mechanical properties.
To mature the required technology, a consortium consisting of OHB System AG, AMOS and Schunk Technical Ceramics GmbH, developed and manufactured a corresponding mirror demonstrator in the frame of an ESA technology development program (TDE).
The 3D printed, reaction bonded SiC from Schunk (IntrinSiC®) provided unique design freedom to optimize for the demanding surface form error requirements of the mirror when loaded with gravity or thermal load cases. Modelling and optimization processes have been developed to find a compliant design.
AMOS developed corresponding metrology concepts, manufacturing jigs, tools and process steps to finally polish this high-performance mirror with large free-form characteristics to a surface form error of < 16 nm rms.

1. INTRODUCTION

The optical telescope of the satellites for the Copernicus Sentinel 2 next generation mission (S2 NG) needs to achieve within a small volume and a low mass a very large field of view by still providing a high ground resolution and opto-mechanical and thermo-elastic stability.
For that reason, mirror surfaces with a strong freeform shape have to be applied, and innovative materials with outstanding thermo-mechanical properties will need to be used.
In the frame of an ESA technology development program, called “Design and Breadboarding of a Wide Field-Of-View Telescope for the next generation Copernicus Sentinel-2” (ESA Contract No. 4000138864/22/NL/AR), the manufacturing process required to produce such kind of free-form mirrors was developed and demonstrated with the design and production of a flight representative free-form optic (FFO) mirror demonstrator (Figure 1).

Figure 1 3D printed, IntrinSiC® (RBSiC), free-form optic mirror demonstrator

The industrial consortium consisted of OHB System AG, as the prime contractor, AMOS and Schunk Technical Ceramics GmbH.

2. REQUIREMENTS

Based on the S2NG phase 0 study, ESA has derived a high-level set of requirements for one single mirror. These requirements are defined, to represent the critical technical challenges associated with the overall S2NG telescope optical system. OHB has derived additional requirements to guarantee a mirror design, suitable for the S2NG mission. The requirements listed in the following are not the complete set, but a relevant selection giving the impression of the challenges.

2.1. Optical and Performance requirements

The mirror overall size shall be 800 mm x 280 mm with a corner radius of 100 mm and an optical clear aperture clearance of 10 mm. The specified, complex free-form is defined by an extended polynomial expression [1], with a global sagita (SAG) of ~40 mm and a delta SAG of ~2 mm (see Figure 2 and Figure 3).

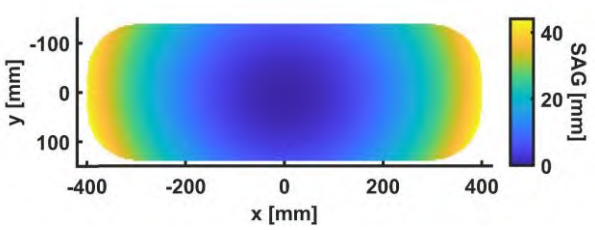

Figure 2 SAG of free-form mirror

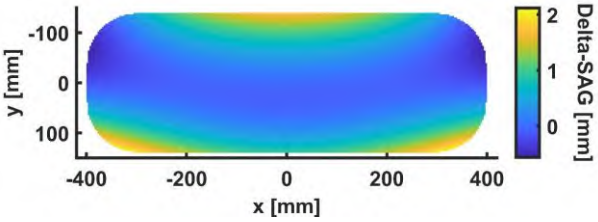

Figure 3 Delta-SAG of free-form mirror

The surface form error (SFE) shall be < 25 nm rms, while the SFE on any disk of 200 mm shall be < 10 nm RMS.
The gravity induced SFE shall be < 10 nm rms for in-plane (IP) loading and < 40 nm rms for out-of-plane (OOP) loading. The temperature induced SFE shall be < 3 nm rms for an operational temperature range of 20°C ± 5K.

2.2. Mechanical and structural requirements

The mass of the mirror shall be < 7 kg, its 1st Eigenfrequency > 500 Hz (without the iso-static mounting) and it shall sustain a quasi-static load of 37 g.
As from the beginning, 7 kg was assessed as too demanding within this project and the focus was on the free-form manufacturing and stability requirements, the goal was set to a mass of 8 kg.

3. INTRINSIC® – 3D PRINTED SIC FOR SPACE

For the realization of the mirror demonstrator the 3D printed, reaction bonded silicon carbide (RBSiC), IntrinSiC®, from the company Schunk Technical Ceramics GmbH, further on called Schunk, was utilized.

3.1. Manufacturing process

The manufacturing process for the RBSiC from Schunk consists of the following 4 major steps:

- Raw material provision and mixture
- Shaping the green body
- Pyrolysis
- Siliconizing

This process is depicted in Figure 4.
SiC powder is mixed with an organic binder and shaped. This shaping process can be done in different ways, e.g. isostatic pressing, slip casting or extrusion. The shaping method, which was utilized for this project was the 3D printing process (Figure 5).

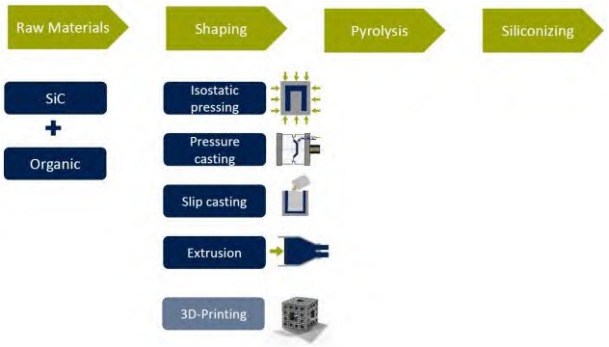

Figure 4 Schunks RBSiC manufacturing process

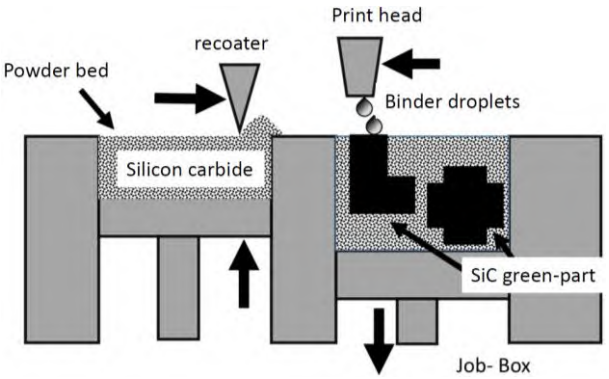

Figure 5 3D printing process of IntrinSiC®

The green body is shaped in a binder jetting process. Silicon carbide is placed in a powder bed with a recoater and a print head is applying binder droplets, binding the powder at the locations, you later on want to have the part material. After the binder has been applied, the powder bed is lowered and the recoater applies the next layer of silicon carbide powder.
The steps after the shaping are the same for all shaping methods. In a high temperature pyrolysis step, the organic material out of the green body is removed and porous carbon is remaining between the primary SiC powder grains (Figure 6).

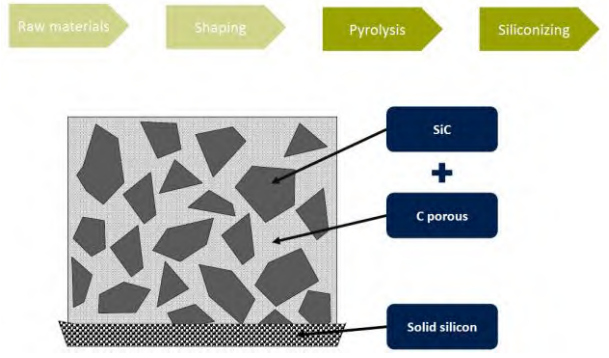

Figure 6 Pyrolysis step

In the final step, liquid silicone is infiltrating the porous carbon forming secondary silicon carbide. The final part thus is consisting of primary silicon carbide, secondary silicon carbide and a silicon phase (Figure 7).

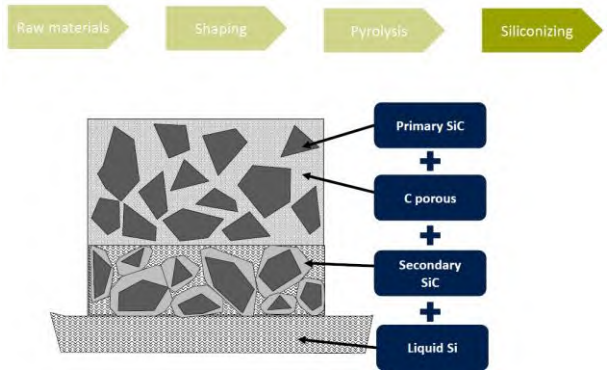

Figure 7 Siliconizing step

3.2. Material Properties

The resulting material properties can be found in [2] and some of them are listed and discussed within this section.
The chemical composition is 86% (mass) of SiC and 14% (mass) of silicon. The achieved density is 3,05 [g/cm³] with 0% of open porosity.
The properties most relevant for high performance optical space components are the specific stiffness and the thermal stability. The first is very relevant to reduce the effect of gravity release in orbit. As optical payloads are assembled and aligned on ground under 1 [g] environment, they experience a -1 [g] load case in space, which deforms them. To minimize this effect, optical payloads need to be designed very stiff with respect to gravity load cases. The thermal stability can be described by the ratio of thermal conductivity and coefficient of thermal expansion (CTE). The higher the conductivity, the smaller the thermal gradients in the parts, causing potentially undesired deformations. For the CTE it is vice versa. The smaller the CTE the smaller undesired deformations in space due to the thermal environment.
These two indicators are illustrated in Figure 8.
It can be seen, that SiC is very advantageous with respect to these properties compared to other materials.

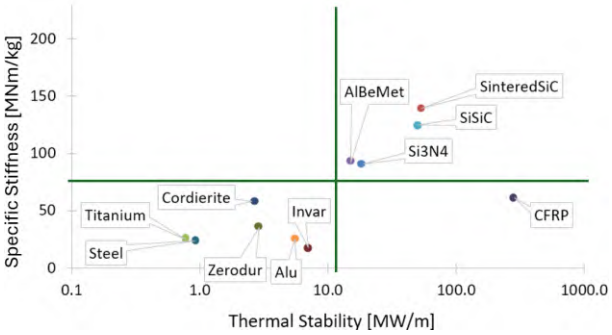

Figure 8 Specific stiffness and thermal stability

For IntrinSiC®, the Young's modulus is 380 [GPa]. Together with the moderate density, this leads to a very high specific stiffness of around 125 [MNm/kg]. The thermal conductivity at 20°C is 200 [W/mK] and the coefficient of thermal expansion at 20°C is 2.2 [1e-6/K]. This leads to a thermal stability of 90 [MW/m], which is a very competitive value.
According to the datasheet, the 4 point bending strength is 210 MPa and the Weibull Modul is 13. While the bending strength is rather low compared to other technical ceramics available, the Weibull modulus is rather high. As the allowable is calculated through a Weibull statistic, this results in acceptable values for designing space optical instruments. This is even more true as the designs for space instruments are typically driven by stiffness and not strength and the 3D printing capability allows to add material were necessary and develop a design suitable for brittle materials (round edges, smooth transitions, etc.).

4. DESIGN AND ANALYSIS

Within this chapter the mechanical design of the free-form optic mirror is introduced, and the analysis methodologies are described how this design and its performance was achieved.

4.1. Design

For this free-form optic mirror the design freedom offered by the 3D printing technology was strongly utilized, which resulted not only in a free form optic but also in a lightweighted, bionic design of the back structure. A very noticeable feature is the tapered backside (Figure 9), which results in a stiffness distribution that is beneficial for the gravity induced deformations.

Figure 9 Tapered mirror backside

The back face is partially closed, increasing the overall stiffness of the mirror. Shear walls inside the mirror are lightweighted by large pockets. Reinforcing ribs and radii are foreseen inside where necessary (Figure 10). These design features were only possible with the 3D printing technology.

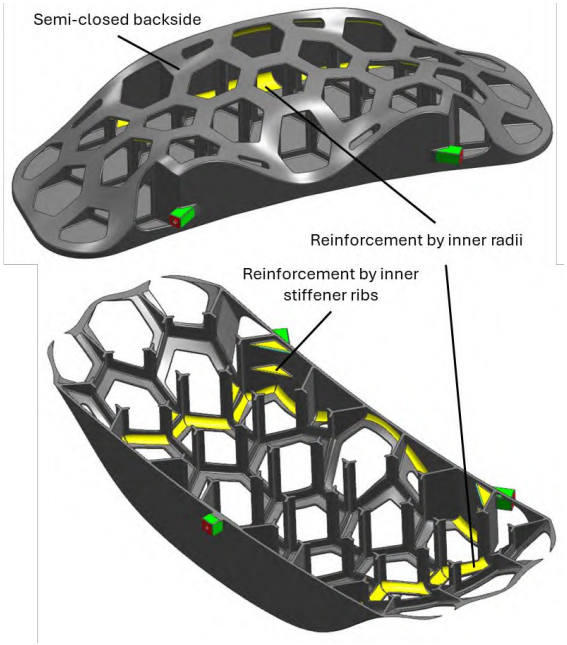

Figure 10 Design features, possible utilizing 3D printing

4.2. Optimization

The driving structural requirement for this mirror was the surface form error, induced by the gravity release. An optimization process was setup to come up with a compliant design for the demanding requirements. As the 3D printing technology allows a huge design freedom, optimization techniques can deploy their whole potential, what was fully utilized here. Before the optimization algorithm was applied, some manual steps were done to define design variables and fix some of the design features, such as Bipod location. For the final optimization step, an optimization finite element model (FEM) was setup in Altair Hypermesh 2022, providing a design space for the optimization algorithm in Optistruct (Figure 11). The mass of the full design space as shown in Figure 11 is 13 kg, exceeding the requirement by far.

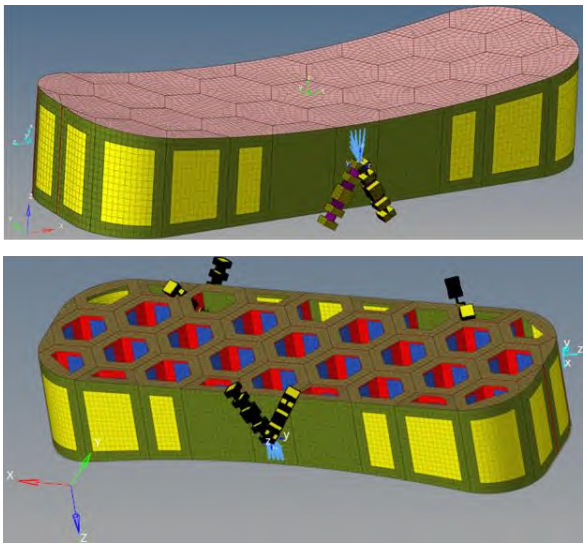

Figure 11 Optimization finite element model

Besides the free size optimization of wall thickness, 38 design variables have been defined, which the optimizer could vary. For example, the shapes of the tapered back structure. Figure 12 shows how the optimization algorithm can modify the shape of the back structure - a) only locally, b) the complete back face.

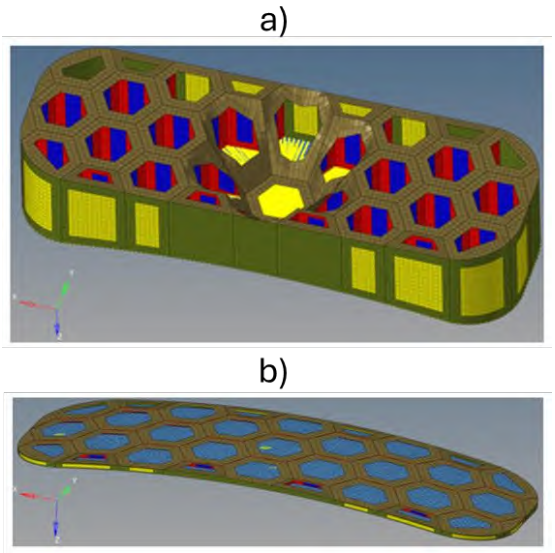

Figure 12 Examples of shape variation

The applied objective function was the surface form error under 1 [g] in x-direction, assuming that the instrument alignment will happen in this orientation. Additionally, constraints were applied, e.g. for mass. This optimization setup can be summarized as follows:

Design variables:
- back face shapes
- other geometrical features
- free size (thickness) of each element

Objective function:
- Minimize SFE RMS under 1 [g] X

Constraints:
- Mirror mass < 8 kg
- Others

The result of this optimization can be seen in Figure 13. The tapered back side is clearly visible. Higher stiffening ribs are necessary close to the bipod interfaces to increase the stiffness. No ribs are required at the mirror edges. The colour code indicates on top the element thickness. Blue is smaller thickness, red is higher thickness. It can be seen that the thickness was increased by the optimizer close to the surface and the back face at the bipod locations and along the ribs along the y-axis.

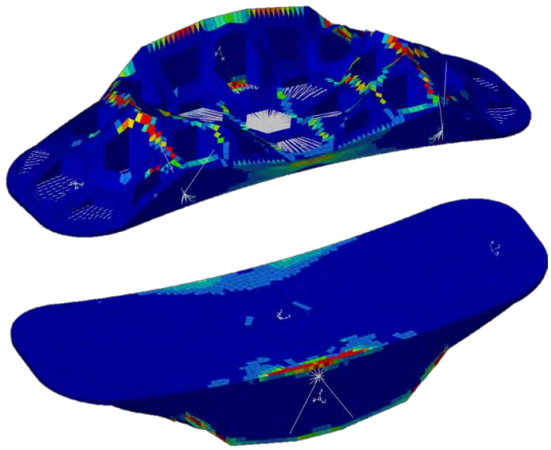

Figure 13 Optimization result

A varying thickness from element to element imposes a large challenge to the implementation from FE software into a CAD design.
Thus, the free-size optimization results cannot be used directly. However, they are implemented into the model by an engineering interpretation. Stiffening radii have been implemented at the locations where the free sizing optimization has added thickness. In a last optimization step, the free sizing has been replaced by additional design variables (e.g. wall thickness of specific surfaces) and different variants of rib lightweighting have been considered.
The final result of the optimization is summarized in Table 1.

Table 1 Optimization results

Objective/Constraint	Requirement	Result
RMS SFE 1g X [nm]	<10	3.34
RMS SFE 1g Y [nm]	<10	7.79
RMS SFE 1 g Z [nm]	<40	39.94
Mass w/o Bipods [kg]	<8	8

4.3. Analysis

As described already before, the optimization output cannot directly be transferred to a manufacturable design and some manual engineering work and design needs to be done leading to the final design. As this design is deviating in the details from the optimization result and the properties are very sensitive, a re-analysis step is added with the final design to confirm compliance. The final finite element model used for is analysis is shown in Figure 14.

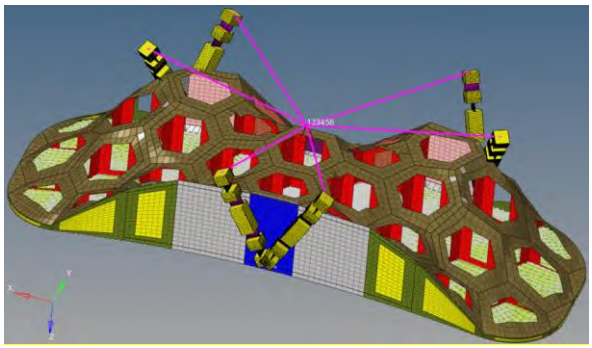

Figure 14 Final finite element model

4.3.1. Stiffness, stress and mass

The modal analysis shows that for the mirror assembly, including the bipods, the first two Eigenfrequencies are 285 Hz and 293 Hz. The mirror body alone without the bipods has an Eigenfrequency of 1038 Hz in a hard mounted configuration, which is well above the required 500 Hz.
Applying quasi-static loads (QSL) of 37 [g] in all three directions leads to stresses as summarized in Table 2. For the mirror principle stresses P1 are evaluated, for the bipods v. Mises stresses. All of these values lead to positive margins of safety.

Table 2 Stress results (QSL)

Load case	Max mirror stress [MPa]	Max bipod stress [MPa]
QSL 37 g X	20.66	195.41
QSL 37 g Y	43.80	166.92
QSL 37 g Z	12.29	83.30

Dynamic loads haven't been analysed as no requirements have been defined. Sine vibration would be covered by QSL as also the first natural frequency is well above the sine range. For random a primary notch would be applied, limiting the interface to the QSL. With these assumptions it is assessed that the mechanical integrity is covered with the QSL load case.
Interface tolerance load cases as well as thermal non-operational load cases have been analysed, leading to comfortable margins of safety for the bipods and the mirror.
A mass of 8 kg results in an area weight of approximately 35 kg/m², which is a competitive value for strongly rectangular mirrors.

4.3.2. Operational performance

To evaluate the operational performance, the surface form error (SFE) under the defined load cases is assessed as the sag deformation after subtraction of the mean displacements and rotations of the mirror surface (best fit plane). For sag deformations with large spherical content (e.g. uniform thermal expansion), a best-fit-sphere is subtracted. The root mean square (rms) of the SFE is computed and compared to the requirement.
The mean displacements and rotations resulting

from the gravity load cases are summarized in Table 3.

Table 3 Mean Displacements/Rotations under 1 g

Load case	Displacement [µm]	Rotation [µrad]
1g X	2.7	0.07
1g Y	3.1	0.2
1g Z	0.6	1.3
Requirement	<10	<5

The resulting SFE rms under the gravity load cases are summarized in Table 4.

Table 4 SFE RMS under 1 g

Load case	Requirement [nm]	SFE RMS [nm]
1g X	<10	3.16
1g Y	<10	7.19
1g Z	<40	37.75

Slight differences of these SFE rms values can be observed compared to the optimization results (Table 1). This can be explained by the manual adjustment of the design and the re-analysis. An exemplary plot for the SFE under gravity is shown in Figure 15.

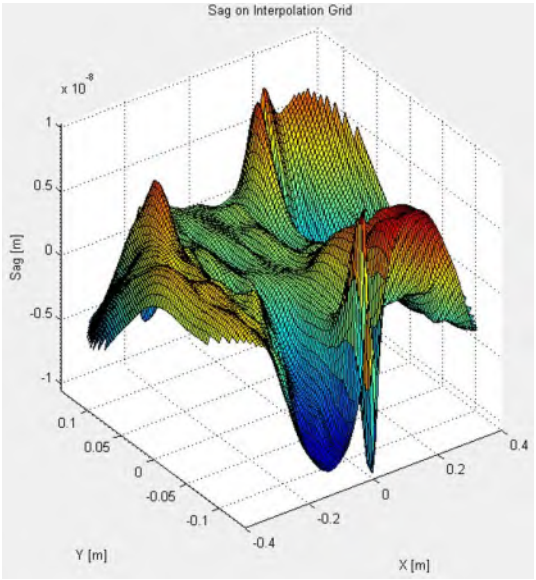

Figure 15 SFE plot for 1 g (X)

For a uniform temperature load of 5K, the SFE rms results in 2.2 nm, which is compliant wrt the required 3 nm. A corresponding SFE plot is depicted in Figure 16.

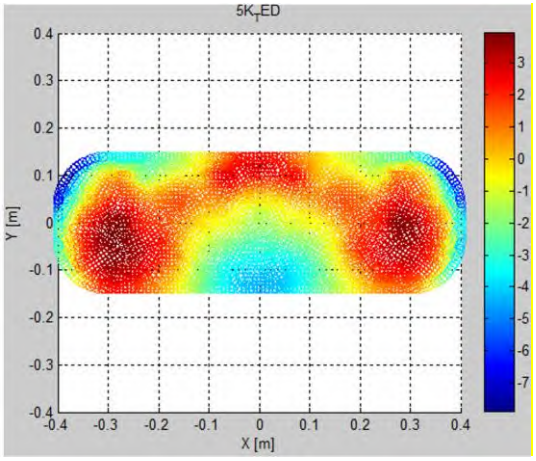

Figure 16 SFE irregularities wrt free-form for 5 K uniform temperature load

5. DEMONSTRATOR MANUFACTURING

The overall manufacturing process consists of the IntrinSiC® manufacturing steps as described in section 3.1, grinding of the functional surfaces, a cladding process to apply a polishable layer and the optical polishing, which itself might consist of several sub-steps.

5.1. Blank manufacturing

Schunk has 3D printing capacity of up to 1.8 m x 1.0 m x 0.7 m. The print job, independent of part size and complexity, is taking 1 day maximum. The printing is followed by some accompanying steps like de-sanding. The resulting green body has not yet its final mechanical strength and needs to be handled with care. The FFO mirror in its green state is shown in Figure 17.

Figure 17 3D printed FFO mirror in its green state

After the shaping by 3D printing, the pyrolysis and infiltration steps follow, before a grinding step finalizes the blank production. Figure 18 shows the FFO after finalization of the grinding, still on the grinding machine.

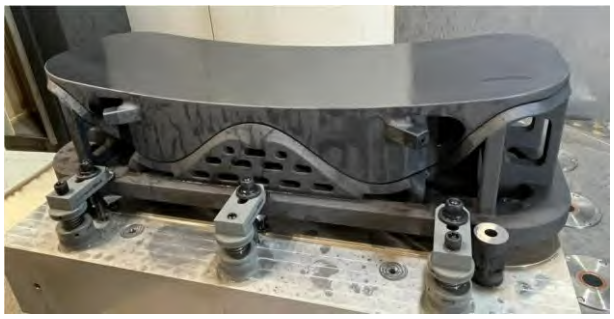

Figure 18 FFO during the grinding step

5.2. Cladding

The two-phase microstructure of reaction-bonded IntrinSiC®, which includes a softer silicon phase, makes it difficult to polish the material to the optical quality required for high-performance missions. Because of this, a layer of highly pure SiC is applied in a chemical vapor deposition (CVD) process by Schunk Carbon Technology. This CVD SiC technology is marketed by Schunk under the name P60 [3].

CVD SiC is a well known coating applied on SiC substrates for several ESA missions, such as Euclid, Gaia and Herschel [4], [5], [6], [7]. To not mix up with a potential final optical coating, this layer is called cladding throughout this paper.

A typical, initial cladding layer for a complex surface to be polished has a thickness of 600 µm. With this thickness, there is typically enough material to machine in, to achieve the final required surface shape. To avoid a 600 µm cladding layer all around the part, which would add a significant amount of mass, a masking can be foreseen to apply the cladding only on the functional surfaces and protect the others. This masked cladding step however is challenging and within this project a problem occurred for the first mirror blank during cladding and it needed to be scrapped. Thanks to a proper attrition concept, the impact on schedule was limited, but as the mass was not the focus within this project, the second mirror was cladded without a masking, successfully. This additional cladding mass led to a final mass of the mirror of 8.85 kg (instead of the 8 kg by design).

Within an OHB internal, parallel activity, the masked cladding could be demonstrated successfully with a 300 mm curved mirror demonstrator (Figure 19).

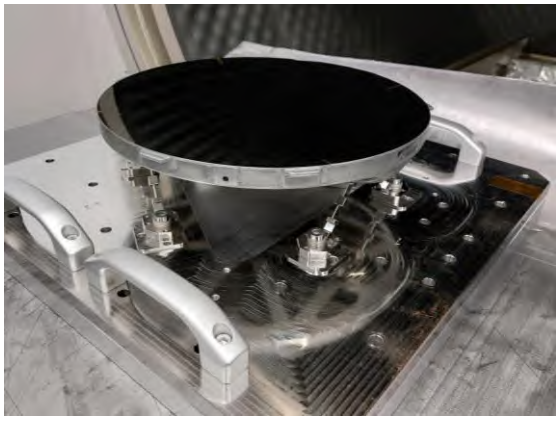

Figure 19 300 mm mirror demonstrator (OHB internal activity)

5.3. Polishing

After the cladding step, different machining steps towards the final mirror surface follow. The necessary steps also depend on the grinding quality before the cladding and can consist of another grinding step, a lapping step, a polishing step and for the final figuring an ion beam figuring step.

Besides the manufacturing tools themselves, the metrology is crucial to manufacture surfaces in the required quality (surface roughness < 1 nm rms; surface form deviation < 25 nm rms). For this reason, different measurement systems are utilized. A coordinate measurement machine (CMM) and laser trackers to align the mirror and a computer generated hologram (CGH) to measure the actual mirror shape (see Figure 20).

Figure 20 FFO in a measurement setup together with the CGH

In the case of the FFO, AMOS started with a lapping step after reception of the cladded mirror blank. AMOS designed a special mounting jig for the lapping operation. The blank mounted in this jig can be seen in Figure 21.

Figure 21 FFO mirror mounted on the lapping jig

Figure 22 shows the FFO mirror during lapping operation. The surface form error after lapping was 1-2 µm rms. Due to the anomaly during the cladding step, the surface form error before lapping was larger than expected and the remaining cladding thickness after lapping was not sufficient to fulfil the surface form error requirement for the full clear aperture, especially along the rim. To reduce the risk of machining through the cladding layer, it was decided, together with the customer, to reduce the relevant clear aperture by 10 mm around the rim. With this new goal, the next polishing steps were tackled.

Figure 22 FFO during lapping operation.

After lapping, a polishing (or classical figuring) step followed, ending up with a surface form error of 35 nm rms with a micro-roughness of 0,8 nm rms. The polishing sequence was finalized with an ion beam figuring step, bringing down the SFE to 16 nm rms. Figure 23 shows the FFO mirror during the ion beam figuring. Figure 24 shows the final surface form error map of the FFO mirror.

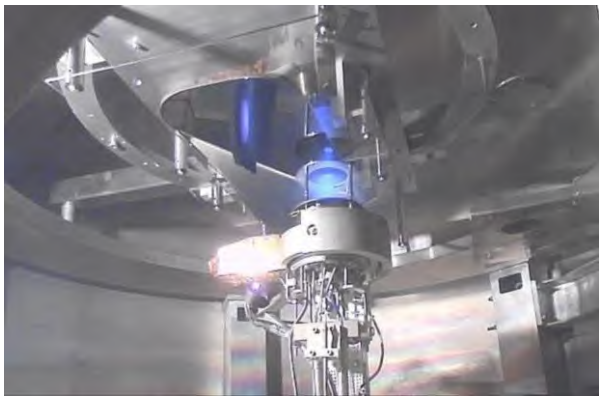

Figure 23 FFO in the ion beam figuring step

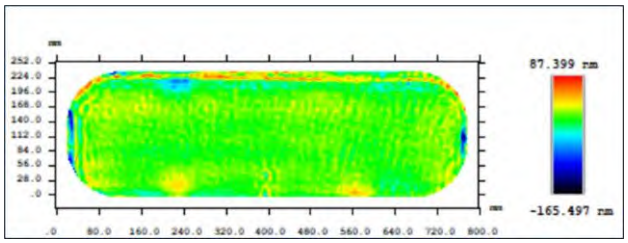

Figure 24 Final surface form error

6. Conclusion

The final state of the mirror demonstrator is shown in Figure 1. It can be concluded that this demanding free-form optic mirror could be designed to compliance wrt the demanding requirements wrt quasi static loads, mass and especially surface form error requirements wrt gravitational and thermal loads. This was possible by developing and applying analyses and optimization methods to derive a compliant mirror shape and utilizing the 3D printing capabilities.
The mass requirement of 8 kg could not be realized with the demonstrator as the required masking for the cladding could not be implemented.
Lapping and polishing were very demanding steps, especially due to the blank with a larger surface form error after cladding than expected. The resulting limited remaining cladding layer resulted in a non-compliance with respect to the original requirement of the clear aperture size. This needed to be reduced by 10 mm around the rim. Within this new relevant clear aperture however, polishing results were compliant and a surface form error of < 16 nm rms and a micro-roughness of 0.8 nm rms could be achieved.

ABSTRACT

Ceramic materials offer outstanding specific stiffness and thermo-elastic stability, making them attractive for next-generation high-performance optical space systems. To utilise these advantages, OHB and Schunk Technical Ceramics have established a comprehensive development roadmap based on 3D printed reaction-bonded silicon carbide like IntrinSiC®.

The roadmap covers material characterization, manufacturing process optimization, design methodologies, and analysis approaches tailored to the requirements of brittle ceramic structures. Advanced design workflows, including topology and parameter optimization, have been applied to fully utilize the freedom offered by additive manufacturing.

Development activities progressed from a representative ceramic optical bench and small-scale mirror demonstrators to lightweight mirrors up to 1.55m diameter, including free-form and aspherical optics. Structural qualification culminated in successful vibration and shock testing of a 1.55m SiC mirror assembly.

The latest milestone is a Ceramic Optical System integrating multiple ceramic mirrors, a mirror bracket, and an optical bench, aiming to demonstrate system-level assembly, environmental qualification, and thermo-elastic stability verification for future optical space missions.

1. INTRODUCTION

Over the past decades, OHB has established a strong heritage in the development of high-performance optical payloads for Earth observation applications, including optical subsystems and payload developments for missions such as EnMAP, MTG, Euclid, FLEX, FORUM, and other advanced European space programs.
As mission requirements continue to evolve toward larger apertures, higher spatial resolution, improved radiometric performance, and increased measurement stability, conventional material solutions increasingly become a limiting factor. In response, OHB identified all-ceramic optical systems, particularly based on silicon carbide (SiC), as a key enabling technology for future high-performance optical satellites. The primary drivers are the exceptionally high specific stiffness of SiC, which minimizes gravity-release effects while enabling lightweight large-aperture mirrors, its superior thermal stability resulting from high thermal conductivity and low coefficient of thermal expansion, and eliminating hygroscopic materials such as CFRP, thereby avoiding moisture-release induced dimensional changes and alignment drifts in orbit. In addition, the possibility of manufacturing mirrors and structural elements from the same material simplifies the realization of highly stable all-ceramic optical assemblies.
Consequently, OHB established a dedicated ceramic optical systems roadmap in 2020 and has since continuously invested in an extensive research and development programme aimed at mastering the complete lifecycle of ceramic space optics, including the realization of large SiC mirrors and structures, complex optical components, ultra-stable optical systems, and the corresponding system-level design, integration, and verification capabilities through full-scale hardware demonstrators and representative environmental testing.

2. INTRINSIC® – 3D PRINTED SIC FOR SPACE

For the realization of the demonstrators presented in this work, OHB partnered with Schunk Technical Ceramics GmbH, who are providing the 3D-printed reaction-bonded silicon carbide (RBSiC) material IntrinSiC® [1]. Schunk was chosen following a comprehensive assessment of available suppliers and manufacturing technologies, considering material performance, industrial maturity, production capacity, quality processes, and long-term supply-chain reliability. Emphasis was also placed on establishing a robust European capability for large optical ceramic components.

IntrinSiC® is manufactured using an additive binder jetting manufacturing process combined with proven RBSiC infiltration technology. The process enables the production of lightweight, highly

integrated, and geometrically complex structures that would be difficult or impossible to realize using conventional manufacturing methods. Furthermore, Schunk provides access to an industrialized production environment with established quality assurance processes and serial-production experience from high-precision semiconductor and industrial applications.

From an optical payload perspective, RBSiC offers an attractive combination of high specific stiffness, low coefficient of thermal expansion, and high thermal conductivity, as illustrated in Figure 1. Additionally, RBSiC has the advantage of near-zero shrinkage in the infiltration process.

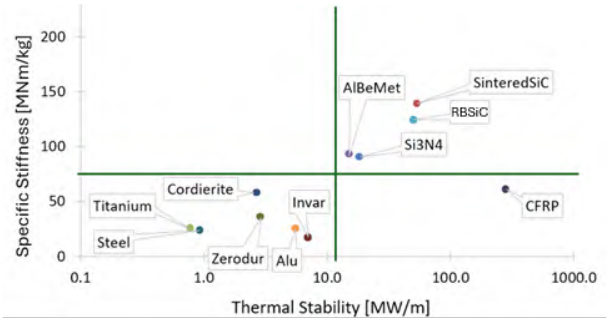

Figure 1 Specific stiffness and thermal stability

Beyond the technical benefits, the collaboration with Schunk provides an independent European supply chain from powder to finished product for advanced ceramic hardware.

3. CERAMIC ROADMAP DEVELOPMENT

The collaborative development between Schunk and OHB was kicked off with the development of a full-scale ceramic optical bench (COB) which was derived from representative requirements for optical systems of its size (Figure 2). The resulting topology optimized optical bench features a semi-closed design, incorporates through-holes and bonded inserts. The resulting design features a mass of 22.8 kg for the SiC part alone and a total mass of 88.4 kg when equipped with bipods, inserts, and four mass dummies representing subsystems mounted on the SiC structure. The first mode of the assembly is at 145 Hz.

Figure 2 ceramic optical bench after insert bonding

The assembly was successfully tested under sine and random vibration loads based on a QSL of 15 g in-plane and 25 g out-of-plane (Figure 3).

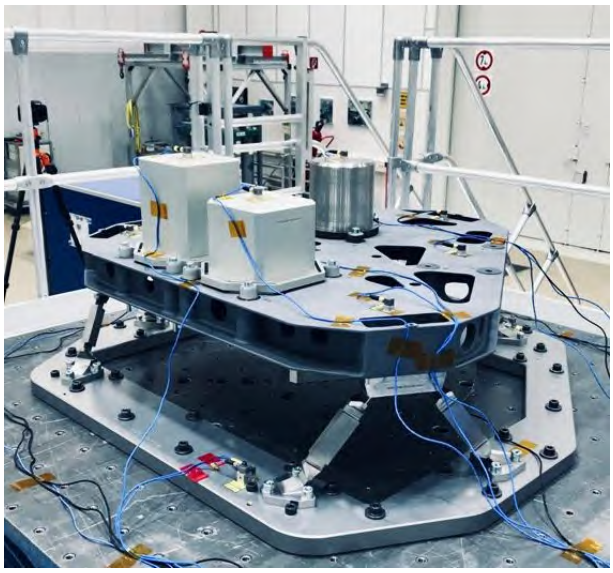

Figure 3 ceramic optical bench during vibration testing

Following the successful development, production, integration and testing of the Ceramic Optical Bench, a strategy was developed to mature the technology by upscaling demonstrator size and complexity of mirrors, mirror assemblies, structures and a full Ceramic Optical System (COS). The roadmap for the development of mirrors and mirror assemblies is shown in Figure 4.
Special emphasize was placed on the development of a green body joining technique, in which the additively manufactured green part is joined from individually printed sections before undergoing the infiltration process, resulting in a monolithic RBSiC part. Additionally, due to limitations of SiSiC / RBSiC with regard to the polishing of optical surfaces (see ch. 5.2), a cladding process was applied by Schunk Carbon Technologies GmbH in order to obtain a pure p60 SiC CVD layer suitable for optical polishing.

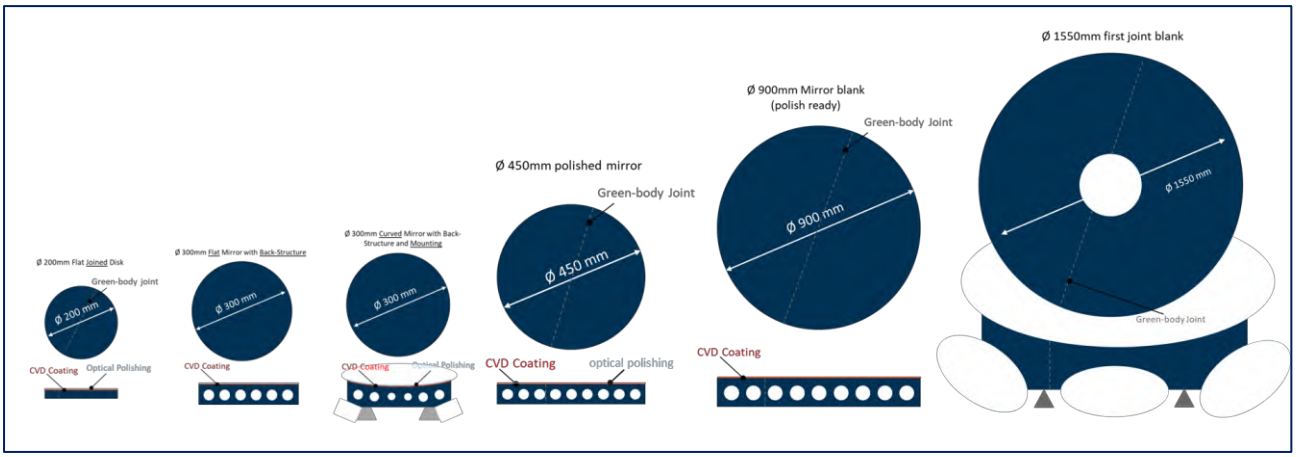

Figure 4 upscaling demonstrator size and complexity of mirror (assemblies)

The first optical component was a pair of Ø200 mm flat discs (Figure 5), one of which was produced with the green body joining technique. Both discs have been cladded with p60 SiC [2] and polished to an RMSt (total deviation) specified as better than 25 nm. These discs underwent unregular interferometric measurements to demonstrate stability following long-term storage, thermal vacuum cycling and damp heat testing.

Figure 5 Ø200 mm flat disc, SiC cladded and polished

The second mirror was a Ø300 mm flat mirror blank, the first mirror blank with a back structure (Figure 6).

Figure 6 Ø300 mm flat mirror blank in green state

The following step was a Ø300 curved mirror with a semi-closed back structure and a bipod bonding interface which is decoupled from the optical face of the mirror in order to avoid effects from curing shrinkage or moisture desorption effects of the adhesive (Figure 7). This mirror benefits from the design freedom possible when using the IntrinSiC® additive manufacturing process and has a competitive mass per optical area of 26.7 kg/m². This mirror blank underwent CVD SiC coating and was subsequently polished to an RMS < λ/4. After integration of INVAR bipods, the mirror assembly has a mass of 2.55 kg and a first eigenmode of 643 Hz. It was environmentally tested under thermal vacuum bake-out and cycling, sine and random vibration to 45g out-of-plane and 30g in-plane (Figure 8) and subjected to thermo-elastic deformation (TED) testing in OHB System AG's optical laboratory. These tests have been accompanied by interferometric SFE measurements before and after bipod bonding and after each environmental test (Figure 9). These measurements showed no deterioration of the optical properties of the mirror. The TED test demonstrated the high thermal stability through quick distribution of disturbances and fast return to initial SFE after application of temperature plateaus or gradients. [1)]

Figure 7 Ø300 mm curved mirror after firing

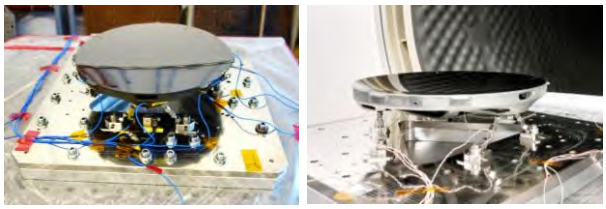

Figure 8 Ø300 mm curved mirror during vibration (left) and before TVAC testing (right)

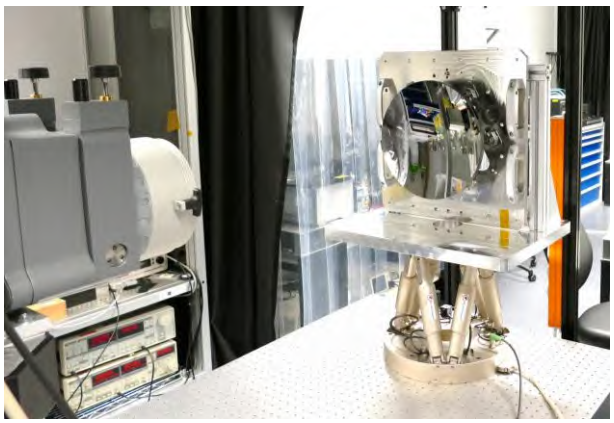

Figure 9 Ø300 mm curved mirror during SFE measurement

The next iteration in size is a Ø450 mm flat mirror which was RSiC coated and polished to specification (Figure 10). The mirror has a mass of 3.7 kg and a mass per optical area of 23.3 kg/m² and was produced with a largely closed back structure. The mirror has been produced from two parts and joined in the green state. The joining is not detectable on the optical surface after polishing.

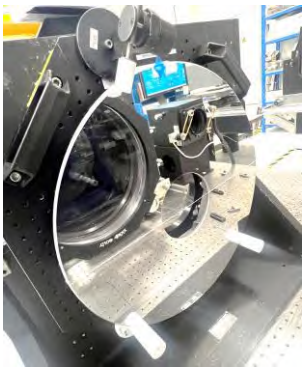

Figure 10 Ø450 mm flat mirror after polishing

Three Ø 900mm mirror blanks with a semi-closed back structure and an area mass of 22.8 kg /m² have been produced (Figure 11). These mirror blanks have been printed in three sections and joined in the green state. Fine grinding of the large curved optical face of the mirror has been applied in order to achieve a precise surface form already before cladding and polishing in order to minimize polishing times, which often drive the schedule for large mirrors. For this mirror, a thin p60 SiC CVD cladding layer was first applied to the full mirror blank and an additional layer for optical polishing applied to the optical surface only.
This mirror type has been used for the development of CT scanning know-how and for demonstrating the capability to perform proof testing on ceramic structures, see ch. 5.4.

Figure 11 Ø900 mm curved mirror blank after firing and grinding of interfaces

The largest element in the development is a Ø1550 mm curved mirror blank produced from three segments and joined in the green state. This IntrinSiC® mirror blank has been integrated with titanium isostatic mounts, which are thermally and mechanically decoupled from the ceramic structure (Figure 12Figure 12). The assembly possesses a first eigenfrequency of 144 Hz despite its large aperture, and a surface mass of only ~25.8 kg/m².
This mirror assembly has been vibration tested under sine and random loads at 15 g in-plane and out-of-plane (Figure 13) and shock tested to a representative level of 200 g SRS. [1)]

Figure 12 Ø1550 mm curved mirror blank after bipod integration

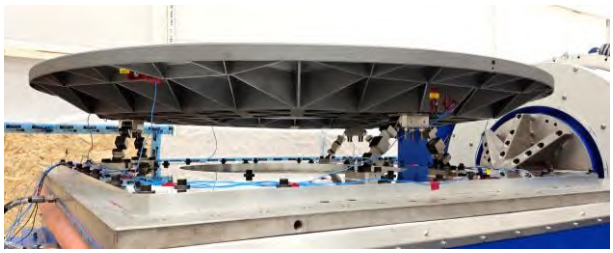

Figure 13 Ø1550 mm curved mirror assembly during vibration testing

4. CERAMIC OPTICAL SYSTEM [1)]

Moving from component to system level, an optical system was envisioned to demonstrate the potential of ultra-stability of full ceramic optical systems (Figure 14). The previously existing Ceramic Optical Bench and Ø300 mm curved mirror assembly serve as the basis for the optical system. As a second mirror with power, a convex folding mirror with integrated suspension and high slopes of ~50mrad (SICFoM, Figure 15) has been defined to meet the optical requirements in the limited envelope of the pre-existing Ceramic Optical Bench. Additionally, a bionic bracket made out of IntrinSiC® was developed to hold the Ø300 mm spherical mirror. The system is completed by a flat reference mirror made from IntrinSiC® which will be used as an absolute reference for positioning of the interferometer for repeated WFE measurements.

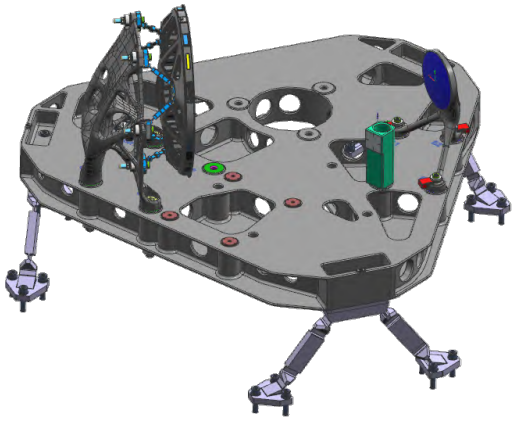

Figure 14 Sketch of the Ceramic Optical System

The design of this system was driven by the goal to achieve maximum optical stability through environmental testing. For this purpose, it is beneficial to reduce the number of non-ceramic parts and the number of interfaces. These requirements, along with the pre-defined interface points on the Ceramic Optical Bench, led to a demanding mechanical design and manufacturing of both the SICFoM and the bionic bracket for the Ø300 mm mirror. The high stiffness of the ceramic parts offers little compliance to interface tolerances, thus, tight tolerancing was defined for and achieved by Schunk, with a common zone better than 10 µm on both SICFoM and the corresponding interfaces on the Ceramic Optical Bench. The SICFoM was cladded all around with a layer of 600 µm before polishing to RMSi < λ/10. Polishing and optical measurement of this complex part required special care and tooling in order to accommodate the integrated design.

Figure 15 SICFoM after polishing

A different approach was taken for the bionic mounting bracket (Figure 16) of the Ø300 mm curved mirror. The topology optimized shape of the bracket and the pre-defined interface positions on the Ceramic Optical Bench drove the decision for a design allowing in-situ tolerance compensation during final integration on the Optical Bench, thereby compensating any tolerancing issues. The bracket weighs 2.5 kg and fully utilizes the capabilities of the ceramic 3D printing process.

Figure 16 Bionic mounting bracket for the Ø300 mm curved mirror

Finally, the reference mirror is the first IntrinSiC® part with p60 CVD SiC cladding which has been delivered by Schunk in the polished state, further strengthening the supply chain for optical space-grade mirrors. The mirror with a mass of 393 grams has been polished to RMSi < λ/10 with a 40/20 Scratch/Dig roughness on a clear aperture of 28mmx28mm (Figure 17). It features a hard-mounted SiC-SiC interface to the optical bench.

Figure 17 reference mirror and SICFoM test-fitted on the Ceramic Optical Bench

All parts of the Ceramic Optical System have been produced successfully and received by OHB System AG. The Ceramic Optical System is, as of summer 2026, in the integration and alignment phase. Once completed, a series of environmental and optical stability tests is planned:

- Repeated optical WFE measurements
- Bake-out and thermal vacuum cycling
- Vibration: sine and random
  15g in-plane, 25g out-of-plane
- Thermo-elastic testing

The goal of this testing is to demonstrate optical stability through-out representative environmental loads, to demonstrate different ceramic joining techniques and material combinations, and to correlate the analytical models used throughout the system design and analysis. Figure 18 shows a real-world mock-up of the COS.

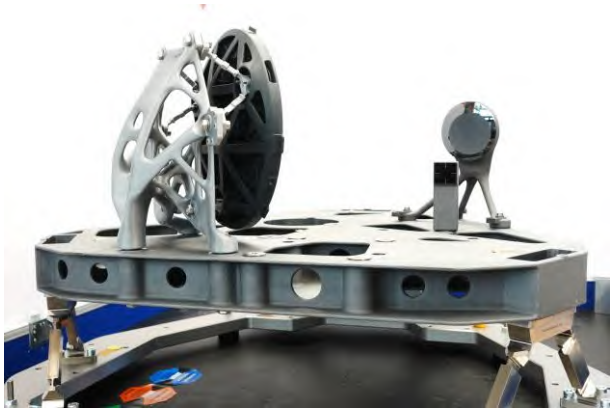

Figure 18 Mock-Up of Ceramic Optical System with as-built SICFoM and reference mirror; plastic mounting bracket and Ø300 mm curved mirror

5. MATERIAL QUALIFICATION AND CERAMIC PROCESS DEVELOPMENT

The ceramic roadmap is supported by a wide variety of material and process characterization methods. These include mechanical and optical properties testing, process optimization for the additive manufacturing, infiltration, machining, cladding and polishing processes. The following subchapters are providing a non-exhaustive selection of testing performed to support the ceramics development, gain a better understanding of material and processes characteristics, validating simulation models and building confidence in the applied technologies.

One area of development was the green body joining technology, in which sections of a larger part are joined in the green state and upon infiltration form a single, monolithic part. A focus of these activities was to demonstrate that the green body joint does not diminish the mechanical properties of the joined part as well as not impacting the optical properties of polished (mirror) parts.

5.1. Mechanical properties

For mechanical strength, bending samples (Figure 19) have been prepared and tested as-fired and grinded, with and without green body joint, and with and without CVD coating in a 4-point-bending (20/40) test according to DIN EN 843-1. A selection of samples underwent humidity and thermal cycling testing, which did not have a significant effect on the material properties, neither did the green body joint. Strength, elastic modulus and Weibull characteristics have been obtained for a statistical evaluation of the material parameters as used by OHB System AG for the development of their ceramic structures.

Figure 19 selection of tested 4-point-bending samples

5.2. Cladding and polishing

Since RBSiC possesses a soft silicon phase, directly polishing the ceramic material for high performance applications is not possible. To compensate for this, a pure SiC CVD cladding is applied by Schunk Carbon Technologies GmbH. This cladding has been qualified according to ECSS-Q-ST-70-17. The initial cladding samples underwent visual inspection, adhesion, cleanability, abrasion, Humidity, TVAC and SEM testing.

Polishability has been proven on full-scale demonstrators, accompanying polishing samples,

as well as dedicated polishing and long-term stability samples. For this purpose, two 200mm flat discs, one with a green body joint and one without, have been polished, subjected to thermal cycling, damp heat exposure, and extended storage duration with repeated WFE measurements in a controlled environment in order to demonstrate their long-term stability (Figure 20). Neither the coating nor the underlying green body joint of one of the discs showed a deterioration of the material or optical properties, supporting the feasibility of producing large space mirrors with the green body joining technology.

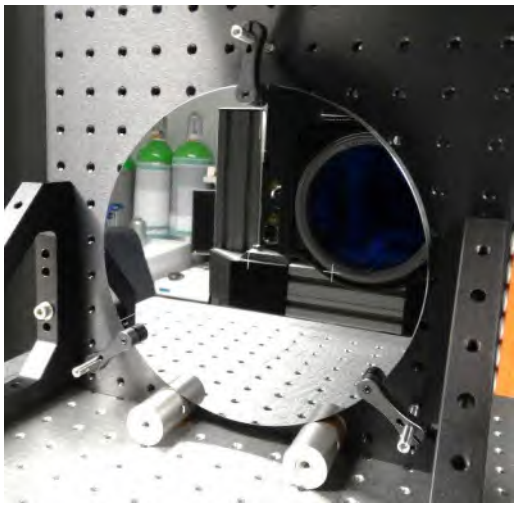

Figure 20 Ø200 mm flat disc, SiC cladded and polished, during SFE measurement

5.3. Joining and Interface Technologies

Interface and joining technology is of special interest for ceramic applications. In order to maximize the benefit of the high thermal stability of IntrinSiC® material, combinations with material of different CTE or thermal conductance shall be avoided. At the same time, (micro-) slippage effects on grinded interfaces, creeping or moisture desorption of adhesives shall be avoided.
To tackle these issues, several test campaigns on sample, part and system level have been conducted.
Pressure tests (Figure 21) have been conducted using typical material combinations like SiC-Aluminium, SiC-SiC, and SiC-Invar-SiC. The scope of the tests was to determinate the maximum compressive strength and, if applicable, the type of fracture failure of different bolted SiC sample assemblies. It has been shown that none of the SiC samples failed under the bearing stress generated by a bolt and corresponding washer even when exceeding the yield strength of the bolt.

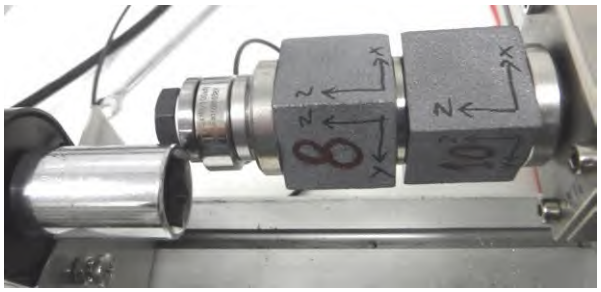

Figure 21 Exemplary bolt pressure test setup (SiC-Invar-SiC)

Standard equipment parts (tie-bases, thermistor dummies) have been bonded to rough as-fired surfaces using different types of typically used adhesives (Figure 22). Half of the bonded standard parts have been subjected to thermal vacuum cycling and damp heat. All artificially aged and reference samples withstood the forces specified in the “Pass” criterion under tensile testing (horizontal and vertical).

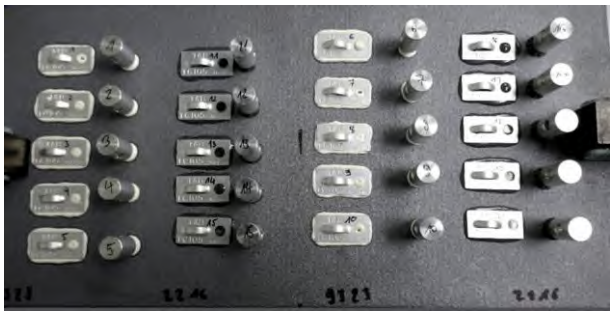

Figure 22 standard part samples after adhesive bonding

Shear and Tensile testing has been performed on adhesively bonded samples (Figure 23) with material combinations Ti6Al4V/CarSIK®-NT, Invar36/CarSIK®-NT, CarSIK®-NT/CarSIK®-NT and OHB standard structural adhesive EC9323-2 B/A. CarSIK®-NT is an isostatically pressed reaction-bonded SiC from Schunk with similar chemical composition as IntrinSiC®. From an adhesive bonding perspective, grinded bonding surfaces made from CarSIK®-NT are adequately comparable to bonding surfaces from grinded IntrinSiC®. All samples underwent a combination of bake-out, thermal vacuum cycling and damp heat.
Additionally, push-out tests have been performed on Invar36/CarSIK®-NT coupons with inserts bonded into a grinded through-hole, as it is typically used to provide threaded inserts in ceramic components (Figure 24).
A- and B-values have been determined from statistical evaluation of the test data and the resulting adhesive strength values have been flown into the development of ceramic parts and systems. The failure mode of all tested samples has been a combination of adhesive and cohesive failure in the adhesive.

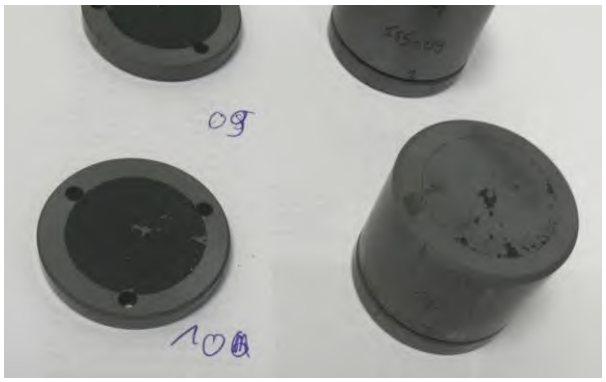

Figure 23 bonding sample after successful testing under shear loading

Figure 24 insert bonding sample after successful push-out testing

5.4. Non-destructive and proof testing

Proof testing has been identified as the most reliable verification technique, since screening of full parts (large samples) for small defects (relevant critical crack size) is challenging. A proof test setup has been developed exemplarily for the 900mm joined mirror (Figure 25), which allows applying static loads on-ground in a lab setting which generate stresses in the bulk material of comparable magnitude, location and shape of the stress field as in the relevant dynamic stress event, including margins. [3]
A benefit of the proof testing approach is the ability to apply relevant test loads and detect potential flaws in the material before integration of structural mounts (thus, the ability to perform vibration testing) and before entering a long and expensive polishing campaign, which is often the schedule driver for large space mirrors.

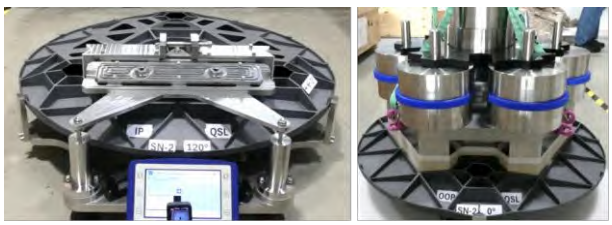

Figure 25 900mm demonstrator - IP (left) and OOP (right) proof test

CT scanning has been performed in critical areas before and after proof testing with support from Comet Technologies Germany GmbH. The non-destructive investigation using CT scanning showed no signs of deterioration from the proof test.

5.5. Supporting process and technology developments

Further investigations have been performed to cover Weibull statistics, CTE characterization, microstructure samples, fracture toughness, hardness, (fine) grinding of large free-form surface, cleaning processes on rough as-fired surfaces for optical-grade clean room conditions and bonding of heaters to as-fired surfaces of different roughness.
All derived values have been implemented in the design and analysis of ceramic parts and systems and successfully proven in environmental testing under representative loads on the respective specimen.

6. OUTLOOK AND CONCLUSION

Over the past five years, OHB System AG and Schunk Ingenieurkeramik GmbH have systematically matured ceramic optical technologies for space utilization from material characterization and process development to large-scale hardware demonstrators and a complete optical system. The performed activities demonstrate the feasibility of additively manufactured RBSiC structures and optics, including large mirror assemblies up to 1.55 m diameter, advanced optical components, and a ceramic optical system of representative size which will be tested under relevant environmental conditions.

The results confirm the suitability of the chosen processes and designs for future high-performance optical payloads requiring large apertures, low mass, and outstanding thermo-mechanical stability. In parallel, a strong industrial partnership with Schunk has established a scalable European capability covering the complete value chain from raw material production, additive manufacturing, cladding and polishing to optical system integration and verification.

The achieved technology maturity provides a solid basis for the application of ceramic optical systems in future Earth observation, science, and security missions, supporting the realization of increasingly large, lightweight, and ultra-stable spaceborne optical instruments.

7. ACKNOWLEDGEMENT

[1)] Schunk Technical Ceramics GmbH and OHB System AG received a partial funding from the German Aerospace Center for the collaborative development of the ceramic optical system, integration and testing of the 300mm curved mirror, and the integration and testing of the 1550mm mirror activities through the project "KeOpS - Keramische Optische Systeme - Teilvorhaben:

System Design, Analyse und Verifikation"; Förderkennzeichen: 50RK2403A

SiC parts have been produced by Schunk Ingenieurkeramik GmbH. Coating and Cladding activities have been performed by Schunk Carbon Technology GmbH. Polishing has been performed by AMOS s.a., Carl Zeiss Jena GmbH, Schunk Ingenieurkeramik GmbH. RSiC coating and polishing was performed by Safran Reosc.

Testing of demonstrators has been performed in-house at OHB System AG, Industrieanlagen-Betriebsgesellschaft mbH and ZARM Technik AG. CT scanning was performed by Comet Technologies Germany GmbH.

Continuous Fiber Additive Manufacturing; Void Structure Analysis; Process–Structure Relationship; Process Qualification; Thermoplastic Composites; Space Structures; Analytical Modelling

ABSTRACT

Continuous fiber-reinforced additive manufacturing (CF-AM) offers considerable potential for lightweight space structures by enabling high material efficiency, geometric flexibility, and functional integration. However, manufacturing-induced voids remain a critical challenge, as they directly influence structural performance and complicate process qualification. This paper presents the application of a methodology for the systematic characterization and prediction of void structures in continuous fiber-reinforced thermoplastic filaments. The methodology combines void subtype classification, image-based characterization, statistical regression, and physics-based analytical modelling to establish transferable process–structure relationships. Experimental investigations were conducted under controlled variations of key impregnation parameters to generate characteristic void morphologies. Regression analysis, together with physically based descriptors such as the modified capillary number and normalized impregnation depth, was used to identify the governing mechanisms of void formation and validate the predictive capability of the proposed framework. The results demonstrate that the methodology provides a defect-oriented assessment beyond conventional void content analysis, enabling a deeper understanding of process-dependent defect evolution. By linking manufacturing conditions to void subtype formation, the proposed approach supports qualification-oriented process development and contributes to the reliable implementation of continuous fiber-reinforced additive manufacturing for future space structures.

1. INTRODUCTION

Continuous fiber-reinforced additive manufacturing (CF-AM) has emerged as a promising manufacturing approach for lightweight composite structures requiring high specific stiffness, functional integration, and geometric design freedom [1-7]. Compared with conventional laminate manufacturing, CF-AM enables the near-net-shape fabrication of complex geometries while reducing material waste and manufacturing effort [5,6]. These capabilities make the technology particularly attractive for future space structures, where stringent mass limitations, structural reliability, and qualification-oriented manufacturing are key design requirements.

Despite these advantages, the qualification of continuous fiber-reinforced additively manufactured components remains a major challenge [8-10]. Unlike conventional composite manufacturing, CF-AM combines filament production, impregnation, consolidation, and deposition into a highly coupled process chain. As a result, manufacturing-induced defects may accumulate throughout the process and significantly influence the final material quality and structural performance.

Among these defects, voids represent one of the most critical quality characteristics [1,3,7]. Numerous studies have demonstrated their detrimental influence on interlaminar strength, fatigue resistance, thermal conductivity, and long-term durability [1-4]. For space applications, these effects become even more significant due to demanding environmental conditions such as thermal cycling, vacuum exposure, radiation, and extended mission lifetimes. Consequently, qualification strategies require a comprehensive understanding of defect formation mechanisms rather than relying solely on global quality indicators.

Most existing studies evaluate manufacturing quality using the overall void content as the primary quality metric [1-5,7]. Although this parameter provides a general assessment of material quality, it neglects differences in void morphology, spatial distribution, and formation mechanisms. Consequently, similar global void fractions may result from fundamentally different manufacturing conditions and therefore cannot adequately explain variations in structural performance or identify the governing process parameters responsible for defect formation.

To overcome these limitations, a methodology for the differentiated characterization and analytical

description of void structures has been developed. The methodology combines systematic void subtype classification, image-based characterization, statistical regression, and physics-based analytical modelling to establish direct process–structure relationships and enable a mechanistic interpretation of void formation.
This paper presents the application of the proposed methodology to continuous fiber-reinforced thermoplastic filament systems with particular emphasis on its relevance for qualification-oriented manufacturing of space composite structures. Rather than introducing another defect characterization technique, the work demonstrates how defect-specific analysis can be used to identify governing process parameters, validate analytical models, and support reliable manufacturing and future qualification strategies for continuous fiber-reinforced additive manufacturing.

2. METHODOLOGY

2.1 Concept of the Methodology

Conventional quality assessment of continuous fiber-reinforced thermoplastic composites is predominantly based on the determination of the global void content. Although this parameter provides a quantitative measure of manufacturing quality, it does not differentiate between void morphologies, spatial distributions, or formation mechanisms. Consequently, comparable global void fractions may result from fundamentally different manufacturing conditions and cannot adequately describe the resulting material quality.
To address this limitation, a methodology for defect-oriented void characterization is proposed. Instead of treating voids as a homogeneous defect population, individual voids are classified according to their geometry, location within the composite architecture, and presumed formation mechanism. This differentiation enables defect-specific evaluation and establishes direct relationships between manufacturing conditions and characteristic void populations.
The methodology comprises four consecutive stages. First, representative filament cross-sections are prepared using standardized metallographic procedures. Subsequently, high-resolution optical microscopy and automated image processing are employed to detect and segment individual voids [11]. The segmented defects are then assigned to predefined void subtypes before subtype-specific statistical evaluation is performed. Finally, the experimental results are combined with regression analysis and physics-based analytical modelling to identify the governing mechanisms of void formation and establish transferable process–structure relationships.
In contrast to conventional empirical process optimization, the proposed methodology links experimental observations with physically interpretable descriptors. This enables a generalized assessment of impregnation quality that is largely independent of a specific machine configuration and therefore transferable to different material systems and manufacturing platforms.

2.2 Experimental Application

The proposed methodology was applied to continuous fiber-reinforced thermoplastic filaments manufactured under controlled laboratory conditions using the experimental setup shown in Figure 1. The manufacturing system enables controlled variation of the principal impregnation parameters while ensuring reproducible processing conditions throughout the experimental campaign.

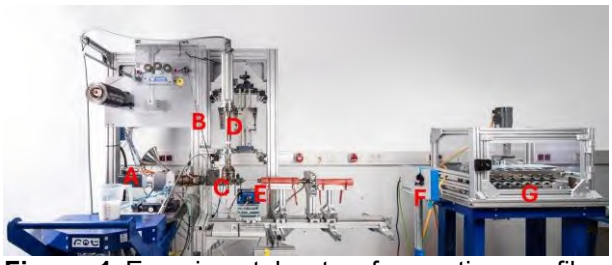

Figure 1 Experimental setup for continuous fiber filament manufacturing: (A) extruder, (B) fiber feed, (C) co-extrusion die, (D) ultrasonic transducer, (E) nozzle module, (F) inline measurement, (G) haul-off.

The experimental programme was designed to generate reproducible variations in impregnation quality while maintaining all remaining boundary conditions constant. Using the manufacturing system shown in Figure 1, processing temperature, consolidation pressure, fiber transport velocity, and ultrasonic excitation were systematically varied to investigate their influence on resin impregnation and void formation. The selected parameter combinations ensured stable manufacturing while generating representative void structures for subsequent analysis.
Following filament production, representative specimens were embedded, polished, and prepared for optical microscopy using a standardized preparation procedure.
The acquired micrographs formed the basis for the subsequent image analysis and void subtype classification. Each detected void was assigned to a predefined subtype prior to statistical evaluation, providing the experimental dataset required for the regression analyses and the validation of the analytical framework presented in the following sections.

3. APPLICATION OF THE METHODOLOGY

3.1 Void Subtype Identification

The application of the proposed methodology begins with the identification and classification of void structures generated during continuous fiber filament manufacturing. In contrast to conventional quality assessment based solely on the global void

fraction, the presented approach differentiates individual void populations according to their morphology, spatial location, and underlying formation mechanisms. This defect-oriented perspective enables a substantially more detailed interpretation of the manufacturing process and establishes the foundation for subsequent analytical evaluation.

Representative filament cross-sections were prepared following standardized preparation procedures and analysed using high-resolution optical microscopy. Automated image processing was subsequently employed to segment fibers, matrix, and void regions before individual defects were assigned to predefined void subtypes according to their geometric characteristics and position within the composite architecture, as illustrated in Figure 2. The classification procedure ensures objective and reproducible identification of defect populations while minimizing operator-dependent influences.

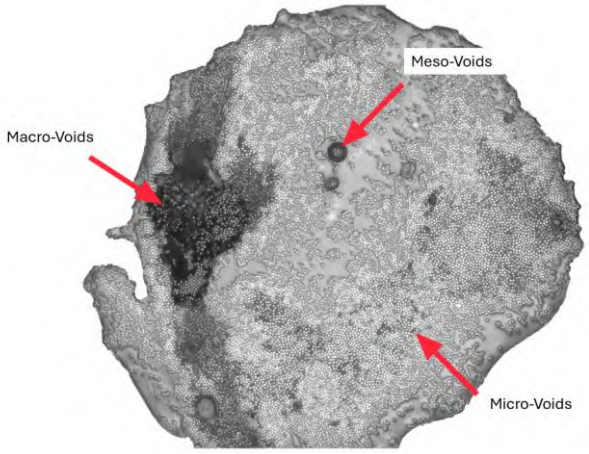

Figure 2 Classification of characteristic void subtypes.

The resulting subtype distributions reveal that comparable global void fractions may originate from fundamentally different manufacturing conditions. While the total void content provides a general indication of material quality, it does not distinguish between voids caused by insufficient fiber impregnation, incomplete consolidation, or local resin flow instabilities. Consequently, identical global quality indicators may represent considerably different defect mechanisms and therefore different implications for structural performance.

Representative examples of filament cross-sections with different impregnation qualities are shown in Figure 3. While homogeneous fiber distribution results in only small isolated voids, insufficient impregnation leads to non-uniform fiber distribution and the formation of pronounced dry regions within the fiber bundle.

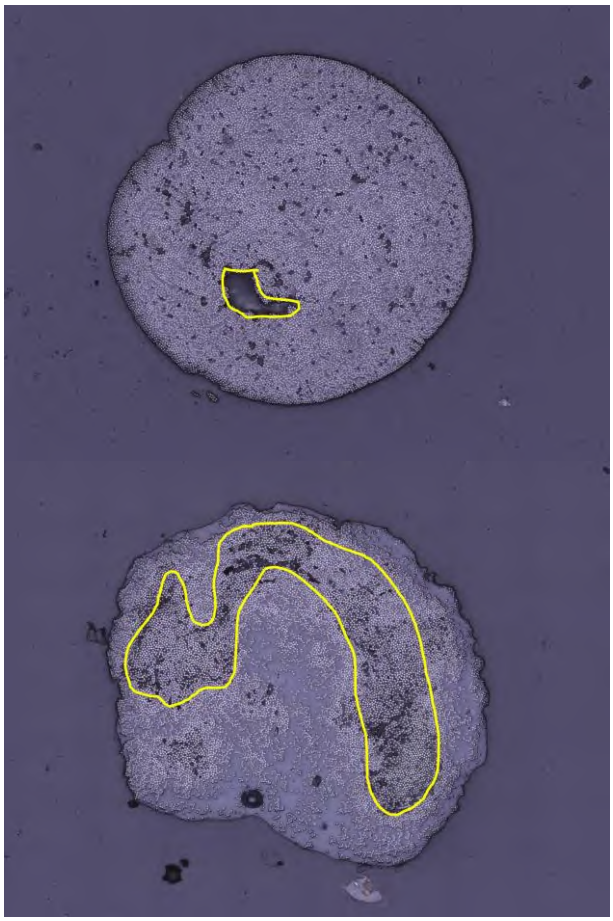

Figure 3 Representative filament cross-sections showing homogeneous (top) and insufficient (bottom) impregnation.

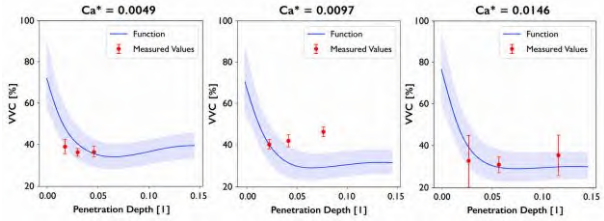
The proposed classification preserves this defect-specific information and enables a mechanistic interpretation of void formation. Instead of reducing manufacturing quality to a single scalar quantity, the defect population is transformed into a multidimensional dataset that forms the basis for statistical evaluation, analytical modelling, and process-specific interpretation.

3.2 Quantitative Image Analysis



Following classification, each void subtype was quantitatively characterised using automated image analysis. Besides the number of voids, additional geometric descriptors including equivalent diameter, projected area, aspect ratio, and spatial distribution were determined for every manufacturing condition. This comprehensive characterization provides substantially more information than conventional void content measurements and enables a detailed comparison between different processing conditions.

To ensure statistical robustness, multiple cross-sections were evaluated for every experimental configuration, resulting in datasets comprising several thousand individual void objects. Rather than averaging all defects into a single quality parameter, subtype-specific distributions were analysed independently. This approach enables characteristic process signatures to be identified

and significantly improves the sensitivity of the evaluation.
The quantitative analysis demonstrates that manufacturing parameters affect individual void populations differently. Whereas certain parameter variations primarily influence intra-bundle impregnation defects, others predominantly affect voids located at the fiber–matrix interface or within matrix-rich regions. These observations indicate that void formation is governed by multiple interacting physical mechanisms rather than a single dominant process.
The resulting datasets provide the experimental basis for establishing statistically robust process–structure relationships. In the next step, subtype-specific regression analyses are performed to quantify the influence of individual manufacturing parameters on the observed void populations.

3.3 Statistical Correlation of Process Parameters

The quantified void subtype distributions were subsequently correlated with the investigated manufacturing parameters to identify the dominant mechanisms governing void formation. Rather than establishing empirical relationships for the overall void content, regression analyses were performed separately for each void subtype [12]. This defect-specific evaluation enables individual process influences to be distinguished and significantly improves the interpretability of the resulting models.
The statistical analysis revealed that the investigated process parameters exhibit markedly different sensitivities depending on the respective void subtype. Consolidation pressure predominantly influences inter-fiber impregnation by enhancing polymer infiltration into the fiber bundle, resulting in a significant reduction of impregnation-related voids. In contrast, processing temperature primarily affects resin viscosity and flow behaviour, thereby influencing matrix-associated defects generated during consolidation. Fiber transport velocity controls the available impregnation time and consequently governs the development of characteristic void morphologies throughout the manufacturing process. Representative regression models are shown in Figure 4.

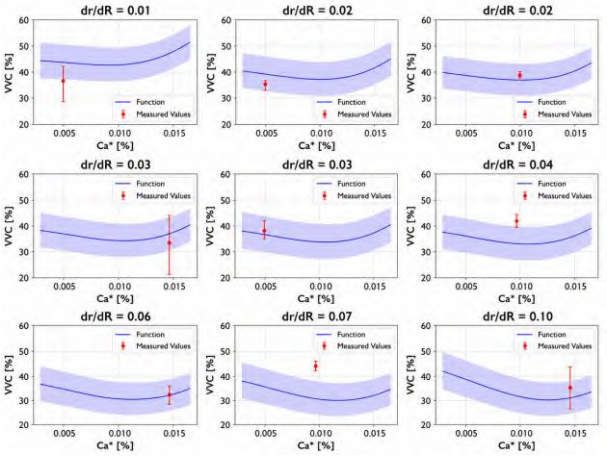


Figure 4 Regression models for predicting characteristic void subtype distributions.

The independent evaluation of individual void populations demonstrates that void formation cannot be attributed to a single governing process parameter. Instead, the observed defect structures result from the interaction of multiple transport, wetting, and consolidation mechanisms acting simultaneously during filament production. This observation explains why manufacturing conditions producing comparable global void fractions may nevertheless exhibit substantially different defect morphologies and, consequently, different structural properties.
Compared with conventional quality assessment based solely on the overall void content, the subtype-specific regression approach considerably increases the sensitivity of process evaluation. Parameter interactions that remain concealed within global quality indicators become directly identifiable when analysed on the level of individual defect populations. The statistical framework therefore enables process signatures to be extracted from the experimental data and provides a quantitative basis for interpreting defect evolution.
Beyond the statistical significance of individual parameter correlations, the regression models provide the experimental foundation for the analytical framework introduced in the following section. While regression analysis identifies which manufacturing parameters govern individual void populations, it does not explain why these relationships exist. Addressing this limitation requires a physics-based description of the impregnation process, allowing the experimentally observed correlations to be interpreted in terms of the governing flow and wetting mechanisms.

3.4 Analytical Prediction of Void Formation

Although the regression models presented in the previous section provide accurate predictions within the investigated process window, their applicability remains limited to the experimentally observed parameter space. To extend the methodology beyond empirical correlations, a physics-based analytical framework was developed that describes

the governing mechanisms of resin impregnation and void formation.
The analytical approach is based on the interaction between viscous resin flow, capillary forces, impregnation time, and the permeability of the continuous fiber bundle [13-15]. Instead of interpreting manufacturing behaviour solely through machine-specific parameters such as processing temperature, consolidation pressure, or fiber transport velocity, these influences are transformed into physically meaningful descriptors that characterize the impregnation process independently of a particular manufacturing system. The relationship between statistical regression and the analytical framework is illustrated in Figure 5. While regression analysis identifies statistically significant process influences, the analytical model provides a physics-based interpretation of the governing impregnation mechanisms and enables the prediction of void subtype formation beyond the investigated experimental conditions.

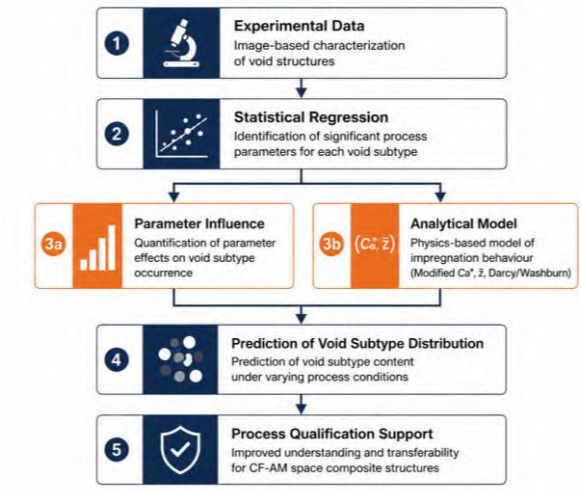

Figure 5 Combined statistical and analytical framework for void prediction.

A central element of the analytical framework is the modified capillary number, which represents the balance between viscous flow and capillary forces during resin infiltration [13-15]. Together with the normalized impregnation depth, describing the penetration of the polymer melt into the fiber bundle, these dimensionless parameters provide a unified representation of the governing impregnation mechanisms [13-15]. Consequently, manufacturing conditions that differ in machine settings or material combinations can be evaluated within the same physical framework.
The calculated analytical descriptors were correlated with the experimentally determined void subtype distributions. The results demonstrate that process conditions exhibiting comparable analytical characteristics also generate similar defect populations, despite differences in the individual manufacturing parameters. Compared with purely empirical regression models, the analytical framework therefore provides a substantially improved physical interpretation of the observed defect evolution.
The transformation from machine-specific process parameters to dimensionless physical descriptors represents one of the principal contributions of the proposed methodology. Rather than describing manufacturing behaviour exclusively through experimental observations, the approach establishes a mechanistic relationship between impregnation physics and defect formation. This significantly improves the transferability of manufacturing knowledge across different equipment configurations, material systems, and processing conditions.
By combining statistical regression with analytical modelling, the methodology links experimental observations with the underlying physical mechanisms governing void formation. While regression analysis identifies which process parameters influence individual void populations, the analytical framework explains why these relationships occur. The resulting combination provides a predictive basis for process optimisation and qualification-oriented manufacturing of continuous fiber-reinforced thermoplastic composites.

3.5 Validation of the Methodology

The predictive capability of the proposed methodology was evaluated by comparing analytically derived process descriptors with experimentally determined void subtype distributions obtained under different manufacturing conditions and material configurations. Rather than validating individual regression models alone, the objective was to assess whether the combined statistical and analytical framework consistently captures the governing mechanisms of void formation.
For each experimental configuration, the analytical descriptors were calculated from the measured manufacturing parameters and compared with the corresponding void subtype distributions obtained from microscopic image analysis. The comparison between measured and regression-predicted total void contents for the PPS/AS7 material system is presented in Figure 6. Overall, a good agreement between predicted and experimentally observed defect characteristics was achieved, demonstrating that the proposed framework adequately represents the dominant impregnation mechanisms responsible for void evolution.

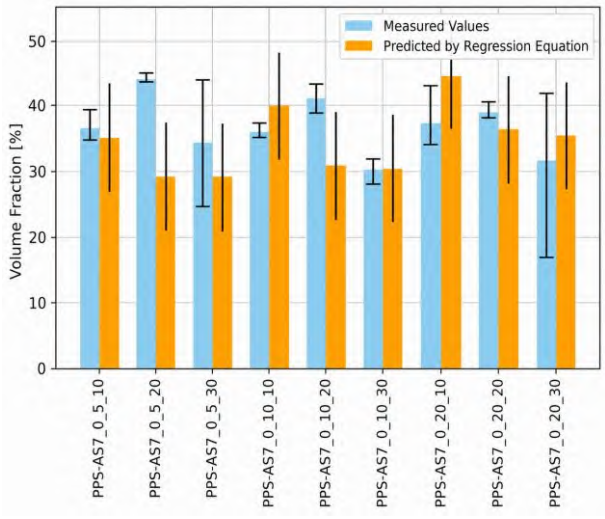

Figure 6 Comparison of measured and regression-predicted total void content (VVC) for PPS/AS7 filaments under different processing conditions. Error bars represent the experimental standard deviation (measured values) and the regression model uncertainty (RMSE) (predicted values). Sample names follow the format: polymer–fibre–ultrasonic influence – fibre velocity (mm s^{-1}) – impregnation pressure (bar).

4. APPLICATION OF THE METHODOLOGY TO SPACE STRUCTURES

4.1 Relevance of Void Characterization for Space Structures

Continuous fiber-reinforced thermoplastic composites are increasingly being considered for lightweight structural components in satellites, launch vehicles, and spaceborne support structures due to their high specific stiffness, corrosion resistance, and potential for functional integration [8-10]. In combination with additive manufacturing, these materials offer new design opportunities by enabling near-net-shape fabrication of highly integrated components while reducing manufacturing waste and assembly effort.

Despite these advantages, qualification remains one of the principal barriers to the adoption of continuous fiber-reinforced additive manufacturing for space applications [8-10]. Unlike conventionally manufactured composite laminates, the mechanical performance of additively manufactured structures is strongly influenced by process-dependent microstructural features generated throughout the manufacturing chain. Consequently, reproducible manufacturing quality is a prerequisite for reliable structural performance.

Among the various manufacturing-induced defects, voids represent one of the most critical microstructural features because they influence not only static strength but also fatigue behaviour, thermal conductivity, damage tolerance, and long-term durability [1-4]. Under representative space environmental conditions—including thermal cycling, vacuum exposure, and extended mission durations—localized defects may act as initiation sites for progressive degradation and premature structural failure [8-10].

Conventional qualification strategies therefore require more than the determination of the global void fraction. A detailed understanding of defect morphology, spatial distribution, and formation mechanisms is required to evaluate the relationship between manufacturing conditions and structural reliability. The methodology presented in this work addresses this requirement by linking characteristic void populations directly to the governing impregnation mechanisms and associated manufacturing parameters.

Rather than serving exclusively as a post-process inspection method, the proposed framework enables defect-informed process evaluation and supports qualification-oriented manufacturing by providing a physically interpretable description of defect formation. Figure 7 summarizes how the methodology links manufacturing parameters with defect evolution, local material properties, structural performance, and ultimately process qualification.

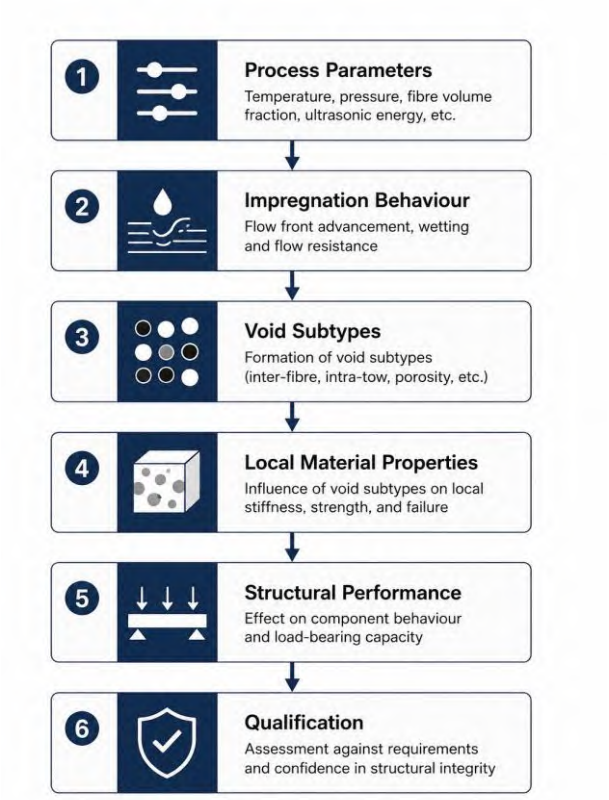

Figure 7 Process–structure–qualification framework of the proposed methodology.

4.2 Contribution to Process Qualification

The principal contribution of the proposed methodology lies in its ability to transform experimentally observed defect populations into transferable manufacturing knowledge. Instead of evaluating composite quality only after production, the methodology establishes quantitative relationships between manufacturing parameters,

impregnation behaviour, and resulting void subtype distributions. This enables process conditions to be assessed according to their expected influence on structural quality before extensive experimental validation is performed.

Within qualification campaigns, this information facilitates the identification of stable manufacturing windows by distinguishing parameter variations that primarily generate non-critical defect populations from those promoting structurally relevant void mechanisms. Consequently, process optimisation can focus on the physical origin of manufacturing defects rather than on global quality indicators alone.

An additional advantage is the use of dimensionless analytical descriptors describing the governing impregnation mechanisms independently of a particular manufacturing platform. Since these descriptors retain their physical interpretation across different equipment configurations and material systems, manufacturing knowledge generated during process development can be transferred more efficiently to future production environments.

Although application-specific validation remains necessary for each qualified component, the presented methodology significantly reduces the experimental effort required during process optimisation. The framework therefore represents a valuable tool for qualification-oriented manufacturing development, where reproducibility, traceability, and process understanding are essential requirements.

4.3 Transferability to Future Space Manufacturing

Although the methodology has been developed using continuous fiber-reinforced thermoplastic filament manufacturing, its underlying concept is not restricted to the investigated process. Because the analytical framework is derived from fundamental impregnation mechanisms and validated through statistically robust defect characterization, the methodology can be transferred to other continuous fiber manufacturing technologies with only minor adaptations.

Potential application fields include automated fiber placement with in-situ consolidation, robotic continuous fiber deposition, hybrid additive manufacturing processes [5-7], and future in-space manufacturing concepts, where process robustness and resource efficiency are expected to become key enabling technologies [8-10].

Beyond the investigated manufacturing process, the proposed methodology establishes a general framework for linking manufacturing conditions with microstructural defect evolution and resulting material quality. This systematic process–structure description provides a suitable basis for future digital qualification workflows combining experimental characterization, analytical modelling, numerical simulation, and process monitoring. The envisioned development pathway of the methodology towards predictive and qualification-oriented manufacturing is illustrated in Figure 8.

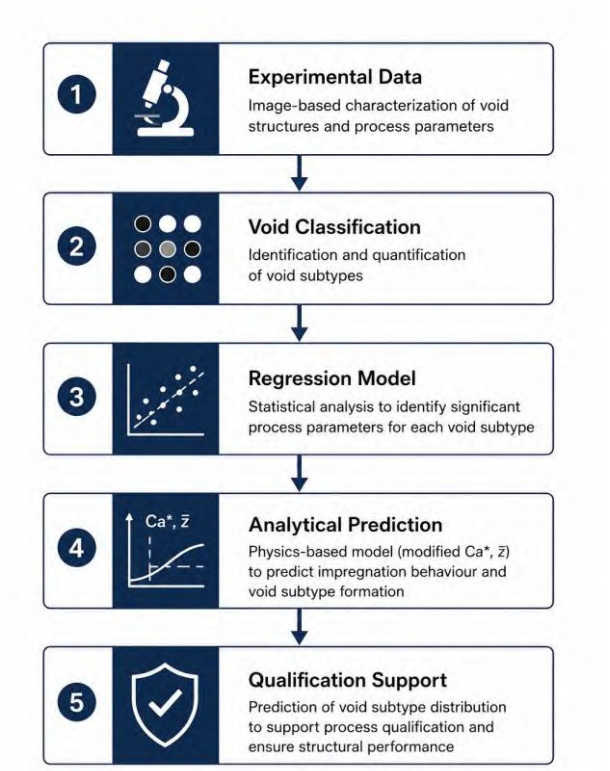

Figure 8 Roadmap towards predictive and qualification-oriented manufacturing of continuous fiber-reinforced composite structures.

Future developments should therefore focus on integrating the methodology with non-destructive evaluation techniques, in-situ monitoring systems, and digital twin concepts. Combined with representative environmental testing under space conditions, these extensions have the potential to establish qualification-oriented manufacturing strategies for continuous fiber-reinforced composite structures used in future space missions.

5. DISCUSSION

The results presented in this work demonstrate that a defect-oriented evaluation of void structures provides substantially more information than conventional quality assessment based solely on the global void fraction [5,6]. By differentiating individual void subtypes and relating them to their governing formation mechanisms, the proposed framework enables manufacturing quality to be interpreted on the basis of process physics rather than empirical quality indicators. This represents a fundamental shift from retrospective defect assessment towards process-oriented quality evaluation.

A key outcome of the investigation is that manufacturing conditions exhibiting comparable global void fractions may generate fundamentally different defect populations. Consequently, identical

global quality indicators cannot be assumed to represent equivalent structural behaviour. The presented methodology addresses this limitation by preserving defect-specific information throughout the evaluation process and establishing direct process–structure relationships between manufacturing conditions and characteristic void morphologies.

Another important contribution is the integration of experimental characterization with statistical evaluation and physics-based analytical modelling. Whereas regression analysis identifies statistically significant relationships between manufacturing parameters and void subtype distributions, the analytical framework provides a mechanistic explanation of the governing impregnation processes. The combination of both approaches extends the applicability of the methodology beyond empirical parameter optimisation and establishes a transferable framework that is largely independent of a specific manufacturing platform.

From a manufacturing perspective, this considerably improves process development by enabling manufacturing knowledge to be transferred between different equipment configurations, material systems, and processing conditions. Instead of generating isolated empirical datasets for individual manufacturing setups, the proposed framework provides generalized process descriptors that retain their physical interpretation across different applications.

For qualification-oriented manufacturing of space structures, this capability is particularly relevant. Future qualification concepts require not only reproducible manufacturing quality but also traceable relationships between manufacturing conditions, defect evolution, and structural performance [8-10]. By combining systematic defect characterization with analytical process modelling, the proposed methodology contributes to the development of physically interpretable qualification strategies for continuous fiber-reinforced additive manufacturing.

Nevertheless, several limitations should be considered. The present investigation is based on laboratory-scale continuous fiber-reinforced thermoplastic filament manufacturing and therefore represents a controlled manufacturing environment. Although the analytical concepts are transferable, additional validation is required for complete additively manufactured components, alternative impregnation technologies, and different thermoplastic material systems. Furthermore, the methodology currently relies on post-process characterization and therefore does not yet provide real-time assessment of manufacturing quality.

The future development of the proposed methodology is summarized in Figure 9. Building upon the experimental and analytical framework presented in this work, future developments aim to integrate inline monitoring, digital twins, and predictive qualification concepts into a unified process qualification strategy.

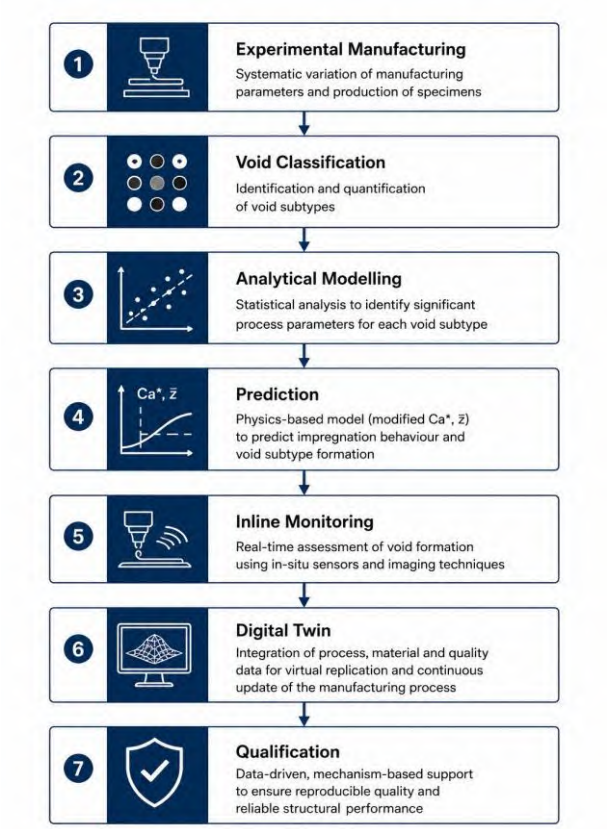

Figure 9 Future development roadmap of the proposed methodology towards predictive process qualification and digital manufacturing of continuous fiber-reinforced composite structures

Future research should therefore focus on extending the proposed framework towards in-situ process monitoring and digital qualification concepts. The integration of optical inspection systems, X-ray computed tomography, machine learning-assisted defect recognition, and process simulations has the potential to establish predictive quality assessment during manufacturing. Combined with digital twin approaches and representative environmental testing, these developments could significantly improve qualification methodologies for continuous fiber-reinforced composite structures used in future space missions.

6. CONCLUSIONS

This paper presented the application of a methodology for the differentiated characterization, analysis, and prediction of void structures in continuous fiber-reinforced thermoplastic composite filaments. By combining systematic void subtype classification with automated image analysis, statistical regression, and physics-based analytical modelling, the proposed framework establishes transferable process–structure relationships that extend beyond conventional void content evaluation.

The results demonstrate that defect-specific characterization provides significantly greater insight into manufacturing quality than global void fraction alone. Individual void subtypes were shown to respond differently to variations in processing conditions, allowing the governing impregnation mechanisms to be identified and interpreted within a unified analytical framework. The combination of statistical evaluation and physically based process descriptors therefore enables both quantitative prediction and mechanistic understanding of void formation.

From a manufacturing perspective, the proposed methodology transforms experimental observations into transferable process knowledge. The use of dimensionless analytical descriptors enables manufacturing behaviour to be compared across different material systems and equipment configurations, reducing the dependence on machine-specific empirical optimisation and supporting more efficient process development.

For qualification-oriented manufacturing of future space structures, the presented framework provides a structured approach for linking manufacturing parameters, defect evolution, and resulting material quality. Although further validation on complete components and under representative space environmental conditions is required, the methodology establishes an important foundation for predictive process qualification of continuous fiber-reinforced additive manufacturing.

Future work will focus on extending the framework towards complete additively manufactured structures, integrating non-destructive inspection techniques and inline process monitoring, and coupling the methodology with digital twins and qualification workflows. These developments have the potential to enable data-driven, physics-based qualification strategies for next-generation lightweight composite structures in space applications.

compliant mechanisms, flexure blades, additive manufacturing (LPBF), warpage compensation

ABSTRACT

Metallic Additive Manufacturing (AM) has opened new possibilities for compliant mechanisms by enabling compact monolithic architectures combining rigid and flexible regions [1], [2]. Over the last decade, several mechanisms developed at CSEM demonstrated the benefits of Laser Powder Bed Fusion (LPBF) for space applications, including reduced lead time, functional integration and highly optimized compliant structures [3], [4], [5] & [6]. Nevertheless, the dimensional accuracy achieved by LPBF remains a significant limitation for high-precision compliant systems. In particular, thin flexure blades are highly sensitive to residual stresses generated during the build process and subsequent thermal treatments, leading to distortions that directly affect guiding performances, stiffness and fatigue life. Previous developments revealed global distortions of 0.3 to 0.9 mm on rigid structures and up to 2 mm on flexure elements.

This paper presents an investigation of distortion prediction and compensation methods applied to a Compliant Roto-Translation Mechanism (CRTM). A workflow based on Simufact Additive process simulation is evaluated for the prediction of warpage, generation of compensated geometries and optimization of support strategies. The limitations of conventional pre-distortion methods for flexure-dominated structures are analysed. A hybrid methodology combining process simulation, stabilization concepts and scan-based mesh morphing is introduced. Initial validation using high-resolution 3D scanning shows a substantial improvement in dimensional conformity. The proposed methodology represents a promising route toward achieving the dimensional accuracy required for future space-grade compliant mechanisms.

1. CONTEXT

Compliant mechanisms have become attractive solutions for space and harsh environment applications requiring tribology-free motion, high positioning accuracy and long lifetime. By relying on elastic deformation instead of conventional joints, they eliminate friction, backlash, lubrication and wear. However, their complex architectures traditionally require lengthy machining and assembly operations.

Recent developments in metallic additive manufacturing have significantly modified this paradigm [1] & [2]. Four major projects conducted by CSEM validated the capability of producing compliant mechanisms by LPBF:

- Interlocked Lattice Flexure Pivot (ILFP) [3]
- PULSAR compliant tripod [4]
- Compliant Rotation Reduction Mechanism (CRRM) [5]
- Compliant Roto-Translation Mech. (CRTM) [6]

These projects demonstrated the feasibility of manufacturing monolithic compliant systems integrating dozens of flexures and optimized structures within a reduced volume.

1.1. Remaining challenge: warpage

Despite these progresses, the dominant limitation for monolithic compliant mechanisms remains dimensional accuracy. Warpage originating from thermal gradients during LPBF and from subsequent thermal treatments affects all investigated materials, including 316L, 17-4PH, Invar 36 and Ti6Al4V. Distortions ranging from several hundred micrometres to nearly two millimetres (due to buckling) were measured on operational prototypes. The quality of flexure blades is critical to the guiding performance of compliant mechanisms. These elements require tight geometric tolerances, particularly for thin and slender structures, while also demanding minimal internal defects and high surface quality.

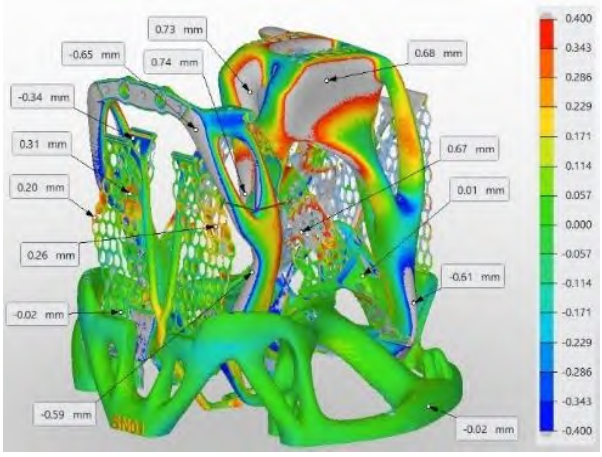

Figure 1. Distortions of CRTM printed in Ti6Al4V without compensation strategy compared to 3D CAD model, scale in mm

1.2. Objective

The objective of this work is to evaluate whether LPBF process simulation based on inherent strain method can be effectively used to predict and compensate distortions in compliant mechanisms and thereby improve the final guiding performances.

2. CRTM DEMONSTRATOR

The study is a follow-up activity with the reuse of the CRTM design developed during the ESA activity "Advanced Manufacturing Technologies for Compliant Mechanisms" ref. 4000122793/17/NL/PS The Compliant Roto-Translation Mechanism converts a rotational input of ±15° into a linear displacement of ±5 mm through a monolithic compliant architecture. It combines an interlocked cross pivot, a screw-based transformation stage and a compliant linear table.
The CRTM represents a particularly demanding test case because it includes multiple thin flexures (8 in total) with high aspect ratios, low bending stiffness and different printing orientations. Earlier prototypes produced in both 17-4PH and Ti6Al4V exhibited significant distortions affecting guiding performances.

Figure 2: Compliant Roto-Translation Mechanism

3. PROCESS SIMULATION METHODOLOGY

3.1. Simufact Additive Workflow

To anticipate manufacturing distortions, simulations were conducted using Cadence Simufact Additive.
The nominal workflow includes:

1. CAD preparation and build orientation selection.
2. Support generation.
3. Layer-wise process simulation.
4. Residual stress estimation.
5. Distortion prediction.
6. Automatic geometry compensation.
7. Iterative refinement.

This methodology – from point 1 to 6 is widely used for rigid LPBF components and aims at achieving first-time-right manufacturing by introducing a compensated CAD geometry before production. The new tool developed in Simufact Additive includes the seventh step with an iterative compensation based on the results of the first print 3D laser or Computed Tomography (CT) scan.
Note that CSEM proposes to choose the printing orientation during the design phase and not after, to fully benefit from the complex shapes possible with AM while considering at best the associated limitations.

3.2. Initial Simulation Results

A first simulation campaign was performed using automated support structures.
The simulations correctly predicted the overall distortion trends observed experimentally. However, significant discrepancies remained in thin flexure regions where nonlinear deformations dominated the behaviour.

4. LIMITATIONS OF CONVENTIONAL PRE-DISTORTION

4.1. Buckling Behaviour of Flexure Blades

Further analysis showed that the dominant distortion mechanism for flexures was not simple thermal shrinkage but rather buckling induced by warpage of the rigid structures linking the blades.
The inability of the iterative distortion optimization to converge provided the first indication of this phenomenon. Flexures behaved similarly to slender columns subjected to axial compression. When the build height exceeded a critical value, large out-of-plane deformations were developed.

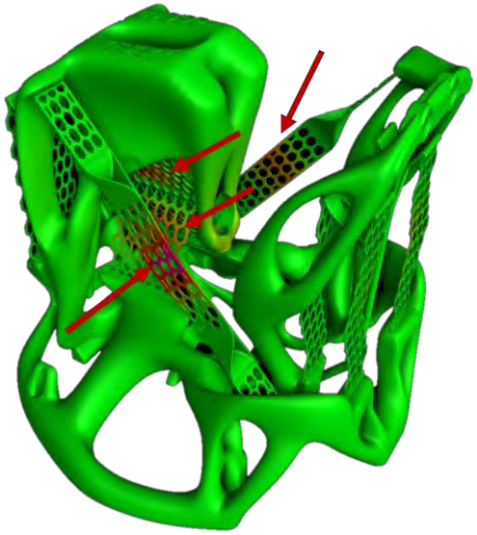

Figure 3: Identified buckling areas by Simufact Additive

These distortions cannot be addressed by conventional geometric compensation alone because the deformed shape depends on structural stability during fabrication.

4.2. Critical Regions

The process simulations identified several regions particularly sensitive to buckling. In conformity with the first results observed in the former project, these locations corresponded to long unsupported flexures and cross-blade structures. Numerical results highlighted that pre-distortion compensation became ineffective whenever the simulated build process entered an unstable regime.

5. IMPROVED COMPENSATION STRATEGY

5.1. Minimum Viable Supports

A first approach involved redefining the support strategy. Instead of maximizing support contact, the objective was to create a "minimum viable support" concept ensuring process stability while limiting post-processing effort and preserving fragile flexures. An additional advantage of this strategy is to ease and lower the support removal effort near delicate structures.
Further support refinement coupled with simulation iterations demonstrated a significant reduction of flexure distortions and enabled successful convergence of the compensation workflow for geometries previously considered impossible to compensate.

6. HYBRID SIMULATION AND METROLOGY APPROACH

Although process simulation captured the dominant deformation modes, discrepancies remained between simulations and measured geometries.

6.1. Limitations of Raw Scan Feedback

Direct use of 3D optical or X-ray CT scan data as a compensation reference is problematic because scans include:

- Surface roughness artefacts
- Residual support marks
- Measurement uncertainty
- Missing scan data
- Local manufacturing defects

These features do not represent systematic distortions and should not be compensated.

6.2. Mesh Morphing Methodology

A hybrid workflow was therefore introduced in Simufact Additive software. Instead of using scan data as the new reference geometry, the measured data is used as a target for mesh morphing applied to the nominal CAD model. This preserves the original design intent while capturing systematic distortion trends.
This methodology is inspired by workflows traditionally used in injection moulding and computed tomography analysis.

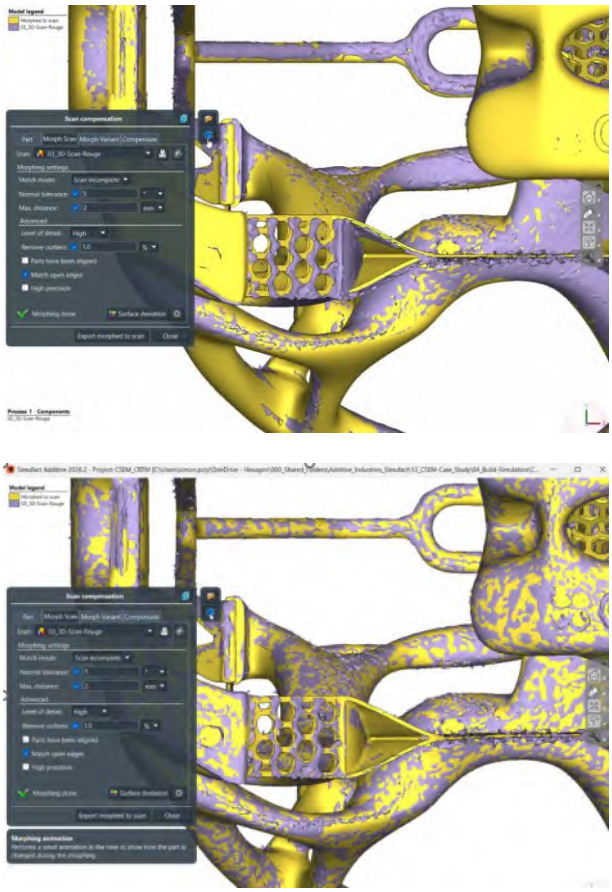

Figure 4: Example of mesh morphing in Simufact Additive, initial (top) and after morphing (bottom)

7. EXPERIMENTAL VALIDATION

7.1. First Compensated Build

Two compensated CRTM demonstrators were produced and inspected using high-resolution optical scanning.
The first build demonstrated encouraging agreement with the target geometry. Approximately 90% of the measured surface profile was located within ±0.2 mm of the reference geometry, including flexible blades.

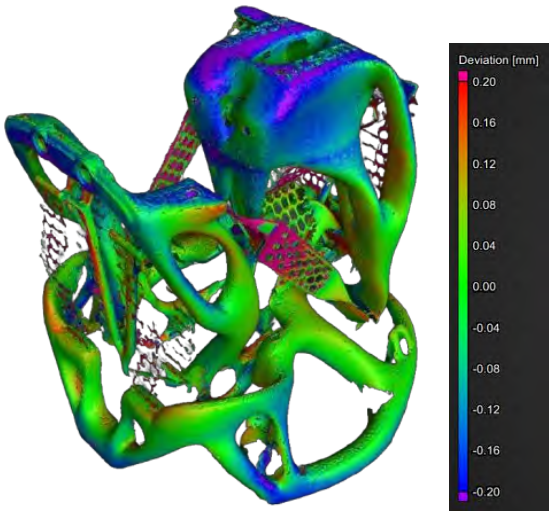

Figure 5: 3D scan of the first build job compared to CAD model

7.2. Geometrical Improvements

Results obtained during the iterative compensation process showed continuous improvement as shown in Table 1. These results demonstrate the capability of combining simulation and metrology to significantly improve dimensional conformity for complex compliant structures.

Table 1: Results with different strategies

Configuration	Surface within ±0.2 mm
Nominal geometry	39% (measured)
Simulation compensation	90% (measured)
Simulation + scan morphing	100% (prediction)

7.3. Impact on Guiding Performances

At the time of writing, correlation between geometrical improvements and guiding performances is ongoing. Future work will determine how the reduction of flexure distortions translates into improvements in parasitic displacement, stiffness prediction and lifetime performance. This evaluation is particularly important since previous projects demonstrated a strong relationship between warpage and guiding inaccuracy.

8. LESSONS LEARNED

Several key conclusions can already be drawn:

- Guiding compliant mechanisms are more sensitive to distortions than conventional rigid structures.
- Buckling induced by residual stresses is a critical distortion comportment for thin flexures.
- Conventional pre-distortion techniques alone are insufficient, especially for compliant geometries.
- Support strategy plays a critical role in distortion control.
- Combining process simulation and scan-based morphing substantially improves compensation performance.

These observations confirm the conclusions previously reached during the CRRM and CRTM projects while providing practical solutions for future developments.

9. CONCLUSIONS

This work investigated distortion prediction and compensation methods for LPBF compliant mechanisms using the CRTM demonstrator as a representative case.
Initial results confirm that Simufact Additive successfully predicts the major distortion modes affecting compliant mechanisms. However, conventional compensation approaches become ineffective when flexure blades enter residual-stress-driven buckling regimes. To address this limitation, dedicated stabilization concepts and a hybrid simulation-metrology methodology were developed.
Experimental validation demonstrated a substantial improvement in dimensional conformity, increasing the proportion of surfaces located within ±0.2 mm of the nominal geometry from 39% to full coverage after iterative compensation. These results represent a significant step towards achieving the dimensional accuracy required for future high-precision space compliant mechanisms.

Future work will focus on validating the methodology through guiding performance measurements, fatigue testing and extension to additional compliant mechanism architectures.

KEYWORDS

Post-Buckling, Sizing, Stability, Launcher Structures, FEA, Simulation, numerical Methods.

ABSTRACT

Large space structures, such as inter-tank skirts in launchers, face critical challenges under complex loading conditions (compression, bending, thermal stresses). Buckling, a primary failure mode, can cause sudden loss of load-carrying capacity, threatening mission success. Traditional design methods often rely on conservative safety margins, leading to over-designed, heavier structures that penalize performance.
To address this, stiffening solutions (ribs, stringers, ring stiffeners) are commonly used to enhance stiffness and delay buckling. However, structures can still retain load-bearing capacity in **the post-buckling regime**, though their behaviour becomes highly nonlinear and sensitive to imperfections. Quantifying this residual strength is essential for accurate structural assessment and mass optimization.

This study proposes a **numerical approach** combining nonlinear static analyses (large displacements, geometric nonlinearities) and incremental buckling analyses to identify critical modes and stiffness degradation, aiming to develop **robust design guidelines** for optimized sizing while ensuring aerospace compliance.

1. CONTEXT

Large space structures, such as the **Inter-Tank Skirt (ITS)**, play a pivotal role in launchers by providing structural continuity between propellant tanks. These components are subjected to complex loading conditions, including compressive, bending, and thermal stresses, which introduce significant **risks of buckling** like a critical failure mode that can lead to sudden loss of load-carrying capacity.

Traditional design philosophies often adopt conservative safety margins to mitigate buckling risks, but this approach frequently results in over-designed structures, penalizing overall system performance due to excess mass and increased costs.

A key question arises: **Can local buckling effects be tolerated in the design?**

Addressing this requires a deep understanding of post-buckling behaviour [1], where structures may retain load-bearing capacity despite initial instability. This regime is characterized by highly nonlinear responses, influenced by factors such as geometric imperfections, material nonlinearities, and boundary conditions.
By quantifying the residual stiffness and load redistribution in this phase via FEA simulations using PERMAS solver [2], engineers can unlock opportunities for mass optimization without compromising structural integrity.
The ITS serves as a prime example of this challenge: it must balance structural reliability with mass and cost constraints, all while adhering to stringent aerospace standards. This study **proposes an FEA-based methodology** to develop robust design guidelines that enable engineers to tolerate controlled buckling where safe, thereby achieving performance-driven sizing for space applications.

1.1. Role or the ITS Skirt

The Inter-Tank Skirt (ITS) serves as a **structural backbone** (Fig. 1) within launchers, fulfilling both mechanical and functional roles. Primarily, it ensures the connection of propellant tanks, guaranteeing structural continuity and load transfer between the upper and lower stages. Beyond its load-bearing function, the ITS provides a mechanical interface for integrating various fluidic and electrical equipment, enabling seamless system integration.

Additionally, the ITS **hosts critical systems**, such as avionics, sensors, and local control units, which are essential for mission operations. Its design also facilitates the routing of harnesses, utilities, and fluidic lines through dedicated trapdoors, optimizing space utilization while maintaining accessibility for maintenance and assembly. This multifunctional role underscores the ITS's importance not only as a structural element but also as a hub for equipment integration in launcher architectures.

Figure 1: Inter-Tank Skirt (ITS)

1.2. Applied Loads

The Inter-Tank Skirt (ITS) is subjected to a complex loading environment during all mission phases. General loads include compressive forces and bending moments transmitted by the upper structure, primarily induced by thrust and aerodynamic pressures during ascent. Additionally, the ITS experiences a global inertia load, a compressive effect generated by the launcher's acceleration, which further increases the axial stress distribution.

At the local scale, the ITS hosts critical equipment (e.g., avionics, sensors, and control units) that introduces Quasi-Static Loads (QSL**)**, adding localized stress concentrations to the global load scenario.

From a boundary condition perspective, the lower interface of the ITS is fully clamped, ensuring rigid fixation to the lower stage. Furthermore, structural interactions with surrounding connected components contribute additional stiffness, influencing the overall mechanical behaviour of the skirt.

This combination of global, inertial, and local loads, along with the constraints and interactions, defines the **critical loading conditions** that must be accounted for in the structural design and analysis of the ITS, as summarized in Fig. 2.

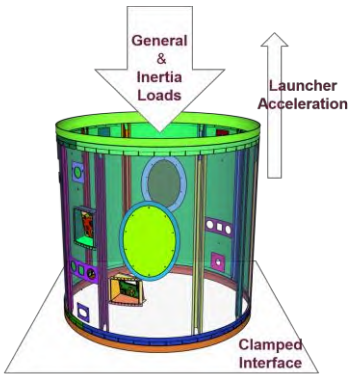

Figure 2: Applied Loads

1.3. Modelling Aspects & Simulation Environment

The Finite Element (FE) model of the ITS was developed using the NX environment, combining CAD modelling, mesh generation, and model completion. The main cylindrical parts, panels, and ribs were modelled using shell elements to efficiently capture bending and membrane behaviours, while flange parts were represented with solid elements to accurately simulate their 3D stress distribution. Local equipment, such as avionics and sensors, was modelled as lumped masses connected to the structure via beam and spring elements, ensuring a balanced trade-off between computational efficiency and accuracy.

To address mesh incompatibilities between different parts, Multi-Point Constraints (MPCs) were employed. Specifically, surface to surface connections *($SURFACE/$MPC ISURFACE – BSURF / BGSET)* were used to handle non-matching meshes. For equipment connections, rigid connectors *($MPC RIGID - RBE2)* and load distributor connectors *($MPC WLSCON - RBE3)* were applied respectively, to ensure robust load transfer while maintaining numerical stability.

Finally, for the simulation tasks, the completed FE model was directly read into the PERMAS solver via the Nastran Door interface [3], enabling seamless integration of the pre-processed model into the simulation environment. This workflow ensures consistency between pre-processing and solving phases, facilitating both accurate and computationally efficient structural analyses. The FE model is shown in Fig. 3.

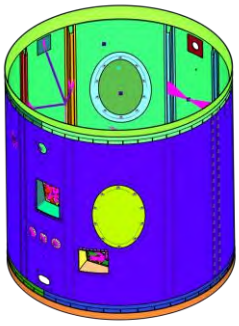

Figure 3: F.E. Model

2. MECHANICAL STRENGTH

A **linear static analysis** was conducted to evaluate the structural performance of the ITS under the applied loads. The results, as illustrated in Fig. 4, reveal that the mechanical strength of the structure is largely respected, with **no failure observed** under static loads. This confirms the design's adequacy for the expected operational conditions.

However, the analysis highlights the presence of localized stress concentrations, or hot spots, marked in Fig. 4 with von Mises stresses. These exhibit critical stress levels exceeding 85% of the material's yield strength (Re), particularly in geometrically discontinuous regions, such as small-

radius fillets (corner windows) or areas with MPC-based mesh connections, where mesh discretization could be refined.

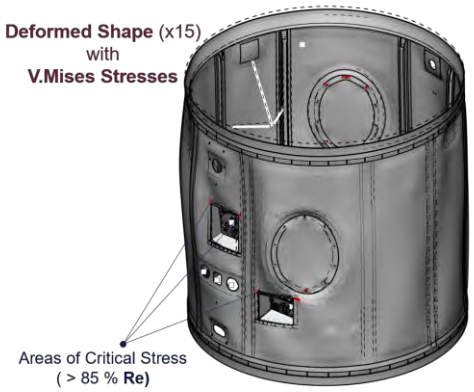

Figure 4: Results from Linear Static Analysis

This observation raises a **key question**: *Even if the mechanical strength is fully satisfied, what is the buckling behaviour of the structure under these conditions?* While the ITS demonstrates sufficient static strength, verification of its stability under compressive and bending loads is necessary. The presence of localized stress concentrations may influence the critical load factors, potentially reducing the buckling margin.

This motivates the need for **buckling analyses** to fully assess the structural robustness and ensure safety margins are maintained.

3. LINEAR BUCKLING

To assess the stability of the ITS under the previously identified loading conditions, a Linear Buckling Analysis (LBA) was performed using the PERMAS solver. This analysis follows a two-step approach, as described below.

3.1. Governing Equations

The LBA is based on the eigenvalue problem derived from the tangential stiffness matrix of the structure. The process involves:

1rst step: Linear Static Analysis (Pre-stress state)

A preliminary linear static analysis is conducted to determine the internal stress state σ_0 under the applied loads, using the elastic stiffness matrix $\boldsymbol{K}_e$:

$$\boldsymbol{K_e} u = F \qquad (1)$$

where u is the nodal displacement vector and F is the external load vector. The internal stress state σ_0 is then used to construct the geometric stiffness matrix $\boldsymbol{K_g}(\sigma_0)$.

2nd step: Eigenvalue Analysis of the Tangential Stiffness Matrix

The eigenvalue problem is formulated as:

$$\boldsymbol{K_t} X = \left[\boldsymbol{K_e} + s\boldsymbol{K_g}(\sigma_0)\right] X = 0 \quad \text{with} \quad X \neq 0 \qquad (2)$$

where $\boldsymbol{K_t}$ is the tangential stiffness matrix, s represents the scaling load factors, and X corresponds to the buckling shapes (eigenmodes). The critical load factors s are derived from the eigenvalues, while the buckling modes X provide insight into the deformation patterns at instability.

3.2. Interpretation of Scaling Load Factors

The scaling load factors s provide insight into the stability of the structure:

- If $s > 1$: The structure is **stable** under the applied load, with no buckling effect.
- If $s = 1$: The structure is at a **critical state** (neutral equilibrium), corresponding to a potential **bifurcation point**. At this point, the structure may:
  - → Collapse,
  - → Undergo bifurcation (e.g., transition to a new equilibrium configuration),
  - → Or remain stable depending on higher-order effects or imperfections.
- If $s < 1$: The structure is **unstable** and has undergone deformation due to buckling, which can manifest as:
  - → **Local buckling** (e.g., in individual components like plates or stiffeners),
  - → **Global buckling** (e.g., Euler buckling of columns or lateral-torsional buckling of beams).

3.3. Stability Check Assumptions

The LBA was performed under the following assumptions:

→ Material behaviour: Linear elastic.
→ Geometry: Perfect (no imperfections).
→ Displacements: Small (linearized theory).
→ Initial state: Pre-stressed.

These assumptions provide a **conservative baseline** for assessing the structure's stability, though they may not fully capture the effects of geometric imperfections or nonlinear material behaviour.

3.4. Results from Linear Buckling Analysis

The LBA results reveal critical load factors s for the ITS, as illustrated in Fig. 5. The first four buckling modes and their corresponding load factors are summarized as follows:

Table 1: Critical Load Factors

Mode	Critical Load Factor s	Description
1	0.71	Local buckling near manhole with 'front' door access
2	0.75	Local buckling in panel regions
3	0.76	Local buckling near manhole with 'rear' door access
4	0.81	Local buckling in stiffener regions

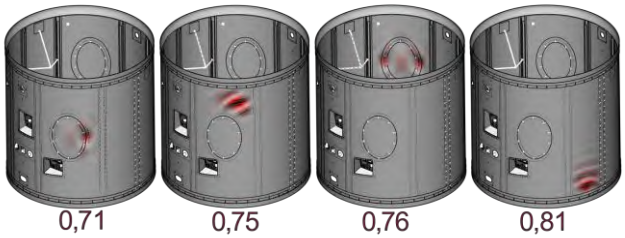

Figure 5: Results from Linear Buckling Analysis

Key observations:

→ The first load factors are below 1, indicating potential instabilities before reaching the nominal load.
→ The critical area is concentrated around the manhole with door access, where geometric discontinuities and stress concentrations are most significant.
→ Mesh discretization and MPC-based mesh connections are critical for the accuracy of the results, as they influence the localisation of buckling modes.

While the mechanical strength is largely respected under static loads, the buckling behaviour is present but does not lead to immediate collapse. This raises two key questions:

→ Is the observed buckling a **local or global effect**?
→ What is the **post-buckling behaviour** of the structure?

4. NON-LINEAR BUCKLING

The need for a non-linear buckling analysis arises from two key observations from the LBA:

→ Buckling occurs before nominal loads are reached,
→ Uncertainties remain regarding the nature of buckling (local vs. global effects) and the post-buckling behaviour of the structure, particularly its ability to retain load-carrying capacity after instability.

However, LBA assumes a linear material behaviour, which may not fully capture the structure's post-buckling response or its load-carrying capacity after instability.

To address these limitations, a post-buckling simulation based on a non-linear static analysis was performed using the PERMAS solver, following the methodology outlined below. This approach allows for:

→ **Assessment of residual strength** after buckling onset.
→ **Understanding of failure progression** and the structure's ability to redistribute loads.

4.1. Methodology: Non-Linear Static Analysis

The non-linear analysis was performed using an incremental loading process with the following key features:

4.1.1. Incremental Loading Process

The analysis accounts for:

→ **Large displacement effects:** Geometric non-linearity is captured through the geometrical stiffness matrix $\boldsymbol{K}_g$.
→ **Arc-length method**: This numerical technique overcomes singular points (e.g., limit points) to capture post-buckling states and track the structure's equilibrium path.
→ **Support for singular/negative diagonal terms**: Enables the simulation of snap-back effects, where the structure experiences sudden reductions in load-carrying capacity, as illustrated in Fig. 6.
→ **Co-rotational theory**: Ensures accurate geometric non-linearity by updating the coordinate system with the structure's deformation.

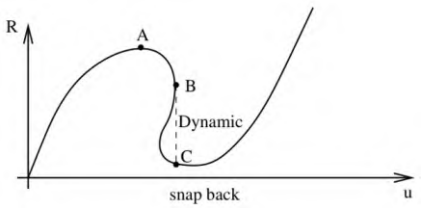

Figure 6: Snap-back Effect

4.1.2. Buckling Analysis at Each Equilibrium State

At each step of the incremental loading process, the tangent stiffness matrix $\boldsymbol{K}_t$ is updated and decomposed into:

→ **Material stiffness** K_m: Accounts for material non-linearity (e.g., plasticity).
→ **Geometrical stiffness** K_g: Accounts for geometric non-linearity (e.g., large displacements).

The eigenvalue analysis of the updated tangential stiffness matrix is performed at each step. This analysis also includes **tracking** of:

→ **Critical buckling modes**: To identify which modes are activated during loading.
→ **Evolution of load factors**: To monitor how the structure's stability changes as the load increases.

4.2. Results from Non-Linear Buckling Analysis

4.2.1. Resultant Load Diagram

The Resultant Load Diagram (Fig. 7) illustrates the load-displacement relationship of the ITS under incremental loading, with key observations:

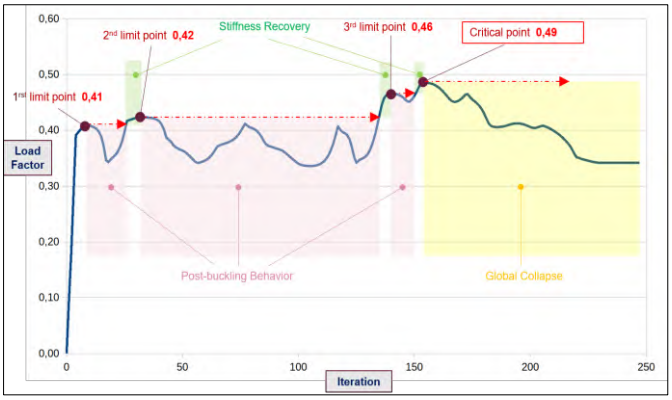

Figure 7: Resultant Load Diagram

Limit Points:

→ 1st limit point (0.41): Marks the onset of initial buckling.
→ 2nd limit point (0.42): Indicates the activation of a local buckling effect.
→ 3rd limit point (0.46): Indicates the activation of local buckling effect.
→ Critical point (0.49): Represents the ultimate load-carrying capacity of the structure before global collapse.

Post-Buckling Behaviour:

The structure exhibits stiffness recovery between limit points, where it temporarily regains stability before undergoing further buckling. This phenomenon is characteristic of non-linear post-buckling behaviour, where the structure can continue to carry load despite local instabilities.

4.2.2. Deformed Shape at Limit Points

Figure 8 illustrates the deformed shape of the ITS at each limit point, as well as at the last converged equilibrium state.

Figure 8: Def. Shapes (x15) with Displ. Length

4.2.3. Tracking Buckling Modes

The first three involved buckling modes (Mode-1, Mode-2, and Mode-3) are tracked throughout the loading process, as shown in Fig. 9.

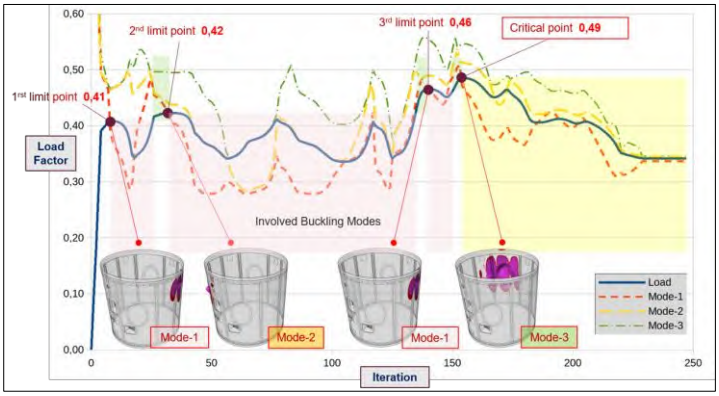

Figure 9: Evolution of Buckling Load Factors with the Load Diagram

For each limit point, the involved buckling mode is clearly identified, as its load factor evolution intersects the load diagram. This intersection explains the local failure mechanism at each stage. This approach demonstrates that the involved buckling modes differ significantly from those predicted by the Linear Buckling Analysis (LBA). Furthermore, the associated load factors are substantially lower than those obtained from the linear approach.

At the critical point, the involved buckling mode (buckling near the manhole with the 'rear' door access) triggers a global collapse effect.

At the last converged state, at least the first three buckling modes are involved (aggregation) in the global collapse mechanism.

4.2.4.: Last Converged State

The last converged state of the ITS, shown in Fig. 10, reveals the deformed shape, with displacement magnitudes and the active buckling modes. In Fig. 11, areas of critical stress (exceeding the material's yield strength R_e) highlighted in the von Mises stress distribution.

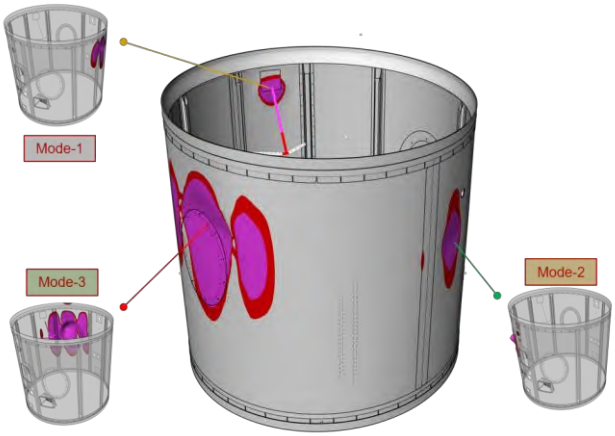

Figure 10: Deformed Shape (x1) with Displ. Length and Active Buckling Modes

The study of the deformed shape shows the participation of the "active" buckling modes:

→ Mode-3: Buckling near the (rear) manhole.
→ Mode-1: Local buckling in panel regions.
→ Mode-2: Local buckling of the cylindrical structure.

The global collapse behaviour is therefore interpreted as the combination of these three active buckling modes.

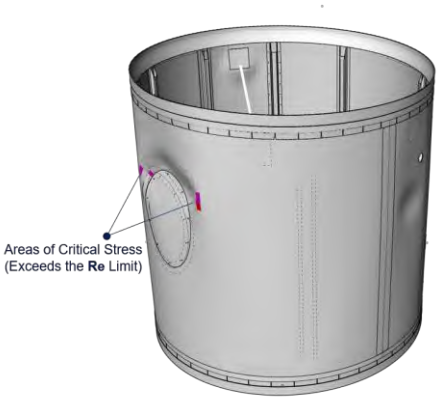

Figure 11: Deformed Shape (x1) with Von-Mises Stresses

Critical stresses, localized in small hot spot areas, imply that the onset of global collapse takes place within the elastic domain, characterizing this as an elastic stability problem.

4.2.5. Upper Interface Behaviour

The focus on the center point of the upper interface of the ITS provides useful insights into its behaviour, exhibiting complex interactions between translation and rotation (Fig. 12).

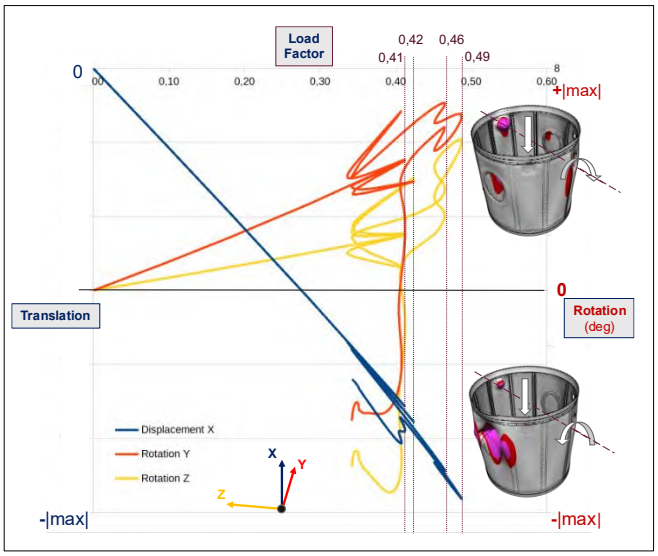

Figure 12: Load-Displacement Curves – Center of Upper Interface

The load-displacement curves at the center point reveal the following:

→ A regular shortening effect, accompanied by several snap-back effects, until the critical load (0.46) is reached, at which point the global collapse begins with the loss of rigidity.
→ A positive rotation in the Y and Z directions occurs alongside the shortening effect until the critical load (0.46). Beyond this point, a complete switch to large negative rotation initiates, marking the onset of the global collapse effect (similar to a tipping/overturning behaviour).

4.3. Conclusion on Non-Linear Buckling Results

The Non-Linear Buckling Analysis (NLBA) of the ITS has provided critical insights into its structural behaviour under realistic loading conditions. The key findings can be summarized as follows:

→ **Lower Critical Limit Load**: The NLBA reveals a critical limit load of 0.49, significantly lower than the 0.71 predicted by the linear analysis.
→ **New Critical Buckling Modes**: The non-linear approach identifies different dominant buckling modes compared to the LBA. These modes arise from the interaction between local instabilities and the global structural response,

providing a more accurate representation of the ITS's behaviour.

→ **Global Failure Initiation**: The onset of global failure is driven by a combination of local critical buckling modes, rather than isolated instabilities. This highlights the importance of considering mode interactions in structural design.

→ **Material Behaviour**: The material remains elastic throughout the analysis, with no significant plastic deformation observed at the applied load levels. This confirms that the buckling behaviour is primarily governed by geometric non-linearities.

→ **Mechanism Clarity**: The NLBA provides a clear explanation of the underlying failure path, revealing how the structure transitions from local buckling to global collapse.

However, the accuracy of these results remains highly sensitive to mesh discretization and MPC-based mesh connections. These factors influence the localization of stress concentrations and the activation of buckling modes, emphasizing the need for careful modelling in critical regions.

5. CONCLUSION & PERSPECTIVES

The analyses conducted in this study, Linear Buckling Analysis (LBA) and Non-Linear Buckling Analysis (NLBA), have provided a comprehensive understanding of the ITS's structural behaviour under nominal loads. The following key findings emerge:

→ **Buckling as a Critical Design Case**: Buckling is confirmed as a critical design consideration for large space structures, where local instabilities can lead to global collapse if not properly accounted for.

→ **Preliminary benchmark** conducted in this study yields **valuable insights** into the structure's post-buckling behaviour and stiffness performance reserves.

The use of PERMAS solver for non-linear analysis has demonstrated its comprehensive tools for efficient post-buckling analysis, including:

→ **Tracking critical buckling modes** during load increments.

→ **Providing clear mechanisms** to explain critical load paths.

The insights gained from this study enable the following practical outcomes:

→ **Targeted Design Modifications**: The results allow for targeted design modifications to overcome critical load limits without compromising mass performance. For example, reinforcing local areas to improve buckling resistance.

→ **Evaluation of Post-Buckling Behaviour**: The study facilitates the evaluation of post-buckling behaviour and stiffness performance reserves, ensuring that the structure can tolerate controlled buckling while maintaining overall stability.

→ **Design Guidelines**: The findings motivate the development of design guidelines that account for:

- Controlled buckling in non-critical regions.
- Post-buckling capacity to ensure safety margins.
- Stress concentrations to mitigate the effects of geometric singularities.

ABSTACT

The CALLISTO project, a trilateral initiative between DLR, CNES, and JAXA, aims to develop a reusable vertical take-off and landing rocket demonstrator. This paper presents a structural stability assessment of the Inter-Tank Structure (ITS) connecting the LOX and LH2 tanks. Using a finite element model of the thin-walled barrel reinforced by hat stiffeners and incorporating equipment platforms and windows, the structure is evaluated under four operational flight load cases. The methodology combines linear perturbation buckling, and non-linear buckling analyses to account for geometric nonlinearities and imperfection sensitivities. By analysing force-displacement curves, critical load factors, safety margins, and stress locations were identified. This study validates the CALLISTO design, contributing to the maturation of European reusable launch vehicle technologies and providing a foundation for subsequent qualification testing campaigns.

ACRONYMS

ITS **–** Inter Tank Structure
LOX – Liquid Oxygen
LH2 – Liquid Hydrogen

1. INTRODUCTION

The development of cost-effective and operationally flexible launch systems has become a strategic priority, driving renewed industry focus on reusability technologies. Within this landscape, the CALLISTO project stands as a pivotal trilateral initiative between the German Aerospace Centre (DLR), the French National Centre for Space Studies (CNES), and the Japanese Aerospace Exploration Agency (JAXA). The program aims to develop and fly a reusable vertical take-off and vertical landing (VTVL) rocket demonstrator that validates critical technologies, refines technical assumptions, and demonstrates return-to-launch-site manoeuvres at a fraction of the cost of an operational vehicle [1]. By demonstrating (i) the capability to recover a vehicle with toss-back trajectory, (ii) Maintenance, Repair, and Overhaul (MRO) procedures to make the vehicle ready for the next fly with minimum turnaround and refurbishment effort, and (iii) to fly with the same reused vehicle, with a capability of several flights [2] [3] [4].

A load-critical element of this architecture is the Inter-Tank Structure (ITS), which mechanically connects the liquid oxygen (LOX) and liquid hydrogen (LH2) propellant tanks. To meet mass budgets, the ITS utilizes a thin-walled barrel design reinforced with hat stiffeners, cut-outs, and equipment platforms. While this lightweight configuration maximizes performance, it inherently increases susceptibility to buckling and geometric instabilities under complex operational loads [5]. During ascent, powered tilt-over manoeuvres, and propulsive landing phases, the structure experiences severe compressive stresses, bending moments, and thermal gradients that can trigger premature failure if not rigorously analysed. Consequently, advanced structural stability assessments are essential to ensure that reusable airframe components safely withstand repeated flight cycles without compromising vehicle structural integrity.

Historically, the design of such structures relied on conservative empirical knockdown factors (KDFs) derived from limited test data. Recently, analysis-based approaches were incorporated into the 2020 revision of NASA SP-8007, allowing less conservative, structure-specific knockdown factors to be determined [6] [7].

Research has demonstrated that initial geometric imperfections, thickness variations, and loading non-uniformities can drastically reduce buckling loads compared to idealized theoretical predictions. Techniques such as the single perturbation load approach and reduced energy methods have been developed to simulate worst-case geometric disturbances, enabling more accurate stability predictions without excessive conservatism [8]. Furthermore, probabilistic frameworks combined with deterministic non-linear analyses provide

robust tools for quantifying uncertainties in material properties, boundary conditions, and load introduction [9]. These modern methodologies underscore the necessity of moving beyond classical linear buckling estimates and explicitly incorporating imperfection sensitivity into the structural validation process.
This paper presents a comprehensive non-linear buckling analysis of the CALLISTO ITS to assess its mechanical stability and structural integrity under four representative operational flight conditions. By considering linear perturbation eigenvalue analyses and geometrically non-linear finite element simulations, the study evaluates load-carrying capacity, identifies critical imperfections, and establishes safety margins against instability. The methodology focuses on analysing force-displacement responses to verify that buckling instability is prevented well beyond nominal flight loads. Ultimately, this structural validation supports subsequent qualification testing campaigns and contributes to the broader maturation of reusable launch vehicle technologies.

2. STRUCTURAL DESCRIPTION AND MODELING

2.1. Geometry and Architecture

The ITS structure connects the LOX and LH2 tanks of the CALLISTO rocket. As shown in Figure 1, the structure consists of a thin-walled barrel reinforced by hat stiffeners and features two cut-outs that provide access to internal structure and equipment installation platforms.

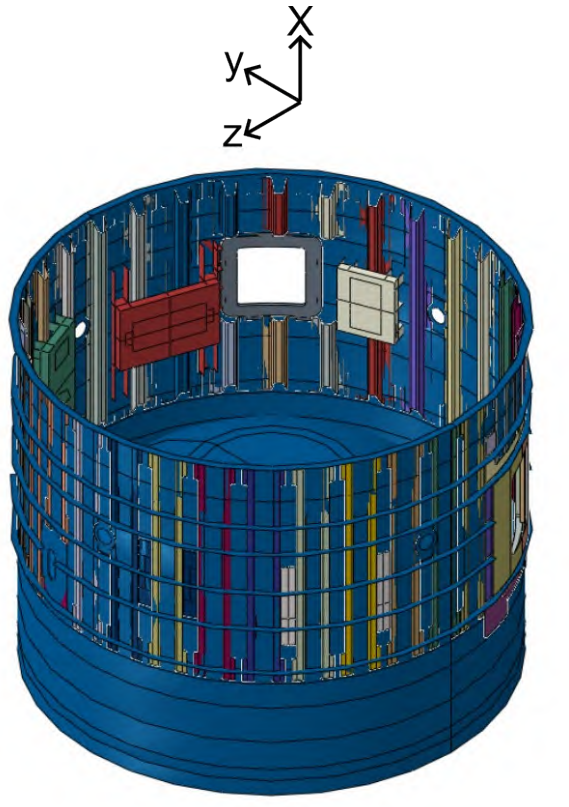

Figure 1: Overview of CALLISTO ITS structure.

The barrel has a nominal thickness of 1 mm, with thicker sections near its upper and lower ends.
The ITS contains 35 omega stringers, most of which span the full length of the barrel. Shorter stringers are used around the cut-outs and platforms. The stringers have a nominal thickness of 1 mm.
The modelled barrel is 875.8 mm long and has an inner diameter of 1100.9 mm, measured at the upper end below the LOX tank flange. The model includes the LH2 dome, connected to the rest of the barrel. The ITS model includes five platforms, two cut-out frames and three frames. Figure 2 defines the location of the equipment installation platforms for the application of the local loads.

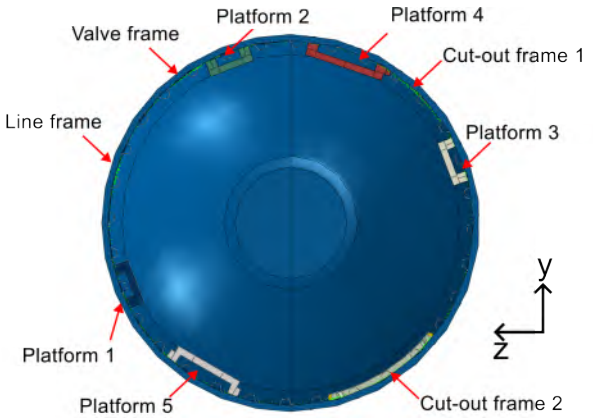

Figure 2: Identification of the system platforms of CALLISTO ITS structure.

The ITS model accounts for other components, such as cable ducts and lines. Although their connections are not explicitly modelled, their effect is represented by locally increasing the thickness.

2.2. Finite Element (FE) Model

The model is created in Abaqus and meshed with 4-node quadrilateral shell elements with reduced integration. The approximate mesh size applied to the barrel is 5 mm, based on the preliminary linear perturbation analysis, a compromise in terms of computational cost and experience. The platforms, stringers and other non-critical parts for the buckling analysis have larger mesh-size (10 mm ca.).
The fasteners are modelled using the Abaqus mesh-independent, point-based fastener formulation. Rigid beam MPCs connect the fastening points on the joined surfaces, while distributing couplings attach these points to the surrounding shell nodes. Distributing couplings (RB3) are also used to apply the local loads from the equipment installation platforms shown in Figure 2. An example of a platform (Fluid Retainer Valve Platform) is presented in Figure 3, highlighting its connectivity.

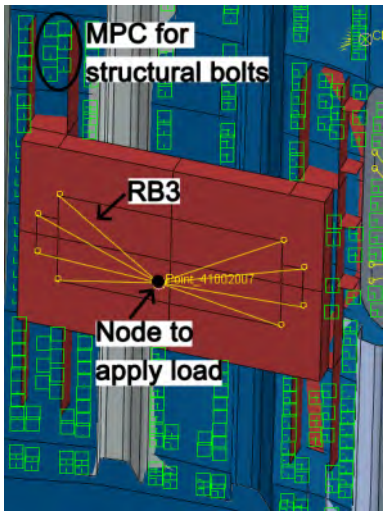

Figure 3: Example of platform connectivity.

The sections of the rocket surrounding the ITS, i.e., LOX and LH2 tanks, are represented in the analysis by super-elements with equivalent stiffness. The LH2 and LOX tank super-elements are defined using 173 and 115 retained nodes, respectively. For the LH2 tank super-element, 172 nodes are distributed around the circumference at the lower end of the ITS, while one node is located at the bottom of the launcher demonstrator, where the boundary conditions are applied. The nodes of the super-elements are connected to the ITS with rigid kinematic coupling (RB2). The modelling strategy for the rocket and the connection of the nodes of the super-elements to the ITS are shown in Figure 4.
The materials are considered in this analysis are reported in Table 1.

Table 1: Material properties. [10]

	Al 2000 series	Al 7000 series
Density [kg/mm^3]	2.851e-6	2.810e-6

v [-]	0.33	0.33
σ_u [MPa]	420	482
Use	Dome assembly, ITS hull, ITS flange	Platforms, Stiffeners, Frames

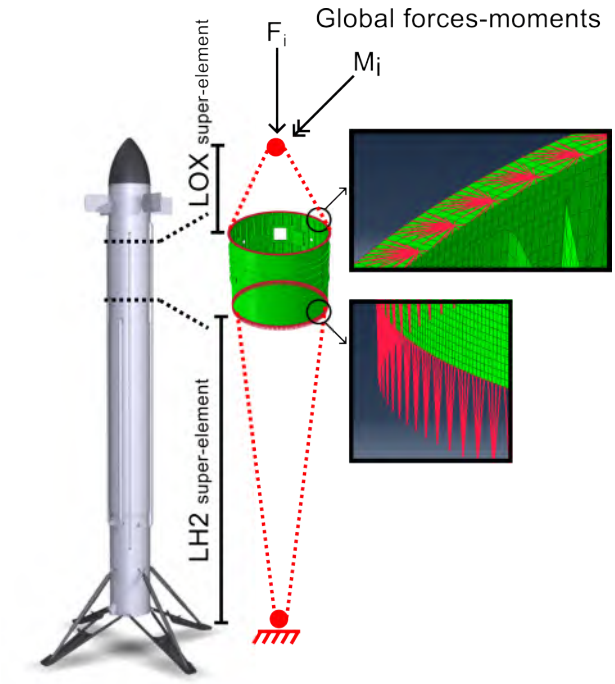

Figure 4: LOX and LH2 super-elements connection to the ITS.

2.3. Boundary Conditions and Load Cases

The boundary condition constraining the model is applied at the bottom-node of the LH2 tank super-element, corresponding to the bottom of the rocket. At this node all degrees of freedom are constrained (Ui = URi = 0, see Figure 4).
In this analysis of the ITS structure, four load-cases are considered. These load cases are defined taking into account all possible global and local loads that the ITS may be subjected to. With respect to buckling, this includes global compression, bending and torsion loads, all of which are applied to the LOX-tank super element. Additionally, an internal negative pressure is considered, together with local force loads introduced via the equipment platforms as well as resulting from the attachment of fluid lines and cable ducts. For the four load-cases regarded in this paper, these loads were combined in a way that maximized compressive principal stress ($\sigma_{I,min}$) inside the ITS.
For each load-case, global force and moments (as in Figure 4) are computed with the LOX tank super-element and applied to its nodes. The loads are then transmitted to the ITS flange according to the connectivity shown in Figure 4.
The concentrated load for each platform and frame is applied with distributed coupling, e.g., see Figure 3. In addition, loads are applied to cable ducts and lines; these loads are applied to the centre of mass of the surface corresponding to the components, then distributing the load on the surface with RB3s.
Table 2 summarizes the loads and moments that are applied in the model. The global forces and moments are reported as function of the components of LC1. The ITS pressure and the LH2 tank pressure is the same for all load-cases. For the

sake of conciseness, platforms loads, frames loads, duct loads and lines loads are reported as generic F_x, F_y and F_z components; a separate set of forces is applied to each of the ITS equipment mentioned.

Table 2: Schematic summary of forces and moments applied in the model

Loads	LC1	LC2	LC3	LC4
Platforms loads		$F_{x,a}$, $F_{y,a}$, $F_{z,a}$		
Frames loads		$F_{x,b}$, $F_{y,b}$, $F_{z,b}$		
Ducts loads		$F_{x,c}$, $F_{y,c}$, $F_{z,c}$		
Lines loads		$F_{y,d}$, $F_{z,d}$		
ITS pressure	$-P_1$	$-P_1$	$-P_1$	$-P_1$
LH2 tank pressure	P2	P2	P2	P2
Global force*	$-F_x$	$-F_x$	$-F_x$	$-F_x$
Global moment*	M_x	M_x	$-M_x$	$-M_x$

2.4. Analysis Approach

The following analyses are presented in this work:

- Linear Perturbation Buckling Analysis,
- Non-linear Buckling Analysis.

2.4.1. Buckling linear perturbation analysis

Buckling linear perturbation analyses are performed with the same boundary condition and loads outlined in Section 2.3. The outcome of the analyses is a scalar factor associated with a deformed shape. A general eigenvalue buckling analysis can provide useful estimates of collapse mode shapes, and the resulting scale factor can be interpreted as a scale factor for the critical buckling load, i.e., provide an initial buckling margin of safety. A total of 30 modes are extracted. Selected modes are then combined and introduced as geometric imperfections in the ITS model. The mode combinations used for each imperfection and load case are presented in Section 2.4.2.

In addition to the linear buckling analysis, a frequency analysis is performed to obtained alternative imperfection shapes. Unlike the localized buckling modes, the selected vibration modes produce imperfection patterns that extend over the entire structure. As these modes are used only as inputs for the nonlinear analysis, the frequency analysis results are not presented separately.

2.4.2. Non-linear buckling analysis

A series of non-linear analyses is carried out for each load-case. First, the non-linear analysis is performed for each load-case, then a combination of imperfections is applied to perturbate the geometry. Four combinations of imperfections are considered for each load-case, in particular, three combinations are the results of the buckling modes predicted by the buckling linear perturbation analysis, and the fourth combination results from the vibration modes. A progressively larger scale factor is applied to the linear combination of the modes. The deformed geometry resulting from the buckling linear perturbation analysis is very localized and usually characterized by buckling half-waves between or underneath stringers, while vibration modes affect the whole geometry and perturbate the whole model. It is worth underlining that the perturbation affects only the geometry and does not carry residual stress.

The scale factor applied to the imperfections multiplies the deformed geometry obtained by the linear perturbation and frequency analyses. For example, the displacement resulting from the buckling linear perturbation analyses is always ranging from 0 to 1, and since the scale factors range from 0.1 to 2, the largest offset from the original geometry for each buckling shape corresponding to an eigenvalue will vary from 0.1 to 2 mm. The scale factor is applied to each imperfection mode, which are linearly combined and applied to the geometry before the analysis starts. Since the displacement resulting from the frequency analyses is not normalized and larger than that from the buckling linear perturbation analyses, the same imperfections scale factors multiplied by a 0.1 factor are considered.

The non-linear analyses are performed by applying a progressively increasing scale factor to all the loads included in the analysis, ranging 0-400 %, in order to capture the instability onset, as well as to consider any change in the global structural behaviour and stress state. A scale factor of 100 % corresponds to the nominal load-cases provided. By applying a progressively increasing scale factor, it is possible to determine margins of safety, by looking at the force (i.e., load scale factor) vs displacement curves, establishing the onset of non-linear behaviour and instability.

The ID of each analysis is presented as follows in this work:

- The ID starts with the load-case considered, i.e., LC1, LC2, LC3 and LC4.
- The type of analysis, i.e., "b" and "nl", for the buckling linear perturbation analysis and non-linear analysis, respectively.

- For the analyses with imperfections, "1", "2", "3" and "4" are used to indicate the imperfection case.
- For the analyses with imperfections, “01”, "05", "10" and "20" are used to indicate the imperfection scale factor of 0.1, 0.5, 1 and 2 for the analyses considering buckling modes and 0.01, 0.05, 0.1 and 0.2 for the analyses considering vibration modes, respectively.

The ID looks like: LC"i" _ "type of analysis" _ "imperfection case" "imperfection scale factor".
In Figure 5 the list of non-linear analyses and the imperfection applied is summarized.

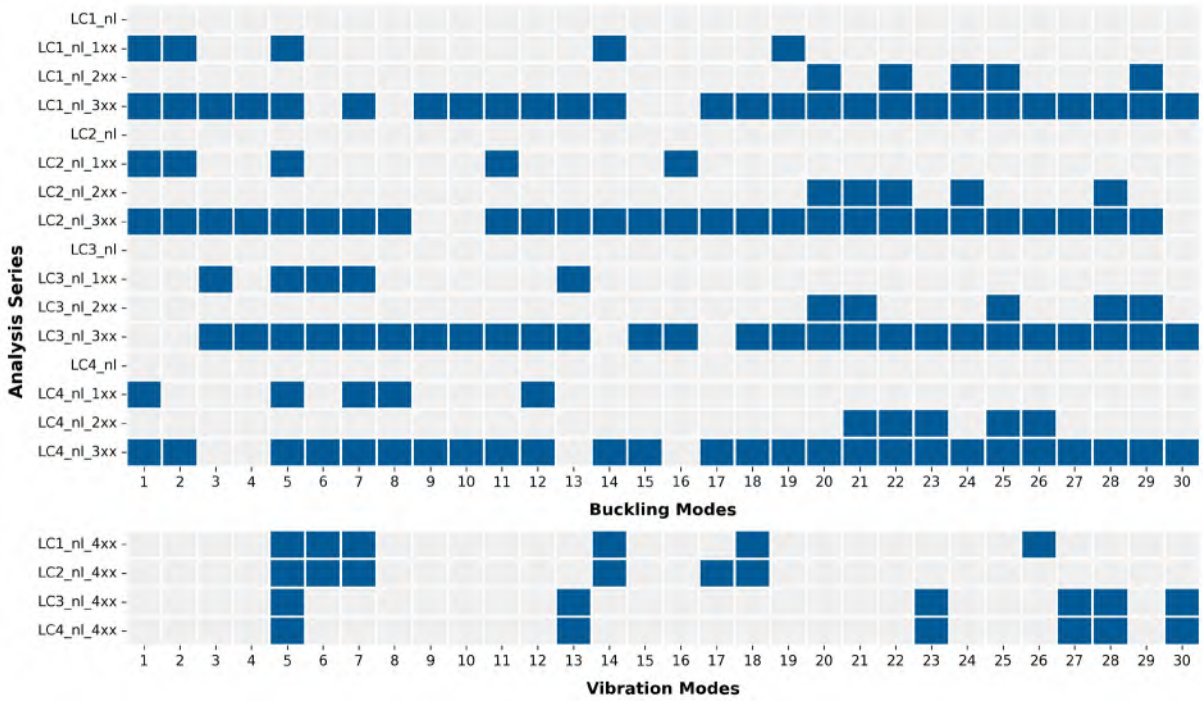

Figure 5: Summary of imperfection cases combination for non-linear analyses.

3. RESULTS AND DISCUSSION

3.1. Buckling Linear Perturbation Analyses

The results from the linear perturbation analysis performed to obtain the buckling eigenvalues are reported in Table 3 and Table 4.

Table 3: Eigenvalues resulting from the linear perturbation analysis – Part 1

Eigenvalue N.	LC1	LC2	LC3	LC4
1	2.40	2.54	-	2.50
2	2.66	2.59	-	2.79
3	2.69	2.70	3.12	-
4	2.94	2.75	3.23	-
5	3.06	2.81	3.32	3.12
6	-	2.82	3.35	3.21
7	3.12	2.85	3.39	3.25
8	-	2.91	3.4	3.28
9	3.35	-	3.42	3.33
10	3.35	-	3.46	3.35
11	3.37	3.05	3.48	3.39
12	3.45	3.12	3.49	3.40
13	3.48	3.13	3.51	-
14	3.52	3.18	-	3.42
15	-	3.20	3.52	3.48

Table 4: Eigenvalues resulting from the linear perturbation analysis – Part 2

Eigenvalue N.	LC1	LC2	LC3	LC4
16	-	3.20	3.53	-
17	3.60	3.22	-	3.50
18	3.63	3.23	3.55	3.52
19	3.66	3.27	3.56	3.55
20	3.67	3.33	3.58	3.55
21	3.67	3.34	3.59	3.61
22	3.70	3.34	3.60	3.62
23	3.71	3.36	3.62	3.62
24	3.72	3.40	3.65	3.65
25	3.77	3.42	3.66	3.68
26	3.79	3.51	3.67	3.73
27	3.79	3.51	3.70	3.73
28	3.81	3.53	3.72	3.74
29	3.84	3.55	3.74	3.75
30	3.87	-	3.76	3.76

The deformed shape of selected modes resulting from the buckling linear perturbation analysis for the Load-Case 1 are reported in Figure 6. The linear perturbation analyses provide the eigenvalues for each of the eigenmode. The resulting parameters can be considered a margin of safety, i.e., the factor that should multiply all the loads to obtain a certain buckling shape. A minimum value of 2.4 or higher

results from the four load-cases, indicating relatively large buckling margins of safety for the load-cases considered in this work. All the modes predicted by this analysis are local modes, so no global buckling was ever captured by the analysis. These local modes tend to occur between or underneath the stringers. When a dash line ("-") is reported in the Table 3, that indicates that the analysis predicts a negative eigenvalue, so a negative scale factor that does not make sense for this analysis.

Finally, the deformed shape of selected modes from the frequency analysis are reported in Figure 7 to highlight the difference in the imperfections and perturbed geometry resulting from the two different strategies.

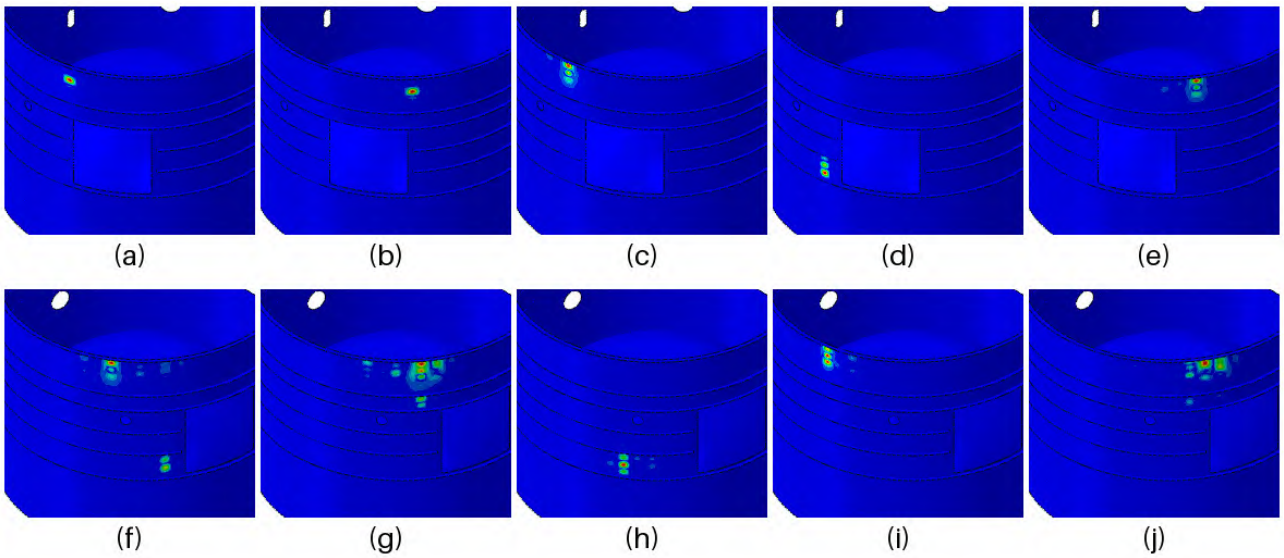

Figure 6: Perturbed geometry of modes 1 (a), 2 (b), 5 (c), 14 (d), 19 (e), 20 (f), 22 (g), 24 (h), 25 (i), and 29 (j) from buckling linear perturbation analysis for LC1

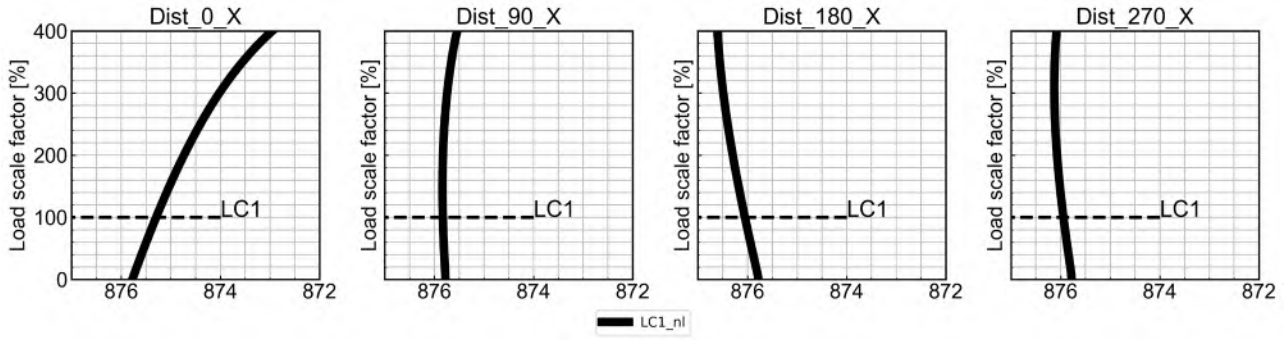
3.2. Non-Linear Buckling Analyses

It is a standard approach when non-linear buckling analyses or tests are performed, to consider the bifurcation point in the force-displacement curve as the onset of instability for a structure. In an ideal shell subjected to longitudinal compression, one can consider the centre of mass of the top and bottom sections to calculate the longitudinal displacement; however, in this work the measurements for the displacement of the centre of mass resulted very small (~1e-1 mm). The reason is that for the load-cases provided, a significant bending was applied to the ITS, resulting in unequal end-shortening around the barrel. In addition, the results showed rigid motion of the rocket, since it was constrained at the bottom of the lower super-element and the force resulting from the bending moments were applied at the top. In Figure 8 the longitudinal displacements along four axes around the barrel are reported, function of the load scale factor (reported as [%] of the load-case). The 0° is considered the radial position of the point in the barrel where the highest stress is found in the analysis; the other three plots then show the displacement for axis aligned along the longitudinal direction of the barrel at radial positions of 90°, 180° and 270°. From the plots it is clear that the end-shortening is greater in one radial position, rather than the other. For this reason, the next plots, addressing the buckling onset and the effect of imperfections, are only reported for the 0° radial position, i.e., θ_i radial position where the element with the highest stress is found in each analysis.



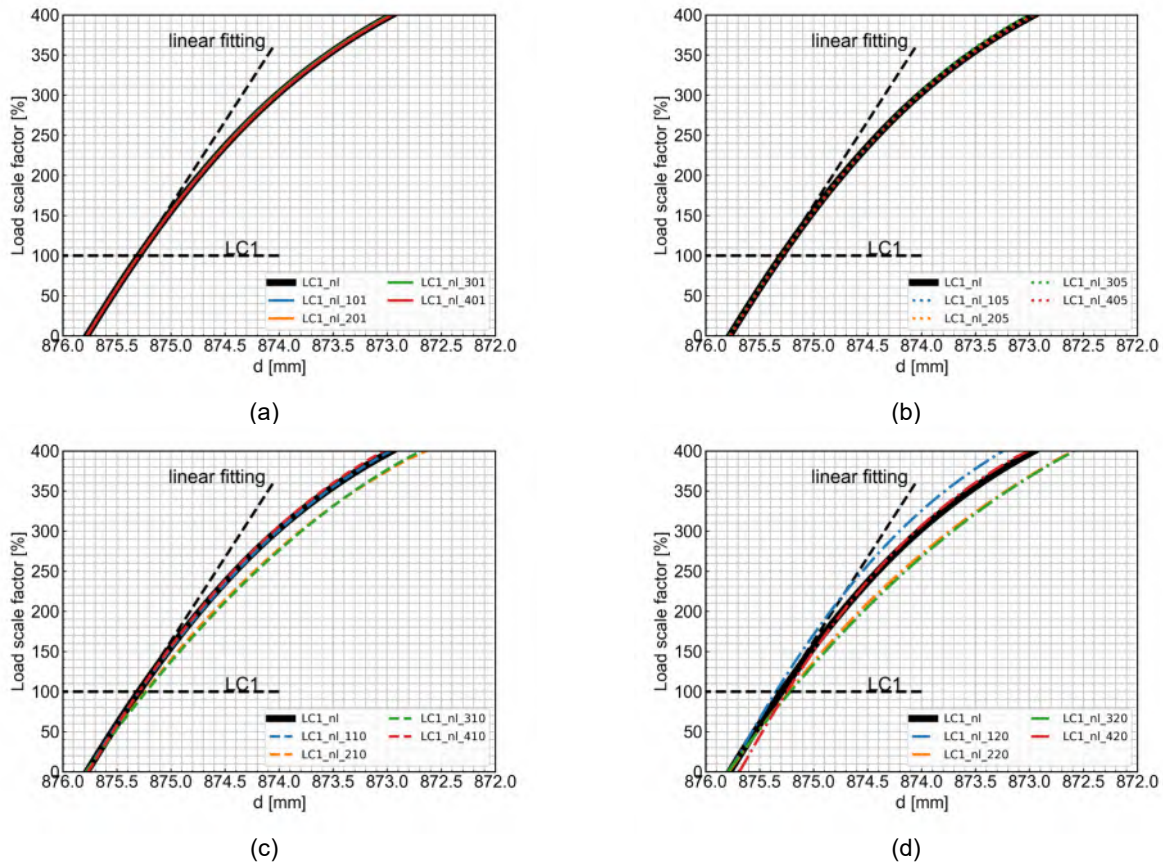


Figure 8: Longitudinal displacement along four axes around the barrel, i.e., (a) 0°, (b) 90°, (c) 180° and 270°, when 0° corresponds to the radial position where the highest stress is found

In Figure 9, Figure 10, Figure 11, and Figure 12 the plots are presented, showing the load scale factor as function of the longitudinal displacement measured along the axis passing on the barrel through the 0° radial position. The straight dashed line obtained from linearly fit the curves without imperfections (i.e., LC1_nl, LC2_nl, LC3_nl and LC4_nl) in the 0-100 % load range, is shown to visually highlight when the structure diverges from the linear behaviour. The results are summarized in Table 5, where the load scale factor corresponding to a 10% difference between the curve and the linear fit, and the percentage difference at 160 % of the load-case are reported for all the load-cases. For the sake of conciseness, for each load-case and imperfections scale factor, the average value and the standard deviation is reported. These two values are meant to give an estimation of the buckling safety factor.

LC4_nl_x10	212%	0.00%	5.8%	0.07%
LC4_nl_x20	213%	1.73%	5.7%	0.12%

By looking at the "load" vs shortening curves, for all load-cases, the benchmark analyses (with no imperfection "_nl") begin showing non-linear behaviour between 150%-200%. As expected, this value is smaller than that predicted by the linear perturbation analyses, but still well above the 100% threshold.

Table 5 reports the load scale factor at which the

load-displacement response deviates by 10% from a linear best-fit, defining the onset of significant structural nonlinearity. For all load cases, this threshold exceeds 200%, indicating that the response remains approximately linear well beyond the reference load. This is further confirmed by the deviations at 160% of the applied load (a safety factor of 1.6), which remain below 10%, validating linear approximations within this critical range. Additionally, higher imperfection scale factors correspond to lower load scale factors, consistent with expectations for larger geometric perturbations. Finally, as expected from non-linear analysis, all reported load scale factors remain below those predicted by linear perturbation buckling analyses.

In Figure 13 the location of the elements with the highest stress is highlighted, and Table 6 summarises the results from the non-linear analyses without imperfections, reporting the highest Von Mises stress from the four load-cases, as well as the margin of safety, evaluated as the ration between the maximum stress and the material ultimate strength.

The results for the stress are presented showing the highest stress at the integration point across the thickness of the shell, and no nodal interpolation (averaging) is applied, effectively showing the worst-case scenario and conservative results. The stress contours are reasonable, and the highest stress is always below the ultimate strength of the Aluminium 2000 series. For the load-cases 2 and 3, the highest stress is located under the rails where a platform is connected, while for the LC1 it is around the frame duct plate and for the LC4 it is under the top flange, above a cable duct. When imperfections are applied, the stress tends to increase or even move to a different position with the larger imperfection scale factors applied. If the location of the highest stress changes, the new location is always in a point of the structure where the imperfections were applied. In some analyses and location, the stress reaches very high values (above plasticization stress), however these analyses are almost always associated with " load " vs shortening that differ from the benchmark curve; hence it can be concluded that these analyses are not reliable for stress analysis because the imperfection are too large.

Table 6: Maximum Mises stress summary

	LC1_nl	LC2_nl	LC3_nl	LC4_nl
Max Mises Stress [MPa]	288.3	279.4	277.3	339.9
Margin of safety [-]	0.69	0.66	0.66	0.81

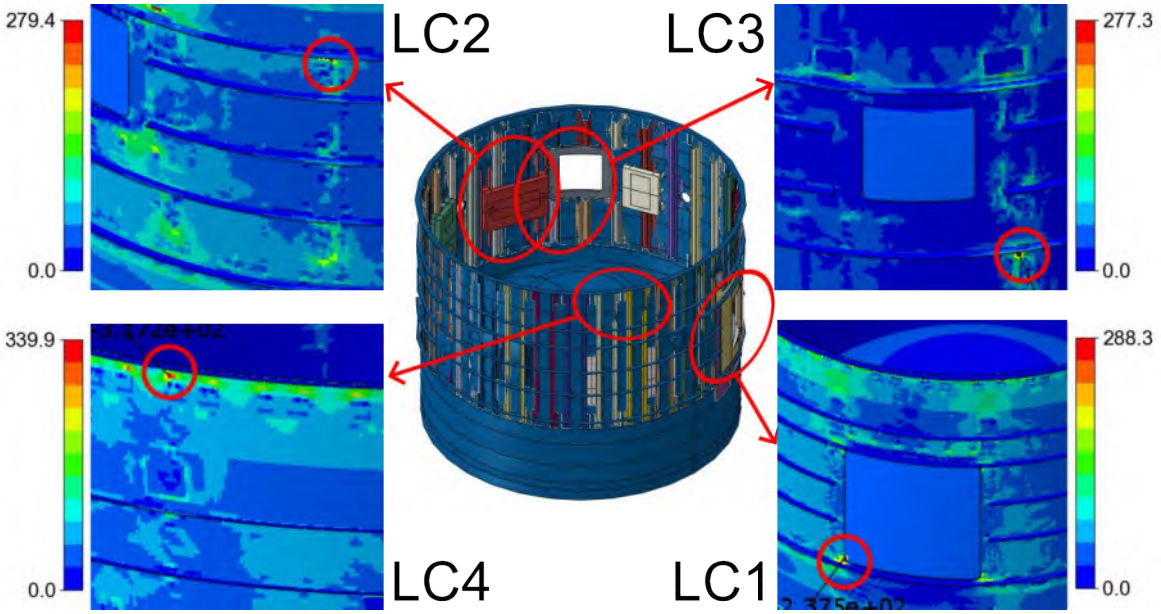

Figure 13: Summary of areas of elements with highest stress for each load-case.

The analysis carried out with imperfection from the vibration modes and scale factor equal to 0.2 ("_420"), differs too much from the benchmark curve, already from the beginning of the simulation, and is not considered reliable; indicating that the scale factor is too large and deforms the whole structure. A similar conclusion can be drawn from analyses with imperfections from the buckling linear perturbation analyses: it often appears that with scale factor equal to 2 that the curve starts from the same point at the beginning of the analysis, because the buckling imperfections are very localized; but then they diverge significantly from the benchmark curve. This is especially true for the combination of imperfection 3 (for all load-cases), this combination of imperfection is likely excessive for the structure and the applied imperfections are too large. The imperfection combination 3 for lower scale factors is comparable to the benchmark curve and deemed acceptable.

4. CONCLUSIONS

In this work the non-linear buckling analyses of the ITS structure of the CALLISTO project are presented; according to the load-cases provided and accounting for geometrical imperfection to investigate possible structure instability.
The objective of the analyses is to validate the design of the rocket, by verifying that instability is prevented given the load-cases, and the goal was achieved by applying a progressively increasing load until a non-linear behaviour of the structure was detected. For all load cases, the predicted buckling load was well above the corresponding reference load, and the structural response remained approximately linear, with no indication of buckling or instability up to a load factor of about 1.6. This relatively high buckling load factors indicate that other failure modes may become critical before buckling. It is also important to remark that all the load-cases had a large bending moment applied to the top of the rocket, resulting in a rigid motion of the rocket; as well as the ITS showing both end-shortening and tension around the structure.
Overall, this structural validation supports the CALLISTO architecture's readiness for subsequent qualification testing and contributes to the broader maturation of reusable vertical take-off and landing technologies.

ABSTRACT

Buckling is one of the primary design criteria in aerospace structures and is particularly critical for cylindrical launcher structures. Although significant progress has been made throughout the years in understanding the buckling behaviour of cylindrical shells, especially through finite element methods, reliably predicting buckling loads during design and validating them experimentally without damaging costly test specimens remains challenging. This is mainly due to the high imperfection sensitivity and unstable post-buckling behaviour of cylindrical shells under axial compression. To address these challenges and meet the demand for safe, lightweight space structures, non-destructive methods for predicting in-situ buckling loads have gained increasing interest. One such method is the Vibration Correlation Technique (VCT), which exploits the relationship between eigenfrequency and applied load. While VCT has shown promising numerical and experimental results for small-scale cylinders, its industrial adoption requires validation on full-scale structures. This paper presents the results of an experimental validation campaign on a full-scale structure.

1. INTRODUCTION

Buckling is a critical design consideration for lightweight thin-walled structures, particularly in aerospace applications where high structural efficiency is required. Cylindrical shells are widely employed in launch vehicles, spacecraft, aircraft, storage tanks, pipelines, and other engineering structures because of their favourable stiffness-to-mass ratio. However, their high sensitivity to geometric imperfections, material and manufacturing variability, and boundary conditions makes their buckling behaviour difficult to predict reliably. This uncertainty is particularly relevant for aerospace structures, where an over-conservative buckling design can result in significant mass penalties, while overprediction of the buckling load can compromise structural safety.

The design of aerospace cylindrical shells is still largely based on the NASA SP-8007 guidelines [1], first published in 1965 and revised in 2020, which provide knock-down factors as a function of the cylinder radius-to-thickness ratio. However, advances in manufacturing, particularly the widespread use of composite materials, have rendered these factors increasingly over-conservative. Finite element methods now enable highly accurate structural analyses, provided that the numerical models capture the structural details, experimental boundary conditions, and relevant imperfections, especially geometric deviations.

Nevertheless, particularly in the aerospace sector, experimental validation remains an indispensable component of the structural qualification process, both for validating numerical predictions and for establishing the actual load-carrying capability of a structure. Conventional buckling tests, however, typically require loading the structure until instability occurs, which can lead to plastic deformations or the complete failure of the test article [2]. This is particularly undesirable for expensive, large-scale structures such as launcher tanks and spacecraft primary structures, where manufacturing and testing costs are substantial, and therefore the possibility of reusing the test article is highly appealing.

These challenges, together with the growing interest in reusable launcher structures, have increased the appeal of non-destructive methods for estimating buckling loads. Among them, the Vibration Correlation Technique (VCT) predicts the buckling load by extrapolating the relationship between vibration frequencies and applied load [3]. By measuring the natural frequencies at several load levels and correlating their evolution with the applied load, the critical buckling load can be estimated without requiring the structure to be driven to failure. This makes VCT particularly

attractive for imperfection-sensitive structures, for which conventional buckling tests can be difficult to repeat, and numerical predictions may be affected significantly by uncertainties in the geometry, load and boundary conditions.

The potential application of VCT extends beyond aerospace structures. Any lightweight or thin-walled cylindrical structure for which buckling represents a relevant failure mode may benefit from a non-destructive buckling assessment. Potential applications include launch-vehicle and spacecraft structures, aircraft fuselage components, pressure vessels and storage tanks, marine structures, pipelines, and other cylindrical shells used in the energy and process industries. In these applications, VCT could provide an additional means of experimentally assessing structural margins while reducing the need for destructive qualification tests. The method's ability to operate on the actual test article also offers the potential to capture the combined effects of manufacturing imperfections, assembly conditions, material variability, and realistic boundary conditions that are difficult to reproduce completely in numerical models.

Despite these advantages, the industrial application of VCT remains challenging. The relationship between vibration characteristics and buckling load is influenced by geometric imperfections, loading and boundary conditions, mode interaction, measurement uncertainties, and the choice of vibration modes used for the correlation. Furthermore, most experimental validation of the technique has historically focused on small-scale cylindrical shells, while its applicability to large-scale industrial structures remains comparatively less established. Demonstrating reliable performance under realistic boundary and loading conditions is therefore an important step towards its wider adoption.

This paper summarises recent developments toward the industrial implementation of VCT and presents its application to a full-scale structural test. The VCT methodology is first introduced, followed by a preliminary numerical analysis used to define the measurement parameters and estimate the expected robustness of the method. Finally, the results of applying VCT to a real-scale test article, representative of a tank section of Ariane 6 lower liquid propulsion module, subjected to two combined bending-compression load cases are shown and discussed.

2. VIBRATION-CORRELATION TECHNIQUE

To the authors' best knowledge, the relationship between structural vibration and buckling load was first observed by Sommerfeld in 1910 [4], who showed that the vibration frequency of a clamped column decreases with increasing compressive load and tends to zero as the buckling load is approached. By the 1950s, this relationship had been analytically validated for beams, plates, and cylinders in the following form [5]:

$$f^2 + p = 1 \tag{1}$$

where f is the ratio between the frequency under load F and the unloaded frequency F_0, and p is the ratio between the applied load P and the critical buckling load P_{cr}. This led to the first theoretical VCT procedure, in which vibration frequencies measured at different load levels are used to establish a linear relationship between f^2 and p, allowing the buckling load to be estimated by extrapolation to the zero-frequency condition. In practice, however, the buckling load was usually directly extrapolated from an F^2 vs P chart, given that the frequency approached 0 Hz at buckling.

Experimentally, VCT requires a means of exciting the structure, typically a mechanical shaker, modal hammer or loudspeaker, and a means of measuring its response, usually accelerometers or laser vibrometers. Measurements are performed at constant load, and vibration modes must be tracked between successive load levels to ensure consistent frequency evolution. The Modal Assurance Criterion (MAC) is commonly used to correlate vibration modes between measurements.

An important mention here is that Eq. 1 is analytically valid only under several assumptions, namely simply supported boundary conditions, pure axial compression, coincident vibration and buckling modes, and geometrically perfect structures. Nevertheless, for imperfection-insensitive structures, like beams, the deviation from linearity is insignificant and the robustness of the method is thus conserved.

On the other hand, for imperfection-sensitive structures, the relationship between f^2 and p becomes increasingly nonlinear as the load increases and f^2 no longer reaches zero at buckling. Therefore, throughout the years, several VCT approaches have been proposed to account for this nonlinear behaviour [3,6,7]. Among them, the formulation introduced by Arbelo in 2014 [3] has become the most widely adopted one. In this approach, an imperfection reduction factor ξ^2 is determined as the minimum of the quadratic curve fitted to the $(1-p)^2$ versus $1-f^2$ characteristic chart. Then, the buckling load is estimated as:

$$P_{VCT} = P_{CR}(1 - \xi) \tag{3}$$

where ξ^2 needs to be larger than 0 for a valid prediction. Unlike the initial linear formulation, this approach assumes that the vibration frequency reaches a minimum, rather than zero, at buckling, thus complying with experimental observations and making it suitable for imperfection-sensitive structures. A schematic of the procedure is shown in Fig. 1.

Then, in 2019, Franzoni showed that rewriting Eq. 1 as a function of the load and frequency parameters proposed by Arbelo leads to the following relation [7]:

$$(1-p)^2 = [1-(1-f^2)]^2 \qquad (2)$$

showing thus analytically the quadratic dependence between $(1\text{-}p)^2$ and $1\text{-}f^2$.

Another difference of this approach with respect to the previous linear one is that an a priori estimate of the critical buckling load P_{cr} is required, and hence this approach is no longer purely experimental. This value may be obtained analytically, semi-analytically, or numerically, with the highest accuracy generally achieved using an idealised perfect structure [8].

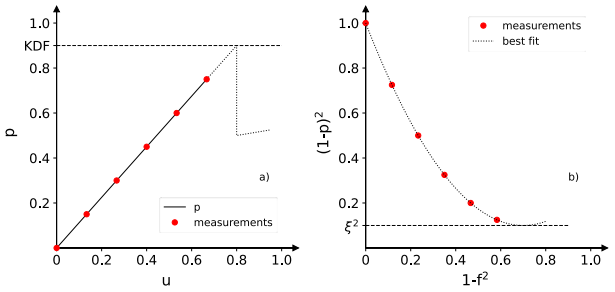

Figure 1: Generic load-shortening curve for cylinders under axial compression and load levels at which vibration measurements are taken a); Generic determination of the minimum value ξ^2 of the quadratic curve fitted between the points of the $(1-p)^2$ vs $(1-f^2)$ VCT characteristic chart b)

In practice, Arbelo's method displayed a low sensitivity to numerous aspects related to the article tested and the experimental environment, as reliable buckling load predictions were obtained in more than 48 experimental tests, using 28 different small-scale cylinders [9]. Within these experimental tests, the method proved equally reliable for isotropic or anisotropic materials, like steel or aluminium, and glass or carbon fibre reinforced plastics, respectively. Likewise, the VCT predictions were equally reliable for monocoque or reinforced cylinders. Furthermore, given the relatively large number of cylinders and testing environments, the low sensitivity of the method towards geometric, boundary and loading imperfections was also implicitly shown.

The aforementioned aspects are also in agreement with the observation drawn from multiple numerical investigations, where the influence of boundary conditions [10], loading [11] and geometric imperfections [12, 13] is easier to isolate and assess.

Besides cylindrical shells, the applicability of VCT to other types of structures was also investigated numerically. In [14], the authors evaluated the applicability of VCT to double-curved shells and showed that its robustness is comparable to that achieved for cylindrical shells. Similarly, in [15], the applicability of VCT to truncated cones was numerically assessed. The authors found that, while the method appeared more sensitive to geometric imperfections and to the maximum load ratio taken into account, VCT was nevertheless able to provide reliable buckling load estimations.

Given that, in practice, the load cases under which cylindrical shells within the industry are tested often contain additional loads besides compression, the feasibility of the method for combined load cases was also investigated. The compression-internal pressure was the first of these to be investigated in [15], numerically and experimentally, for a stiffened steel cylinder with pressure levels up to 0.03 bar. The authors reported that VCT provided accurate buckling load estimations for all the pressure levels tested, in both their numerical and experimental investigations.

Other combined load cases, in which additional bending, shear and torsion loads were applied besides compression, were also numerically assessed in [8]. In this investigation, the authors introduced the aforementioned additional loads either individually or all together, and compression was applied either sequentially or simultaneously with these additional loads. The outcome of this numerical investigation was that VCT provided reliable estimations of the compressive load at which the cylinders buckled, provided that the magnitude of the additional load was low enough, this magnitude being load-case dependent. Furthermore, for a simultaneous load introduction, a higher sensitivity of the predictions with respect to the maximum load level taken into account was observed and the magnitude of the additional loads applied beyond which VCT ceased to provide reliable estimations was also lower than when compression was introduced sequentially. Lastly, whether the additional load should be taken into account when determining the reference P_{cr} needed for the buckling load estimation also varied between the load cases. In this regard, for bending-compression, the P_{cr} in which the bending load was taken into account provided the best results, while for shear-compression the value obtained for the pure compression load case provided the best predictions. On the other hand, for the torsion-compression load case, as well as for the case in which bending, shear and torsion were applied alongside compression, the type of P_{cr} providing the best estimation depended on the cylinder, as well as on whether compression was applied sequentially or simultaneously alongside the additional loads.

3. TEST ARTICLE AND SETUP

The test article was a cylindrical barrel section representative of the Ariane 6 lower liquid hydrogen propulsion module, with a diameter of ~5.4 m, a height of ~3.1 m, and a wall thickness of 2.55 mm. A schematic of the barrel in the context of Ariane 6's lower liquid propulsion module is shown in Fig. 2.

The barrel structure was manufactured by MT Aerospace AG and comprised shaping 4 aluminium panels through a shot peening process up to the desired curvature and then welding them together using the TIG procedure. The material properties of the aluminium used are listed in Table 1.

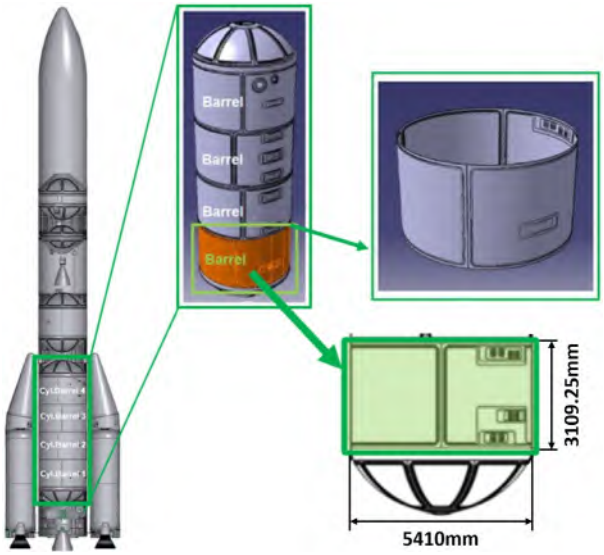

Figure 2: Barrel tank section in the context of Ariane 6's lower liquid propulsion module

Table 1: Aluminium alloy material properties

E [GPa]	ν_{12}	ρ [g/cm^3]
70	0.33	2.823

The barrel test was commissioned to IMA Dresden, who provided all the prerequisites for the buckling test under the supervision of MT Aerospace AG. The load was introduced by 4 hydraulic actuators distributed equally across the barrel's circumference and connected to the upper and lower loading surfaces of the test rig. The boundary conditions provided were simply supported via contact, with additional inner radial support. A schematic of the panel designation, actuator position, barrel in the test rig and boundary conditions is shown in Fig. 3.

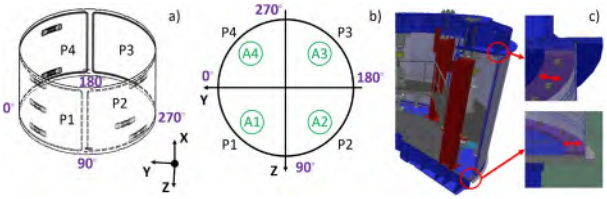

Figure 3: Panel labels a); Actuator layout b); Test rig and boundary conditions schematic c)

Two load cases were tested, defined to promote buckling initiation on specific areas of interest. The first load case was defined such that buckling would initiate on the bay of panel P2, this aspect being promoted by the higher load applied by actuator 2 with respect to the adjacent ones. Conversely, the second load case was defined to favour buckling initiation near the weld seam between panels P2 and P3, by having the same load magnitude applied by actuators 2 and 3. The load ratios applied during the two load cases tested are shown in Tab. 2. In the load application procedure, actuator 2 was considered the main one and applied a displacement-based load. Then, the loads of the secondary ones were defined based on the reaction force measured at actuator 2, such that the load ratios shown in Tab. 2 were applied. Furthermore, the influence of loading imperfections was mitigated by filling the gaps between the barrel edges and the load introduction surfaces with aluminium shims.

Table 2: Actuator load ratios for the tested load cases

Actuator	1	**2 (primary)**	3	4
Load case 1	0.898	1	0.898	0
Load case 2	0	1	1	0

The VCT measurement setup was composed of a loudspeaker placed at a 1-2 cm distance from the barrel to excite the structure and a Polytec PSV400 2D laser vibrometer to measure its vibration response. The former can be seen in Fig. 4, showing the top view of the barrel and test rig.
The load levels at which the vibration measurements were taken were based on the numerical estimates provided by MT Aerospace, given the higher level of detail of their numerical models, which included the measured shape imperfection as well. Given the limitations regarding the testing time, the vibration response was measured at 9 load levels for the first load case. The number of measurements was chosen based on the investigation shown in [10], where 9 measurements were found to be a minimum sufficient to significantly alleviate the influence of measurement deviations. Then, since the testing time for the first load case was longer than expected, the number of measurements was further reduced to 8 for the second load case. Additionally, the number of points in the grid measured was also reduced from 10x8 in the first load case to 7x9 for the second load case.

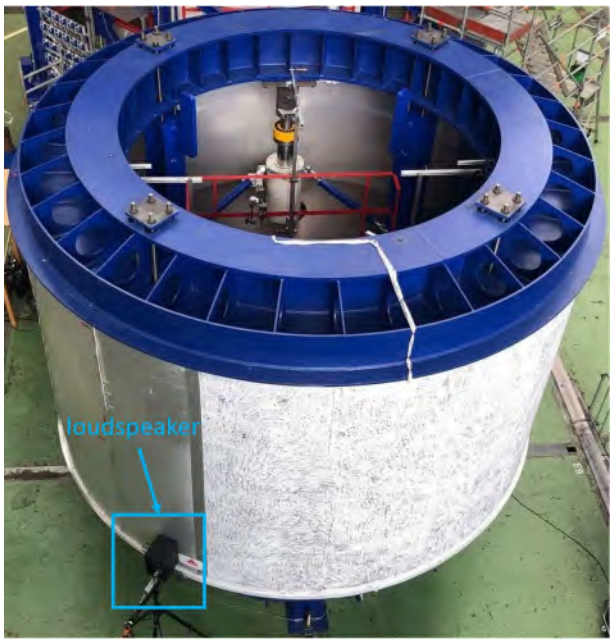

Figure 4: Top view of the barrel and test rig

Furthermore, given the novelty of applying VCT to a real-scale structure and even more notably, the

importance of the qualification test, precautionary measures were taken to minimise the risk of buckling occurring during the vibration measurements performed under constant load. These implied applying pre-loads before the last 3 vibration measurements at a magnitude significantly exceeding the load level of the subsequent vibration measurements. A more comprehensive description of the test article and experimental setup can be found in [16].

4. FINITE ELEMENT MODEL AND ANALYSIS

The finite element model used in this investigation was built in Abaqus, based on the original one in Nastran provided by MT Aerospace AG. In the original Nastran model, the barrel was meshed with 4-node CQUAD4 quadrilateral and 3-node CTRIA3 triangular shell elements, the Abaqus equivalent being the S4R and S3 shell elements, respectively. To introduce the loads and constrain the model, reference points were defined at the ends of the actuators and at the bottom of the test rig. The reference point at the bottom of the test rig was kinematically coupled with the nodes at the interface between the bottom loading plate and the test rig supporting legs and a clamped boundary condition was specified at this node. Similarly, the reference points at the ends of the actuators were coupled with the nodes at the interfaces between the actuator ends and the top and bottom loading plates. Then, the connection between the barrel and the loading surfaces of the top and bottom of the test rig was established via a tie constraint, given that under load the barrel edges would closely follow the displacements of the loading surfaces of the test rig. Lastly, the load was introduced by prescribing forces at top reference points, while the in-plane translations were constrained. The reference points used and regions with which they were coupled are shown in Fig. 5 a) and b), while the FE model in which the tie constraint is highlighted in red is shown in Fig. 5 c).

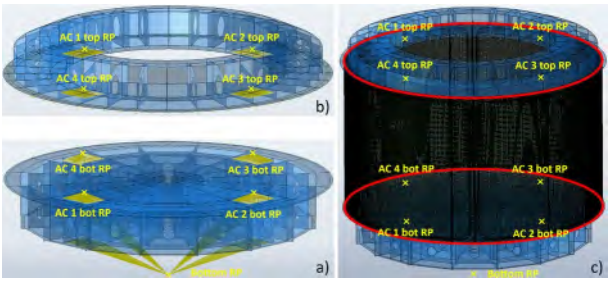

Figure 5: Couplings at the bottom of the test rig a); couplings at the top of the test rig b); FE model with tie constraint between the barrel edges and the load introduction surfaces of the test rig highlighted c)

5. NUMERICAL ANALYSIS

Considering that VCT estimates the knock-down factor as 1- ξ, buckling analyses were run using the Lanczos solver to obtain the P_{cr} values for the two load cases tested. Given that the shape imperfection measurement was not available, a buckling analysis was also run for the pure compression load case to extract the eigenmodes used in the non-linear analyses to introduce shape imperfections. A total of three buckling modes were chosen to disturb the mesh on the panel P2, including the welding seam between P2 and P3 panels. The magnitude with which these were applied was such that the maximum deviation from the original shape was 50% with respect to the barrel's wall thickness of 2.55 mm. These buckling modes are shown in Fig. 6.

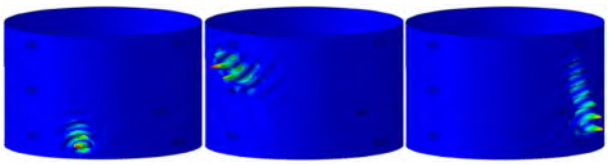

Figure 6: Buckling modes used in the non-linear analyses

The non-linear analyses were run using the Newton-Raphson solver, with the primary scope of performing numerical VCT. This involved running vibration analyses, using the Lanczos solver, at load levels in steps of 5% with respect to the non-linear buckling loads of the two load cases (20 load levels).

Besides providing an initial estimation of the expected robustness of VCT for the two load cases tested, these analyses also provided valuable initial estimates used to set up the measurement parameters. Namely, the starting point of the frequency measurement window was based on the vibration frequency of the first mode in an unloaded state, which had a value around 24Hz. Next, the initial measurement resolution was defined based on the lowest frequency change of the vibration modes between the first two load steps, this value being around 0.125Hz.

The relative errors of the numerical VCT predictions with respect to the non-linear buckling loads for the two load cases are shown in Fig. 7, as a function of the maximum load ratio used.

As shown in Fig. 7, for the first load case, the prediction accuracy was within 20% for the majority of the first 10 vibration modes for a load ratio of at least 75% and within 10% for a maximum load ratio of at least 85%. Conversely, for the second load case, the same was valid only for load ratios of at least 85% and 95%, respectively.

In addition, the sensitivity of the VCT prediction with respect to the maximum load ratio used was significantly larger for the second load case. For the first load case, once the evolution of the VCT predictions with respect to the maximum load ratio used became quasi-linear and ascending, the errors ranged from -30% to +8%. On the other hand, for the second load case, these ranged from -60% to -1%, showing thus a much greater sensitivity of the VCT predictions with respect to the maximum load level used. This was attributed to the higher bending component for the load case, this increase in the prediction sensitivity with increasing the bending

load being also found in [9].

6. EXPERIMENTAL RESULTS

6.1. Load case 1

Fig. 8 shows the load versus time curve for the first load case, in which the former is normalised with respect to the buckling load. As can be seen in this figure, the first measurement was taken at a relatively low load level, considered sufficient to provide consistent boundary conditions with the subsequent measurements. Furthermore, the pre-load approach for this load case was to increase the load to a level significantly above the levels of the last three vibration measurements. However, during this single, high pre-load, local bending occurred and remained present even when the load was decreased for the next vibration measurement.

This local bending also brought a change in the vibration response, meaning that most of the vibration modes identified up to the 6th load step could not be identified in the subsequent measurements. This change is best seen on the frequency response chart shown in Fig. 9, where it can also be noticed that the measurement at the lowest load level was omitted, as this load level proved to be insufficient to provide consistent boundary conditions with the subsequent ones.

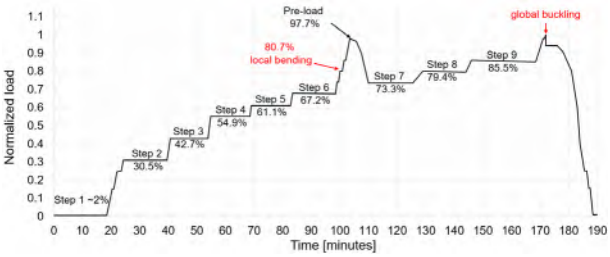

Figure 8: Load case 1 load-time history

When following the peaks within the 29-30Hz window, depicting the vibration mode frequencies, it can be seen that the vibration mode vanished completely beyond the 6th load step/vibration measurement. Conversely, when looking at the peaks within a 32.5-33.5Hz window, it can be seen that those corresponding to the last three measurements have the same frequency.

Another important aspect that can be seen in Fig. 9 is that peaks at 25Hz were recorded regardless of the load level tested. These were considered to be caused by interference from other functioning electronic equipment in the facility, especially since the frequency of 25Hz is half of that of the power supply and that at these frequencies no vibration modes were identified. A somewhat similar case can be seen around a frequency of 24Hz, for which no actual vibration modes were identified either. However, while these peaks might also be caused by some interference, this effect was not seen across all the measurements, as no such peak occurred during the third measurement.

Furthermore, it is also noticeable that some of the peaks were not that well defined. This implied that the 0.125Hz measurement resolution was not sufficient to accurately determine the vibration mode frequencies of all the modes identified.

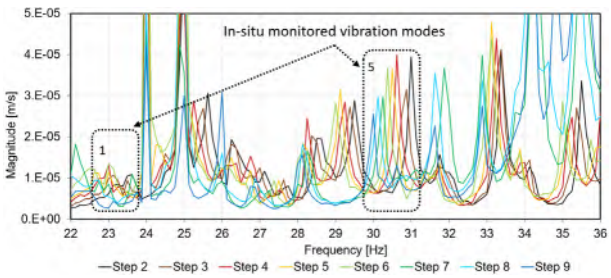

Figure 9: Vibration response chart for load case 1

Although the majority of the vibration modes could not be found after the frequency response change induced by the local bending occurring during the pre-load, there were still some vibration modes consistently found across the load levels measured and which showed the expected frequency decrease. Namely, the vibration modes labelled 1 and 5 showed in Fig. 10, with the latter also being considered the most reliable one during the test.

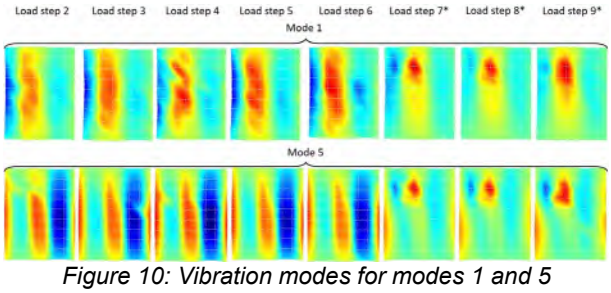

Figure 10: Vibration modes for modes 1 and 5

The relative errors of the VCT buckling prediction using the aforementioned vibration modes are shown in Fig. 11. Here, it is important to mention that the predictions were performed in-situ and provided before the buckling load was reached.

Nevertheless, to emphasise the accuracy of the method, the relative error of these predictions with respect to the experimental buckling load, instead of the actual buckling load prediction, is shown.
As considered during the test, indeed the best accuracy was obtained using mode 5, with a relative error around -6%. Moreover, the prediction using mode 1, although with a poorer accuracy around -20%, for a maximum load ratio of 85%, was still around the expected accuracy based on the preliminary numerical analysis.

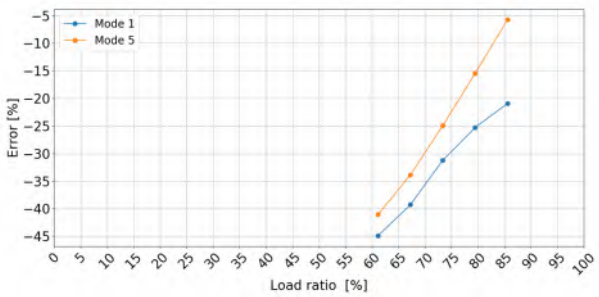

Figure 11: Relative error of the VCT predictions for vibration modes for Mode 1 and 5

On the other hand, the sensitivity of the experimental VCT prediction to the maximum load level used was significantly more pronounced than the one observed in the numerical results. This aspect can be clearly seen by comparing the relative errors from Fig.11 to those in Fig. 7a), where, for a load ratio around 60%, the experimental predictions were in a -45% to -41% window, while the numerical ones were in a -28% to -5% window.
Under the time constraints during the test to provide reliable in-situ predictions, focus was given to the first few occurring vibration modes, out of which modes 1 and 5 were identified as the most promising ones. However, the number of vibration modes within the 20-60Hz measurement window was significantly larger, and VCT predictions were performed using all the vibration modes identified in a post-test analysis. Nevertheless, the best predictions remained the ones performed in-situ.

6.2. Load case 2

Fig 12. shows the normalised load versus time curve for the second load case. Given the experience from the first test, several modifications were implemented for the second one. Firstly, the number of measurements during the test was reduced from 9 to 8, primarily due to time constraints. This implied dropping the measurement at a load ratio around 2%, particularly since for the first load case the vibration response at this load level was not consistent with those for the subsequent load levels. However, during the buckling test after the first vibration measurement was performed, it was found that some of the vibration modes identified in the pre-test calibration measurement remained. Therefore, the calibration measurement is also shown in Fig. 12, despite the fact that the test had only 8 planned vibration measurements for the purpose of VCT.
Secondly, measurement resolution was refined to 0.1 Hz, given that the 0.125Hz one used in the first test was not sufficient to accurately determine the frequencies for all the vibration modes identified.
Thirdly, the measurement window was increased from 20-60Hz for the first load case, to 20-100Hz for the second load case, to investigate the feasibility of the predictions using higher-order vibration modes.

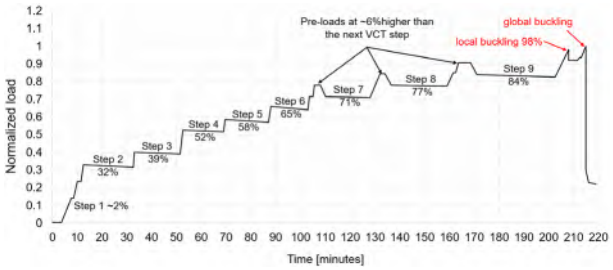

Figure 12: Load case 2 load-time history

Lastly, the risk of losing vibration modes due to local effects at high load levels was reduced by implementing a different pre-loading procedure. Instead of applying a single pre-load covering the load levels of the last three vibration measurements, a smaller pre-load was applied before each of the last three measurements.
During the test, similarly to the first load case, the vibration modes considered the most likely to provide the best predictions were identified. These can be seen in the vibration response chart shown in Fig. 13, while their shapes are shown in Fig. 14.
Also similarly to the first load case, a change in the vibration response occurred during the test of the second load case, here between the last two vibration measurements. This change can be easily observed when looking at the peaks in the 34-35Hz window from Fig. 13, where the peak in dark blue, corresponding to the last measurement, sits further than even the black one corresponding to the second measurement, thus describing a vibration mode frequency increase, instead of the expected decrease.

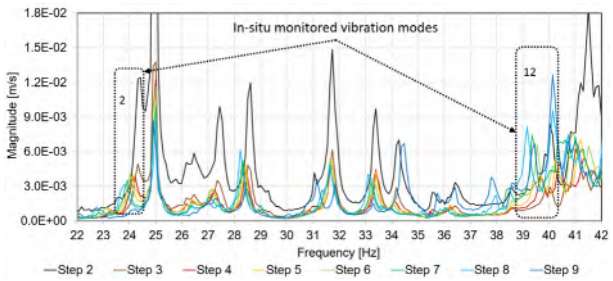

Figure 13: Vibration response chart for load case 2

Furthermore, while based solely on the frequency response chart it might seem that the change consisted primarily in a mere frequency shift of the vibration modes' frequencies, the visual inspection of the vibration modes revealed that the modes

found in the last measurement, although with frequencies close to the previously identified modes, had entirely different shapes. This implied that, unlike for the first load case, for the second load case none of the previously monitored vibration modes could be found after the change in the vibration response occurred. Hence, the maximum load ratio for the second load case that could be taken into account for VCT was 77%, as the measurement at 84% could not be used.

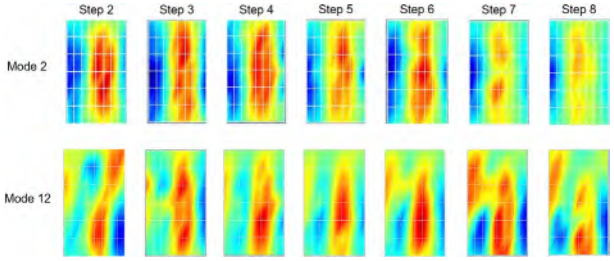

Figure 14: Vibration modes 2 and 12

Another aspect that can be noticed from Fig. 13 is that the definition of the peaks is still not ideal. Nevertheless, the improvement when compared to those in Fig. 9 for the first load case is clearly noticeable. Moreover, choosing an even finer resolution posed the risk of exceeding the time allocated for the test, especially since the testing time for the second load case already took longer than the first one, despite the fewer planned vibration measurements.

When comparing this figure with its counterpart Fig. 9 for the first load case, it can be seen that the constant signal at 25Hz was still present in each measurement. Similarly, there were no distinct vibration modes at this frequency, thus further supporting the assumption that it was caused by interference with the other functioning electronic equipment. In contrast, for the second load case, the peak at 24Hz seen for the first load case was no longer found.

Another similarity with the first load case is that, for the modes considered during the test to provide the best predictions, the measurement at a 2% load ratio could not be used.

The relative errors of the in-situ experimental buckling load predictions for the second load case are shown in Fig. 15. When comparing this figure with its corresponding Fig. 11 for the first load case, it can be noticed that the accuracy of VCT for this load case was poorer. For the second load case, the best prediction had a relative error around -15% and was obtained using mode 2, while the prediction based on mode 12 had an error around -24%. Although the accuracy of the VCT prediction for the second load case was lower than for the first one, for a maximum load ratio of 77%, these predictions were well within the estimated range based on the numerical analysis as well.

The lower VCT accuracy for the second load case was attributed firstly to the lower maximum load ratio that could be used for the VCT predictions (77% instead of 86%) and secondly, to the larger bending component compared to the one for the first load case.

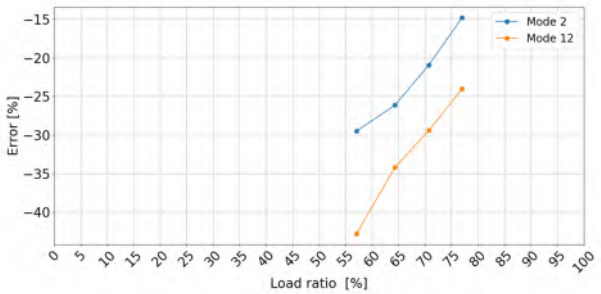

Figure 15: Relative error of the VCT predictions for vibration modes for Mode 2 and 12

A post-test investigation in which VCT predictions were performed for all the modes identified was also performed for the second load case. Although the number of vibration modes was significantly higher than for the first load case, due to the wider frequency range measured, there was only one potential mode providing a prediction better than the ones provided in situ, with a relative error of -1%. However, a vibration mode shape could not be found for all the peaks attributed to this mode in the visual inspection of the mode shapes. Therefore, the degree of confidence in the VCT prediction based on this potential mode is significantly lower than in the in-situ ones.

7. DISCUSSION

Given the novelty of applying VCT for both a real-scale structure and load cases presuming significant bending components, plus the designation of the test article itself, there are several aspects regarding the test and its limitations that need further discussion and contextualisation.

As already suggested throughout the paper, the learning curve was steep and there are multiple aspects that can be better optimised for future tests. As previously mentioned, the structure tested was a tank section representative of the Ariane 6 lower liquid hydrogen tank manufactured by MT Aerospace AG. For such a test article at the forefront of engineering innovation and efficiency, a full disclosure of its details to a third party is generally avoided. In this case, there was no information regarding the geometric imperfections.

For the sole purpose of assessing the feasibility of VCT for such load cases and scale, retaining this information for these particular tests had only a marginal impact, since the critical buckling loads provided were based on their high-fidelity models. However, having the shape and thickness imperfections implemented in the FE models used in the preliminary numerical VCT assessment could have improved the correlation between the numerical and experimental results in the context of VCT.

Arguably the most restraining factor during this

testing campaign was related to the limited testing time. For the first load case, the number of planned measurements was 9, which in an ideal scenario should be sufficient to significantly alleviate the influence of measurement deviations [9]. However, the load level of the first measurement was not sufficient to provide consistent boundary conditions. Therefore, the vibration response was different from that in the subsequent measurements, and this measurement could not be used for the purpose of VCT. Furthermore, the local bending that occurred during the pre-load and remained there for the last 3 measurements changed the vibration response. This implied that, for the majority of the vibration modes, there were only 5/9 measurements that could be used to perform VCT. At that point, had more time been available, the load could be dropped until the local bending disappeared, or the entire test could have been repeated without applying the pre-load, as it was already verified that the structure does not buckle globally at the load level of the last planned vibration measurement.

The measurement resolution chosen for the first test of 0.125Hz, although initially thought conservative, proved insufficient to accurately determine the frequencies of all vibration modes identified. For such small changes in the vibration mode frequencies as observed in this test, these inaccuracies may have had a significant influence even for the predictions based on the modes found across 8 load levels, let alone for those based on modes found only across 5. However, using a finer resolution would have increased the measurement time, given that the points in the grid measured would have likely needed an increased number of repeated measurements for an even finer measurement resolution.

The relatively long testing time for the first load case led to a further reduction in the number of vibration measurements performed during the test, from 9 for the first load case to 8 for the second one. As a compromise for this reduction and based on the experience gained during the first test, the measurement resolution was refined to 0.1Hz, the number of points in the grid measured was reduced, and the pre-loading procedure was changed. In hindsight, the latter modification proved to be an inspired one, given that a change in the frequency response was observed between the last two vibration measurements. Hence, using the same pre-load procedure as for the first load case would have probably rendered the two vibration measurements before this change occurred unusable for the purpose of VCT as well.

Given the change in the vibration response between the last two measurements for the second load case, the maximum load ratio that could be used was 77%, instead of 84%. Unlike for the first load case, the source and load level at which this change occurred could not be determined, especially without access to displacement and strain measurements, due to confidentiality reasons.

Nevertheless, a plausible estimate of the interval in which the best VCT prediction error could have been found can be made. Considering that generally the evolution of the predictions tends to become quasi-linear upon exceeding a certain load ratio threshold, the predictions based on modes 2 and 12 can be extrapolated to match the maximum load ratio measured of 84%. When doing so, an error around -9% is obtained for mode 2 and a -18% one for mode 12. Hence, had a vibration measurement been performed just before the change in the frequency response occurred, the relative error of VCT prediction for mode 2 would have likely been between -15% and -9% and for mode 12 between -24% and -18%.

8. CONCLUSIONS

In this paper, to the authors' best knowledge, the results of the first application of VCT for buckling load prediction for a real-scale structure, subjected to load cases with significant bending components, are shown.

The preliminary numerical analyses proved fairly reliable in preparing the measurement setup and parameters, even without the possibility to include the influence of measured imperfections in the FE model. For both load cases tested, the frequency at which the first vibration mode would appear was well predicted, given that in the vibration measurements the first vibration mode occurred in a 23-24 Hz frequency window, while in the numerical model it appeared at 24Hz. Furthermore, the accuracy of the method was within the expected range for the highest load levels available for both load cases as well. On the other hand, the sensitivity of the predictions with respect to the maximum load level used was only well predicted for the second load case, while for the first load case this sensitivity was significantly underestimated. Lastly, the numerical estimation of the vibration mode frequencies drop as the load increases was only fair, since the measurement resolution required to accurately determine the vibration frequencies of all the modes during the test was higher than the numerical estimate.

The best in-situ buckling load predictions for the first load case had an error around -6%, obtained for a maximum load ratio of 86%, while for the second load case the best in-situ prediction had an error around -15%, at a load ratio of 77%. However, the lower accuracy for the second load case is attributed primarily to the lower maximum load ratio available and secondly to the larger bending magnitude.

Overall, VCT was able to provide reliable in-situ buckling load predictions for the load cases tested. This achievement is particularly encouraging for the adoption of the method in further experimental campaigns, as its application not only proved successful for real-scale structures with complex loading and boundary conditions, but also under bending-compression load cases. Furthermore,

even without the possibility to include measured imperfections in the FE model used in the preliminary numerical analysis, a fairly good correlation between the numerical and experimental VCT results was achieved. Moreover, relevant aspects like the frequency at which the first vibration mode would occur and the required measurement resolution were also relatively well predicted. Lastly, vibration modes providing better predictions than the in-situ ones were not identified in the post-test investigation.

In light of the aforementioned considerations, VCT proved to be a reliable non-destructive method to predict the buckling load of cylindrical shells of sizes and testing scenarios relevant within the aerospace field.

ABSTRACT

This paper presents the development, characterization, and full-scale testing of a novel concept of primary structural joints on payload adaptors for launch vehicles. The proposed design replaces the conventional metallic ring-based riveted interfaces between composite shells with an integrated CFRP ring, providing enough local thickness to accommodate bolted joint connections and thereby reducing the number of discrete joints in the load path.

The interest in this type of joint is mainly due to its potential for mass reduction and simplified assembly, as it eliminates an integration step and the associated metallic ring. This approach enables a more efficient load transfer while maintaining, or potentially improving, the overall structural stiffness.

However, the sizing of such CFRP integrated ring cannot be based solely on analytical methods, as the governing failure modes are not straightforward. Consequently, a greater initial effort is required to ensure that the laminate definition, manufacturing process, and final geometry are compatible with the expected load levels. A dedicated test campaign with representative specimens is therefore necessary to validate the design and achieve proper characterization of the joint behaviour.

The concept is presented, highlighting the distinctive features and differences between several flight structures that use CFRP rings, including materials and manufacturing processes. Then, the characterization process is described, considering the set-up definition. The characterization process is based on applying the main critical external loads of the joints generating two different load cases, traction and moments loads. Once the load levels that the CFRP ring can withstand are known, capacity curves are derived and used as the basis for the evaluation of the joint margins under flight load conditions.

Once the previously defined approach is established, a challenging application case is presented in which two different CFRP integrated rings were implemented as internal interfaces for the same payload adapter, considering that the load levels in internal interfaces are higher than those typically found in launcher interfaces, where this kind of concepts were previously used. In this configuration, the joint design posed challenges for pure traction characterization, as the offset with respect to the structural axis introduced a local bending moment. A comprehensive instrumentation strategy was therefore required to enable validation of the structural behaviour and capacity by using a strain-based approach.

The development test campaign of representative specimens is presented, including the attempts to achieve correlation, as well as the use of the acquired data to support the real-time monitoring and assessment of the full-scale qualification test, ultimately resulting in a successful qualification campaign of a flight model.

1. INTRODUCTION

Structural joints in primary structures of launch vehicles play a critical role in load transfer between the payload and the launch interface, as well as in the overall stiffness and mass efficiency. In certain missions, particularly those involving multiple payload configurations, the mass of payload adapters becomes a critical parameter, as it directly impacts the payload capacity of the launcher. As a result, adapter mass is often strongly constrained, and solutions that enable mass optimization while maintaining structural performance are of significant interest from a programmatic and commercial perspective. Conventional solutions typically rely on metallic rings mechanically fastened to composite shells, introducing additional interfaces and integration steps.

Airbus Defence and Space in Madrid (ADSM) has been developing CFRP integrated ring concepts since 2003 using different technologies and design approaches. These developments have resulted in a broad portfolio of flight-qualified structures incorporating various integrated ring configurations, which have been successfully implemented in multiple missions.

Fig. 1 shows the SSO-A mission stack that successfully launched 64 customer spacecraft into orbit onboard a Falcon 9 launch vehicle on 3 December 2018. In that flight, the ADSM CFRP HUB payload adapter was part of the stack, Fig. 2, whose both upper and lower interface are manufactured with the CFRP interface ring solution.

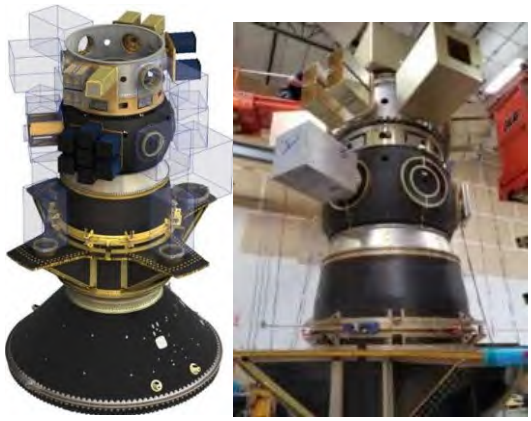

Figure 1: SSO-A mission. Multiple payload adapter stack [1].

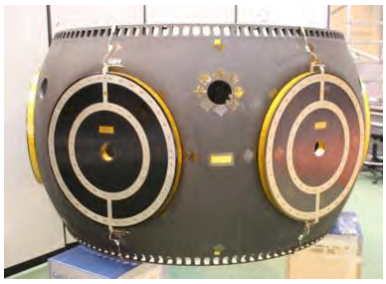

Figure 2: HUB – ADSM multiple payload adaptor.

This work builds upon the previously developed CFRP integrated ring concepts and their characterization methodologies. In Section 2, an overview of different CFRP integrated ring solutions, including the geometrical concepts, materials, and validated manufacturing processes is discussed. Additionally, the characterization methodology is presented to have a better understanding of how these joints behave and what their main failure modes are.

Then, Section 3 is focused on the solution implemented in a multiple-payload adapter (called MAS-H) with internal highly loaded CFRP interfaces. In this case, the presence of an offset between the bolt interface and the structural neutral axis introduces additional complexity, requiring an adaptation of the standard characterization approach for this particular application.

The evolution of the characterization methodology is described, including the use of strain-based measurements and enhanced instrumentation strategies to obtain representative structural data. This approach supports the correlation between specimen-level testing and full-scale behaviour, finally reported in Section 4, enabling the qualification of the flight structure under representative loading conditions.

Lastly, Section 5 outlines the conclusions of the new methodology and addresses the unresolved open points to guide future work.

2. STATE OF THE ART AND DESIGN CONCEPT

Traditional joint configurations are based on metallic rings riveted to CFRP shells, providing a mechanical interface for bolted connections to adjacent structures. This approach results in multiple discrete joints within the load path. Fig. 3 shows an example of a payload adaptor with metallic SC IF (Spacecraft Interface) and LV IF (Launch Vehicle Interface) riveted to the CFRP shell.

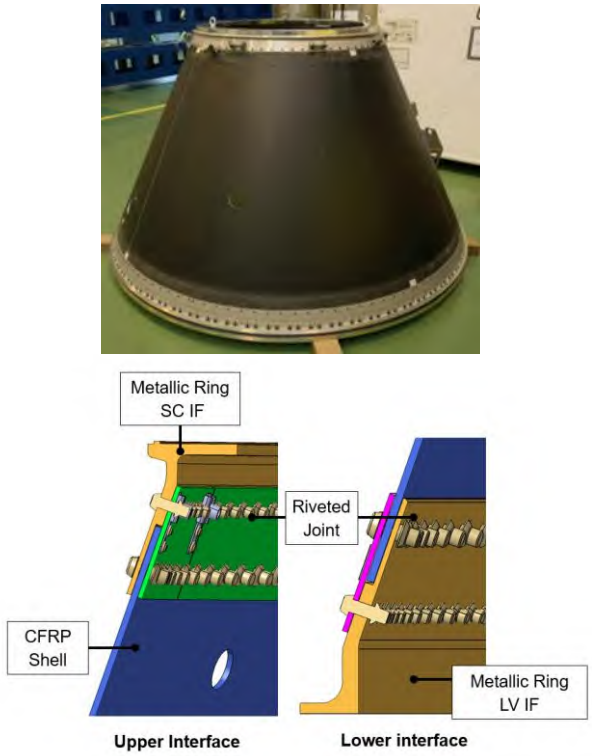

Figure 3: Payload Adaptor with traditional riveted joints between CFRP shells and metallic rings.

Integrated composite rings were first introduced in the 1194H payload adapter for Ariane 5 to reduce the mass and cost associated with metallic interface rings, Fig. 4. The concept aimed to compensate for the manufacturing and integration complexity of metallic rings (forged block production, machining, drilling, and fastening) by integrating the interface functionality directly into the composite structure.

In this approach, the composite shell is locally thickened at its edges and subsequently machined

to meet interface requirements, including flange definition and hole drilling, Fig. 4. This results in a more integrated structural solution with a reduced number of parts and interfaces

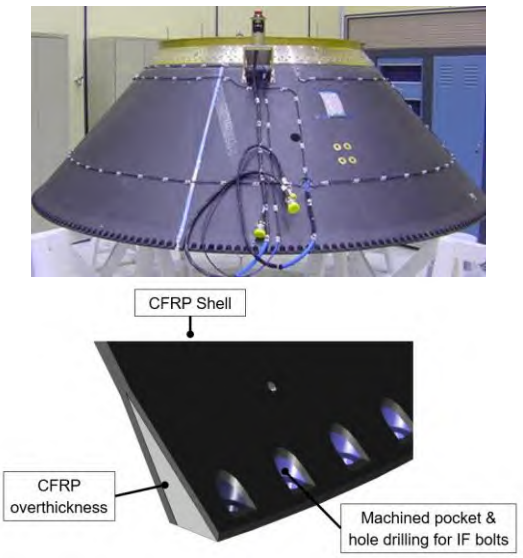

Figure 4: 1194H payload adapter for Ariane 5. Lower interface with CFRP integrated rings.

The replacement of forged aluminium rings with integrated CFRP rings provides several advantages:

- Mass reduction (up to approximately 9% at system level and up to 20% at joint level).
- Assembly time reduction (typically between 30% and 40%).
- Elimination of dedicated assembly tooling.
- Reduction in the number of parts within the manufacturing flow.

Two different concepts are proposed for the integrated rings: Recessed Ring and Castellated Ring.

Figure 5: 3936 ESC cone of Ariane 5 [2].

The **Recessed Ring** configuration was first implemented in the lower interface of the 1194H payload adapter for Ariane 5, Fig. 4. Since then, it has been applied in multiple flight structures, including payload adapter systems (PAS), as in the 3936 ESC cone of Ariane 5 ECA, Fig. 5. The structural capability of this configuration has been established through component-level testing, where combined loading conditions involving bending moments and longitudinal forces were applied to derive interaction relationships used for margin assessment. More details about the strength characterization will be discussed in Section 3.1.

In contrast, the **Castellated Ring** concept was initially investigated at component level and then implemented with the HUB in a flight hardware, Fig. 2. This configuration was assessed for both launch vehicle inter-stage structures and spacecraft structures, covering different thickness ranges and material. For launcher applications, the ring was integrated into a monolithic shell of approximately 8 mm thickness using high-strength carbon fiber, whereas for spacecraft structures, a thinner configuration of approximately 2 mm was evaluated using a high-modulus carbon fiber, Fig. 6

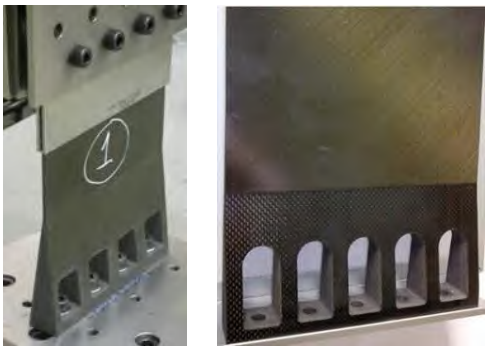

Figure 6: Castellated ring. Composite Design for Spacecraft Structures (left). Composite Design for Launch Vehicles (right).

To date, the Castellated Ring solution is widely used in multiple-launch dispensers with different carbon fiber materials (e.g., high-modulus and high-strength), whose geometry is close to a cylinder instead of a cone. Some examples are the HUB dispenser, Fig. 2, Skyfall multi-payload adaptor and Clessidra dispenser, Fig. 7.

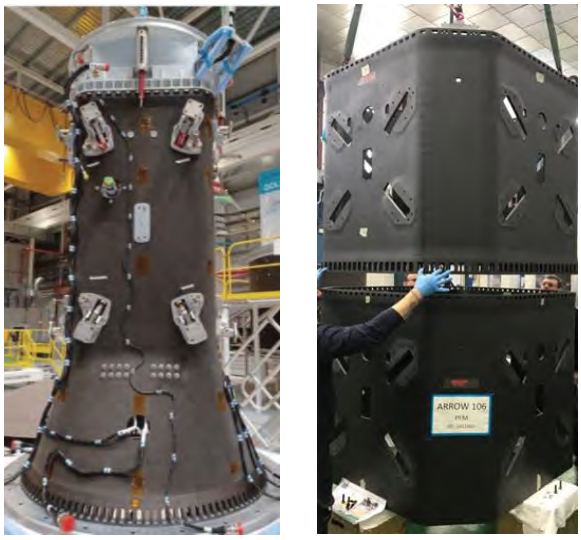

Figure 7: Multi-payload adaptor with Castellated ring. Clessidra Dispenser (left) and Skyfall Dispenser (right).

To address manufacturing cost and performance requirements, co-bonding technologies have been widely adopted. These allow integration of different composite subcomponents while improving structural continuity and reducing assembly complexity.

Two main manufacturing approaches have been developed for CFRP integrated rings:

Local Thickness Increase by Fiber Placement (FP)
The integrated ring is achieved through local thickening of the laminate using Automated Fiber Placement, Fig. 8. This approach allows direct integration of the joint region within the primary structure. Design validation is performed through dedicated testing.

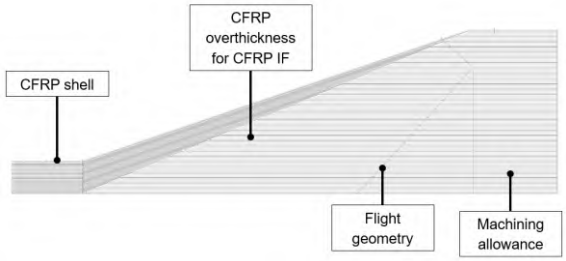

Figure 8: Local thickness increase by Fiber Placement

RTM-Manufactured Sectors with Co-Bonding
An alternative solution consists of manufacturing CFRP sectors (wedges) using Resin Transfer Molding (RTM), which are subsequently co-bonded to the main structure, Fig. 9. These wedges typically have lengths on the order of 800 mm and are manufactured using dry fiber and RTM-compatible resins. Co-bonding is performed using structural adhesives.

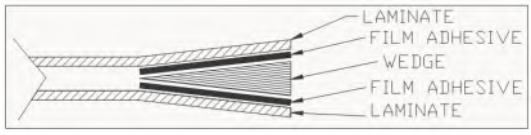

Figure 9: RTM-Manufactured Sectors with co-Bonding

Different laminate architectures (or lay-up and ply orientations) can be defined depending on the selected manufacturing approach, particularly for fiber placement-based solutions. Several lay-up examples of different implemented solutions are shown in Fig. 10. The definition of ply orientations, stacking sequences, and local reinforcements in the joint region is critical to ensure adequate load transfer and failure resistance.

Both approaches have been successfully validated through testing. For instance, the Cone 3936 adapter incorporating RTM wedges demonstrated equivalent structural performance to fiber placement-based integrated rings. Additionally, RTM-based solutions have shown robustness with respect to manufacturing tolerances, with no significant impact on structural performance due to positioning deviations during assembly.

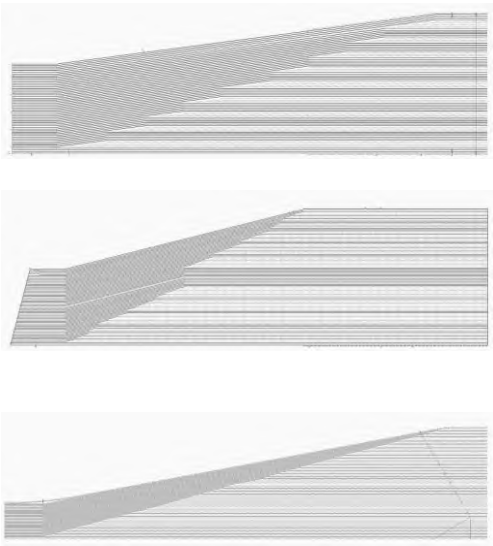

Figure 10: Laminate architectures by Fiber Placement

However, some manufacturing challenges remain. CFRP block-based solutions may require intermediate machining steps due to the lack of net-shape capability in prepreg processes. In contrast, RTM-based approaches rely strongly on dimensional accuracy to ensure proper co-bonding performance and overall structural integrity.

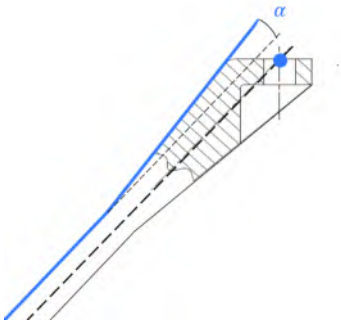

Figure 11: Local laminate geometry for bolted interfaces. Neutral line aligned with bolt IF

Additionally, from a manufacturing perspective, integrated CFRP ring solutions have historically been designed such that the neutral axis of the structure overlaps with the bolt interface. This requirement has led to the development of dedicated tooling with tailored geometries, including local thickness variations and angular features to accommodate fibre placement and ensure proper load alignment. In Fig. 11 the tooling surface is marked in blue, with a local change in the angle of

the cone. However, such tooling solutions are often associated with long lead times and require a high level of design maturity, which may not be compatible with project constraints.

2.1. Characterization Methodology

The sizing of CFRP integrated ring joints must consider the following design principle:

- No sliding at 1.1 x Limit Load
- No rupture at 1.25 x Limit Load (ultimate).

For in-plane loading, shear-out is typically the governing failure mode, defining the minimum edge distance and influencing the local joint geometry.

Given the complexity of the stress state and the limitations of purely analytical approaches, an empirical line load-based sizing methodology is adopted. This approach compares the acting loads—expressed as line force and line moment at a given circumferential position of the ring—with allowable values derived from experimental characterization. The relevant load components are the longitudinal line force and the circumferential moment, assumed to capture the dominant behaviour of the joint, see Fig. 12.

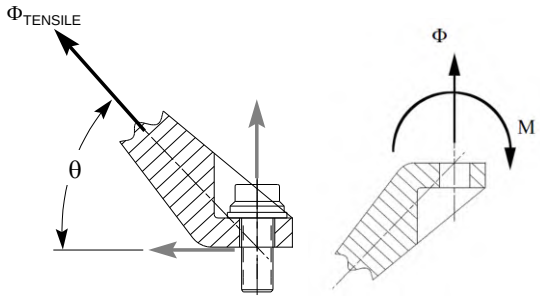

Figure 12: Local Loads for sizing CFRP integrated rings

A failure envelope is defined to represent the interaction between both load components. The allowable tensile line force decreases with increasing applied line moment, based on test results, and is represented by a bilinear relationship. In contrast, the allowable compressive line force is considered independent of the applied moment up to a limiting value, see Fig. 13.

The typical characterization is restricted to a representative quadrant of the load interaction domain, consistent with the expected loading conditions and sign convention adopted for the joint. This simplification assumes that the structural capability is governed by the interaction between axial force and circumferential moment, which is later supported through experimental validation. An example is shown in Fig. 14.

To characterize the joint behaviour and define the failure envelope, three types of tests are required: pure tension, pure moment, and combined loading.

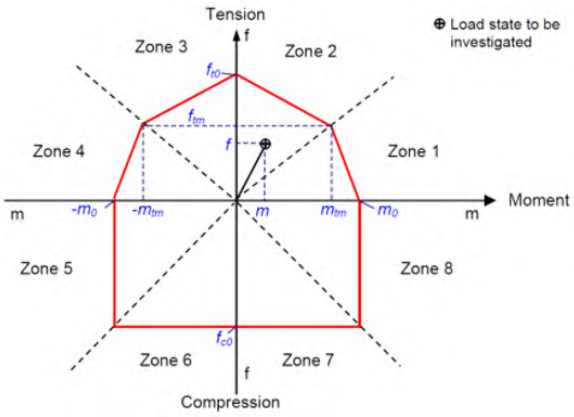

Figure 13: Failure envelope

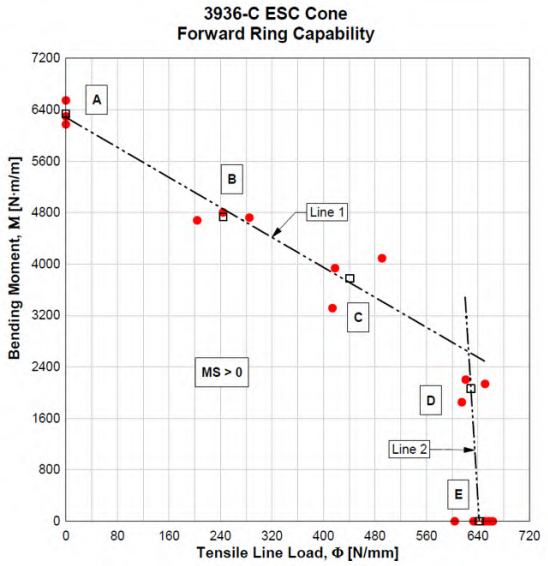

Figure 14: Failure envelope deduced from a specimen test campaign for 3936-C ESC Cone.

The characterization is performed using a dedicated set of specimens. Although the actual geometry of the ring is curved, specimens are typically manufactured as flat panels for practicality, provided that the same CFRP material and manufacturing process are used, Fig. 15. Comparative assessments between hand lay-up and automated fiber placement have shown no significant impact on the structural response for equivalent configurations. To ensure representativeness, all specimens must be extracted from the same panel and properly identified and inspected prior to testing.

The test configuration depends on the available facilities but generally aims to maximize setup commonality. Pure tension and pure moment tests are typically performed using the same fixture, with specimen orientation adjusted to apply the corresponding load condition, see Fig. 16.

Combined loading tests require a symmetric setup in which the bending moment is introduced through an offset or lateral load applied at the interface. These tests are inherently more complex and require iterative calibration and repeated executions to achieve the desired loading condition corresponding to specific points of the interaction curve.

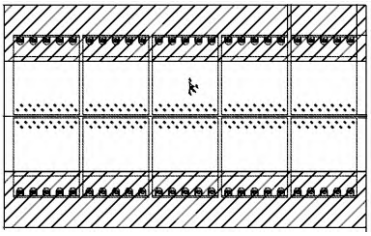

Figure 15: Typical drawing for manufacturing flat test pieces.

In standard practice, specimens are typically not instrumented, as the characterization is based on ultimate load capacity. The identification of failure is therefore derived from the load–displacement response recorded by the test machine, with limited insight into the local structural behaviour.

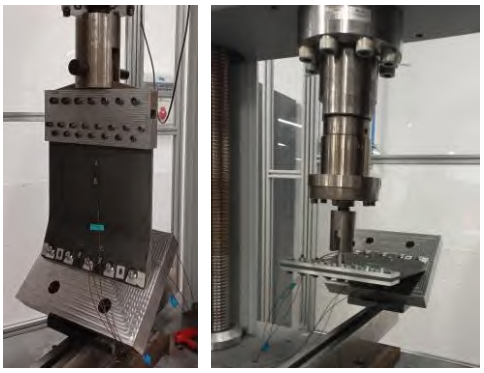

Figure 16: Test configuration for pure traction (left) and pure moment (right).

However, the present work highlights the potential advantages of incorporating strain gauge instrumentation, enabling a more detailed understanding of the load transfer mechanisms, local strain distributions, and progressive damage evolution within the joint.

A key limitation of the current methodology is the absence of reliable analytical or finite element models capable of accurately reproducing the observed failure modes. These joints exhibit highly non-linear behaviour driven by material characteristics and complex stress concentrations (pressure contact), particularly in regions with significant ply drop-offs over short distances. As a result, experimental characterization remains essential for defining allowable values and supporting design.

Experimental results enable the construction of representative failure envelopes, which form the basis for the empirical sizing methodology and subsequent structural assessment.

3. APPLICATION CASE: INTERNAL INTERFACES OF A PAYLOAD ADAPTER

The integrated CFRP ring concepts presented to date have been primarily applied to external interfaces of payload adapters. In such configurations, the load path is typically driven by the transfer of loads from an upper interface (payload) to a lower interface (launcher interface), resulting in conical or cylindrical structures that ensure an efficient distribution of axial and bending loads.

The case study addressed in this work departs from this conventional approach. It corresponds to a payload dispenser designed to accommodate two large spacecraft in side-by-side arrangement.

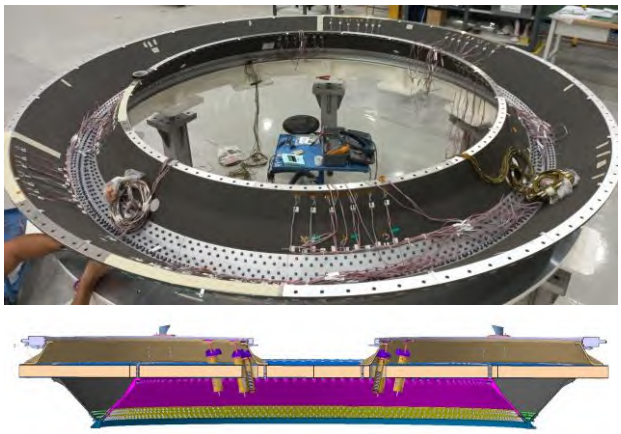

Figure 17: MASH dispenser. Inner and outer cone arrangement.

The configuration consists of two conical structures: an Outer inverted Cone, where the larger interface is located at the top, and an Inner Cone with a standard orientation, where the larger interface is located at the bottom, see Fig. 17. Both structures are connected through a common sandwich platform, which provides the support plane for both spacecraft, see Fig. 18. In this structure, the CFRP rings are in contact with the platform, namely the interfaces of the Inner and Outer cones with the platform.

This architecture introduces a significant deviation from traditional load paths, as the interfaces of interest are internal to the structure and are subjected to higher load levels than those typically encountered in external launcher interfaces. Additionally, the load introduction is more complex due to the geometric configuration and the interaction between both cones.

As mentioned in Section 2, structures with integrated rings have been designed such that the

neutral axis of the structure overlaps with the bolt interface. This requires developing a dedicated tooling associated with long lead times.

Figure 18: MASH dispenser with 2 Spacecraft in side-by-side arrangement.

In this case, an alternative approach was explored to increase design flexibility and reduce development time. The concept is based on the use of smooth tooling geometries, allowing the structure to be manufactured without complex local features. As a result, the integrated ring interface is no longer aligned with the structural neutral axis, introducing an offset that generates local bending loads at the joint level, see Fig. 19.

This design choice enables the reuse of existing tooling by adapting the structural geometry to mission-specific requirements, for instance by trimming the cone height to match the target interface diameters.

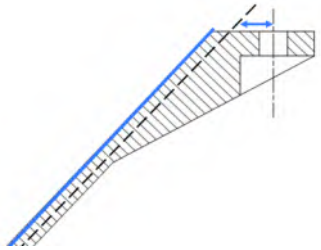

Figure 19: Local laminate geometry for bolted interfaces. Offset between neutral line and bolt IF.

While this approach provides clear advantages in terms of manufacturability and lead time, it also introduces additional challenges in terms of structural characterization and validation, particularly due to the combined loading state induced at the joint.

3.1. Strain – Based Characterization

To characterize the joint behaviour, a test campaign based on the traditional approach was defined, including the following load cases: Tension (T1) and Positive Moment (M1). The objective was to identify the governing failure modes and assess the interaction between axial force and bending moment, see Fig. 20. Additionally, a Negative Moment (M2) and Compression case (C1) were performed to verify that they are not the ones that size these joints. A total of 12 pieces were tested, 5 for T1 test, 5 for M1 test, and only 1 for C1 and M2.

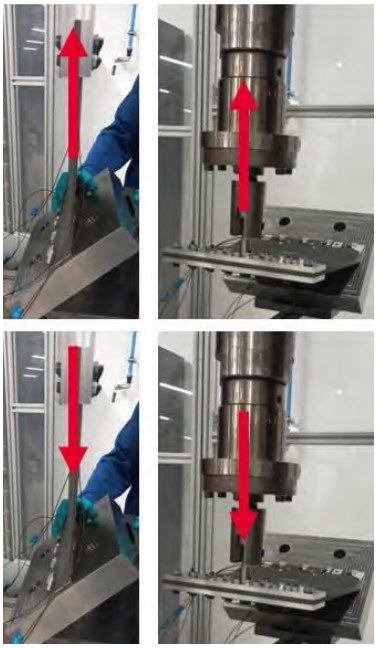

Figure 20: Load Cases for joint characterization. Top Left: Tension (T1); Top Right: Positive Moment (M1); Bottom Left: Compression (C1); Bottom Right: Negative Moment (M2)

Figure 21: Failure mode of the joint. Top Left: Tension (T1); Top Right: Positive Moment (M1); Bottom: Negative Moment (M2).

The experimental results showed that, due to the presence of the offset, the failure mode observed under pure tension (T1) was equivalent to that obtained under one of the bending configurations

(M1), as it can be seen in Fig. 21. This confirms that the induced moment associated with the offset dominates the local stress state, even under nominally axial loading. The failure mode seems to be associated with the local compression that appears close to the bolt interface, for both T1 and M1 loading.

In contrast, the failure mode associated with the opposite bending configuration (M2) occurred in a different region of the specimen and was identified as non-critical for the actual flight configuration), see Fig. 21.

A complementary compression test was also performed to verify the relevance of this load case. The results confirmed that compression is not a driving failure mode for these CFRP joints, with a demonstrated capacity exceeding the required flight levels by a factor of approximately three (the limit of the test facility was achieved before the failure of the joint. As a consequence, the failure mode could not be observed).

A simplified linear finite element model was used to extract the axial force and bending moment at the joint to support the interpretation of the test results. When represented in the classical force–moment interaction diagram, the available test data primarily covered the moment-driven region of the envelope, Fig. 22. While this was enough to cover the load conditions of the Outer Cone, it was identified that, for the Inner Cone—characterized by lower bending and higher axial load—a significant portion of the interaction domain remained uncharacterized.

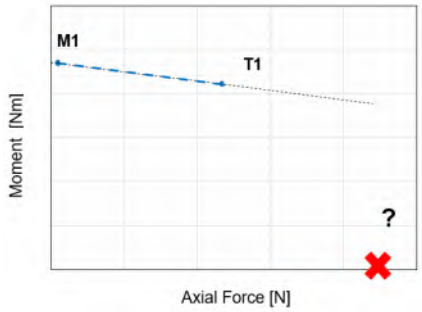

Figure 22: Failure envelope.

It should be noted that, in typical development campaigns, the most critical configuration is selected for testing. In this case, the Outer Cone was initially considered under the assumption that it would envelope the behaviour of both configurations. However, the test results highlighted the importance of local behaviour and strain distribution, which cannot be fully captured through global load metrics alone.

Furthermore, it is important to consider that flat specimens provide a conservative representation of the structural behaviour, as cylindrical or closed structures distribute circumferential moments more uniformly. This, combined with the incomplete definition of the interaction envelope, motivated the adoption of a different approach.

Figure 23: Test Specimen instrumentation on internal and external face on the test piece.

Specimens were instrumented to gain insight into the load distribution and local behaviour, as Fig. 23 shows. Strain gauges were placed at mid-height to monitor global load introduction, as well as on the castellated regions on both internal and external faces, from middle width to the edge, to ensure that failure was not driven by edge effects or non-uniform loading.

The measurements revealed a significant asymmetry in the strain distribution under tensile loading (T1), where the external face experienced compressive strains approximately 80% higher than the tensile strains measured on the internal face. This behaviour is a direct consequence of the offset in the joint. A similar strain distribution was observed in M1 tests, with comparable strain levels at failure on both faces, further supporting the equivalence between T1 and M1 loading conditions. In Fig. 24, the average levels of T1 and M1 are the same.

In contrast, Compression tests (C1) exhibited compressive strains on the internal face approximately 30% higher than the tensile strains measured on the external face. Local compression appeared in the internal face, which is the non-machined face. When comparing the local compression capacity of the internal face in T1 and C1 loading state (Average Min. of C1 vs. Average Min. of T1), the lectures during C1 test are double the ones during the T1. Note that the C1 test could not reach failure, which means that locally the non-machined face can support a higher local compression.

Based on the observed failure modes and strain measurements, a local strain-based failure criterion was defined using the experimental data. This criterion was then applied to the flight hardware by instrumenting the most loaded areas, Fig. 25, of these joints of the structure with strain gauges, enabling in-situ monitoring of the structural response during qualification testing.

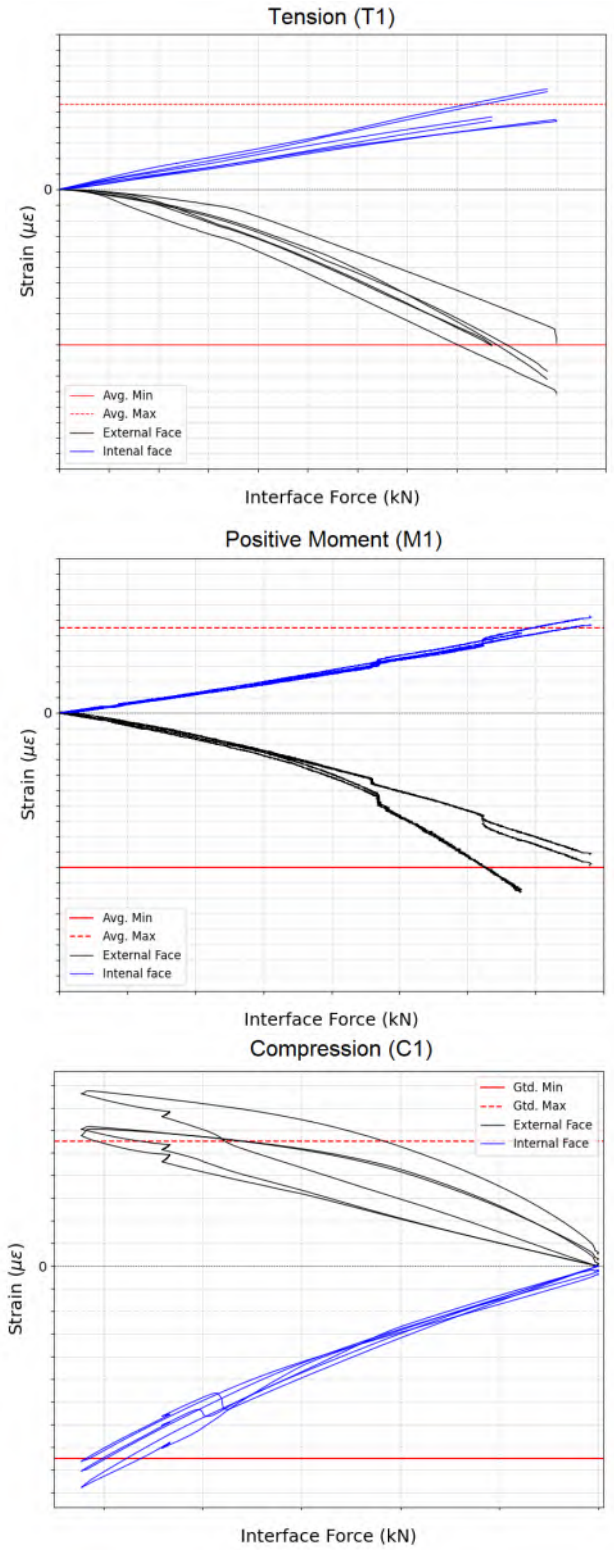

Figure 24: Local measurements during T1, M1 and C1 tests.

As no dedicated specimens were available for the Inner Cone, the same strain-based criterion was applied according to its expected (and then verified) behaviour, considering that the failure is triggered by local compression during the tensile loading state caused by the induced moment, Fig. 26.

This approach enabled the completion of the characterization despite the limitations in test coverage, providing a consistent and conservative basis for the subsequent full-scale qualification.

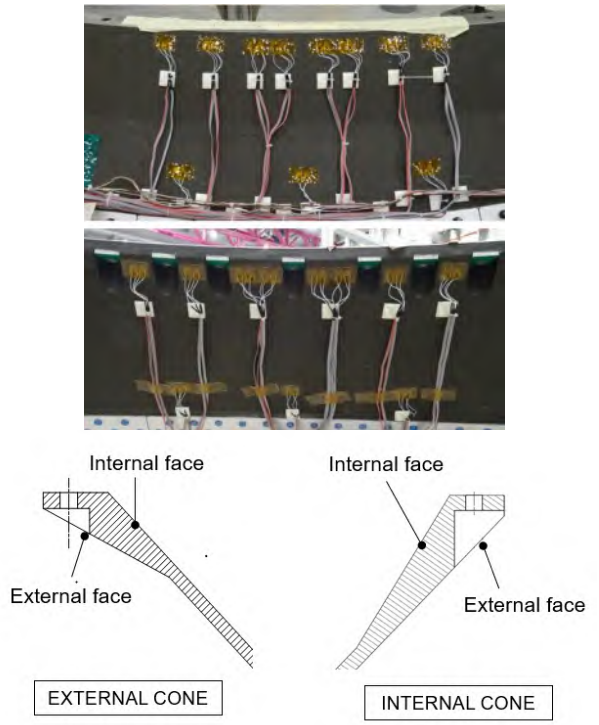

Figure 25: Proto-Flight Model (PFM) strain-gauges instrumentation at the internal and external face of both cones.

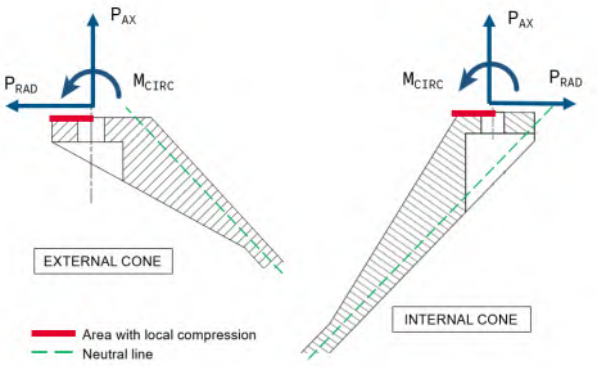

Figure 26: Comparison between Inner and Outer Cone behaviour.

4. PROTOFLIGHT MODEL QUALIFICATION RESULTS

The Qualification Test Campaign is composed of a stiffness test and a strength test. The objective of the stiffness test is to provide data for FEM (Finite Element Model) correlation to ensure the integrity of the structure during the strength tests, while the objective of the strength test is to demonstrate the load capability of the structure when subjected to critical loads (qualification loads).

A successful qualification campaign requires a detailed understanding of the expected structural

behaviour. To this end, predictions are generated using the same finite element model employed for the structural sizing, adapted to represent the test setup and associated boundary conditions, as shown in Fig. 27. The model is used to define expected global and local responses, as well as to support the placement and interpretation of instrumentation.

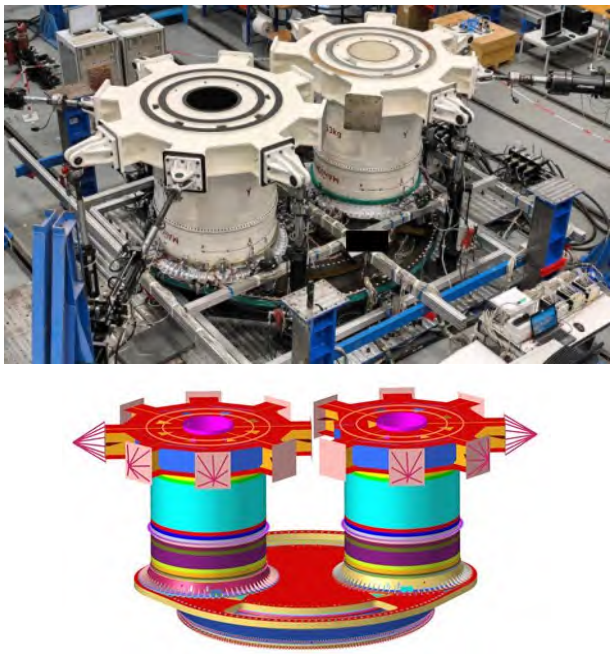

Figure 27: MASH qualification test set-up (top) and Finite Element Model (FEM) for test predictions (bottom)

The instrumentation strategy includes displacement transducers to validate the global stiffness of the structure, and strain gauges to assess load distribution across structural components. These measurements enable verification that the load paths are correctly represented and that no localised overloading occurs beyond the predicted levels.

Traditionally, structural margins were derived from the classical force–moment interaction curves, and instrumentation was typically placed slightly away from the joint, in regions where the mathematical model could provide reliable strain predictions.

In the present case, the methodology was extended by directly instrumenting the integrated ring interfaces, as Fig. 25. The strain measurements obtained during the Qualification Test were compared against the allowable limits derived from the specimen characterization campaign. This approach enabled a direct verification of the joint behaviour at full scale, using experimentally-based strain thresholds as a reference.

By combining model predictions for the global behaviour with experimentally derived local criteria for the joint, it was possible to achieve a more comprehensive validation of the structure.

4.1. Stiffness Correlation

The Stiffness Qualification Test aimed to verify the global structural behaviour of the flight model through correlation between predicted and measured displacements. The test campaign comprised six load cases:

- A1: Pure axial tension.
- A2: Pure compression.
- L1: lateral load in +X.
- L2: lateral load in +Y.
- B1: Moment about +X.
- B2: moment about +Y.

These load cases enabled the derivation of the global stiffness matrix of the structure.

For all cases, the acceptance criterion of a maximum 10% deviation between predicted and measured displacements was fulfilled. Additionally, it was consistently observed that the predicted displacements were higher than those measured during the test. Fig. 28 shows the comparison between the predicted values and the actual readings during the stiffness test; each point represents different displacements captors used during the test. The results indicate that the flight structure exhibited a stiffer global response than anticipated by the model, and therefore the stiffness requirement was successfully validated with a conservative margin.

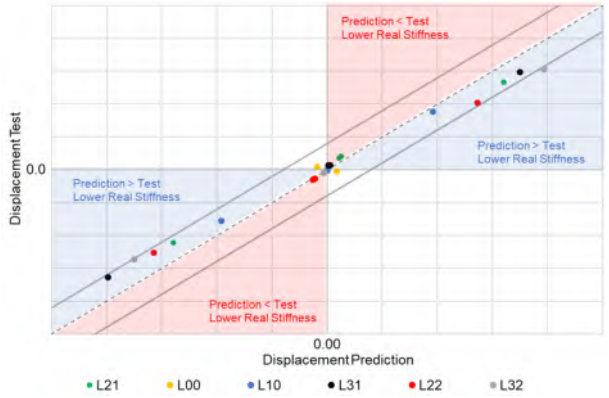

Figure 28: Predicted displacements vs. Actual displacement captor's readings.

Strain gauge measurements were also used to support the validation of the numerical model, particularly in terms of load introduction and load path distribution. For the CFRP integrated ring interfaces, the lateral +X and +Y load cases (L1 and L2) were identified as the most representative within the stiffness campaign, as they induced significant tensile loading in the cones.

The comparison between test measurements and specimen characterization data showed a good agreement for the Outer Cone, where strain levels

were consistent with those obtained during the development test campaign, see Fig. 29. In the case of the Inner Cone, the measured strain levels remained within a lower range, which is consistent with the reduced bending moment at the interface and the relatively low load levels associated with the stiffness test cases.

These results provided confidence in both the global structural model and the local behaviour of the integrated ring interfaces, supporting the transition to the resistance qualification phase.

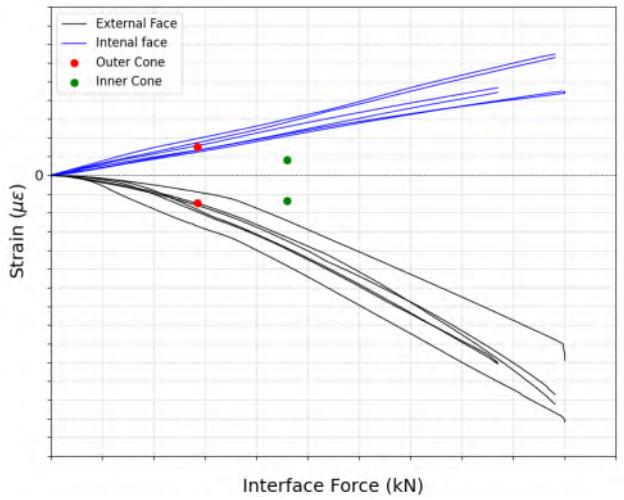

Figure 29: Maximum measured micro-strains during stiffness test campaign for Inner and Outer Cone.

4.2. Strength qualification

The Strength Qualification Test comprised five load cases representative of the critical conditions of the structure:

- S1: corresponding to the critical load case for the platform (non-critical for the cones).
- E1 and E2, representing maximum tension and compression, respectively, in the Outer Cone.
- I1 and I2, corresponding to maximum tension and compression, respectively, in the Inner Cone.

The S1 load case was used as an initial reference to extrapolate the load levels at the CFRP integrated ring interfaces and to confirm that enough margin existed for the subsequent critical cases. Following this verification, the four cone-driven load cases were executed, with the tensile cases (E1 and I1) identified as the most critical for the integrated joints.

For the Outer Cone, it was observed that, as the applied load increased, the local strain response progressively deviated from the trend obtained in the flat specimen characterization tests, increasing with a lower slope, as Fig. 30 shows. This behaviour is consistent with the expected differences between how circumferential moment is reacted in a closed geometry and in a flat specimen. As a result, qualification levels could be reached by maintaining enough margin with the defined guaranteed limits (green lines).

In the case of the Inner Cone, the strain evolution on both faces of the joint showed an asymmetric behaviour due to the local offset of the interface. This offset induces a moment in the opposite direction to that of the Outer Cone, resulting in very low strain levels on the external face (which has local compression), while the internal face (located at the bolted interface) carries the majority of the tensile load. The Maximum Compression load case of the Outer Cone (E2) was used to extrapolate the expected values for the Maximum Tension load case of the Inner Cone (I1), which was the most critical one since no data was available. The strain-gauges readings of the Inner Cone in comparison with the Outer Cone test pieces result are shown in Fig. 31.

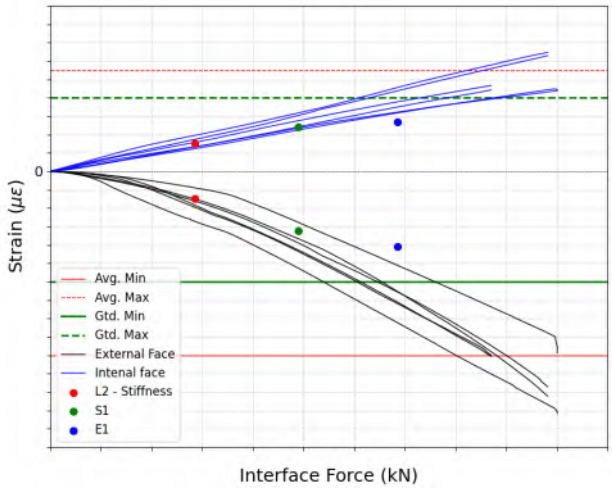

Figure 30: Maximum measured micro-strains during the strength test campaign for Outer Cone.

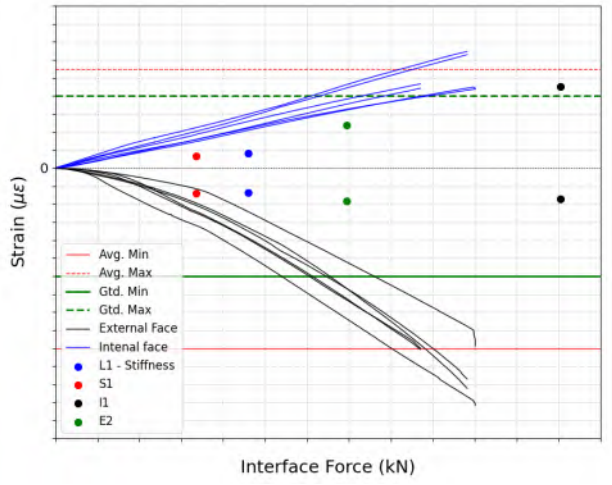

Figure 31: Maximum measured micro-strains during the strength test campaign for Inner Cone.

Although the maximum measurements at the

internal face were higher than the original threshold, note that this is the non-machined face in the Inner Cone configuration, as Fig. 25 shows. As a result, the deviation was accepted during the test due to the lack of risk, allowing the complete qualification of the flight model.

The successful completion of the Strength Qualification Test validates the proposed methodology, combining empirical characterization, strain-based criteria, and full-scale instrumentation to ensure the structural integrity of CFRP integrated ring interfaces under complex loading conditions.

5. CONCLUSIONS AND LESSONS LEARNED

This work has presented the evolution of CFRP integrated ring concepts from conventional external interfaces towards more complex internal interface applications. An empirical characterization methodology based on line loads and interaction envelopes has been reviewed and extended to account for configurations where axial and bending effects are inherently coupled due to geometric offsets.

A representative case study involving a dual-cone payload dispenser has been investigated, highlighting the impact of joint offset, manufacturing constraints, and assembly requirements on the local structural behaviour. The limitations of traditional approaches based solely on global load metrics for all applications have been addressed through the introduction of a strain-based characterization methodology, supported by dedicated specimen testing and local instrumentation.

The proposed approach has been successfully applied during the full-scale qualification of a flight model. Stiffness test results demonstrated good correlation with predictions, and strength test results confirmed that the integrated ring interfaces met the required performance with sufficient margin.

The direct monitoring of the joints provided valuable insight into their behaviour under representative loading conditions, enabling validation beyond conventional methods.

5.1. FUTURE WORK AND OPEN POINTS

Future developments should focus on extending the characterization database to cover a wider range of configurations and loading conditions, including the systematic testing of all relevant geometrical variants to reduce reliance on envelope assumptions. Although not critical in the present case, incomplete coverage could lead to unaccounted risks in other designs.

Additionally, further work is recommended to refine strain-based criteria and improve their integration into design and verification processes. The methodology presented offers clear advantages in terms of flexibility, reduced development time, and applicability to future structures with increased geometric and functional complexity.

CFRP, satellite structures, AFP, launcher interface frame

ABSTRACT

Over the past several years, MT Aerospace AG has significantly advanced its expertise in Automated Fiber Placement (AFP), expanding the variety of composite structures and tanks that can be manufactured using this technology. As both technological capabilities and associated design knowledge have matured, the range of potential design solutions has increased, enabling components to be more precisely tailored to their specific requirements.
In addition to next-generation launcher applications, MT Aerospace has successfully applied AFP to satellite structures. One of the focused parts is the Launcher Interface Frame (LIF) for ESA's HARMONY mission, in which a CFRP frame represents the main interface towards the launcher through a dual launch adapter.

1. INTRODUCTION

The AFP technology opens up exciting new possibilities for designing satellite structures, delivering clear benefits over conventional metallic approaches-such as an improved stiffness-to-mass ratio and superior thermo-elastic performance. At the same time, it challenges the limitations of traditional co-bonded sandwich components by enabling complex, customised geometries that precisely meet mission requirements. This shift mitigates the dependency on manual layup techniques, thereby improving manufacturing repeatability and overall structural performance. Currently, MT Aerospace and OHB are developing a CFRP launcher interface frame (LIF) representing the core structure and main interface towards the launcher for the OHB Systems AG satellites of ESA's HARMONY mission, see Fig. 1.

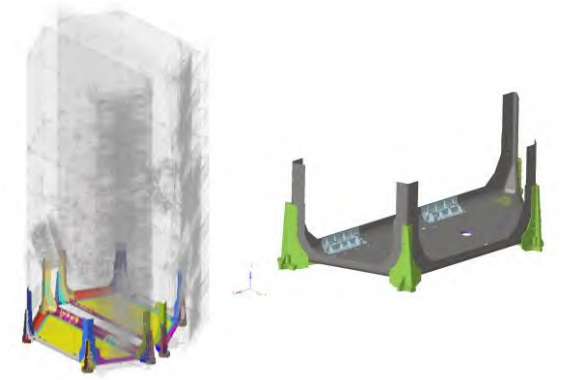

Figure 1: FE model of AFP manufactured CFRP frame with sandwich bottom part: integrated in spacecraft (left) and LIF w/o other parts (right)

Due to the high flexibility of the AFP process, the spectrum of design options for enhancing the performance extends from local reinforcements of the laminate or local adjustments of fiber orientations to the combination with stiffeners, and even to the integration of core materials to form sandwich structures. The latter approach is being implemented to the base plate of the depicted frame, demonstrating how advanced manufacturing can directly translate into performance gains and greater design freedom.
Notably, while the benefits are evident, the AFP process must be pushed to its limits for this structure. Especially the development of proper tow paths around the corners is challenging in terms of the material, the machine and the corresponding manufacturing engineering process. To fully leverage the advantages offered by complex design solutions, an integrated approach is essential - ensuring that critical manufacturing details, such as local fibre orientations, are consistently embedded in the sizing and validation process.
In 2025, MT Aerospace successfully designed and fabricated a structural model (SM) for qualification testing of the launcher interface frame, see Fig. 2 and Fig. 3.

Figure 2: AFP layup of the outer facesheet

Figure 3: AFP layup of the demolded raw part

The test sequence is currently conducted jointly with OHB in July/August 2026. The test setup includes not only the launcher interface frame itself but also one-third of the satellite structure, see Fig. 4. Static stiffness and strength tests are performed at MT Aerospace's facilities. The CFRP launcher interface frame, including metallic brackets, has been supplied by MT Aerospace, while OHB has provided the connected CFRP panels with integrated inserts (see Fig. 5). The test simulates both global satellite loads and localized high magnitude loads from a propellant tank. Given the tight project timeline, the Prototype Flight Model (PFM) is manufactured in parallel.

This paper presents the design, justification, manufacturing, and qualification process of the CFRP launcher interface frame - the primary interface between the OHB satellites of the HARMONY mission and the launcher.
Some content of this document has been published in [1] before.

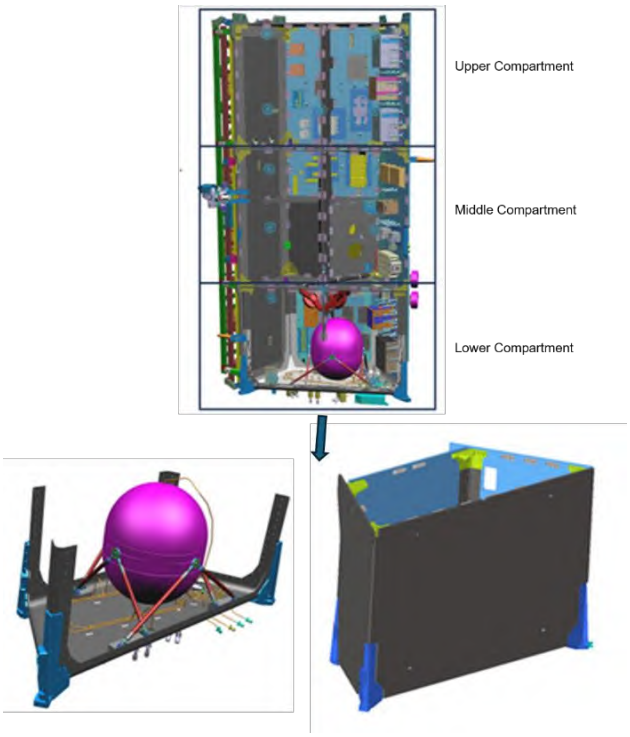

Figure 4: Harmony SM overview [1]

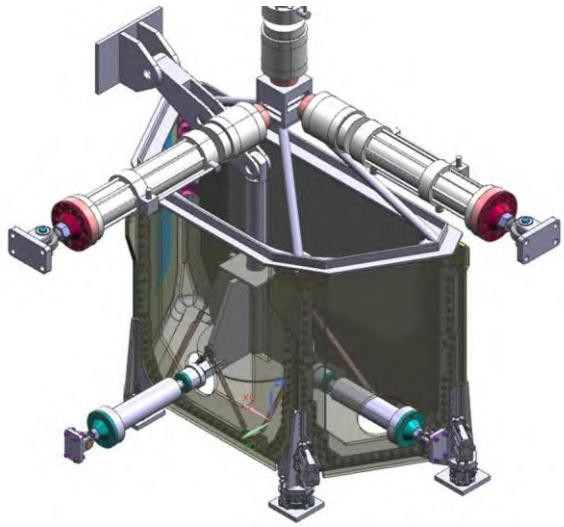

Figure 5: Structural Model of Harmony Spacecraft in Test Configuration

2. DESIGN AND JUSTIFICATION OF LIF

The MT Aerospace portion of the Harmony satellite structure is the LIF, which represents the primary interface to the launcher via a dual launch adapter. Beside the CFRP frame, the LIF includes also the HDRM (hold down release mechanism) and tank brackets including joints (see Fig. 6).

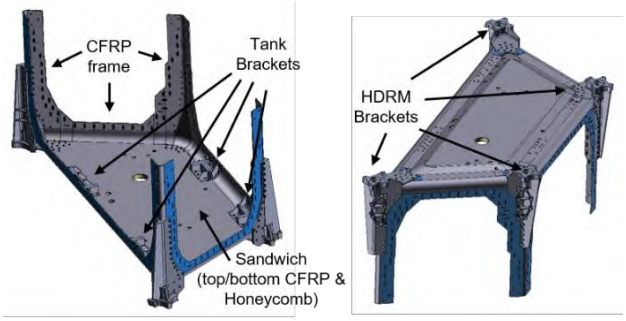

Figure 6: Top and bottom view of the design of the Harmony Launcher Interface Frame (LIF) with all components MT-A is responsible

The requirements for the LIF, which is a critical element of the Harmony spacecraft, must be coupled inherent with the spacecraft structure. Initial FE investigations demonstrated that the stiffness of the LIF can only be accurately analysed if the boundary conditions are modelled realistically. Furthermore, it was determined that the natural frequency requirement is the primary driver of mass. Consequently, the decision was made to perform the optimization using the full spacecraft (satellite) model (see Fig.7 left). Strength justifications were ultimately conducted on basis of the spacecraft model. At dedicated intervals, the current LIF design was regularly analysed within the SM (structural model) test configuration (see Fig. 7 right). To ensure representativity of the full spacecraft, the same structural interfaces, materials and components which will be used for the spacecraft are also used in the SM.

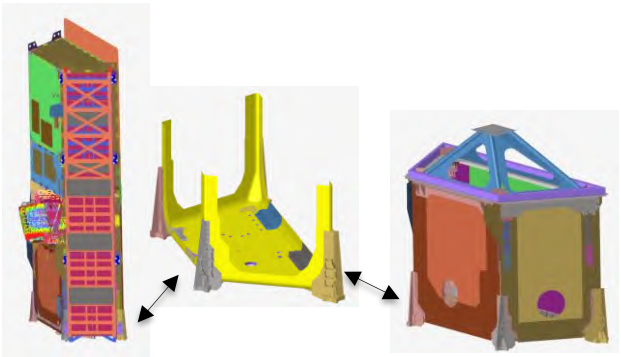

Figure 7: Spacecraft FE model for stiffness and strength evaluations (left), SM test configuration model (right) and all LIF components MT-A is responsible for (middle)

The most demanding aspect of the LIF is the development and production of its CFRP components. They constitute the structural core of the LIF (see Fig. 6.). The design of the LIF must facilitate interfaces for four HDRM brackets, four side sandwich panels, and the propellant tank support assembly. To manage the load transmission requirements of the additional interfaces on the ground of the LIF, a sandwich configuration was integrated into the bottom section of the CFRP component.

The geometry of the LIF's box-like configuration was heavily driven by the manufacturability requirements of the AFP process, especially at the challenging HDRM bracket corner interfaces. A key objective was to maximize ply continuity across structural transitions to achieve a high-performance laminate. Additionally, maintaining precise fiber orientations through these continuous plies was critical for ensuring optimal stiffness and strength. Through detailed engineering and tailored layup adaptations, a robust solution was implemented that meets all structural and manufacturing requirements, delivering a high-performance and manufacturable design.

During the design and justification process, FE analyses are performed. As previously stated, the LIF design is primarily stiffness-driven and is therefore optimized according to natural frequency requirements.

The CFRP frame (see Fig. 6) is modelled using shell elements (CQUAD4 and CTRIA3). The sandwich core, including the primary cut-outs, is discretized using solid elements (CHEXA8) with an orthotropic material definition. The tank and HDRM brackets are modelled using a hybrid approach consisting of solid and shell elements (CTRETRA10 and CTRIA6 on the outer surface). Within the MT-A scope, three specific joints are present: the connection from the CFRP frame to the HDRM brackets, the connection from the tank brackets to the CFRP frame, and the connection from the CFRP frame to the side panels; these joints are modelled using RBE2 and CBUSH elements.

For the CFRP parts the ply orientations are derived from AFP manufacturing data. To accurately predict the structural behavior of the complex CFRP component during stiffness and strength justifications, precise representation of the laminate layup within the finite element (FE) model is imperative. This requirement is intensified by the significant local variations in fiber orientation throughout the LIF geometry, particularly in high-load regions. To fully exploit the design's performance potential, an integrated methodology is employed, incorporating manufacturing-derived insights - such as precise local fiber orientations - directly into the sizing and verification workflow. This integration is achieved by systematically mapping the fiber orientations obtained from manufacturing simulations onto the FE mesh on an element-by-element basis.

Fig. 8 illustrates an example ply within the LIF corner region, showing how the simulated fiber layout is transferred to the finite element mesh.

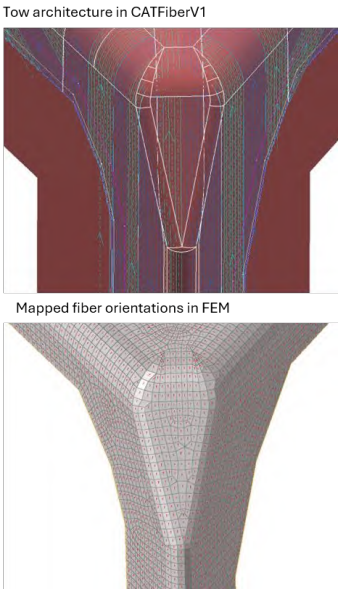

Figure 8: Tow architecture in CATFiberV1 (upper) and extracted fiber orientation mapped to FE (lower) [1]

Strength and local sandwich stability margins determined from customer-provided load cases:

- global quasi-static loads
- tank quasi-static loads
- local antenna load cases acting simultaneously on two HDRM brackets on the SAR (synthetic aperture radar) antenna interface

Given the absence of CFRP inter-fiber failure and metallic component yielding (specifically regarding the HDRM and tank brackets), as well as the occurrence of only small deformations, a linear strength analysis approach utilizing the Nastran SOL 101 solver (version 2022.4 64-Bit) is considered appropriate.
Overall, the design process and the co-engineering between OHB as prime and MT-A as supplier has resulted in a lightweight yet robust design that fully meets the requirements
At dedicated time points, the structural model (SM) was derived from the spacecraft model. The SM represents the lower compartment of the spacecraft (see Fig 9). The FE model of the SM test configuration comprises

- the Launcher Interface Frame (LIF)
- four PRM (payload release mechanism) brackets
- four sandwich panels
- the propellant-tank supporting structure incl. tank dummy
- Adjacent structure:
  - Load introduction frame
  - Load cells

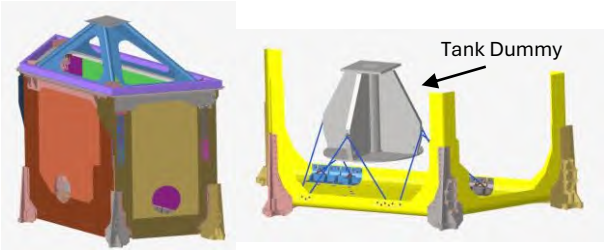

Figure 9: SM test configuration FE-model (left) and FE-model of LIF incl. tank dummy (right)

The SM test load cases are derived from the load cases investigated with the spacecraft model which are delivered to OHB. As a result of this, OHB as prime selected seven total test load cases for strength justification of the LIF: five based on Global Quasi-Static Loads (GQSL) and two based on Quasi-Static Tank Loads (Tank-QSL), selected from previous investigations.

3. MANUFACTURING PROCESS

The detailed manufacturing process is already published in [1]. Here a short overview is given.
The transformation of a composite design into a tow-discrete fiber architecture, tailored to manufacturing constraints, is a critical step in AFP engineering, providing the basis for robot trajectory generation and NC-code production. The process is implemented via the Coriolis CATFiberV1 R2024 software plug-in for CATIA V5. The main difficulty in complex AFP geometries is managing fiber steering to comply with requirements for angular deviation, ply coverage, and curvature. To optimize laminate quality for the SM, a detailed MBB-level study was conducted to facilitate local adjustments to the fiber architecture. Figure 10 depicts this optimization in a corner area; specifically, the wrinkles identified in the MBB (highlighted in red due to low steering radii) were successfully eliminated in the SM via targeted local optimizations.

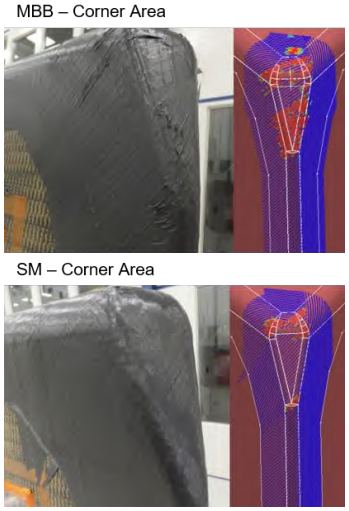

Figure 10: Optimization of the tow architecture: fiber steering analysis and corresponding layup result for MBB (upper) and SM (lower) in a corner area [1]

A linear compensation strategy was implemented to address spring-in and warpage effects during the transition from MBB to SM. By utilizing geometrical data derived from the MBB, the layup and curing tooling surfaces were remilled to ensure compliance with demanding geometrical tolerances. Manufacturing of the raw parts was conducted at MT Aerospace in Augsburg, Germany, where a Coriolis C1 8 x ¼" robot-based AFP system was used for the CFRP layup process, as illustrated in Fig. 11.

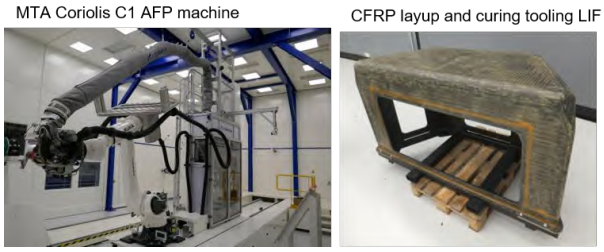

Figure 11: AFP machine and CFRP layup and curing tooling LIF [1]

The layup sequence for the LIF raw part is illustrated in Fig. 12. Following tooling preparation, the tool is mounted onto the vertical positioner system within the AFP workcell and calibrated. The process commences with the layup of the inner facesheet (IFS) CFRP laminate. Given the implementation of a one-shot curing process, the honeycomb core is integrated directly onto the uncured IFS. This is followed by the application of the outer facesheet (OFS). As a final lamination step, sacrificial GFRP patches are applied to the external interface areas.

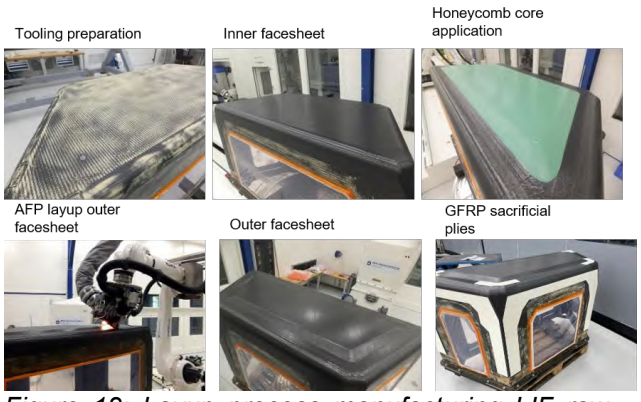

Figure 12: Layup process manufacturing LIF raw part [1]

After finishing the layup process, the frame is cured in an autoclave process (Fig. 13).

Figure 13: Curing process manufacturing LIF raw part [1]

Geometrical measurement of MBB and SM frame raw parts are performed. Measured deviations from the CAD model are shown in Fig. 14 via color-coded maps of the front view and pillar XpXn cross-sections.

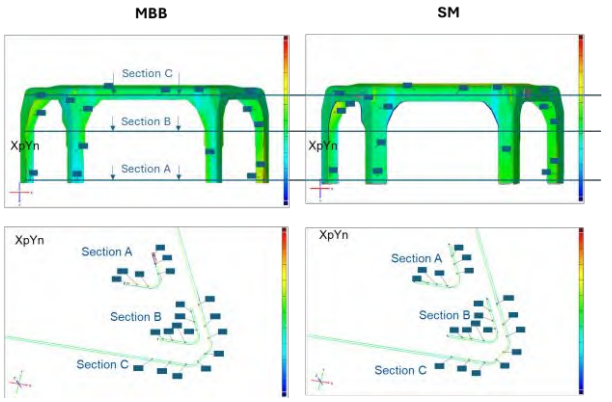

Figure 14: Results geometrical measurement MBB and SM - front view & sections XpXn pillar [1]

The MBB (Fig. 14 left) displays significant post-curing warpage, particularly in the pillars, where deviations intensify toward the tips (Sections A–C). The SM results (Fig. 14 right) confirm the success of the tooling compensation methodology, as evidenced by reduced overall deviations and the removal of torsional deformation.
Laminate quality was verified using squirter ultrasonic inspection for sandwich areas and manual impulse-echo for monolithic CFRP. MBB sections were further investigated macroscopically (Fig. 15) and via microscopy.

Figure 15: Section LIF MBB [1]

Following part release, the LIF is machined and assembled through milling and riveting, then integrated into the test rig via a test adapter for component testing.

4. QUALIFICATION PROCESS

To qualify the SM, a structural test is performed. The test was designed to support the qualification of the primary structure and its critical interfaces with major appendages, specifically the propellant tank, regarding the combined ground and flight acceleration envelopes, including associated local and global resonance effects. Compliance with strength and stiffness requirements shall be verified through the measurement of strains and displacements under representative static loads. Furthermore, the test shall demonstrate that the structure exhibits linear behavior within the elastic

range. Finally, the test data shall validate the mechanical analyses by correlating the stiffness and stress distribution of the finite element models with the measured values.
Prior to the test, a predictive analysis of the SM was conducted using the same mathematical model employed for the SM LIF justification. Generally, the prediction indicated low deformations and strains across all test and unit load cases, with a maximum overall deformation of approximately 2.6 mm (at the load introduction point of the loading frame) and approximately 1.2 mm in the area of the LIF components (upper end of the CFRP pillars). The highest CFRP strain among the selected sensors was predicted at approximately 260 µε, occurring perpendicular to the fiber direction on the inner side of pillar XNYP. These low values confirm that the structure is stiffness driven.
Following a successful Test Readiness Review (TRR) in July 2026, the test is conducted at the MT Aerospace testing facilities in Augsburg in July/August 2026. The test specimen, including the test setup, is shown in Fig. 16 and consists of:

- Launcher Interface Frame (LIF)
- Four sandwich panels
- Propellant-tank supporting structure
- Four Payload Release Module (PRM) Brackets
- Four PRMs
- Tertiary structures connecting panels and LIF

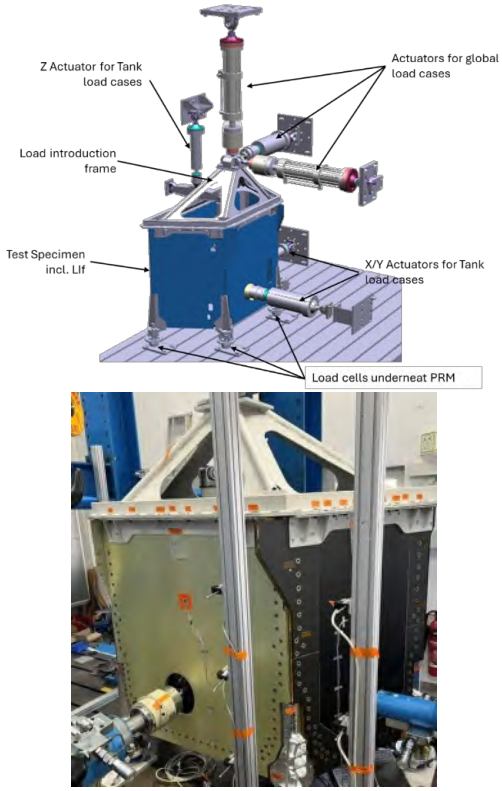

Figure 16: *CAD Model of SM test setup (upper) and side view of SM incl. load introduction frame (lower)*

The experimental setup incorporates three distinct types of sensors to facilitate data acquisition. First, load cells are utilized to measure and record loads and moments. Second, uni-directional and multi-directional strain gauges are integrated onto the LIF CFRP structure and its associated panels to monitor strains. Finally, displacement sensors are employed to track movement. These sensors are decoupled from the test specimen through a specialized supporting rig constructed from aluminum profiles.
As previously stated, OHB provided five test load cases based on global quasi-static loads and two test load cases based on quasi-static tank loads, selected from previous investigations. The derived forces are applied to the LIF structure via specific actuators. The following load levels and holding times are defined for the testing sequence:

- 40% Qualification Load, with a 30-second hold
- Deloading
- 80% Qualification Load, with a 30-second hold
- Deloading
- 100% Qualification Load, with a 60-second hold
- Deloading

In addition to the qualification load cases, unidirectional load cases will be applied following the QSL and Tank QSL load cases, to facilitate model correlation. These unidirectional load cases consist of a load application amounting to 90% of the full load in the respective directions.
Currently the qualification tests are performed at MT-A. All displacement and strain sensors are fully operational, providing data suitable for initial correlation studies. Fig 17 illustrates a strain sensor positioned on the inner surface of the SM bottom section, located within the LIF CFRP sandwich structure.

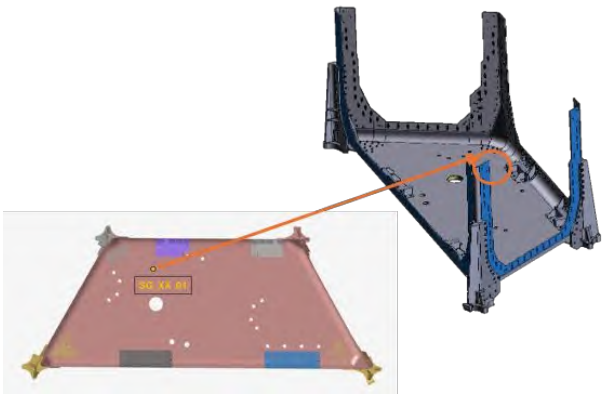

Figure 17: *Strain gauge on the inner side of the SM bottom on the LIF CFRP of the sandwich*

First evaluation of this strain sensor at the Tank QSL load case shows good agreements to the FE analysis, see Fig. 18.

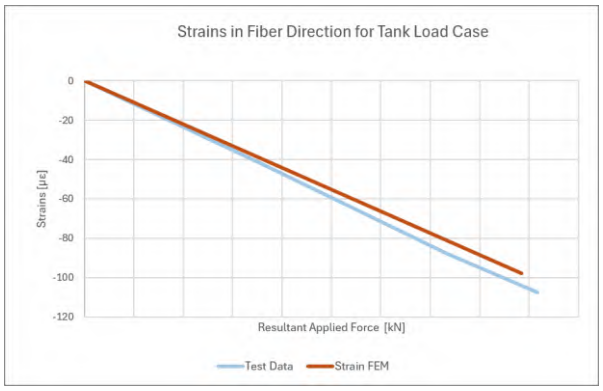

Figure 18: *Strain in Fiber Direction Test vs. FE results - Tank QSL load case*

5. CONCLUSION

The development and validation of the Launcher Interface Frame (LIF) for ESA's HARMONY mission demonstrates a significant advancement in utilizing Automated Fibre Placement (AFP) for primary satellite structures. The LIF requirements are coupled inherent with the spacecraft structure. By basing optimization and strength justification on the full spacecraft model, the design process ensured high structural fidelity and reliable validation of the LIF within the integrated spacecraft context. The justification performance is maximized by integrating manufacturing-derived fiber orientations into the sizing and verification workflow. The iterative manufacture transition from a Manufacturing Breadboard (MBB) to the Structural Model (SM) established a robust feedback loop. MBB-level studies identified critical warpage and spring-in effects, which were successfully mitigated through measurement-based tooling compensation and tow-architecture optimization.

SM structural testing for strength and stiffness verification is currently in progress. These tests serve also as basis for validation of the mechanical analysis.

The present development stage establishes a solid foundation for the ongoing advancement of AFP technology within the domain of primary satellite structures.

KEYWORDS

Sensors, carbon fiber reinforced polymers, health monitoring composites

ABSTRACT

Structural Health Monitoring (SHM) of fiber-reinforced composite structures is becoming increasingly important, as carbon fiber reinforced polymers (CFRP) exhibit complex damage mechanisms that often develop beneath the visible surface. Typical damage modes such as matrix cracking, fiber–matrix debonding, delamination, and fiber fracture can gradually degrade structural integrity and are difficult to detect reliably. Embedded sensor systems therefore offer a promising approach for continuous monitoring of the material state.

In the present project, an integrated SHM system is developed for a CFRP rocket thrust chamber support jacket. The focus is on the selection and evaluation of suitable sensor technologies, including fiber-optic, acoustic, and piezoelectric sensors, for monitoring parameters such as strain, temperature, and damage-related events. A key challenge is the integration of sensors into the laminate without significantly affecting its mechanical properties. Therefore, sensor integration is investigated using both hand-laminated specimens and an automated filament winding process.

In parallel, a simulation-based model is developed to investigate the interaction between embedded sensors and the laminate structure.

The model focuses on the main model setup, sub-models, input parameters, and boundary conditions, enabling the prediction of sensor-induced effects on the mechanical behavior. The study presents the design and validation approach of the SHM concept and provides an outlook on the planned correlation of sensor data with mechanical material properties using quasi-static and cyclic testing.

1. STRUCUTRAL HEALTH MONITORING

Structural Health Monitoring refers to the repeated or continuous collection and evaluation of structural condition parameters using permanently or repeatedly installed sensors. The goal is not just to detect a deviation, but depending on the system also to locate, quantify, and assess it. An SHM chain includes the sensor or actuator, signal processing, data acquisition and transmission, data processing, and condition-related interpretation.

The suitability of a method depends on the diagnostic task. Local sensors can offer high sensitivity in their immediate area, while surface or distributed methods can cover a larger structural region. Additionally, long-term stability, calibratable, environmental influences, wiring, data volume, and the impact of sensor integration on the structure need to be considered. integration on the structure need to be considered.

Components show various, often interconnected damage mechanisms due to their heterogeneous and layered structure. The main types of damage include intralaminar matrix cracks, fiber-matrix debonding, and fiber breaks, as well as interlaminar delaminations. Their occurrence and development are influenced by factors such as the type of load, layer structure, manufacturing deviations, and environmental conditions [1–3].

Matrix cracks and interface failures can affect the local load transfer between fiber and matrix, which in turn can promote further damage mechanisms. Especially under impact loads, matrix cracks often appear together with delamination, fiber breaks, and local indentations. Delaminations weaken the interlaminar load paths and can thereby reduce the component's stiffness, stability, and load-bearing capacity [1, 4].

Fiber breaks, on the other hand, interrupt the load-bearing fibers and can especially cause significant changes in the electrical properties of electrically conductive CFRP structures [5].

Under cyclic loading, existing cracks and delaminations can grow and new damage can occur. Additionally, drilled holes and other geometric discontinuities can act as starting points for damage. Temperature and humidity effects can influence both the polymer matrix and fiber-matrix interfaces as well as the electrical measurement properties [2, 5, 6].

The complex interaction of these mechanisms makes it difficult to clearly assign measured signals to specific types of damage and highlights the importance of suitable, particularly non-destructive, monitoring methods for CFRP components.

1.1. Damage Mechanism in CFK Structures

Components show various, often interconnected damage mechanisms due to their heterogeneous and layered structure. The main types of damage include intralaminar matrix cracks, fiber-matrix debonding, and fiber breaks, as well as interlaminar delaminations. Their occurrence and development are influenced by factors such as the type of load, layer structure, manufacturing deviations, and environmental conditions [1–3].

Matrix cracks and interface failures can affect the local load transfer between fiber and matrix, which in turn can promote further damage mechanisms. Especially under impact loads, matrix cracks often appear together with delamination, fiber breaks, and local indentations. Delaminations weaken the interlaminar load paths and can thereby reduce the component's stiffness, stability, and load-bearing capacity [1, 4].

Fiber breaks, on the other hand, interrupt the load-bearing fibers and can especially cause significant changes in the electrical properties of electrically conductive CFRP structures [5].

Under cyclic loading, existing cracks and delaminations can grow and new damage can occur. Additionally, drilled holes and other geometric discontinuities can act as starting points for damage. Temperature and humidity effects can influence both the polymer matrix and fiber-matrix interfaces as well as the electrical measurement properties [2, 5, 6].

The complex interaction of these mechanisms makes it difficult to clearly assign measured signals to specific types of damage and highlights the importance of suitable, particularly non-destructive, monitoring methods for CFRP components.

1.2. Sensor technologies (embedded sensor systems)

For structural health monitoring (SHM), different sensor principles are used, which vary in terms of what they measure, their detection range, and the effort required to integrate them.

Piezoelectric sensors allow active monitoring by exciting and detecting guided waves and are particularly suitable for detecting local changes in stiffness. Fiber optic sensors, especially fiber Bragg gratings (FBGs), detect strain and temperature influences through spectral wavelength changes and are noted for their small size, light weight, and resistance to electromagnetic interference. Acoustic emission allows for passive monitoring by capturing elastic waves that occur during damage development and evaluating them based on their characteristic features. However, clearly assigning them to specific damage mechanisms is challenging due to overlapping signal characteristics [3].

In contrast, piezoresistive and self-sensing systems use changes in the electrical conductivity of the composite material caused by strain or damage. For CFRP, the intrinsically conductive carbon fiber network can be used for this purpose, which can sometimes eliminate the need for additional sensors [7, 8].

For electrical measurement methods, factors like electrode contact, temperature, humidity, measurement noise, and drift are particularly important. While single measurements mainly provide overall information about the area between the electrodes, using multiple electrodes and different current paths allows for spatial damage localization. A more advanced approach is Electrical Impedance Tomography (EIT), where spatial conductivity distribution—or changes in it—is reconstructed from electrical boundary measurements using a forward and inverse model [9–12].

1.3. Electrical Impedance Tomography (EIT)

Electrical health monitoring of CFRP initially evolved from global resistance measurements to spatially resolved techniques. Early studies demonstrated that strain, fiber breakage, and delamination cause measurable changes in electrical resistance or potential, with results heavily dependent on electrode arrangement, measurement configuration, and the anisotropic conductivity of the CFRP [5, 7]. Utilizing multiple electrodes and various measurement paths can improve damage localization; however, unambiguously correlating electrical changes with specific damage types and geometries remains challenging [5, 8]. The introduction of Electrical Impedance Tomography (EIT) expanded electrical health monitoring to include model-based spatial reconstruction. Research on CFRP indicates that EIT is fundamentally suitable for localizing impact damage and delamination and offers the potential for structural integration by leveraging the intrinsically conductive carbon fiber network [13]. However, the reconstructed conductivity distribution does not represent a direct geometric image of the actual damage. Reconstruction quality is significantly influenced by anisotropic material behavior, the forward model, electrode contact, the reference state, and the chosen measurement pattern [13]. Consequently, current research increasingly focuses on optimizing measurement configurations and improving damage characterization. Studies show that the number and selection of electrode combinations, as well as the current injection pattern, significantly affect localization, resolution, and artifacts [11, 13, 14]. While reducing the number of measurement channels is feasible in principle, such reductions must be tailored to the specific component geometry, layup, and underlying forward model [14]. Overall, the research focus is thus shifting from the mere detection of electrical changes toward the model-based localization and characterization of damage. Reliable application to CFRP requires, in particular, suitable material modeling, reproducible electrode contacts, and measurement and reconstruction procedures tailored to the specific component and type of damage. Electrode Contacting and Three-Dimensional EIT Electrode contacting is a critical factor in the EIT measurement chain, as electrode material, contact area, ply layup, and manufacturing conditions can influence the measured electrical resistance [10]. Embedded electrodes enable permanent, low-profile contact but require investigation into their long-term mechanical and electrical stability within the specific laminate layup. Furthermore, reliable EIT application necessitates considering not only the reconstruction process itself but also measurement noise, drift, accuracy, and the reproducibility of the entire measurement chain [9] . Conventional EIT systems with a single electrode plane provide spatially distributed sensitivity, from which primarily two-dimensional reconstructions are derived. Consequently, the position of damage located outside the plane of interest may be misinterpreted. Multiple electrode planes theoretically enable three-dimensional reconstruction, thereby improving the ability to determine damage location across the component thickness [12, 15]. However, for thin CFRP laminates, depth resolution poses a particular challenge due to the limited component thickness and pronounced electrical anisotropy. Reliable 3D reconstruction therefore requires appropriate consideration of geometry, electrode contact, conductivity, and the electrical coupling between individual plies.

Electrical Impedance Tomography (EIT) enables the reconstruction of a spatial conductivity distribution from electrical boundary measurements. To do this, defined currents are injected into the component via electrodes, and the resulting potentials are measured. By varying the pairs of injection and measurement electrodes, a measurement vector is generated, from which the conductivity distribution—or changes therein—is determined using a forward model and an inverse method [11].

Under quasi-stationary conditions and in the absence of internal current sources, the electric potential u in the domain Ω is given by.

$$\nabla \cdot (\sigma \nabla u) = 0 \; in \; \Omega \quad (1)$$

The current density is given by j = −σ∇u. Geometry, conductivity, electrode areas, contact impedances, and applied currents constitute the inputs to the forward problem. For complex geometries, the domain is typically discretized using the finite element method.

The forward problem describes the distribution of the electric potential within the component based on geometry, material conductivity, electrodes, and contact conditions. For complex component geometries, the finite element method is typically used for this purpose. The inverse problem, on the other hand, is ill-posed, since even small measurement or model deviations can lead to significant changes in the reconstructed conductivity distribution. In differential EIT, therefore, the current measurement state is compared with a reference state, and the change in conductivity is reconstructed [11].

The inverse problem consists of inferring the internal conductivity from boundary measurements. It is nonlinear and ill-posed: small deviations in measurements or models can cause large changes in the reconstructed distribution. In difference EIT, measurements of a state are compared with a reference. For small changes, the relationship can be linearized around a reference state:

$$\Delta v \approx J \, \Delta \sigma \quad (2)$$

where Δv denotes the voltage difference vector, Δσ the discretized conductivity change, and J the sensitivity or Jacobian matrix.

A regularized linear solution can generally be formulated as

$$\hat{\Delta\sigma} = (JTWJ + \lambda R)^{-1} JTW\Delta v \quad (3)$$

W weights the measurement data, R describes the regularization, and λ controls the trade-off between data fitting and stability.

The specific meaning of these quantities depends on the reconstruction method employed.

Regularization methods are used to stabilize the reconstruction. Among other things, Gauss–Newton methods enable the reconstruction of the change in conductivity, while the NOSER method stabilizes the solution to the inverse problem. The quality of the reconstruction can be assessed using various criteria such as position [11].

2. EXPERIMENTAL VALIDATION ON PLANAR SURFACES

For the experimental investigations, CFRP specimens are manufactured using the hand lay-up process. Unidirectional carbon fiber fabric serves as the reinforcement, combined with a three-component epoxy resin system consisting of resin, hardener, and accelerator. Thin copper foils are integrated into the laminates as electrodes to establish electrical contact. The manufacturing process is carried out under vacuum and comprises material preparation, a defined ply layup, and subsequent curing (Figure 1).

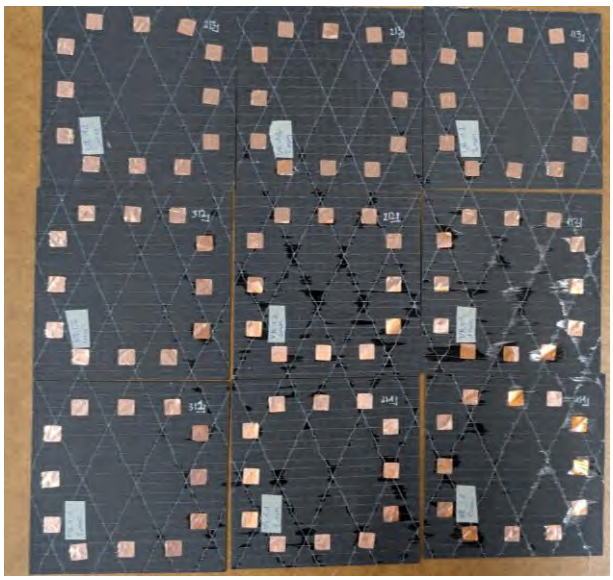

Figure 1: Testspecimen

The investigations are organized into three test series as stated in Figure 2. The first series employs four-ply CFRP specimens featuring a single electrode layer to investigate drilling-induced defects. The second series involves the fabrication of eight-ply specimens with electrode layers integrated on both sides and embedded Kapton inserts to simulate interlaminar defects. These specimens are subsequently used for EIT measurements in the third test series, which examines both the detection of the simulated defects and the influence of different measurement patterns.

Figure 2: Schematic representation of the different laminate layups

Three test series (VR1–VR3) are defined for the experimental investigation, differing in terms of laminate layup, electrode arrangement, and the method of defect introduction. In VR1, four-ply CFRP specimens featuring a single electrode layer are used to investigate drilling-induced defects. For VR2, eight-ply specimens are fabricated with electrode layers integrated on both sides. Kapton inserts are embedded at various ply positions to simulate defined interlaminar defects. The specimens produced in VR2 are subsequently used for EIT testing in VR3, where both the detectability of the simulated defects and the influence of different measurement patterns are analyzed.

Specimen fabrication thus differs between VR1 and VR2. While VR1 employs a uniform four-ply laminate layup, three variants are realized within a single laminate panel for VR2. Variant VR2.1 serves as a defect-free reference state. In VR2.2, a Kapton insert is positioned between the first and second plies, whereas in VR2.3, the insert is placed between the fourth and fifth plies. This variation in insert positioning creates defects at different depths within the laminate, enabling an investigation into the influence of defect location on EIT reconstruction.

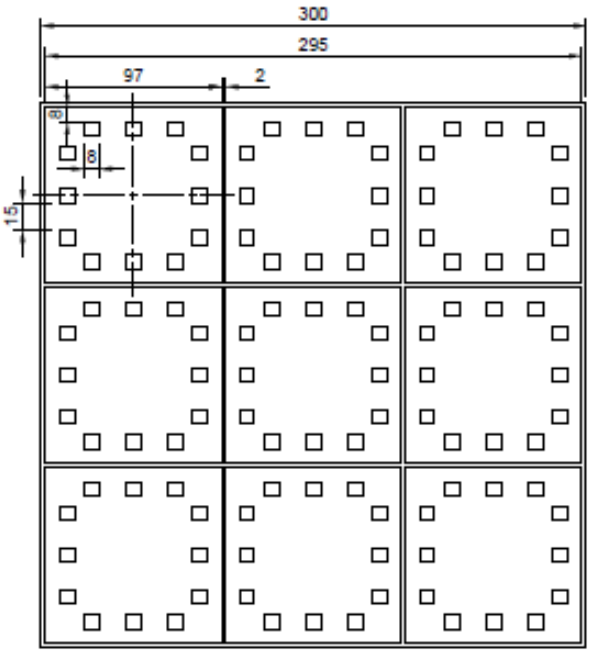

Figure 3: Plate geometry & electrode arrangement

Figure 3 shows that for each test specimen, up to twelve adjacent electrode pairs on side A were evaluated; non-conductive pairs were excluded from the statistics. n denotes the number of soldered test specimens with both pre- and post-test measurements. The relative change for each specimen is defined as $(R_{med,post} - R_{med,pre})/R_{med,pre}$.

Table 1: Resistances of adjacent electrode pairs (Side A) before and after soldering, summarized by laminate board. Shown are the median of the specimen medians, their range, and the median relative change of the median per specimen.

		R_{med} vor in Ω		R_{med} nach in Ω		
Laminatplatte	n	Median	Spannweite	Median	Spannweite	ΔR_{med} median
VR1 P1	9	5,50	2,75–18,80	20,85	6,20–69,70	+233 %
VR1 P2	6	3,55	2,25–12,50	11,78	5,25–31,50	+143 %
VR1 P3	7	4,45	2,10–17,25	23,65	4,15–56,55	+136 %
VR1 P4	7	7,70	3,45–17,95	34,85	9,60–67,20	+178 %
VR3 P1	3	4,30	4,00–4,75	5,10	5,05–7,60	+28 %
VR3 P2	6	7,92	3,60–14,65	11,55	5,35–26,65	+62 %

3. RESULTS

The test series VR1 investigates the influence of bore diameter (VR1.1), bore position (VR1.2), and electrode connection (VR1.3 and VR1.4) on EIT reconstruction. The reconstruction results are evaluated based on the reconstructed center of gravity (CoG), the positional error (PE), and the reconstruction energy (E).

For visualization purposes, a representative individual case is presented for each test condition. This selection is based on the mean positional error across the two reference states used. The statistical analysis of the entire test groups is performed using the parameters listed in Table 1.

Table 2: VR1: Reconstruction metrics from the primary analysis. Shown are the group median of the position error (PE) with its range, and the group median of the reconstruction energy (E) for each reference type.

			virtuelle Referenz		simulierte Referenz	
Bedingung	Serie	n	PE in mm	E in $(S/m)^2$	PE in mm	E in $(S/m)^2$
Ø 1 mm, zentrisch	VR1.1	3	6,9 (6,4–15,7)	29,4	7,2 (5,8–9,4)	15,0
Ø 2 mm, zentrisch	VR1.1	3	23,2 (14,5–25,1)	28,6	16,1 (3,2–19,2)	66,9
Ø 4 mm, zentrisch	VR1.1	3	13,4 (7,6–33,3)	23,9	5,8 (4,1–10,8)	61,0
Ø 4 mm, 10 mm versetzt	VR1.2	3	21,8 (19,7–23,7)	49,7	26,4 (18,6–35,5)	44,8
Ø 4 mm, 20 mm versetzt	VR1.2	3	36,6 (21,3–41,1)	41,4	22,4 (16,4–40,7)	157,2
Ø 4 mm, schlechte Anbindung	VR1.3	2	14,0 (3,3–24,7)	120,0	8,8 (8,6–9,1)	147,7
Ø 4 mm, repariert	VR1.4	2	17,1 (9,4–24,9)	61,7	10,6 (9,1–12,1)	143,3

3.1. Influence of the bore diameter

Table 2 shows the conductivity changes reconstructed via EIT for borehole diameters of 4, 2, and 1 mm, using both a virtual and a simulated reference. For all defect sizes investigated, the reconstructed centroid is located in the vicinity of the centrally placed borehole. However, the positional error shows no clear correlation with the borehole diameter. Similarly, no systematic trend is discernible regarding the reconstruction energy. Thus, the increase in reconstruction energy with increasing defect size—as predicted by the simulation—is not confirmed by the experimental results.

3.2. Influence of the delamination location in the laminate

In test series VR3, the interlaminar defects simulated using Kapton inserts are reconstructed using measurements from intact reference specimens. For each damaged specimen, the Top-only-Star and Top-Skip35 (TS35) measurement patterns are compared with respect to their suitability for damage detection and localization. The primary analysis includes three specimens with the defect located between plies 1 and 2 (Delam12) and two specimens with the defect located between plies 4 and 5 (Delam45). For statistical evaluation, the reconstruction results of each damaged specimen are first aggregated across the corresponding compatible reference specimens using the median. The resulting performance metrics are summarized in Table 3.

Table 3: VR3: Reconstruction of primary analysis metrics (group medians based on sample medians; positional error additionally includes range).

Lagenposition	Muster	n	PE in mm	E in $(S/m)^2$
Lage 1–2 (Delam12)	Star	3	11,5 (8,9–25,4)	25,3
Lage 1–2 (Delam12)	TS35	3	7,3 (3,1–12,4)	16,4
Lage 4–5 (Delam45)	Star	2	10,2 (2,7–17,7)	331,1
Lage 4–5 (Delam45)	TS35	2	8,1 (4,2–12,0)	161,2

Figure 4 show, for both ply positions, the released specimen exhibiting the lowest combined localization error obtained using the Star and TS35 measurement patterns against the same reference. The black rectangle indicates the nominal position of the Kapton insert, measuring 30 mm × 15 mm and located at the center of the plate.

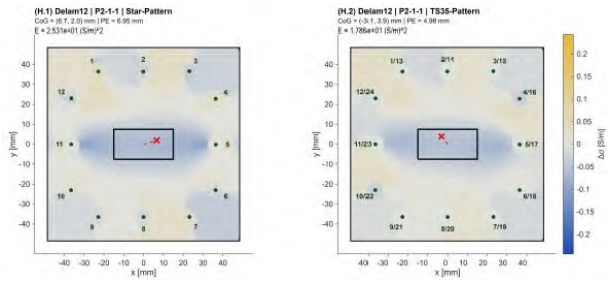

Figure 4: Reconstruction results VR3, Kapton insert between layer 1–2, sample P2-1-1 (left: Top-only Star, right: Top-Skip35)

In both cases, a continuous zone of reduced effective conductivity is reconstructed in the region of the Kapton insert, elongated along its longitudinal axis. The reconstructed centers of gravity are located within or directly adjacent to the nominal insert region. For the ply position between plies 1 and 2, the group median position errors are 11.5 mm for the Star pattern and 7.3 mm for the TS35 pattern. For the ply position between plies 4 and 5, the corresponding values are 10.2 mm and 8.1 mm, respectively.

Considerable variation between specimens is observed. Within the Delam12 group, for example, the position error obtained with the Star pattern ranges from 8.9 mm to 25.4 mm. Given the limited sample sizes (n = 3 and n = 2), no systematic difference in localization performance between the two ply positions can be established. Furthermore, the present analysis does not allow a reliable assessment of the reconstructed depth position of the inserts, as the reported metrics describe the in-plane localization and no systematic validation of depth resolution was performed on the experimental data.

3.3. Experimental validation on curved surfaces

Two concepts were investigated for the surface integration of the sensors during filament winding. In both concepts, the specimens were wound onto a 50 mm diameter PVA core, which can be removed after curing (see cross-section in Figure 5b).

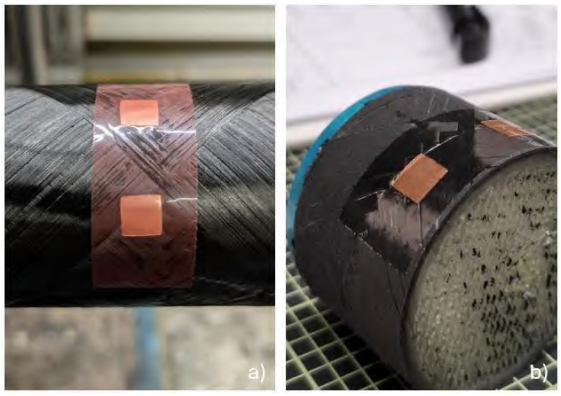

Figure 5: Recording of the wrapped test specimens a) uncured with red release film b) after curing and removing the film

Fine, high-modulus carbon fibers were used, with each roving consisting of 6000 filaments. A low-temperature-curing epoxy resin was used as the matrix material, with a glass transition temperature of approximately 100 °C.

In concept a), a release agent was applied to the upper sensor surface. The sensors were then aligned and wrapped with tensioning tape to ensure their positioning during the winding process. In concept b), the sensors were left untreated, while their upper surfaces were covered with a release film (red area in Figure 5a) and subsequently wrapped with tensioning tape. One specimen was manufactured according to each concept.

3.3.1. Electrical measurement

The electrical connection between the sensors and the surrounding carbon structure was evaluated by measuring the electrical resistance between the midpoints of the two sensors. The measured resistance was classified as good for values of 1–2 Ω, moderate for 10–30 Ω, and poor for 50–60.

3.3.2. Results

For concept a), the release agent applied to the sensor surfaces also spread to the underside of the sensors and consequently impaired their physical bonding to the carbon surface. In contrast, the electrical connection achieved with concept b) was measured at 1.6 Ω and was therefore classified as good according to the defined criteria.

To protect the sensors during removal of the PVA core, the sensor surfaces were covered with

polyester-film adhesive tape. After removal of the core, the adhesive tape was removed and the specimen was subsequently tempered. The electrical resistance measured after these processing steps remained low at 1.7–1.8 Ω, indicating a good and stable electrical connection.

Optical inspection at increased magnification showed a slight ingress of resin onto the upper sensor surface along the sensor edges. This resin accumulation forms a visible edge seal and provides additional mechanical protection against local delamination or lifting of the sensor edges (see Figure 6).

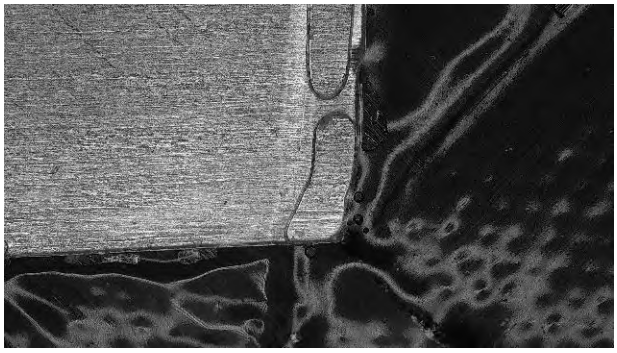

Figure 6: Enlarged image of the transition: sensor to component

4. SIMULATION

The simulation model offers significant advantages for optimizing the structural shell by enabling the simulation of laminate behavior under real-world conditions prior to manufacturing. In Ansys ACP, the simulation model is constructed using the base model of the structural shell, derived from the existing pipe model. This model is progressively refined to incorporate specific requirements and insights. A key aspect previously unaddressed is the assessment of the laminate's leak-tightness. To this end, small-scale samples are modeled and analyzed for micro-cracking and delamination under cryogenic loading. These simulation results must subsequently be correlated with actual damage patterns and experimental permeability data—ideally including cyclic loading—to evaluate damage progression. The structural shell is then simulated over multiple cryogenic cycles, allowing for an estimation of service life and leak-tightness. Additionally, an internal pipe coating can be simulated to reduce thermal gradients within the laminate.

A further step involves stress analysis of the pipe following manufacture. This entails analyzing the residual stresses generated by temperature differentials during the curing process. Simultaneously, winding tension plays a role and is integrated into the model to more accurately represent the stress distribution. Beyond residual stresses, the behavior of the interface between layers must be considered; this can be addressed by inserting an additional layer with specific material properties or, if applicable, an adhesive layer. The layup and individual layer properties must be modeled to reflect the specific manufacturing process in order to achieve realistic results. The manufacturing process itself must be taken into account, as tapering effects can impact structural integrity. A sandwich laminate structure could also be an option to provide additional stability. Realistic boundary conditions must be established for the interface region, particularly given the difficulty of predicting interface behavior under varying loads. Ansys now offers capabilities for simulating threaded connections within laminates, which can be integrated into the analysis. This process accounts for the effects of the thrust chamber, and transient thermal loads must be modeled precisely to ensure accurate results.

Additionally, the modeling approach is being expanded to include embedded sensors, the impact of which on structural strength must be factored into the simulation. Submodeling may prove beneficial for detailed analyses of specific areas—such as cryogenic tightness, interface behavior, and embedded sensors. This method employs a coarse, global model for rapid computation while utilizing detailed submodels at critical locations that adopt the boundary conditions from the larger model.

4.1. Workflow

Figure 7 illustrates the simulation workflow implemented in ANSYS Workbench. The workflow consists of several interconnected analysis systems that transfer the defined geometry and engineering data through material definition, composite layup modeling, and structural analysis. The composite laminates are defined using ACP (Pre), where the

laminate geometry, material properties, fiber orientations, and ply configuration are specified. The resulting composite model is subsequently transferred to the Mechanical environment, where the boundary conditions and loading are defined and the structural response is calculated using a Static Structural analysis. This sequential workflow enables the consistent transfer of the composite laminate definition into the structural analysis and provides the basis for evaluating the mechanical behavior of the investigated component under the specified loading conditions.

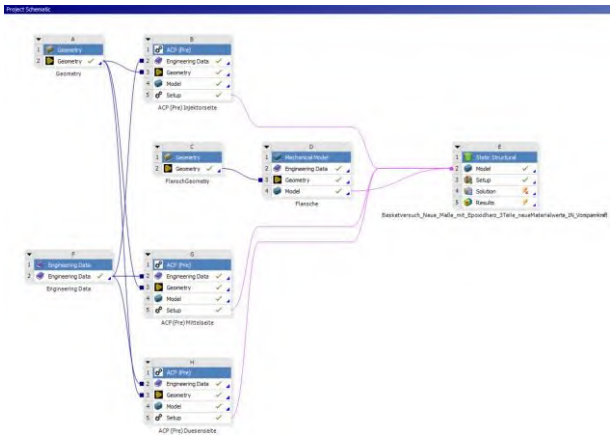

Figure 7: Figure X: Simulation workflow implemented in ANSYS Workbench

Figure 7 presents the finite element model of a slender structural assembly analyzed using a static structural simulation. The model consists of a long, approximately beam-like structural member connected to end components. The analysis setup is shown together with the applied boundary conditions and bolt-pretension loads.

The model tree on the left-hand side indicates that the simulation contains a static structural analysis with several load and constraint definitions. In particular, a fixed support, multiple prescribed displacement constraints, and bolt-pretension loads are included. The legend in the graphics window identifies the individual boundary conditions by color:

Fixed Support (blue): A fixed support is applied at one of the structural interfaces. This constraint suppresses the relevant translational and/or rotational degrees of freedom and provides the reference condition required for the static structural analysis.

Displacement 2 and Displacement 3 (yellow/green): Prescribed displacement boundary conditions are defined at selected locations of the structure. These constraints control the motion of the corresponding regions and can be used to represent mechanical guidance, support conditions, or imposed deformation.

Bolt Pretension (red): The red symbols indicate bolt-pretension loading. The model contains pretensioned bolted connections at the structural interfaces. The pretension is introduced into the bolts before the subsequent structural loading is evaluated, allowing the influence of the initial bolt preload on the mechanical response of the assembly to be considered.

Bolt Pretension: M20a / M20: The notation visible in the simulation tree indicates a pretensioned M20 bolted connection or a corresponding bolt-pretension definition. This suggests that the bolted interfaces are explicitly represented in the numerical model rather than being treated solely as simplified fixed connections.

The central graphical view shows the complete structural assembly in an isometric representation. The long central member extends between two end regions, where the connection and support components are located. The colored symbols overlaid on the geometry do not represent stress or deformation contours; rather, they visualize the locations and types of applied boundary conditions and loads.

The coordinate triad in the upper-left portion of the graphics window defines the global orientation of the model. The scale bar at the bottom indicates the approximate geometric extent of the structure, with the displayed range reaching approximately 500 mm. The model therefore represents a component with a characteristic length on the order of several hundred millimeters.

Importantly, the figure represents the simulation setup rather than a simulation result. No von Mises stress, strain, or displacement contour is displayed in the current view. Instead, the figure documents how the structural model is mechanically

constrained and how the pretensioned bolted connections are defined. These boundary conditions determine the load path and the resulting deformation and stress state calculated by the subsequent finite element analysis.

Figure 8 illustrates the finite element model and boundary conditions used for the static structural analysis of the pretensioned assembly. The model consists of a slender structural member with bolted connections at both ends. A fixed support, prescribed displacement constraints, and bolt-pretension loads are applied to reproduce the mechanical constraints and preload conditions of the investigated structure. The colored symbols identify the respective boundary conditions, while the model tree summarizes the corresponding analysis definitions. The figure shows the numerical model setup and does not represent a stress or deformation result.

Figure 8: Finite Element Model and Boundary Conditions of the Pretensioned Structural Assembly

The composite structure was modelled in ANSYS ACP (Pre) using a multi-material laminate layup. The laminate consists of carbon-fibre-reinforced epoxy plies combined with SAN foam core layers. Both unidirectional (UD) and woven carbon-fibre fabrics are considered, with material data defined according to their respective areal weights and fibre architectures.

The layup includes biaxial and triaxial carbon/epoxy fabric layers, as indicated in the ACP model, together with foam layers providing the required sandwich-core thickness. The individual plies are assigned within the ACP stacking sequence, allowing the local laminate thickness and fibre orientation to be explicitly defined. According to the displayed model, the resulting laminate thickness varies between approximately 19.98 and 20.94 mm over the analysed component (Figure 9).

This modelling approach enables the anisotropic mechanical behaviour of the composite to be captured while accounting for the influence of the individual fibre orientations, material properties, and sandwich-core configuration on the structural response.

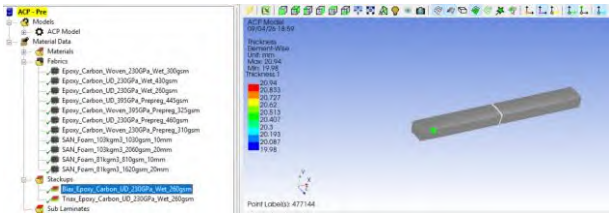

Figure 9: Laminate layup and through-thickness distribution of the composite structure in ANSYS ACP (Pre)

5. DISCUSSION AND OUTLOOK

The experimental investigations demonstrate the feasibility of EIT for detecting and localizing artificially introduced defects in CFRP laminates. The reconstructed conductivity changes were generally located close to the actual defect positions. However, no clear correlation between borehole diameter and reconstruction energy or positional error was observed. The results further show that the measurement pattern influences the localization accuracy, with the TS35 pattern providing lower median positional errors than the Star pattern for the investigated delamination positions. Due to the limited number of specimens, these findings should be considered indicative rather than statistically conclusive.

The experiments also demonstrate the importance of reliable electrode integration. The second integration concept achieved a stable electrical resistance of 1.6–1.8 Ω after manufacturing and thermal treatment, providing a suitable basis for further development of the embedded EIT system. The measured electrical contact behavior should be considered in future numerical models, as electrode

contact and material anisotropy can significantly influence the reconstructed conductivity distribution.

These experimental findings provide the basis for extending the numerical model. In addition to the mechanical behavior of the CFRP load jacket, the model should incorporate the anisotropic electrical properties of the laminate, electrode geometry, and contact conditions. Local submodels can be used to investigate the influence of embedded sensors on the mechanical behavior and to simulate defects at different positions within the laminate.

In a subsequent step, the numerical EIT model will be correlated with the experimental measurements. Different electrode configurations, defect sizes, and defect positions can then be systematically investigated. The validated model can subsequently be transferred from planar specimens to the curved CFRP load jacket and combined with the structural simulation.

For the final application, the model will be extended to thermo-mechanical and cyclic cryogenic loading. The aim is to investigate the relationship between damage development, changes in electrical conductivity, and structural integrity. This combined experimental and numerical approach provides the basis for a component-specific SHM system capable of relating measured electrical changes to damage evolution in the CFRP load jacket.

Thermoplastic composites; induction heating; physics-informed machine learning; surrogate modelling; space manufacturing.

ABSTRACT

Thermoplastic carbon-fibre-reinforced polymers are attractive for future spacecraft structures because they combine low mass with weldability and the potential for automated or in-space assembly. Induction heating is particularly promising, but its repeatability is limited by the coupled electromagnetic and thermal response of anisotropic laminates. This work develops a physics-informed machine-learning framework that combines experiments, an electrothermal finite-element model, and low-cost neural-network surrogates. Four predictive routes are assessed: a semi-empirical first-order model, a fully data-driven model, a surrogate of the finite-element solution, and a hybrid residual model that corrects the physics-based prediction using experimental data. The hybrid formulation reduces the final-test RMSE from 43.3 °C for the FEM surrogate to 10.8 °C while retaining a physically meaningful baseline. The resulting model is used to construct power-time process maps and identify underheated, weldable, and thermally critical regions for different laminate thicknesses.

1. INTRODUCTION

Thermoplastic composite structures are increasingly considered for lightweight aerospace and space applications because they offer high specific properties together with short processing cycles, damage tolerance and, importantly, the possibility of fusion joining [1]. Welding avoids drilled holes, fasteners and long adhesive-curing operations and can therefore simplify assembly while reducing added mass. Among the available techniques, induction welding is attractive because energy is delivered without direct contact, heating can be rapid, and the process can be integrated with automated manufacturing equipment [2].

These characteristics are also relevant to future in-space manufacturing and assembly. Large structures may benefit from modular architectures in which thermoplastic subcomponents are joined after launch or repaired locally. In such scenarios the joining process must be energy-efficient, compact and robust, while the thermal history must remain within a narrow window: insufficient heating prevents adequate polymer interdiffusion, whereas excessive temperature can produce matrix degradation, distortion or damage to neighbouring components.

Achieving repeatable thermal histories remains a major challenge in the induction heating of carbon-fibre-reinforced polymers (CFRPs). Even under nominally identical process conditions, variations in the laminate can modify the electrical pathways through which induced currents circulate and, consequently, the resulting heat generation. In particular, differences in consolidation and interlaminar microstructure alter fibre-to-fibre contacts and through-thickness electrical conduction, producing markedly different induction-heating patterns [3]. Electrical conductivity itself is anisotropic and inherently variable, and uncertainty in its magnitude propagates directly into variability of the predicted temperature field [4]. This material-induced variability is compounded by the strong sensitivity of inductive heating to process parameters: heating rates depend on frequency, generator power, coil geometry and, particularly, coil-to-part coupling distance [5]. Consequently, relatively small material or process variations can produce appreciable differences in the thermal response, making robust prediction and repeatable temperature control difficult.

High-fidelity finite-element (FEM) models provide physical insight and spatial temperature fields, but calibration is demanding and repeated simulations are too expensive for rapid process exploration or control. Recent studies have explored neural networks and surrogate models to accelerate temperature prediction in induction-heating

processes, reducing the computational cost of repeated multiphysics simulations [6]–[8]. However, a key challenge remains to retain the physical information provided by FEM models while correcting their discrepancy from experimental CFRP heating behaviour. The objective of this work is therefore to develop a fast, experimentally corrected physics-informed framework for CFRP induction heating. The study: (i) compares semi-empirical, fully data-driven and physics-based predictive approaches; (ii) combines a FEM surrogate with data-driven residual correction; and (iii) exploits the resulting hybrid model to investigate power–time process windows relevant to thermoplastic welding.

2. EXPERIMENTAL AND PHYSICAL FRAMEWORK

2.1. Experimental Setup and Test Matrix

The experimental set-up consists of an induction welding head positioned close to a flat CFRP coupon (Fig.1). Temperature is monitored using thermocouples on the laminate, an infrared camera and pyrometers. The combination of contact and non-contact measurements provides both local time histories and information on the spatial thermal field. The coil is water cooled and mounted in a repeatable fixture relative to the panel.

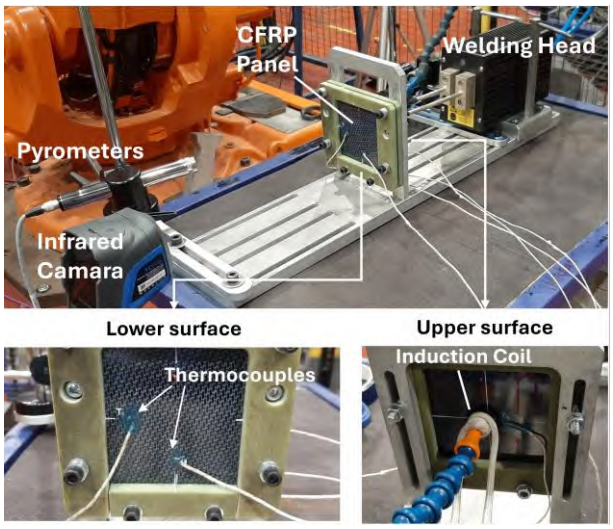

Figure 1 Induction-heating experimental setup and temperature instrumentation.

Three nominal laminate thicknesses were investigated: 0.62, 1.24 and 2.48 mm. Applied power was varied between 10 and 60% of the maximum available power (12 kW) according to the experimental matrix reported in Tab.1. Cases used for model development were separated from an independent test subset.

Table 1: Summary of the experimental design.

Case_ID	Thickness [mm]	Power [%]	Subset
EXP 1	0,62	10	Development
EXP 2		15	
EXP 3		20	
EXP 4		25	
EXP 5		30	
EXP 6		40	
EXP 7	1,24	10	Test
EXP 8		15	
EXP 9		20	
EXP 10		30	
EXP 11	2,48	10	Development
EXP 12		15	
EXP 13		20	
EXP 14		40	
EXP 15		60	

Data were partitioned on a case-wise basis, so that all time samples belonging to the same experimental heating history were assigned to the same dataset. This prevents information leakage between training and testing and provides a more representative assessment of the model performance on unseen experimental cases.

2.2. Physical Background

Induction heating of CFRP results from the coupling between the electromagnetic and thermal fields. The alternating current supplied to the induction coil generates a time-varying magnetic field, which induces electric fields and current densities within the electrically conductive carbon-fibre network. Under the quasi-static electromagnetic approximation, the local current density is related to the electric field through the electrical conductivity tensor,

$$J = \sigma E \qquad (1)$$

where J is the induced current density, E is the electric field, and σ is the electrical conductivity tensor of the laminate. CFRP exhibits strongly anisotropic electrical conductivity, with conductivity along the carbon fibres being several orders of magnitude greater than that in the transverse and through-thickness directions. Consequently, the induced current paths and the associated heat generation depend on the laminate architecture, ply orientation, coil geometry, and relative coil–laminate position.

The electromagnetic energy dissipated within the laminate is converted into heat by Joule losses. The corresponding volumetric heat source is

$$Q_{em} = J \cdot E \qquad (2)$$

For the non-ferromagnetic CFRP considered here, Joule dissipation associated with the induced currents represents the relevant electromagnetic heating mechanism. The resulting heat-source field is generally non-uniform and inherits the spatial characteristics of the electromagnetic coupling.
The subsequent temperature evolution is governed by transient heat conduction,

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + Q_{em} \qquad (3)$$

where ρ is the laminate density, c_p is the specific heat capacity, and k is the thermal-conductivity tensor. As for the electrical properties, the thermal response of CFRP is anisotropic, with heat transport depending on the fibre directions and stacking sequence. Heat is simultaneously transferred within the laminate and dissipated to the surroundings. At the external boundaries, the main thermal losses can be represented by convection and radiation as

$$q_{conv} = h(T - T_0),\ q_{rad} = \varepsilon \sigma_{SB}(T^4 - T_0^4) \qquad (4)$$

where h is the convective heat-transfer coefficient, T_0 is the ambient temperature, ε is the surface emissivity, and σ_{SB} is the Stefan–Boltzmann constant. The measured thermal response therefore results from the balance between electromagnetic power deposition, thermal energy storage, anisotropic heat diffusion, and heat exchange with the environment.
For reduced-order modelling, this distributed thermal problem can be **approximated by a lumped energy balance** when the response at a given location is represented by a single dominant thermal timescale. For constant heating conditions, the balance may be expressed as

$$C_{th} \frac{dT}{dt} = \dot{Q}_{in} - G_{th}(T - T_0) \qquad (5)$$

where C_{th} is an effective thermal capacitance, G_{th} is an effective thermal conductance accounting for heat removal from the considered thermal domain, and $\dot{Q}_{in}$in represents the effective absorbed heating power. Assuming these effective quantities remain approximately constant during heating, integration gives the first-order response

$$T(t) = T_0 + (T_{steady} - T_0)\left(1 - e^{-t/\tau}\right) \qquad (6)$$

with

$$T_{steady} = T_0 + \frac{\dot{Q}_{in}}{G_{th}}, \qquad \tau = \frac{C_{th}}{G_{th}} \qquad (7)$$

Here, T_{steady} represents the asymptotic temperature associated with the balance between absorbed power and thermal losses, and τ is the effective thermal time constant governing the rate at which this condition is approached.
This reduced representation does not resolve the spatially distributed electromagnetic and thermal fields described by Eqs. 1-4. Instead, T_{steady} and τ condense their combined effect into two effective response parameters. This distinction provides the physical basis for the two modelling strategies investigated in this work: the **semi-empirical first-order model**, which predicts these reduced thermal parameters from the operating conditions, and the higher-fidelity data-driven and physics-guided models, which directly represent the transient temperature response without imposing a first-order temporal evolution.

3. PREDICTIVE MODELLING METHODOLOGY

Four AI-based predictive models were developed to reproduce the transient thermal response of CFRP laminates under induction heating, using experimental measurements, physics-based FEM simulations, or a combination of both.
Fig. 2 summarizes the overall modelling strategy. Experimental temperature histories are used to develop the semi-empirical and fully data-driven models, whereas numerical temperature histories generated by the electrothermal FEM are used to train the FEM surrogate. Experimental and physics-based information are finally combined in the hybrid model through a learned residual correction.

3.1. Experimental-Based Thermal Models

The first two models rely exclusively on experimental data. The **semi-empirical first-order model** uses the reduced thermal formulation introduced in Section 2.2. A feed-forward neural network predicts T_{steady} and $ln(\tau)$ from the applied power P, laminate thickness d, and thermocouple coordinates (x_{TC}, y_{TC}, z_{TC}). The predicted parameters are then used in Eq. 6 to reconstruct the complete temperature history.
The **fully data-driven model** removes the first-order assumption and directly predicts $T(t)$ from the same process and spatial variables, with heating time t included as an additional input. This formulation can therefore learn the transient response without imposing a predefined temporal

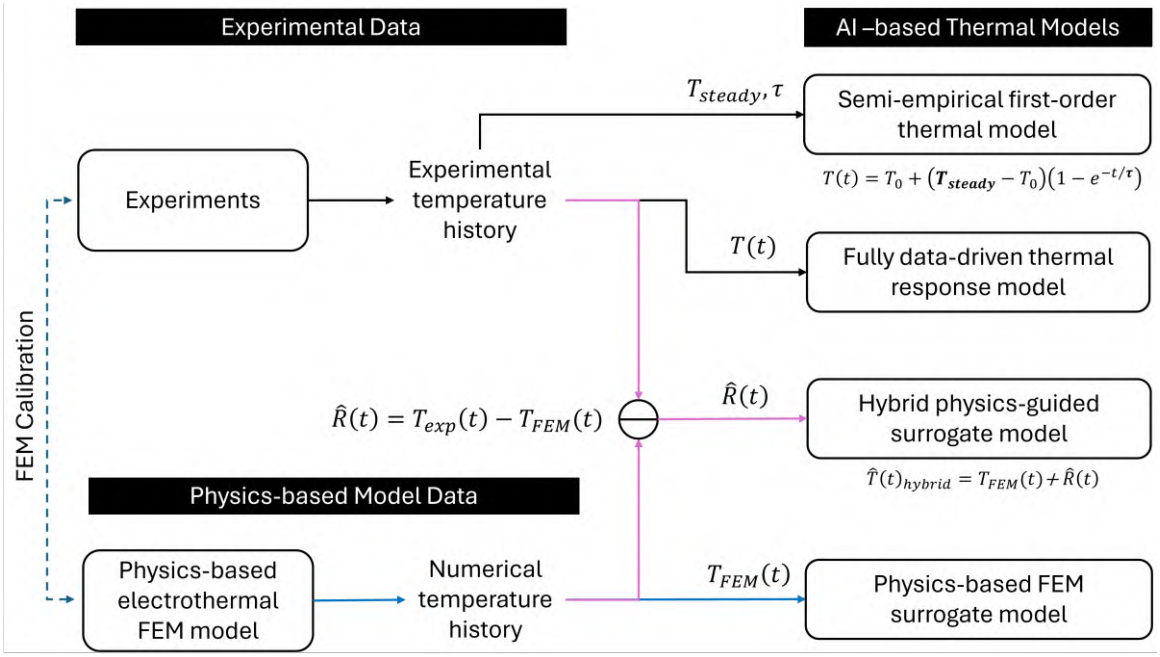

Figure 2 Predictive modelling framework combining experimental data, physics-based FEM simulations, and AI-based thermal models.

evolution. The architectures of both models are shown in Fig. 3 (a,b).

3.2. FEM Surrogate and Hybrid Physics-Guided Model

A coupled electrothermal model was implemented in COMSOL® Multiphysics to reproduce the induction-heating process. The computational domain includes the CFRP laminate, induction coil, and surrounding air, as shown in Fig. 4. Electromagnetic power deposition is coupled with transient anisotropic heat transfer, and the model is calibrated against the experimental temperature histories. The numerical temperature histories were subsequently used to train the **physics-based FEM surrogate model** shown in Fig. 3(c), which predicts the temperature increment ΔT_{FEM} from P , d , thermocouple coordinates, and time. This provides a computationally inexpensive approximation of the FEM response.

Finally, the **hybrid physics-guided model** learns the discrepancy between experimental and FEM temperatures using the network architecture shown in Fig. 3(d). The correction is learned from the residual between the experimental and numerical temperatures

$$\hat{R}(t) = T_{exp}(t) - T_{FEM}(t) \qquad (8)$$

thereby retaining the physics-based description of the process while compensating for systematic discrepancies between the numerical model and the experiments.

The corrected temperature prediction is

$$\hat{T}_{hybrid}(t) = T_{FEM}(t) + \hat{R}(t) \qquad (9)$$

All four neural models use three fully connected hidden layers with 32 neurons per layer. Inputs and outputs are standardised using training-set statistics, and independent test cases are excluded from model training.

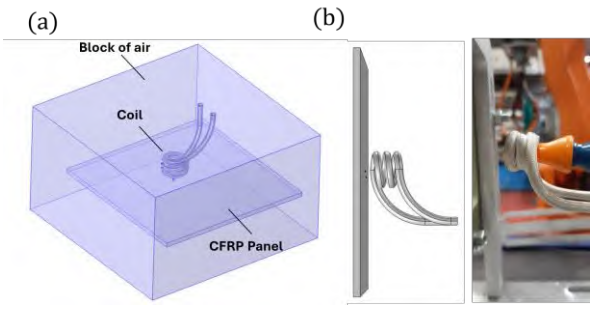

Figure 3 (a) Electrothermal FEM domain, (b) coil geometry and experimental coil.

3.3. Evaluation Metrics

Prediction performance is quantified by root-mean-square error (RMSE), mean absolute error (MAE) and mean bias. Metrics are calculated over the final-test temperature samples. Parity plots and residual-versus-temperature plots are used to identify systematic trends that a single scalar metric can hide.

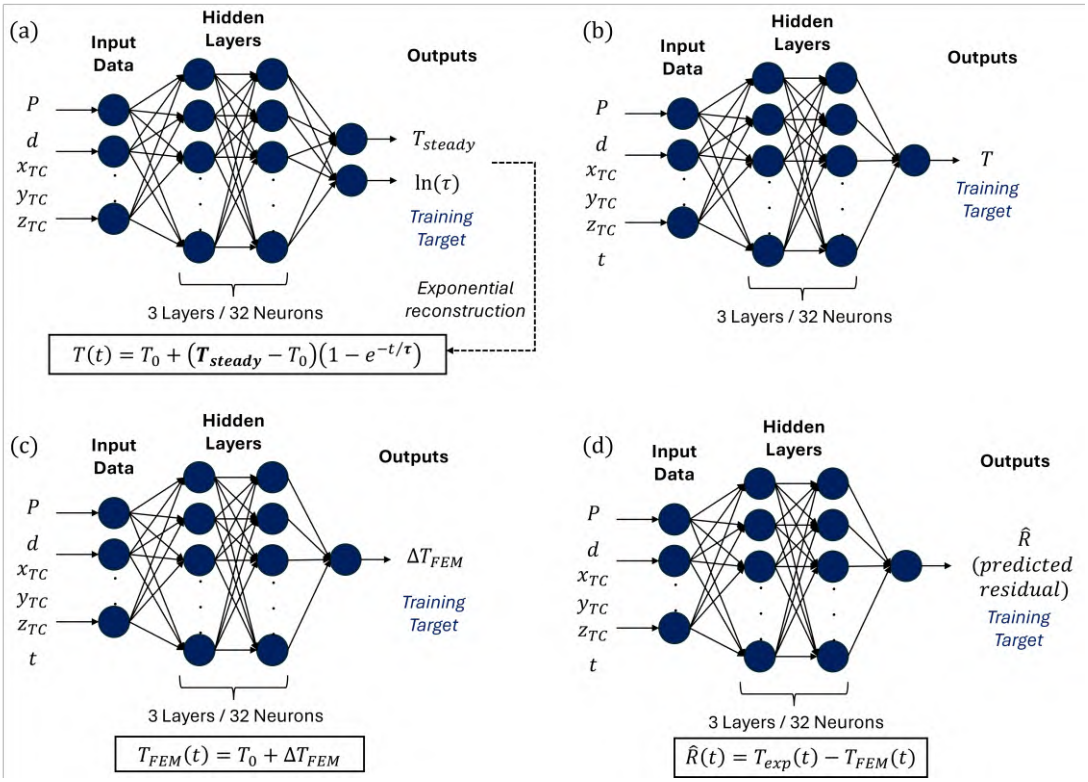

Figure 4 Neural-network architectures of the four predictive models: (a) semi-empirical first-order model, (b) fully data-driven temperature model; (c) physics-based FEM surrogate and (d) hybrid residual model.

4. RESULTS AND DISCUSSION

4.1. Physical Interpretability of the Semi-Empirical Model

The predicted first-order parameters show clear trends with laminate thickness and applied power (Fig. 5). As thickness increases, T_{steady} rises progressively from approximately 100 to 200 °C, reflecting the combined effects of electromagnetic power deposition, heat diffusion and thermal losses. In contrast, τ remains nearly constant at about 30 s for thicknesses up to 1.2-1.4 mm and increases thereafter. This behaviour suggests that, for thinner laminates, changes in thermal storage and heat transfer partially compensate each other, whereas at larger thicknesses the increased effective thermal inertia becomes more influential. Applied power has a stronger effect on T_{steady}, which increases from approximately 125 to 260 °C, while τ varies only moderately and approaches a plateau at high power. This different sensitivity is consistent with the physical meaning of the two parameters: T_{steady} is primarily associated with the balance between deposited energy and thermal losses, and is therefore strongly affected by the heating input, whereas τ represents the effective timescale resulting from the combined thermal storage and heat-transfer mechanisms.

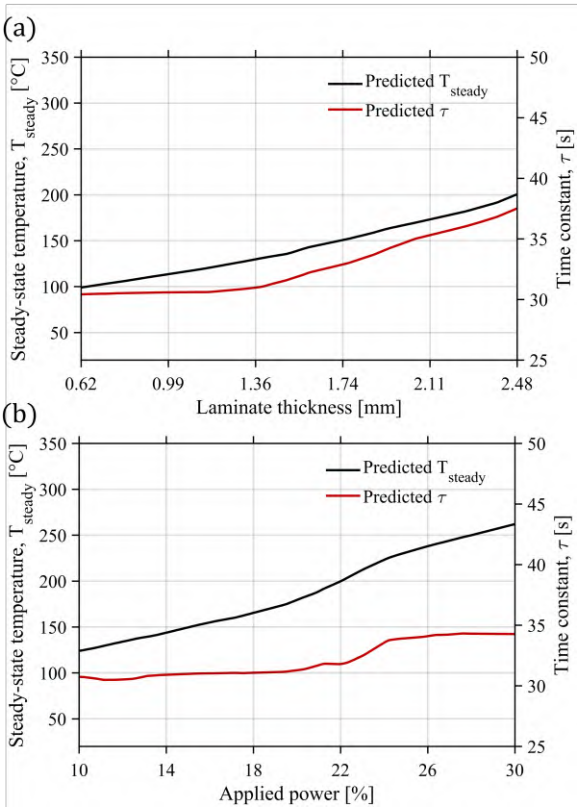

Figure 5 Predicted steady-state temperature and time constant versus (a) laminate thickness and (b) applied power.

Overall, the different responses of T_{steady} and τ demonstrate the value of the semi-empirical formulation not only for temperature prediction, but also as a compact representation of how the heating dynamics vary across the investigated process conditions.

4.2. Experimental Data-Driven Prediction

Representative test histories in Fig. 6 show that both experimental-data models reproduce the initial heating rate and the overall temperature evolution, although their performance differs as the heating conditions become more demanding.

At 10% of maximum power (Fig. 6(a)), both approaches provide a reasonable approximation of the measured response. At 20% and 30% (Fig. 6(b,c)), the fully data-driven model follows the experimental curves more closely, particularly during the transition from the rapid heating stage to the slower temperature evolution at longer times. The first-order model can instead underpredict or overpredict the final temperature when the measured response departs from a single exponential behaviour. This difference originates from the formulation of the two approaches. The semi-empirical model compresses each heating history into only two predicted quantities, T_{steady} and τ, and reconstructs the response using the first-order expression. This provides physical interpretability but constrains the shape of the predicted curve. Conversely, the fully data-driven model directly learns the relationship between process conditions, spatial position, heating time and temperature, allowing it to reproduce changes in the transient response without imposing a predefined temporal evolution. This flexibility becomes particularly beneficial when the heating rate changes during the experiment or when a clear steady state is not reached.

The improved interpolation capability is also reflected in the global final-test results reported in Tab. 2. The fully data-driven model reduces the RMSE from 20.0 to 15.3 °C and the MAE from 16.2 to 12.6 °C compared with the semi-empirical formulation. Both models show a negative mean bias, although its magnitude is slightly reduced from −6.2 to −5.1 °C, indicating an overall tendency to underpredict the measured temperatures.

Table 2: Final-test accuracy of the experimental-data models.

Model	RMSE [°C]	MAE [°C]	Bias [°C]
Semi-empirical first-order	20.0	16.2	-6.2
Fully data-driven	15.3	12.6	-5.1

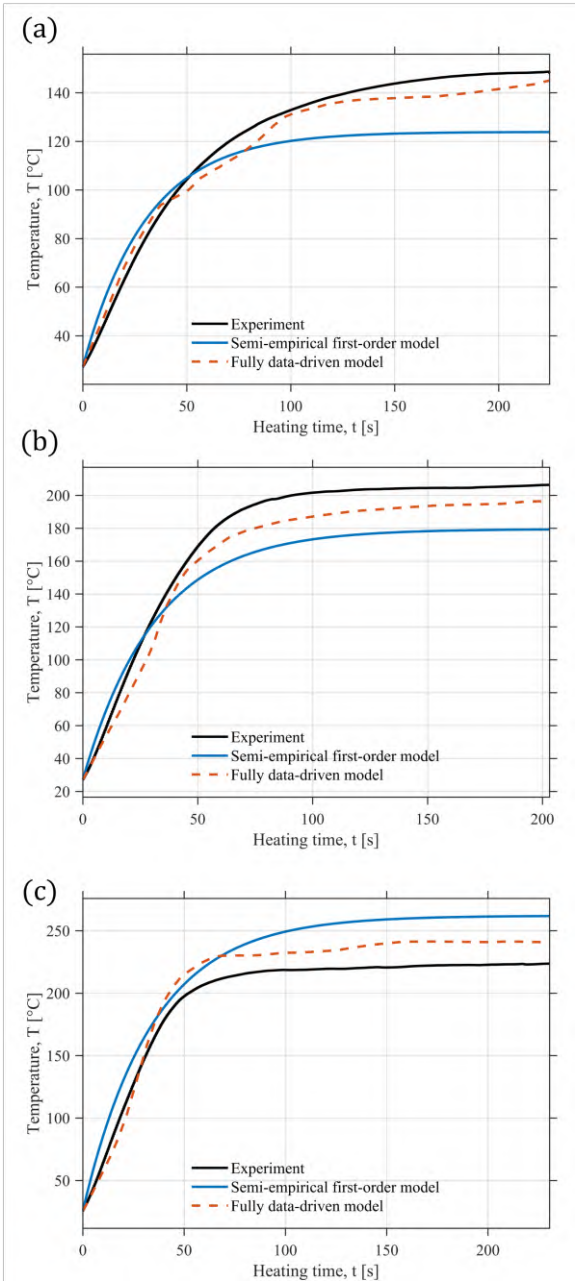

Figure 6 Representative experimental histories and predictions at (a) 10, (b) 20 and (c) 30% power for the 1.24 mm laminate.

The parity plot in Fig. 7(a) shows good overall agreement around the ideal-prediction line at low and intermediate temperatures, while the dispersion increases towards the upper part of the temperature range. The residual distributions in Fig. 7(b) show that prediction errors are not uniformly scattered around zero but follow distinct trends associated with individual heating histories. This indicates that some features of the transient response are not fully captured by the models. The larger residual spread at high temperatures further suggests reduced predictive accuracy under the more demanding

heating conditions. Nevertheless, the lower global errors reported in Tab. 2 demonstrate that the fully data-driven model provides the more accurate interpolation of the experimental thermal response, while the semi-empirical formulation retains the advantage of a compact and physically interpretable representation.

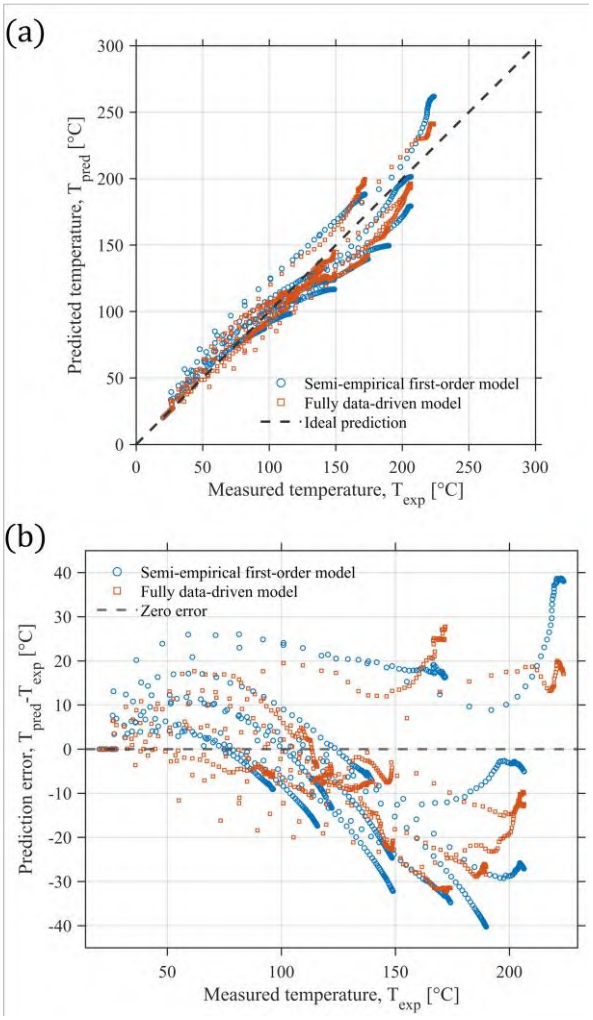

Figure 7 Parity and residual comparison of the semi-empirical and fully data-driven models.

4.3. Physics-Based FEM and Surrogate

The electrothermal FEM provides information that cannot be obtained from the limited number of experimental sensors. In addition to the local temperature histories, it resolves the complete temperature field and therefore allows hot-spot location, thermal gradients and spatial heat redistribution to be investigated. A representative field is shown in Fig. 8, where the highest temperatures are concentrated beneath the induction coil and the non-uniform distribution reflects the coupled electromagnetic and anisotropic thermal response of the CFRP laminate. This physical detail comes at the cost of a challenging calibration and validation process. Induction heating of CFRP involves strongly coupled electromagnetic and thermal phenomena, while several material properties are anisotropic, temperature dependent and affected by the laminate architecture. The numerical model necessarily introduces equivalent properties and simplified descriptions of heat losses and material behaviour. Moreover, uncertainties in electromagnetic coupling, through-thickness properties and experimental boundary conditions cannot be fully identified from a limited number of temperature measurements.

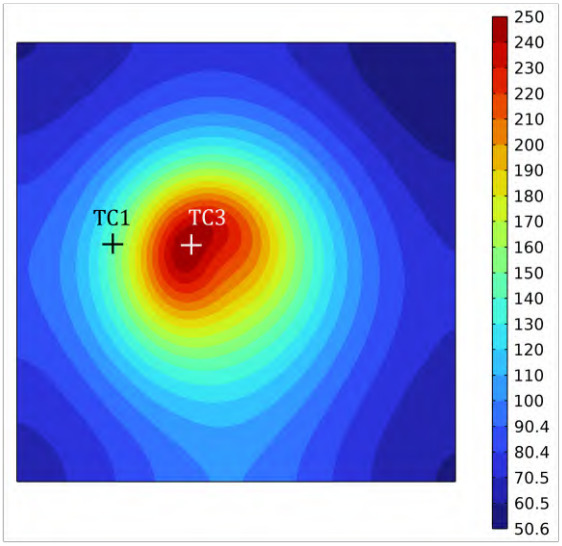

Figure 8 Representative FEM temperature field on the lower laminate surface, opposite to the induction coil. The markers indicate the locations of two of the four thermocouples used for experimental temperature measurements (TC1 and TC3).

These limitations are reflected in the comparison with the experiments. As reported in Tab. 3, the FEM RMSE increases from 36.6 °C for the 0.62 mm laminate to 44.2 °C for the 2.48 mm laminate, while the bias changes from −13.1 to 2.2 °C. The thickness dependence of the discrepancy indicates that a single calibrated parameter set does not fully capture the evolution of the coupled thermal response across the investigated design space. This represents an important limitation for direct predictive use of the FEM, despite the much richer physical information that it provides.

A second limitation is computational cost. Repeated transient multiphysics simulations become impractical when a large number of process conditions, spatial locations or heating times must be evaluated. The FEM surrogate addresses this

limitation by learning the numerical response and providing rapid access to selected FEM information without repeating the complete electrothermal solution.

Table 3: Experimental validation error of the calibrated electrothermal FEM as a function of laminate thickness.

Thickness [mm]	RMSE [°C]	MAE [°C]	Bias [°C]
0.62	36.6	33.9	-13.1
1.24	39.8	37.4	-1.5
2.48	44.2	39.8	2.2

The results in Fig. 9 demonstrate that this approximation introduces only a very small additional error.

The surrogate predictions closely follow the numerical FEM data over the complete temperature range, with RMSE = 2.44 °C, MAE = 1.73 °C and R2=0.999. The residuals remain predominantly concentrated around zero, with larger deviations limited to specific regions of the numerical dataset.

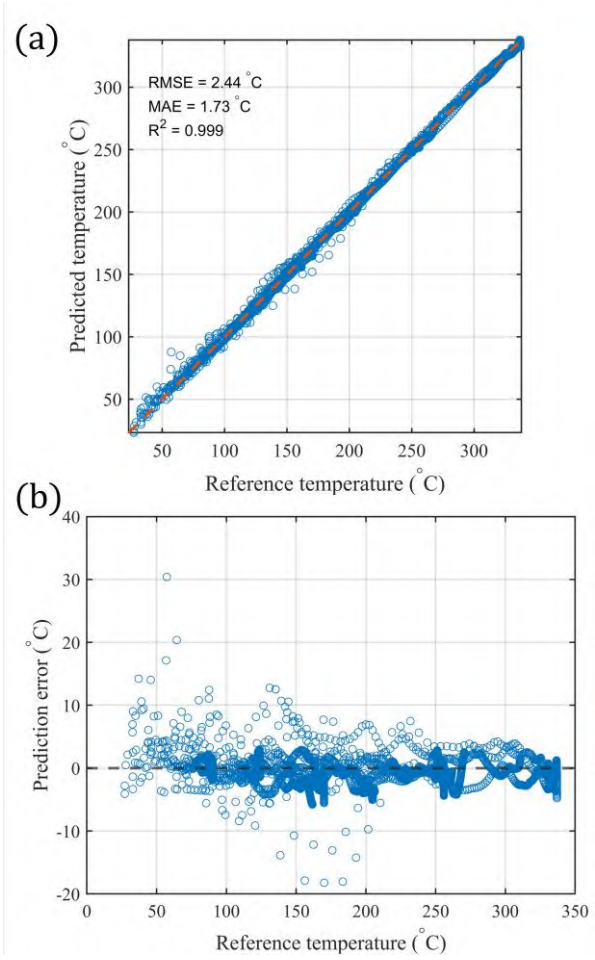

Figure 9 FEM-surrogate performance against numerical FEM data: (a) parity plot and (b) prediction residuals.

The surrogate therefore reproduces and interpolates the FEM response with high accuracy while substantially reducing the computational effort required for inference. Even though the surrogate does not correct the physical-model discrepancy identified in Table 3, it provides a computationally efficient representation of the calibrated FEM.

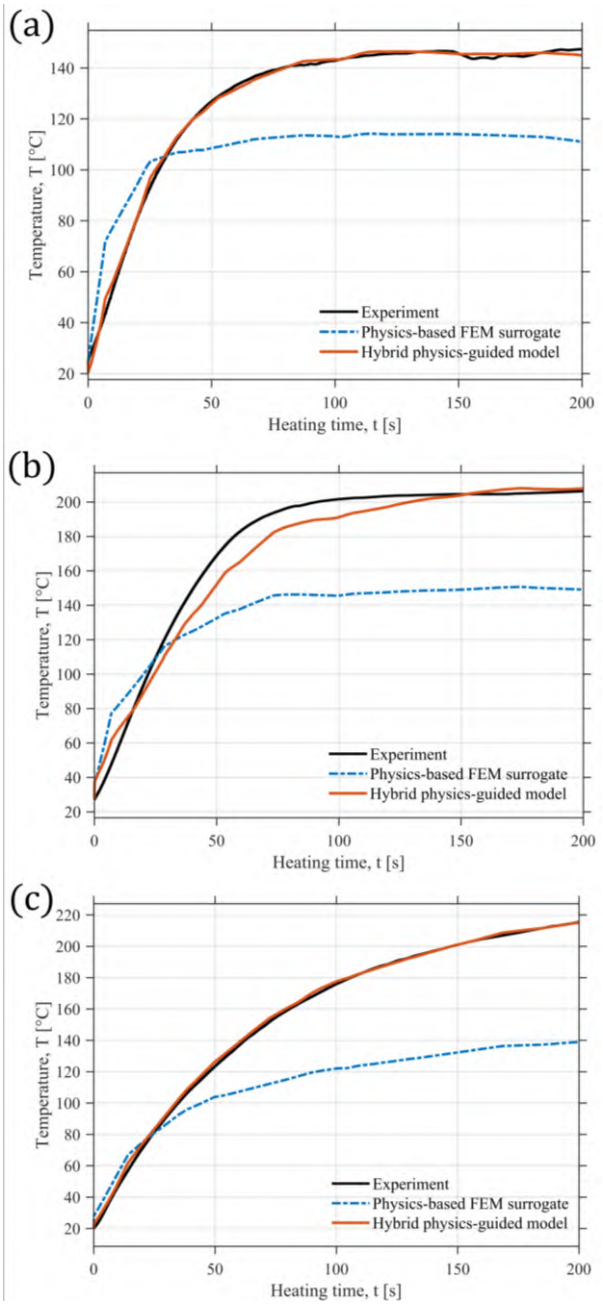

Figure 10 Representative experimental, FEM-surrogate and hybrid temperature histories. (a) 0.62, (b) 1.24, (c) 2.48 mm thickness.

This distinction motivates the hybrid strategy presented in the following section, where

experimental information is used to correct the systematic FEM-to-experiment residual.

4.4. Hybrid Physics-Guided Residual Correction

The hybrid approach addresses the main limitation identified for the physics-based model by learning the systematic discrepancy between FEM and experimental temperatures rather than replacing the physical prediction.

The FEM surrogate provides the baseline thermal response, while the residual network estimates the correction required to recover the measured behaviour.

This formulation combines the physical information embedded in the electrothermal model with the ability of experimental data to account for effects that are difficult to represent through a single set of calibrated material and boundary-condition parameters.

The representative histories in Fig. 10 clearly illustrate this behaviour. The FEM surrogate generally reproduces the overall heating trend but can substantially underestimate the temperature level, with the discrepancy depending on the investigated condition. After residual correction, the hybrid prediction follows both the transient heating rate and the final temperature much more closely. This is particularly evident in cases where the FEM captures the shape of the thermal response but incorrectly estimates the effective electromagnetic-to-thermal coupling. The correction is therefore not simply an adjustment of the final temperature, but acts over the complete transient response.

The improvement is confirmed quantitatively by the independent final-test results in Tab. 4. The RMSE decreases from 43.3 °C for the FEM surrogate to 10.8 °C for the hybrid model, corresponding to a reduction of approximately 75%. The MAE similarly decreases from 36.0 to 8.2 °C, while the mean bias is reduced from 4.2 to 1.5 °C. These results show that a large fraction of the FEM-to-experiment discrepancy is sufficiently systematic to be learned from the available experimental data.

Table 4: Final-test performance of the physics-based FEM surrogate before and after residual correction.

Model	RMSE [°C]	MAE [°C]	Bias [°C]
Physics-based FEM surrogate	43.3	36.0	4.2
Hybrid FEM + residual	10.8	8.2	1.5

The parity and residual distributions in Fig. 11 further confirm the improvement achieved by the hybrid model. The predictions closely follow the ideal parity line over most of the investigated temperature range, showing strong agreement with the experimental measurements. Consistently, the residuals are predominantly concentrated around zero and are substantially reduced compared with the uncorrected FEM surrogate. Some larger deviations remain at the highest temperatures, where prediction is more challenging. Overall, the results demonstrate that the learned residual effectively corrects the systematic FEM-to-experiment discrepancy and provides reliable temperature predictions across the investigated domain, including independent test cases never seen during model training. From a practical perspective, the hybrid architecture provides an important compromise between computational efficiency, physical information and predictive accuracy. Once the FEM surrogate and residual network have been trained, temperature predictions can be obtained without performing additional transient multiphysics simulations or repeatedly recalibrating the complete FEM for each operating condition.

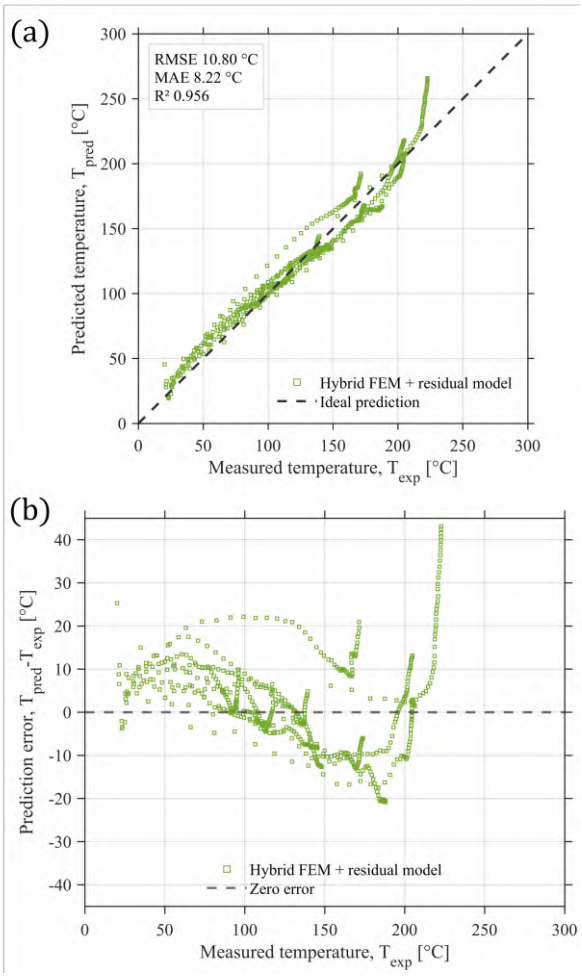

Figure 11 Final-test performance of the hybrid physics-guided model: (a) parity plot and (b) prediction residuals as a function of measured temperature.

The surrogate retains access to the physics-based baseline, while the residual model compensates for systematic model-form and calibration errors using experimental evidence. The resulting framework is therefore particularly attractive for rapid process exploration and prediction over the calibrated operating domain, where repeated high-fidelity FEM simulations would otherwise impose substantial computational time and resources.

4.5. Physics-Informed Process Window

The low inference cost of the hybrid framework enables dense exploration of the power–time design space beyond individual temperature histories.

Fig.12 maps the predicted temperature at a specific laminate location, corresponding to TC3, for the three investigated thicknesses. The 180 and 250 °C contours are adopted as lower and upper thermal criteria, respectively, defining a candidate processing window for thermoplastic joining. These limits provide preliminary thermal criteria, while the actual weld-quality boundaries may also depend on polymer grade, consolidation pressure, dwell time and joint configuration.

The maps can be directly used to identify the power–time combinations required to reach a target temperature. Considering 180 °C as the minimum criterion, for example, a minimum power level is required for each thickness: below approximately 25% for the 0.62 mm laminate and 17% for the 1.24 mm laminate, the predicted steady-state temperature remains below 180 °C and the target cannot be reached regardless of heating time. Above these thresholds, increasing power progressively reduces the heating time required to reach 180 °C, as illustrated by the corresponding contour. At longer heating times, the contour tends to flatten because the temperature approaches its steady-state value: the generated heat is increasingly balanced by conduction away from the heated region and heat losses to the surroundings, so extending the heating time produces progressively smaller temperature increases.

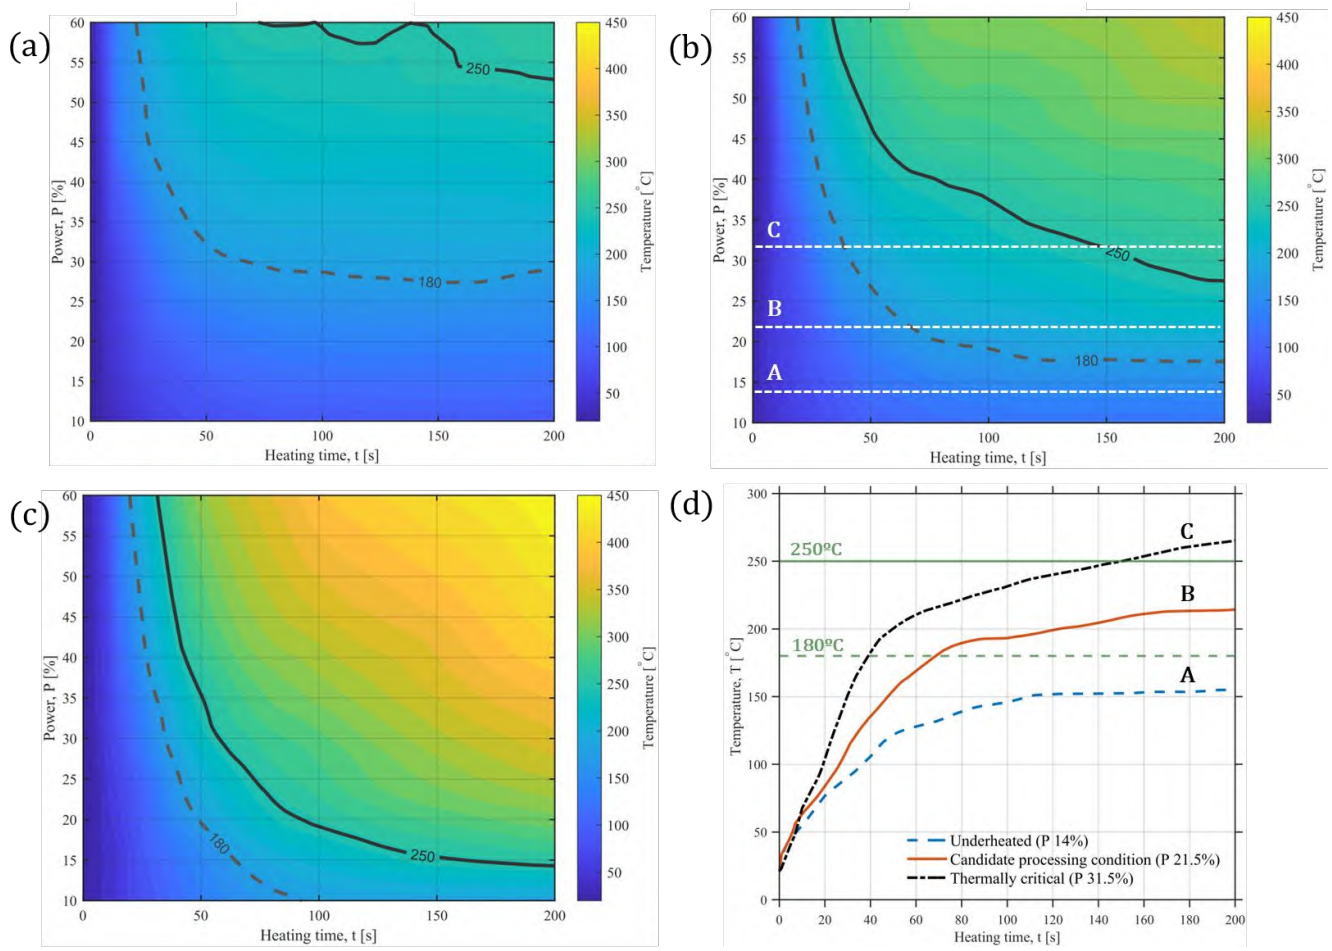

Figure 12 Hybrid-model power–time process maps for laminate thicknesses of (a) 0.62 mm, (b) 1.24 mm and (c) 2.48 mm, with 180 and 250 °C thermal criteria; (d) representative heating histories for underheated (A), candidate processing-window (B) and thermally critical (C) conditions.

Table 5: Computational requirements for power–time process-map generation using the electrothermal FEM and hybrid surrogate.

Approach	No. of considered temperature curves	Computational time	Computational resources	Relative cost
FEM	302	~ 54.6 h*	14 CPU cores	1×
Hybrid surrogate	302	54 s	1 CPU	~3640 × faster

*FEM computational time was extrapolated from 40 transient simulations requiring around 7 h and 12 min in total

Fig. 12(d) illustrates this interpretation for the 1.24 mm laminate, where condition A remains below the lower thermal criterion, condition B reaches the candidate processing range, and condition C exceeds the upper temperature limit.

Laminate thickness markedly shifts these thermal boundaries. For the 0.62 mm laminate, the 180 °C criterion requires comparatively high power and the 250 °C contour is largely outside the investigated domain, whereas increasing thickness shifts both contours towards lower power and shorter heating times.

A particularly important consequence is the strong dependence of the thermal processing window on laminate thickness. Increasing thickness reduces the power and heating time required to reach the minimum temperature criterion, but also shortens the margin before the upper thermal limit is exceeded. For the 1.24 mm laminate, the region between 180 and 250 °C covers a relatively broad range of power–time combinations, whereas for the 2.48 mm laminate the 250 °C contour shifts markedly towards lower powers and shorter times, resulting in a narrower operating window. This behaviour arises from the thickness-dependent electromagnetic–thermal response: changes in conductive volume and induced-current paths affect electromagnetic power deposition, while thermal storage and heat diffusion also vary with thickness. Under the investigated conditions, the resulting balance produces a faster temperature rise at larger thicknesses, making the process increasingly sensitive to the selected power–time combination and reducing the operating margin before potentially damaging temperatures are reached.

The value of these process maps therefore lies not only in identifying thickness-dependent operating limits, but also in the possibility of exploring them at low computational cost. As summarised in Tab. 5, generating an equivalent power–time map directly with the electrothermal FEM would require repeated transient multiphysics simulations and substantial computational resources.

Once trained, the hybrid surrogate evaluates the same design space with a much lower inference time, enabling dense screening of operating conditions while retaining the physics-based FEM response corrected against experimental measurements. This capability is particularly relevant for induction joining in space manufacturing, where robust parameter selection and process repeatability are critical and opportunities for rework may be limited. With further validation and the inclusion of weld-quality indicators, the approach could support rapid process optimisation and ultimately model-assisted closed-loop control.

5. CONCLUSIONS

A physics-informed machine-learning approach was developed for induction heating of thermoplastic CFRP laminates by combining experimental data, electrothermal FEM modelling and neural-network surrogates. While the semi-empirical and fully data-driven models provide complementary descriptions of the experimental thermal response, their accuracy is inherently constrained by the availability and coverage of experimental training data. The proposed hybrid approach complements this information with a physics-based FEM prediction and learns its systematic discrepancy from experimental data. This residual correction reduces the final-test RMSE from 43.3 °C to 10.8 °C and the MAE from 36.0 °C to 8.2 °C on independent cases not used during training.

The low inference cost of the hybrid surrogate enables dense exploration of the power–time design space, revealing a strong thickness dependence of the candidate thermal processing window and a reduced operating margin at larger thicknesses. The approach therefore provides a computationally efficient tool for process investigation and parameter selection while retaining a physics-based description of the thermal response. The present maps are limited to temperature-based criteria within the investigated experimental domain and coil configuration. Future work will extend the process domain, establish a direct link between thermal predictions and weld quality, and investigate model-assisted closed-loop control.

ABSTRACT

Within the FLPP COSTELAS and A6 CIP C-ITS (Composite ULPM Inter Tank Structure) projects, MT Aerospace AG in Augsburg has been developing a composite inter tank structure (ITS) for the ARIANE 6 upper stage (d ≈ 5.4 m) using sandwich-technologies.

The development included the manufacturing of a full-scale demonstrator and various test components to show the design's potential for a full product development within the launch vehicle program.

In this paper, an overview of the projects COSTELAS and A6 C-ITS will be given. Special focus will be set on the complete full-scale manufacturing demonstrator and the test breadboards TBB1 and TBB2. The design of the C-ITS is developed to fulfil the same requirements and exhibits the same interfaces as the metallic ITS so that a 1:1 swap from the metallic to the composite ITS would be possible. The design follows a segmented approach of eight sandwich panels, which are manufactured in a one-shot curing process. The strength of the design is evaluated and justified by finite element analyses in ABAQUS.

To verify the structural performance of the design as well as the implementation approach, several components of critical design elements have been manufactured, tested and correlated to the analyses.

1. INTRODUCTION

The competitive landscape of the launch vehicle market requires efforts concerning improved performance through mass and cost reduction. In this context, the replacement of conventional metallic structures by advanced composite materials offers a viable path towards these objectives. Composite materials, particularly carbon fibre-reinforced polymers (CFRP), provide high specific stiffness and strength, enabling lighter robust structural designs. When combined with automated manufacturing processes, such as automated fibre placement (AFP), they support scalable production while reducing cycle times and material waste.

MT Aerospace AG in Augsburg has been developing a composite upper liquid propulsion module (ULPM) inter tank structure (C-ITS) with sandwich technology based on requirements of the ARIANE 6 launch vehicle. Fig. 1 shows the ARIANE 6 with its metallic ULPM inter tank structure to be replaced by the composite structure.

The decision for a general sandwich design has been taken after a trade-off between the sandwich and the technology of lattice structures [1]. It was driven by a balance of stiffness-to-mass ratio, manufacturability, integration compatibility and cost. A general sandwich design offers superior out-of-plane rigidity and consistent load distribution, which aligns with the requirements for inter tank stability under launch loads and thermal gradients. The current design demonstrates compliance with key structural and interface requirements.

The initiative evolved under ESA's **F**uture **L**aunchers **P**reparatory **P**rogramme (FLPP), beginning with the PACE (**P**reparatory **A**ctivities for **C**FRP Sandwich T**e**chnologies) and COSTELAS (**C**ost **O**ptimised **S**andwich **Te**chnology for **La**rge-Scale **S**tructures) projects in 2021. These projects focused on demonstrating the feasibility of composite sandwich panels, including material characterisation, process development for cost-efficient manufacturing of large CFRP sandwich structures and full-scale test breadboard validation.

The C-ITS project, which ran under the A6 Competitiveness Improvement Programme (CIP), project aimed to mature the design to a tailored pMG5 (product Maturity Gate 5) status, which supports future integration into product development.

To validate the design and manufacturing strategy, a full-scale demonstrator (DM0, see Fig. 20) was manufactured following multiple test elements and test breadboards (TBB1 and TBB2).

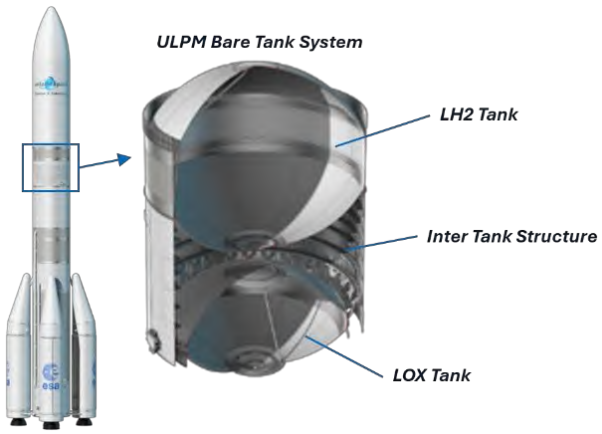

Fig. 1: ARIANE 6 Launcher ULPM Bare Tank System [©ESA]

2. INTER TANK STRUCUTRE

The ARIANE 6 has two metallic inter tank structures, one for the lower liquid propulsion module (LLPM) and one for the upper liquid propulsion module (ULPM), see Fig. 2. They serve as the primary structural interface between the liquid hydrogen (LH2) tank and the liquid oxygen (LOx) tank, while accommodating equipment access and tank connections.

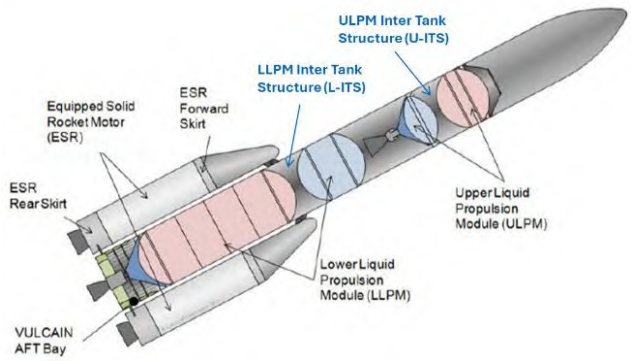

Fig. 2: Schematic View of ARIANE 6 Launcher [©ESA]

Within the launcher architecture, the upper stage plays a critical role in determining payload performance. Unlike the main stage, where mass savings yield a payload increase ratio of approximately 1:0.3, every kilogram saved in the upper stage directly translates to a 1:1 payload gain. This makes structural optimization at this level particularly important and is the reason why the upper stage inter tank structure has been chosen. The C-ITS design is fully aligned with the baseline of the existing metallic A6 U-ITS in terms of geometrical bounds, local and global loads as well as mechanical interfaces.

3. DEVELOPMENT AND VERIFICATION APPROACH

To improve the technology (TRL) and manufacturing readiness level (MRL) and achieve a tailored pMG5 status maturity level, coupon samples, test elements and breadboards were designed, manufactured and tested while ensuring that all design decisions are backed by analytical validation, experimental evidence, and manufacturability assessments. Additionally, a full-scale manufacturing demonstrator has been produced featuring the principle design of the reference architecture. This approach follows a hierarchical progression from material-level characterization to full-scale structural demonstration, with each stage feeding into the next to reduce uncertainty and build-up confidence in the final reference architecture, see Fig. 3.

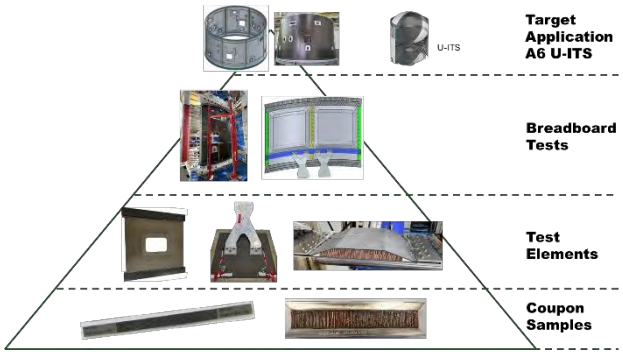

Fig. 3: Development and Verification Approach

The reference architecture is the basis of this development logic. It represents the intended full-scale target application design, a 1:1 scale composite inter-tank structure for the ARIANE 6 upper stage. The reference architecture provides the basis, from which the smaller scale elements are derived. On the lowest level are the coupon tests, which are used for material characterisation, providing the input for the analyses. Test elements are used for testing of singular effects and critical regions under representative loading conditions. Breadboard tests provide the experimental verification of the target application. The demonstrator verifies the manufacturing and assembly capabilities of the full structure. Each level serves a distinct purpose: material property acquisition, functional validation of key design features, verification of manufacturing processes and system-level demonstration while enabling iterative refinement of both physical and numerical models.

3.1. C-ITS Reference Architecture

The key requirements of the C-ITS reference architecture, which is the full-scale target application design as shown in Fig. 4, include the ability to transfer high flux loads in compression and

tension, connections to the adjacent structures like the metallic LOx and LH2 tank as well as the composite interface structure (IFS) which connects main and upper stage of the launcher. Furthermore, compliance with local interfaces and their loads for equipment and access, ability to withstand high thermal gradients as well as providing considerable mass and cost savings compared to the metallic U-ITS while using a highly automated manufacturing process with AFP are main goals of the project. Functional integration is achieved through monolithic regions at cut-outs and interfaces, which simplify mounting and preserve structural integrity. The design leverages existing metallic interface geometries to ensure compatibility without requiring major rework of adjacent sub-systems. The C-ITS reference architecture is arranged as a segmented structure composed of eight composite sandwich panels, replicating the segmentation and interface layout of the existing metallic inter tank structure.

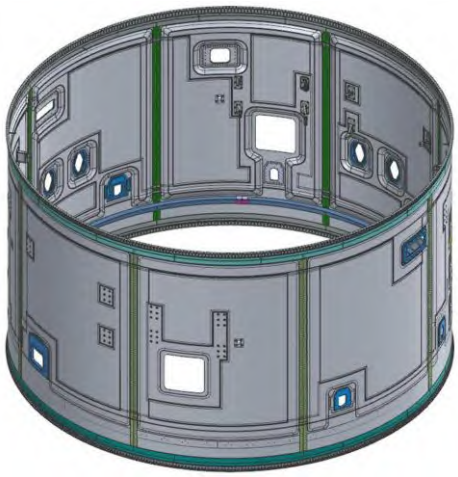

Fig. 4: C-ITS Reference Architecture

Riveted joints using composite splice sheets connect adjacent panels and metallic interface rings are retained for integration with metallic adjacent structures. The panels utilize a sandwich design with honeycomb cores, optimized into far- and near-field zoning: high core density and thicker face sheets are implemented in regions of high mechanical demand (e.g. interfaces and load transfer zones), while lower core density and thinner face sheets are used in less critical areas to achieve mass savings (see Fig. 5). Monolithic zones are incorporated at all interface locations to enable robust mechanical fastening to metallic components, ensuring structural continuity and ease of integration.

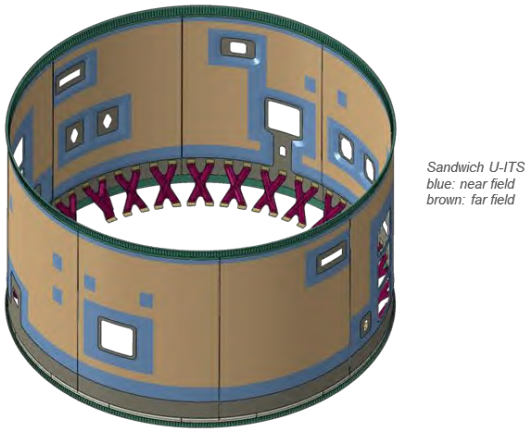

Fig. 5: C-ITS Far- and Near-Field distribution

Structural performance is assessed through a multi-scale non-linear finite element analysis (FEA) approach using ABAQUS. A global FE model (GFEM, see Fig. 6), implemented with solid and shell elements, captures the overall deformation and load distribution. Adjacent structures like the LOx tank and IFS are included in the model to generated representative boundary conditions.

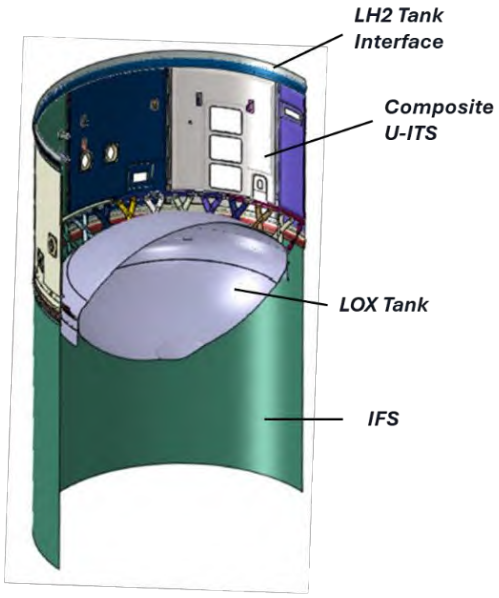

Fig. 6: Global FE Model (GFEM) for C-ITS

Local detailed FE models (DFEMs) are employed at critical zones such as the main and LOx tank attachment structure (LTAS) interfaces to resolve high-stress gradients and joint behaviour, see Fig. 7. The nodal displacements of the GFEM are used as boundary conditions to drive the DFEMs as sub-models. Mechanical loads from relevant flight phases are combined with thermal fields from transient analyses for the structural assessment.

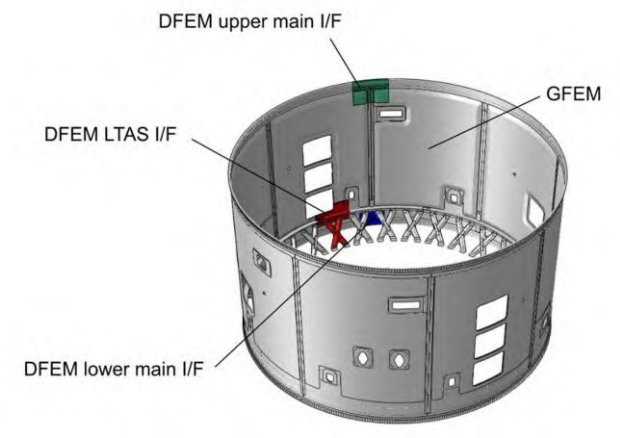

Fig. 7: Overview of FE Models for C-ITS Reference Architecture without LOX Tank and IFS

The reference architecture provides the basis from which the smaller scale elements are derived. The data obtained from the various tests are utilized to validate and calibrate the analysis approach.

3.2. Coupon Tests

Following the initial optimization loops of the reference architecture, the material selection has been finalized. Based on these results, coupon samples (see Fig. 8) are utilized to characterize the general mechanical behavior of the selected materials under varying environmental conditions. These tests are conducted using the same manufacturing processes as the higher level elements and the reference architecture, ensuring that the material data reflect the structural performance in the application. The primary objective is to determine key mechanical properties such as strength and modulus as well as thermal expansion coefficients for all material directions across different environmental conditions.

Fig. 8: Honeycomb core coupon samples

Furthermore, statistical design allowables are derived to account for material variability and enable robust design margins in subsequent FE modelling and structural justifications.

3.3. Test Elements

Following material characterisation, test elements are derived to validate specific technology elements under representative loading conditions. These elements are not full-scale components but rather derived from the design of the reference architecture to isolate and assess singular structural features that are critical for the integrity of the reference architecture. The primary purpose of the test elements is twofold: first, to calibrate and verify finite element (FE) models against experimental data and second, to demonstrate the feasibility of individual design solutions prior to integration. All test elements are evaluated at room temperature under controlled loading conditions to eliminate thermal complexities during initial validation. Load paths are designed to mimic those expected in the reference architecture, allowing for direct correlation between simulation and test results. The resulting data are used to refine analysis aspects, such as failure modes or rivet loads, as these are treated with conservative analytical approaches.

3.3.1. Cut-outs

Cut-outs are necessary for integrating local equipment, sensors, access points, and internal hardware within the inter tank structure. These features introduce significant stress concentrations and local load redistribution, making them high-risk areas for structural integrity. In the C-ITS reference architecture, cut-outs are designed as monolithic sections for an easier integration (via riveting) of metallic components like interface plates. The test element includes a representative cut-out geometry concerning size and shape, see Fig. 9. It is subjected to compression loading representing the axial flux loads acting in the reference architecture.

Fig. 9: Cut-out test element

The test is conducted until failure, with displacement transducers, strain gauges and digital image correlation (DIC) used to monitor deformation fields and identify the onset of failure up to final fibre failure propagating from the monolithic cut-out area. The failure load and mode are compared against predictions from FE models. A close correlation between measured and predicted results (see Fig. 10) confirms the fidelity of the modelling approach.

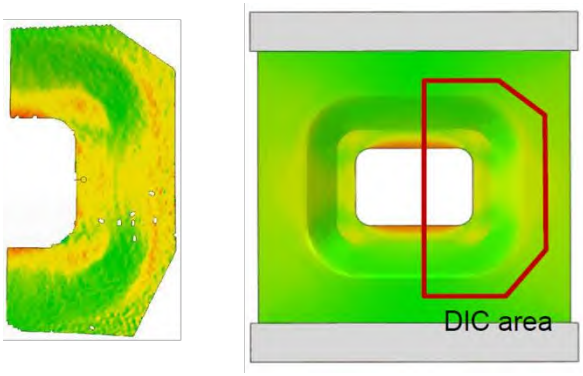

Fig. 10: Major strain from DIC (left) and FEA (right)

3.3.2. LTAS Interface

The **L**Ox **T**ank **A**ttachment **S**tructure (LTAS) interface is a critical connection point that transfers out-of-plane loads from the LOx tank and the Vinci engine into the C-ITS. The corresponding test element evaluated the mechanical behaviour of the LTAS interface in a monolithic composite design. It features a metallic attachment structure with a bolted connection joint, see Fig. 11.

Fig. 11: LTAS interface test element

The test assessed failure load and failure mode under quasi-static out-of-plane tension loading. Digital image correlation (DIC) and strain gauges provided detailed deformation and strain data across the interface. The relating finite element model was able to capture the characteristics of the test sample during the test. The reached load level confirmed the feasibility of the interface concept for the reference architecture.

3.3.3. Main Interface

The main interfaces at the upper and lower ends of the C-ITS connect the composite panels to metallic rings, which in turn link to the metallic LH2 tank as well as the composite interface structure (IFS). The test element, in this case for the upper main interface, depicts the full configuration, including the core ramp from sandwich to monolithic and the riveted joint between composite panel and metal ring, see Fig. 12. Testing under tensile loading conditions is used to verify the interface design and analysis approach.

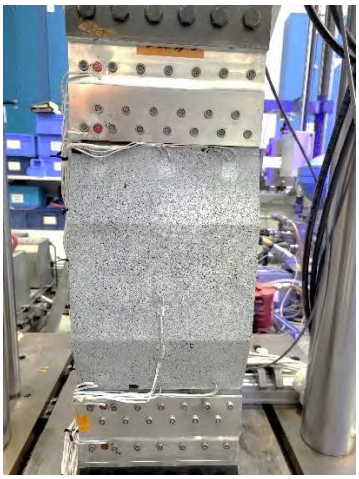

Fig. 12: Main interface test element

Failure initiation for the test element occurred in the form of delamination at the tip of the sandwich ramp. This could be replicated in FEA via VCCT analysis. The whole ramp configuration including the riveted joint was able to transfer loads higher than the required load level j>1.25, which validates the interface design for the reference architecture.

3.4. Breadboards

With the foundational elements validated, the next phase involved breadboard testing, which serves as a bridge between component-level validation and sub-system-level demonstration. Two primary breadboards are defined: Test breadboard 1 (TBB1) and test breadboard 2 (TBB2). The first one is focussing on the test of a single panel out of the C-ITS and the second one on the test of the panel joint configuration.

3.4.1. TBB1 – Full-Scale Panel Test

TBB1 is a 1:1 scale panel representative of the reference architecture, produced using the same materials, manufacturing and assembly processes. It incorporates key features like cut-outs, interface rings and reinforcement zones, see Fig. 13. Struts at the lateral interface were introduced to mimic boundary conditions equivalent to those in a complete U-ITS with all panels.
The test objective is to experimentally demonstrate the structural definition, manufacturing quality, numerical model fidelity and cost realism. The test was carried out in collaboration with Applus+ IMA Dresden. The panel is subjected to representative global compression loads derived from the reference architecture, where the load level has

been adjusted to match the most critical failure mode and load identified in the reference architecture.

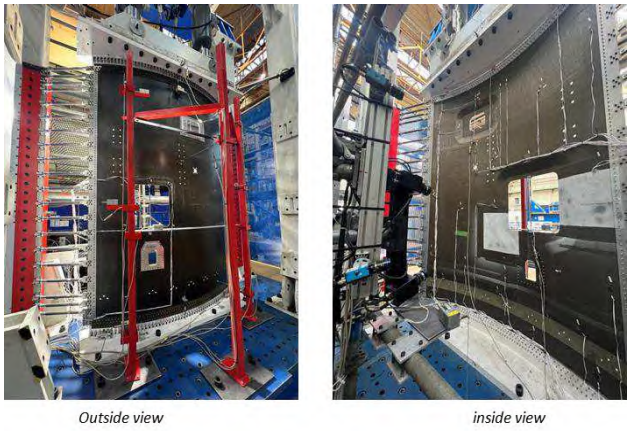

Fig. 13: TBB1 breadboard test set-up

FE analyses are employed to predict the test behaviour and to evaluate the experimental results, particularly with respect to deformation characteristics and failure mechanisms. Failure initiation occurred at the large cut-out following a significant out-of-plane deformation at the lateral edge. The final failure of the panel occurred significantly above the required load level relating the reference architecture (j>1.25). Consequently, the required load level with the required safety margins were reached before failure. The failure could be replicated in the FEA by a dynamic implicit analysis, see Fig. 14. Furthermore, the deformation behaviour observed during the test monitored via strain gauges, displacement transducers, and digital image correlation (DIC) was generally well reproduced in the numerical simulations. The successful test confirms that the technology works as intended in a relevant environment, proving structural integrity of the design under primary loading. It also demonstrates that manufacturing processes are mature enough to produce high-quality, repeatable components.

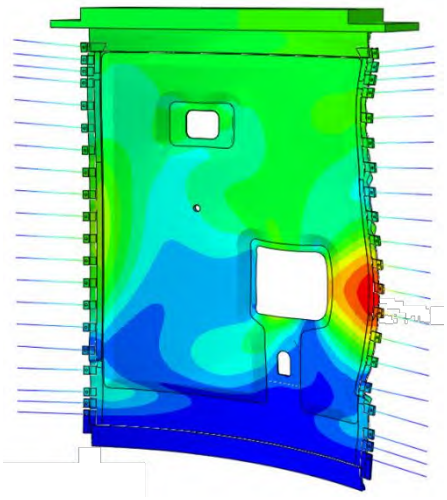

Fig. 14: TBB1 global FE deformation at failure load (scale x10)

3.4.2. TBB2 – Panel-to-Panel Interface Test

TBB2 focuses on the panel-to-panel joint, which is a challenging interface in the segmented C-ITS (see Fig. 15). This joint is realized by a riveted splice joint and an additional reinforcing composite L-frame. The test reproduces the combined axial (compression) and out-of-plane loading in this area representing loading conditions seen in the reference architecture in flight load cases.

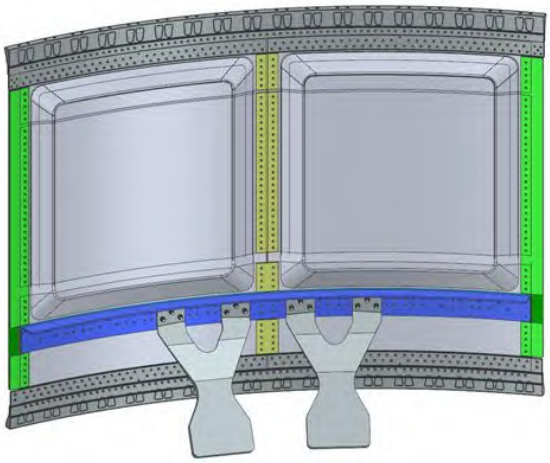

Fig. 15: TBB2 breadboard design

The breadboard consists of two adjacent panels joined by splice sheets with rivets installed using a production tooling. A simplified, in the interface area representative, LTAS structure is used to introduce out-of-plane loads during the test. This out-of-plane load is generating local loads in circumferential direction in the panel joint. Strain gauges, displacement sensors, and DIC were used to capture deformation fields across the TBB2 with focus on the joint region. The test was performed at an external site - Applus+ IMA in Dresden. A suitable test bench (see Fig. 16) has been defined in a co-engineering phase with the external partner. The necessary boundary conditions, test machine

interface, test bed interface and lateral interface (segment joint) to compensate for the missing circumferential stiffness were defined in close cooperation.

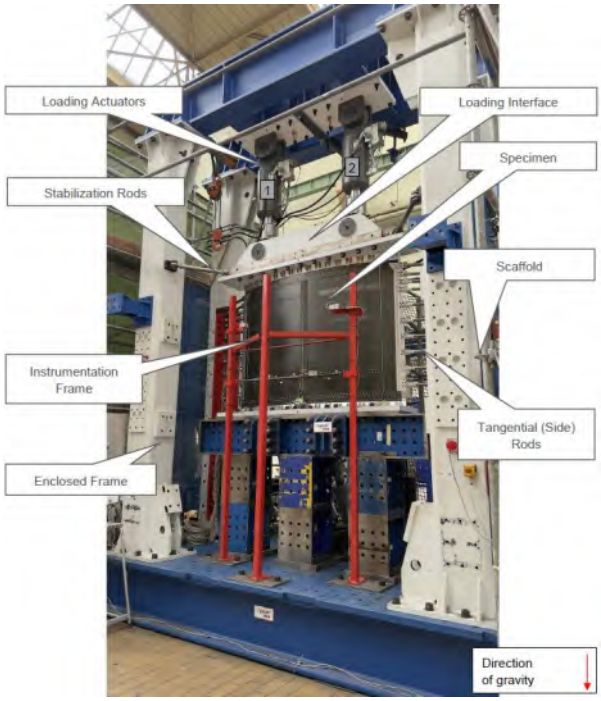

Fig. 16: TBB2 breadboard test set-up

FE analyses are performed in conjunction with the test to further increase the accuracy of numerical modelling techniques of joint behavior and validate the design of the segmented C-ITS. Not only the TBB2 bread board but also a wide area of the test rig, especially the lower part, is implemented in the FE analyses. This leads to a more realistic adjacent stiffness. For the out-of-plane load introduction, a representative approach by including the actuator itself in form of a connector element of ABAQUS type axial is considered. The out-of-plane load is applied via a connector force (see Fig. 17).

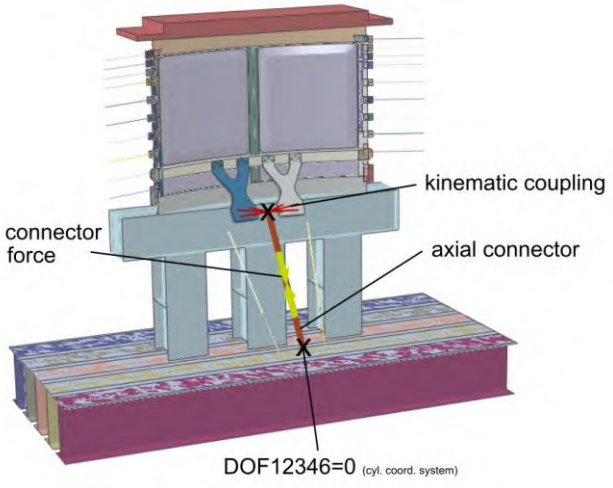

Fig. 17: FE Model of TBB2 breadboard test

The C-ITS TBB2 has been tested under global compression and local out-of-plane tension load. The failure has been determined at a load level of j=1.50 (F=660 kN) due to local fiber failure in the area of the out-of-plane load introduction. The failure followed a preceding deformation of the TBB2, which has been marked by high non-linearities resulting from the out-of-plane loading. The FEA could reproduce the general characteristics observed in the test. A good correlation of the deformations could be achieved. Only in areas with small deformations, higher relative deviations between test and FEA occur. Also, the failure mode and load (fiber failure at out-of-plane load introduction) correlates to the test very good (see Fig. 18).

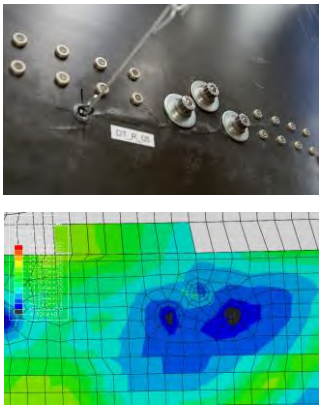

Fig. 18: Comparison of the failure mode in test and FEA

The analyses show that the implementation method of such structures in FE is very suitable for further investigations.

3.5. Full-scale demonstrator model

The focus of this development logic is the final full-scale C-ITS target application design. Gained knowledge from the tests on different levels are introduced and taken over in the design of the C-ITS target application. In addition, the analysis methods were refined according to the derived results especially during the evaluations of the various test results. Based on the final design, the Demonstrator Model 0 (DM0, see Fig. 20) has been built. DM0, which has a diameter of roughly 5.4 m and a height of about 3 m, is a full-scale prototype that incorporates all relevant design features of the reference architecture: eight panels, cut-outs, interfaces, splice sheets, and joint details.
DM0 serves to validate manufacturing capabilities, process repeatability, and assembly fidelity, demonstrating end-to-end production readiness.
Manufacturing is driven by full automation in CFRP part layup via automated fibre placement (AFP, see Fig. 19), enabling high repeatability and reduced

manufacturing costs. Digital integration links design, analysis, and manufacturing workflows, ensuring consistency and traceability. Each sandwich structure is cured in a single cycle, minimizing production steps and enhancing process efficiency. This approach aligns with planned industrial production setups for serial production.

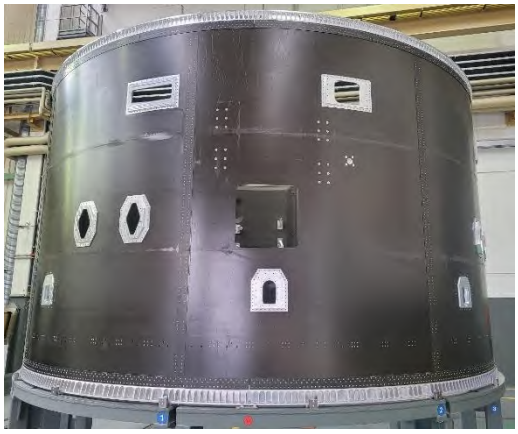

Fig. 20: Assembled C-ITS demonstrator DM0

3.6. Conclusion

The described development approach ensures that by the time the maturation toward flight qualification is reached, all key risks have been mitigated through incremental validation, resulting in a design with high technical confidence.

4. FURTHER DEVELOPMENT

The project ARESCA (Advanced Resistance WElding for ThermoSet Carbon Assembly), set up as in the framework of FLPP, continues the development of a high-performance future composite launcher upper stage structure. Within this project, the riveted joints between the structural panels as well as between the L-frame and the panels shall be replaced by welded joints, providing mass savings as well as a reduction in manufacturing and rivet costs. This includes the development of a robust welding process for thermoset CFRP structures, to be scaled from coupon level to part level and to be tested (DM1) in comparison to a riveted structure. The demonstrator model to be tested is a replica of TBB2 from the C-ITS project, in which the rivets in the panel joint region and at the attachment of the stiffener frame are replaced by resistance welding (see Fig. 21).

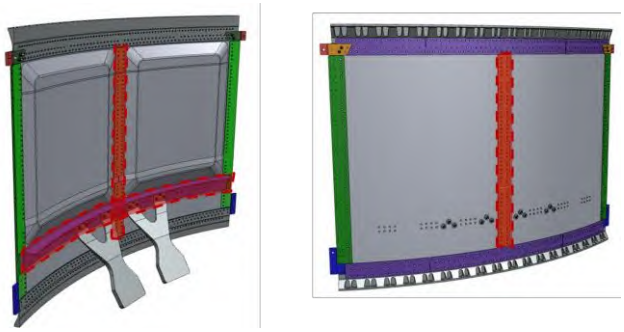

Fig. 21: DM1 sketch, red dotted: welded interface

The testing for the DM1 is currently planned in the first months of 2027.

5. CONCLUSION AND OUTLOOK

The development of the composite upper stage inter tank structure (C-ITS) successfully demonstrates the feasibility of replacing the conventional metallic design with a full-scale composite sandwich architecture. Based on the COSTELAS technology foundation, C-ITS achieved a tailored pMG5 level, confirming readiness for advancement towards flight application. Key performance targets, particularly in mass reduction of about 200 kg and manufacturing cost efficiency, are proven through detailed design, analysis, and demonstrator validation. Since mass savings in the upper stage directly increase payload capability, the associated economic benefit, expressed in terms of launch cost per kilogram, enables the development costs to be amortized after only a limited number of launches. The 1:1 scale DM0 technology demonstrator, produced with segmented composite panels and integrated metallic interface plates and rings, has proven the manufacturability of the complete structure from panel to assembly, including critical features such as cut-outs and interface joints. The testing of TBB1 and TBB2 proved the overall stability of the panels and the riveted joints between two CFRP panels under representative loading conditions. Finite element (FE) modelling approaches have been continuously validated through correlation with test data from test elements and breadboard assessments.
Looking forward, the development is continued by replacing riveted joints by welds to improve mass saving and reduce costs.

The current development status establishes a solid foundation for a continuous improvement of the ARIANE 6. The C-ITS program marks a key step towards lightweight, high-performance composite

sandwich structures in future launch vehicle systems.

6. ACKNOWLEDGEMENTS

MT Aerospace would like to thank our customers, main suppliers and partners. The technology maturation and development of a composite inter tank structure is only possible due to the German funding of the DLR Agency via ESA's Future Launchers Preparatory Programme (FLPP) and A6 Competitiveness Improvement Programme (CIP). Without our project partner, ArianeGroup Germany, and their input, the project C-ITS wouldn't be possible.
Furthermore, we thank all our partners, especially Applus+ IMA Dresden and Euro-Composites S.A. for the good collaboration.

ABSTRACT

Three lattice composite multi-payload adapter (lattice CMPA) configurations were developed, analysed, and assessed against equivalent metallic ESPA ring designs using standard launcher static and vibration environments, as well as payload capacities of 7711 kg for the primary payload and 450 kg/700 kg for each secondary payload. Predicted mass savings ranged from 21% to 41%. A breadboard test campaign on a near 1:1 scale was also undertaken, focusing on the secondary payload port region, including its interface with the grid-stiffened structure. Testing was successful, showing good correlation with predictions, and de-risked future full-scale demonstrator design, manufacturing and qualification, which are currently underway as part of a follow-on project.

1. INTRODUCTION

Small satellites and lighter payloads (<500 kg) are traditionally deployed using metallic multi-payload adapters (MPAs), such as EELV Secondary Payload Adaptor (ESPA) rings, which provide a universal interface for multiple payloads on a single launch, increasing payload mass utilisation and reducing deployment costs.

Historically, MPAs have been metallic structures machined directly from single billets of 7000-series aluminium, an expensive and time-consuming process with high levels of material wastage, which also results in heavier components. These ESPA adaptors are available in a variety of sizes and configurations, while still adhering to standard interface dimensions to facilitate their use on multiple launchers. However, these metallic structures are still heavy in comparison to composite structures, so potential savings in the cost/kg of payload as well as mission extension options would offer significant benefits if efficient composite alternatives can be found. ATG Europe has therefore designed and analysed replacement lattice CMPAs as a solution to this problem.

Lattice structures consist of a repeating grid pattern of intersecting stiffeners or ribs creating a mass optimised structural design. Composite lattice designs can provide potential mass savings of up to 30-50% in comparison to traditional designs (sandwich, monolithic, etc), making them incredibly attractive for structural applications in large scale space components. ATG Europe has developed [1-7] and patented [8] a cost-efficient manufacturing methodology for continuous pre-preg fibre placed grid-stiffened and lattice structures that allows for the manufacturing of high quality, complex, integrated grid-stiffened composite products in a true one-shot process. Two examples of ATG's lattice structures are shown in Fig. 1.

Figure 1: Example of ATG's lattice structures, specifically an interstage for RFA ONE (top) and a central tube demonstrator (bottom).

The project presented in this paper aimed to assess ATG's lattice CMPA designs versus the current standard metallic ESPA designs to evaluate viability of these structures as a replacement component. Compared to a traditional ESPA ring, a CFRP lattice CMPA would provide the following major benefits:

- Significant mass-savings and associated launch cost reductions and/or mission extension options.
- Increased production sustainability through significant reduction in material wastage and optimized manufacturing process.
- Increased flexibility in the production process through accommodation of change in size and/or location of payload ports during the design and manufacturing phase.

2. PROJECT OUTLINE AND GOALS

To assess the feasibility of lattice CMPAs as an alternative to traditional ESPA rings, the following technical objectives were defined. This paper covers each objective in its own respective section.

- Consolidation of requirements for ESPA rings.
- Design and iterative analysis of lattice CMPAs as a replacement to ESPA ring variants.
- Mass comparison against existing metallic ESPA counterpart.
- Manufacture and testing of lattice CMPA breadboard samples to de-risk and validate the port region design, analysis, and manufacturing.

3. EXISTING ESPA RINGS AND THEIR REQUIREMENTS

3.1. Existing ESPA ring configurations

An ESPA consists of a cylindrical ring structure with two standardised Launch Vehicle Adapter (LVA) interfaces at the forward and aft of the structure, as well as a number of payload ports (4-12 depending on port sizes) located around the circumference of the ESPA ring. The LVA interfaces, which allow for the integration of the ESPA between the launch vehicle and the primary payload, consist of a standard EELV 1575 mm diameter bolt circle with 120 equally spaced holes.

The port interfaces allow for the attachment of secondary payloads to the ESPA and consist of a number of different designs. The most common ports designs are the standard 15" and 24" designs, which follow a similar pattern to the LVA ring where an equally spaced bolt pattern of 24 and 36 holes, for the 15" and 24" ports respectively, are used to attach payloads to the ESPA port structures. Additional ports sizes exist, but are less common.

While the LVA interfaces and port structures are the common features of ESPAs, there are multiple configurations for their designs which are identified with a part number defined as:

ESPA N-D-H

N = Number of circular ports, between 4-12
D = Port diameter in inches, usually 15" or 24"
H = Ring height in inches, usually 24" or 42"

The most common ESPA designs which act as a "baseline" are listed in Tab. 1.

Table 1: Baseline ESPA configurations [9]

Name	N	D	H	Payload Capacity (kg) *		ESPA Mass (kg)
				Second. Port	Primary	
ESPA Heavy	6	15	24	450	7711	133
Grande Heavy	4	24	42	700	7711	211
ESPA Stretched	4	24	60	700	7711	286

** Port payload capacities assume payload centre of gravity at 508 mm from port interface and use of load factors derived from the ESPA MAC [9]*

3.2. Existing ESPA ring requirements

The main technical requirements for the ESPA/CMPA design centre around its major functions and the loads it must support during all launch activities. Given the large number of requirements, this paper focuses on those that are key design drivers. ESPAs are currently only rated for flight on the Delta IV, Atlas V, and Falcon launch vehicles (based on historical design definitions for the ESPA load envelopes) and this project aimed to produce a 1:1 comparison between lattice CMPAs and existing ESPA ring qualification campaigns. The static load environment is presented in Tab. 2., while Payload masses and their offset distances are listed in Tab. 3. Both the primary and secondary payload factors have been derived from the ESPA ring user manual [9] and qualification campaigns [10].

Table 2: Static load factors (limit level) for primary and secondary payloads on ESPA rings [9, 10]

Load Case	Primary		Secondary			
			15" & 450 kg		24" & 700 kg	
Set	**Radial**	**Axial**	**Radial**	**Axial**	**Radial**	**Axial**
LS1	0.5g	-6.5g	5.6g	-6.5g	4.6g	-6.5g
LS2	2.0g	-3.5g	5.6g	-6.5g	4.6g	-6.5g

Table 3: Payload masses and offset distances [9]

Payload Location	Mass (kg)	Offset Distance (m)	Offset Location
Primary	7711	3.05	LVA Interface
Secondary 15" Port	450	0.508	Port Interface
Secondary 24" Port	700	0.508	Port Interface

Modal frequency requirements and sinusoidal vibration limits have been assessed against Falcon 9 requirements [11] where axial and lateral frequency limits of 25 Hz and 10 Hz respectively have been defined, while the sine vibration design limits are showcased in Tab. 4. Additional requirements for Random Vibration, Acoustic response and Shock are defined in [11], but are not reported here since they were not used for the preliminary design activities reported in this paper.

Table 4: Falcon 9 sinusoidal vibration environment (limit level) [11]

Axial		Lateral	
Freq. (Hz)	**Acceler. (g)**	**Freq. (Hz)**	**Acceler. (g)**
5	0.5	5	0.5
20	0.8	85	0.5
35	0.8	100	0.6
35	0.6		
75	0.6		
85	0.9		
100	0.9		

4. DESIGN OF ATG'S LATTICE COMPOSITE MULTI-PAYLOAD ADAPTER (CMPA)

4.1. ATG lattice background

The lattice grid is comprised of unidirectional composite pre-preg tows which are arranged in a repeating, overlapping pattern. Due to the use of uninterrupted tows (which do not feature fibre cuts along their length), this architecture manifests in the creation of strong, stiff, and ultra-lightweight structures. The sections of unidirectional tows (with no overlaps) are referred to as ribs, while the overlapping sections are referred to as nodes.

Figure 2: several types of attachment patches on ATG's lattice central tube demonstrator (see Fig. 1)

To accommodate global load introduction, the lattice grid transitions into a monolithic composite laminate. This section can then be used to interface to other structures (e.g. by attaching an interface ring). The means of local load introduction is through interface patches, shown in Fig. 2. The patches are areas of a filled in lattice cell, using regularly laminated pre-preg layers which are interwoven with the rib plies. These patches allow for attaching payloads and assemblies. Patches can also be implemented to provide localized reinforcement when needed, allowing for design changes late into the design and manufacturing process, with minimal localized changes to tooling.

4.2. Lattice CMPA designs

Since the purpose of this project was to provide a direct lattice alternative to existing ESPA rings, specific ESPA designs and configurations had to be selected in order to carry out a 1:1 comparison Considering the wide range of ESPA ring designs and configurations, it was decided to focus on the most common designs that would also cover a wide envelope of secondary payloads (see Tab. 1). The corresponding lattice CMPA designs were therefore named CMPA 6-15-24, CMPA 4-24-42 and CMPA 4-24-60. All three designs share the same basic architecture (shown in Fig. 3 for lattice CMPA 4-24-42):

- Carbon fibre composite main body, using ATG's proprietary lattice technology in a grid-stiffened configuration (i.e. a skin is present).
- Metallic ports to attach secondary payloads.
- Cutouts are surrounded by attachment patches (to fasten the ports) and reinforcement patches.
- Metallic rings for primary interfaces (fastened to monolithic end-laminates).

ATG's lattice grid does not possess a set of fixed design parameters. As a result, the grid geometry, size and configuration can be optimized for each specific application. Some of the design parameters optimized across each of the three lattice CMPA designs include: number of ribs, angle of ribs, height and width of ribs, height and thickness of the monolithic end-laminates, skin layup and thickness, patch layup and thickness. The optimization loops were carried out across several iterations of the analyses covered in Section 4.3.

The 15-inch and 24-inch metallic ports, as well as the primary interface rings are bespoke designs engineered by ATG specifically for the lattice CMPA. Both port designs can be seen in Fig. 3, Fig. 7 and Fig. 8. The ports are fastened to the lattice CMPA by means of Hi-Lite fasteners. Fig. 8 (right) also shows the grid design of lattice CMPA 6-15-24, which is also representative of lattice CMPA 4-24-42 and 4-24-60.

As shown in Fig. 3, Fig. 7 and Fig. 8, the cutouts were designed with a hexagonal shape and are delimited by the ribs, thus preserving the integrity of adjacent cells.

Figure 3: Example of lattice CMPA design, specifically CMPA 4-24-42, featuring four 24-inch ports, and 42 inches tall in total.

4.3. Lattice CMPA analyses and performance

Finite Element (FE) models were used to iteratively design the three lattice CMPAs introduced in Section 4.2. The models used linear plate elements for the structure along with mass elements (CONM2) for the payload masses. Primary and secondary payloads were connected via rigid RBE2 elements to each model, with the physical port structures and primary interface rings included through bolted connections within the models. An example of such an FE model is shown in Fig. 4. The following analyses were run for each lattice CMPA design: linear quasi static (QSL), modal, linear buckling, and sine vibration. The results of each analysis are summarized in the subsections below.

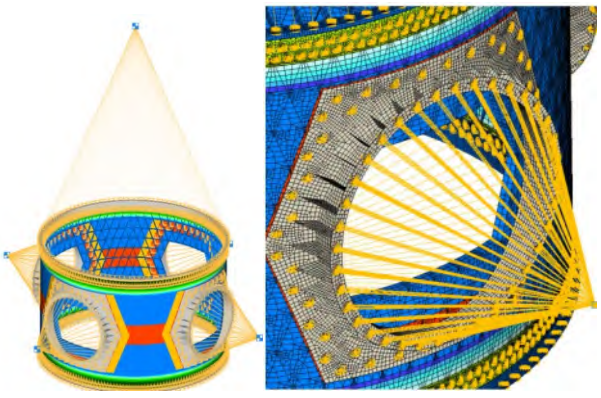

Figure 4: example of FE model setup for the lattice CMPA 4-24-42 (left: overview, right: detail)

4.3.1. Quasi Static Load (QSL) FE Results

The CMPA designs show positive strength margins across the majority of the structure. A few small areas of localized negative margins were also predicted, induced by modelling discontinuities and numerical peaks. The bolted interface points are an example of such numerical discontinuity, where infinitely rigid CBUSH and RBE2 spiders represent the bolted connections, thus introducing notable conservativism in the stresses seen immediately around the bolt.

An example of QSL results is provided in Fig. 5, for the lattice CMPA 4-24-42. Numerical values have been removed from the colour bar to preserve the confidentiality of the (preliminary) design's performance. Negative margins (in black) are only present in a handful of small areas, all confined to the few expected instances of numerical artifacts (such as the one mentioned above). The most "widespread" highly loaded areas (in yellow) still provide a comfortable margin of safety.

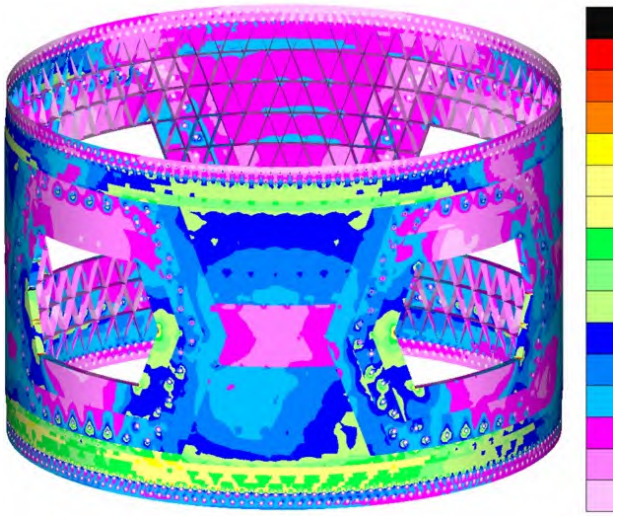

Figure 5: Enveloped laminate Failure Indices (FI) for all QSL load cases of the lattice CMPA 4-24-42. Colour-bar values intentionally omitted.

4.3.2. Modal and linear buckling FE Results

Tab. 5 summarizes the performance of all three lattice CMPA designs under modal and linear buckling FE analyses. The requirements are met with an ample margin of safety.

Table 5: Summary of lattice CMPA performance under modal and linear buckling FE analyses.

Lattice CMPA	First Lateral Mode (Hz)	First Axial Mode (Hz)	First Buckling Eigenvalue (-)
6-15-24	≥ 15	≥ 34	> 4
4-24-42	≥ 15	≥ 34	> 4
4-24-60	≥ 15	≥ 34	> 4
Min. Allowable	10	25	2

4.3.3. Sine Vibration FE results

Across all sine vibration analyses, primary notching was performed to ensure that dynamic loads did not exceed QSL levels. The overall output of sine analyses is similar to the QSL results (Section

4.3.1), presenting positive strength margins across the majority of the structure, accompanied however by a wider variety of small areas of localized negative margins. These include, for example, some bolted connection points, a few small regions in hoop ribs at the equator, and a few of the stiffness transitions areas (e.g. adjacent reinforcement patches of different thickness). Fig. 6 provides a representative example of a sine vibration FE output, showing levels similar to those seen in QSL, albeit with a few more regions of slightly higher negative margins.

Sine vibration analyses in the follow-on phase of this project (Section 6.2) have already indicated that the application of secondary notching (keeping the secondary payloads within QSL levels) results in positive margins of safety in the aforementioned regions, therefore bringing sine vibration failure indices in line with QSL performance (Section 4.3.1). As a last precaution, if during detailed design analyses any regions were to present negative margins of safety, reinforcement patches could be added within the interested cells to increase the strength and stiffness of the affected area.

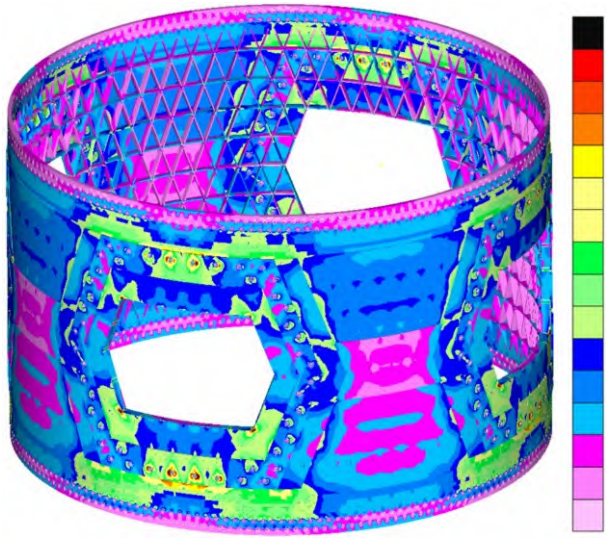

Figure 6: Laminate Failure Indices (FI) for axial sine excitation of the lattice CMPA 4-24-42. Colour-bar values intentionally omitted

4.4. Mass performance comparison

Tab. 5 provides a mass overview for the three lattice CMPA designs, including a comparison against their ESPA counterparts. A mass maturity margin (MMM) of 20% is included in the CMPA mass values. Lattice CMPAs present substantial mass savings of 6-29% with MMM, and 22-41% reductions without the MMM.

It should be noted that metallic components (secondary ports and primary interface rings) still represent a considerable fraction of the total mass of the lattice CMPA designs. This is particularly true for shorter designs (such as the 6-15-24), where the secondary payload ports extend over a large portion of the design. The follow-on project (Section 6.2) has already identified potential for additional mass savings in the metallic interfaces thanks to additional design iteration loops. Potential for further mass savings has also been identified in the CFRP components. Therefore, it is reasonable to expect the final mass savings for the lattice CMPA to be in line with the "savings without 20% MMM" from Tab. 5. This would yield savings of 20% to 40% compared to the corresponding ESPA designs.

Table 6: Mass savings overview for ESPA and CMPA designs in kg. A 20% mass maturity margin (MMM) is included for CMPA only.

Mass (kg)	6-15-24		4-24-42		4-24-60	
	ESPA	CMPA	ESPA	CMPA	ESPA	CMPA
Metallic	133	61	211	73	286	70
CFRP	-	63	-	96	-	132
Total	**133**	**125**	**211**	**169**	**286**	**202**
Savings with 20% MMM	**-**	**6%**	**-**	**20%**	**-**	**29%**
Savings without 20% MMM	**-**	**22%**	**-**	**33%**	**-**	**41%**

5. BREADBOARD SAMPLE DESIGN, MANUFACTURING AND TESTING

The integration of secondary payload metallic ports onto ATG's grid stiffened structures represented the most critical aspect of lattice CMPA design that ATG wished to de-risk and validate within this project. To this end, a static breadboard test was performed on a flat grid stiffened panel with a metallic port integrated to it, with both the panel and port bearing the same design parameters used in the CMPA designs presented in this paper (specifically the lattice CMPA 6-15-24).

The breadboard tests therefore served to de-risk and validate the designs, analysis, manufacture and integration of the port region, with each of these aspects being discussed in its respective Section below.

5.1. Breadboard sample design

The test breadboard (TBB) sample design is shown schematically in Fig. 7. The TBB sample features a flat CFRP grid stiffened panel, encased along its boundaries in a potting compound (for fixation with the test frame). A flat, 15-inch metallic port is fastened to the panel by means of Hi-Lite fasteners.

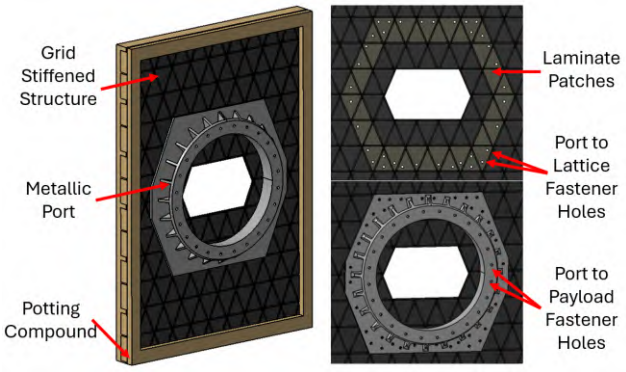

Figure 7: Test breadboard (TBB) sample design.

Some concessions had to be made when translating the "full" lattice CMPA 6-15-24 design into a simplified flat TBB sample. The grid-stiffened panel presents the same grid parameters (rib size, angle and spacing) as the lattice CMPA design, but its skin and patches are thinner with a balanced/symmetric layup (to limit warpage), while the patch layout has also been simplified by removing adjacent reinforcement patches. The port uses the exact same design ATG developed for the lattice CMPA 6-15-24.
It follows that the test sample cannot explicitly achieve the same performance as a 1:1 CMPA design, but this does not hinder the de-risking and validation goals discussed at the beginning of Section 5.

5.2. Breadboard sample manufacturing

Two TBB samples were manufactured, one of which is shown in Fig. 8. The metallic port was manufactured by machining an aluminium billet. Panel manufacturing and port integration activities were carried out at Eligio Re Fraschini (in Legnano, Italy), with the support of ATG personnel.

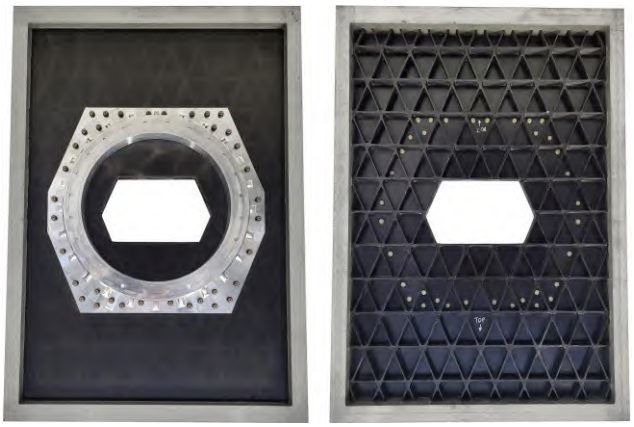

Figure 8: Front (port) and back (grid) views of TBB sample nr1.

As a result of the successful manufacturing of both TBB samples, the following items were de-risked and validated:

- Cutout manufacturing and integration.
- Port manufacturing and integration, including the performance assessment of multiple fasteners within a single patch, and fasteners in close proximity to ribs.
- Manufacturing of equivalent lattice design parameters (rib height, cell size, etc.).

5.3. Breadboard sample testing

5.3.1. Test plan

The test load environment consisted of a single shear load, aligned with the axial direction of the TBB sample and applied at a distance of 0.508 meters from the payload port (see Tab. 3).

The test sequence accounted for three cycles at low load levels to assess repeatability and ensure sample embedding. These were to be followed by ramps and holds at increasingly higher load levels, until total sample failure is achieved.

The applied load and displacement were controlled by manually increasing (or decreasing) the hydraulic pressure in the actuator. The hydraulic system setup ensured that the actuator could only move at a maximum speed of 0.125 mm/s, thus ensuring that no sudden load changes could be imparted by the system.

The load cell, potentiometer and strain gauges were to record data over the entirety of the test including during integration of the test panel within the test setup, to capture any assembly strains. The tests were carried out at DTM Technologies in Modena (Italy)

5.3.2. Test setup

The overall test setup is shown in Fig. 9. The test load was introduced through contraction of the actuator, which is supported by the actuator support and load head. Both pieces of bespoke MGSE were made of S355 steel and were sufficiently stiff to ensure that their own deformations were negligible compared to test displacements. The head fixture was designed to ensure even load introduction into the port, at a distance of 0.508 meters from the port.

The sample was held in place by the sample fixation frame, which provided sliding contact (normal to load direction) at the front and back of the panel, and reaction contact (aligned with load direction) at the top and bottom. The fixation frame interfaced exclusively with the panel's potting, without touching the rest of the sample. The fixation frame rested on spacer disks which ensured planarity of the sample.

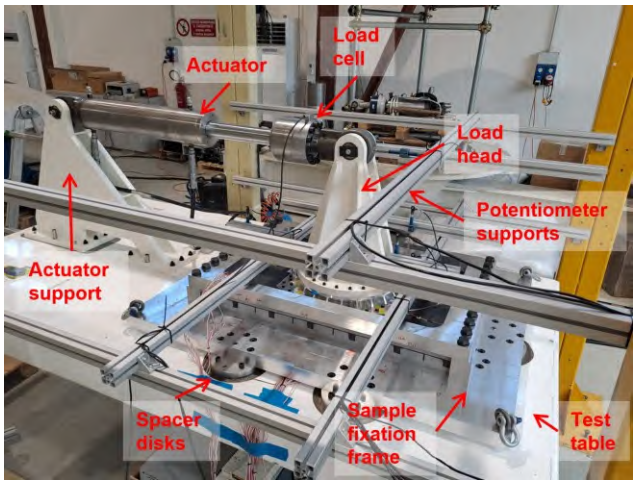

Figure 9: Breadboard test setup

The load was recorded by means of a load cell sitting between the actuator and load head. Strains were measured through 48 strain gauges per sample, of which 42 were placed on the panel, with 34 on the ribs (which carry the majority of the load), and 8 on the laminate patches and skin. The focus was placed on areas that would experience high loads, high deformations, and around the cutout. The remaining 6 strain gauges were placed on the metallic port. Displacements were measured through 8 linear potentiometers. Out of the 8 potentiometers, 3 were placed on the skin (port-side) of the panel, at locations expected to experience higher deformations; 2 were positioned at the load application point to track displacement along the loading direction, and to verify that the load remained centred. Finally, 1 potentiometer tracked displacement at the base of the load head, and 2 were positioned on the fixation frame to ensure deformations would be negligible.

5.3.3. Test results

The actuator displacement and normalized load are plotted against test time in Fig. 10 for both TBB samples. The applied load has been normalized against the failure load observed in FE analyses of the TBB sample. In comparing the two sets of results, it should be noted that the "shift" in x-axis values between the two is caused by the test execution times differing between samples. The following can be observed:

- The embedding cycles were successful, with excellent repeatability of loads and displacements across both samples.
- Repeatability of loads and displacement, and the associated "sample stiffness", remained excellent at higher load cycles, both within a same sample as the load increased, and across both samples for the same load values.
- Failure of samples 1 and 2 was sudden and occurred at 113% and 105% of the FE failure load (respectively).

The above observations demonstrate that the samples behaved linearly until failure, with both samples also exhibiting the same stiffness and very similar failure loads. As explained below, both samples also presented the same failure mode. The repeatability and consistency across both samples proves that that the de-risking and validation of manufacturing and integration activities (see end of Section 5.2) was successfully demonstrated by this test campaign.

Sample failure occurred as a rib delamination affecting the half of the panel on which the metallic port exerted a pulling force.

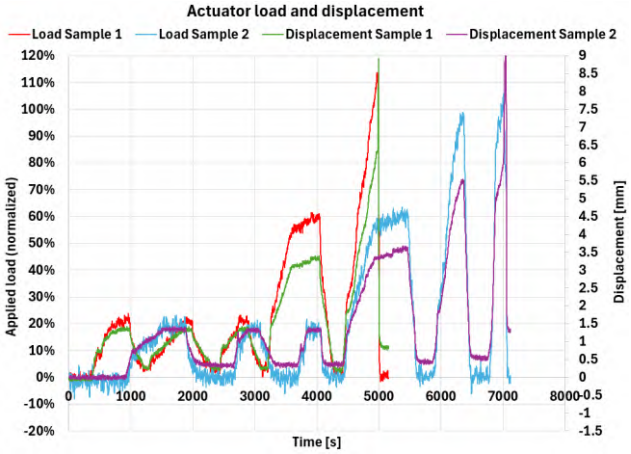

Figure 10: Actuator displacement and applied load (normalized against FE failure load), plotted against time, for TBB samples 1 and 2.

5.3.4. Test FE model and correlation

The detailed FE model of the TBB test includes both the test sample and test setup. The composite grid stiffened panel was modelled using a structured mesh consisting of PCOMPS elements. Other components were modelled with PSOLID definitions.

The metallic port is fastened to the panel by means of RBE2 spiders. Each fastener hole has two spiders: one connected to the port, and one connected to the panel. The independent nodes of the two spiders then interface into a coincident zero length CBUSH at the midpoint of the fastener. The same RBE2 spider configuration is used for the fasteners securing the port to the load head.

Components of the test setup in direct contact with the sample (sample fixation frame, load head) were modelled with solid elements, while shell elements were used for the test table and the actuator support. Linear contact was used between the potting and fixation frame to provide realistic boundary conditions to the sample. Linear contact was also set up between the panel's skin and port to ensure proper load distribution in regions where the shear load on the load head caused the port to "push" against the panel's skin.

Strain correlation of the FE model against test data

yielded good results. All trends observed in the strain data were captured by the predictions, with the FE remaining slightly conservative in critical (highly loaded) areas. After removal of obvious outliers, all strain gauge readings were within the expected range based on FE correlation results. Correlation of displacement data was also excellent, with no outliers among the 8 potentiometers, and with the recorded values being again within the expected range based on FE correlation.

As illustrated in Section 5.3.3, failure of both samples occurred in the form of a delamination within the ribs in the "top half" of the panel (being "pulled" by the port).

Due to the nature and location of the failure, it is hypothesized that the delamination originated within a rib in close proximity to one of the fasteners being loaded under tension by the port. This is in line with the FE predictions, which present failure index hotspots in the two regions highlighted in Fig. 11 (top), specifically in proximity to the fasteners (see example in Fig. 11 bottom). Actual FE results are not shown to preserve the confidentiality of the FE methods and practices ATG developed to model lattice structures. Normalized against the test failure loads of samples 1 and 2 respectively, these failure indices yield failure loads of 89% and 96% for one hotspot, and 111% and 120% for the other hotspot. Designating the most critical hotspot as the failure predictor, the failure mode observed during the test is correctly predicted by the FE model while still being slightly conservative, thus demonstrating that ATG's FE methodology has been successfully validated through this test and can be relied upon for further design of the secondary payload port region. Strain data recorded during the test seems to support the failure hypothesis presented above, since at the exact moment of failure initiation for sample 2, a small spike in strain readings was recorded in one of the regions shown in Fig. 11 (sample 1 strain recordings did not present the same spike).

To evenly distribute out of plane loads from the fasteners into the surrounding ribs, an optimal design should guarantee a minimum rib-fastener distance, dependent on fastener load. As mentioned in Section 5.2, ATG wished to further explore the performance envelope for this design by integrating multiple fasteners within a single patch and positioning some of them in close proximity to the ribs (see Fig. 11). To this end, this test has provided valuable data, asserting the importance of fastener-rib distance while also validating the accuracy of ATG's FE models, which were capable of accounting for this effect, and correctly predict the failure mode, load and location.

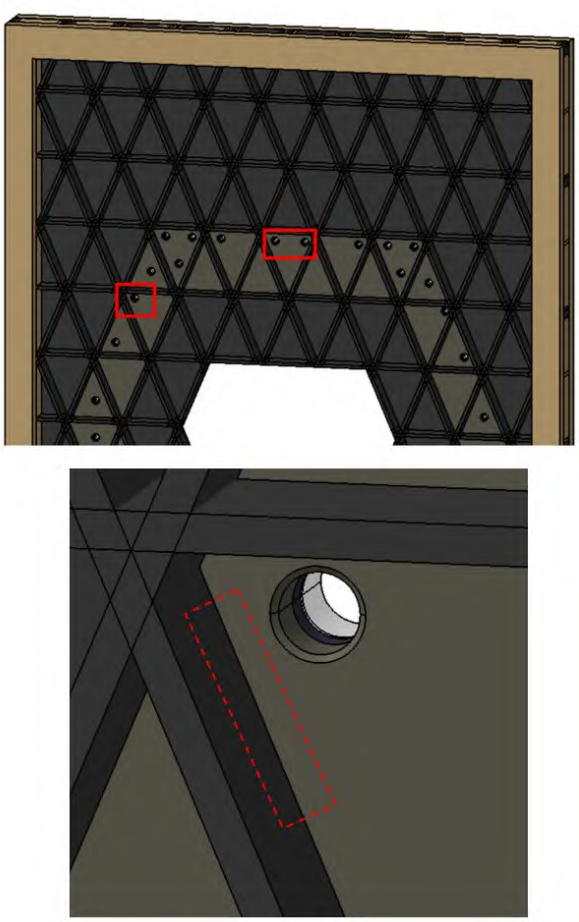

Figure 11: TOP, suspected locations of failure initiation. BOTTOM, closeup of region adjacent to fastener hole, where FE analyses predict failure index peaks (dashed rectangle).

6. CONCLUSIONS AND FOLLOW-ON PROJECT

6.1. Conclusions

ATG designed three lattice CMPAs as a direct alternative to existing ESPA ring designs. Analysis of each lattice CMPA covered QSL, primary modal frequencies, buckling, and dynamic responses based on defined levels from Falcon 9 launch vehicles [11] and previous metallic ESPA tests and defined performances [9, 10].
Overall, the lattice CMPA designs are deemed to be compliant with requirements with limited alterations and mass penalties moving forward. This is a positive result and, combined with the mass comparisons in Section 4.4, shows that the lattice CMPA designs offer significant mass savings across all designs analysed (6-29% with mass maturity margin, 22-41% without, where potential for further mass savings has already been identified in a follow-on project).

The TBB samples have successfully de-risked and validated the port-to-lattice interface, having successfully carried out its design, analysis, manufacturing, assembly and testing. The port-

lattice interface represents the most critical region of the lattice CMPA design. Manufacturing and assembly of the lattice CMPA TBB sample with the metallic port included the addition of a cutout structure for access, as well as all integration steps necessary for the port assembly procedure. These steps have directly informed future manufacturing studies and have shown successful production methods for all components.

Testing of the TBB samples showed repeatable linear behaviour for all load, displacement, and strain measurements, with all sensors falling within the expected range based on FE correlation results. Failure correlation showed accurate and conservative assessments of the predicted failure location and loads, with significant lessons learned for the lattice CMPA designs based on these findings.

Overall, the lattice CMPA designs and analyses have shown compliance with ESPA requirements and prescribed load environments while offering reduced mass, meaning these structures offer strategic improvements over their metallic ESPA counterparts for lightweighting of structures, allowing for additional payload and enhanced mission operation capabilities. The design and manufacture of the lattice samples and ports, machining of the cutouts, and assembly of the entire structure, have significantly de-risked future operations for lattice CMPA components. The lessons learned from design and test outcomes will contribute to future programs, showcasing the impact of this program and enhanced knowledge gained from its undertaking.

6.2. Follow-on project

A follow-on project is already underway. The most promising lattice CMPA design will be selected (among the three presented in this paper). The selected design will undergo detailed analysis and iteration loops, followed by manufacturing of a full-scale qualification model, which will then undergo qualification testing.

7. ACKNOWLEDGEMENTS

The authors would like to acknowledge the funding and support provided by the European Space Agency (ESA) and the Italian Space Agency (ASI) under the Future Launchers Preparatory programme (FLPP), without whom this project would not have been possible. They would also like to thank the manufacturing team at Eligio Re Fraschini in Legnano, the testing team at DTM Technologies in Modena, as well as the ESA Technical Officer for this project, Bernard Decotignie and his colleagues. This highly collaborative project would not have succeeded without the effort and dedication of all involved.

Space radiation, shielding, composite material, structure, spacecraft

ABSTRACT

Commercial off-the-shelf electronics deliver the performance and low cost that space missions rely on, but they are the most vulnerable to space radiation. Passive structural shielding is a complementary protection, yet the materials that shield best are not structural. This feasibility study investigates whether the core volume of a carbon fibre reinforced polymer sandwich panel can be converted into a shielding element using hydrogen-rich, space-relevant materials. Two concepts were manufactured and tested in four-point bending: an aluminium honeycomb filled with polyamide 11 inserts, and a layered core of polyetherimide plates and epoxy-impregnated aramid. The layered concept responds 40 to 43 % stiffer in bending than the honeycomb reference with identical face sheets, while the areal density rises from 0.48 to 1.56 g/cm^2. The layered core combines shielding function with enhanced mechanical performance and remains transferable to established manufacturing routes.

1. INTRODUCTION

Spacecraft increasingly rely on commercial off-the-shelf (COTS) electronics, which offer state-of-the-art performance at competitive cost and short procurement times, but are the least resistant design class against space radiation [1,2]. In orbit, electronics are exposed to trapped particles, solar particle events (SPE), and galactic cosmic rays (GCR) [3], which degrade components through the total ionising dose (TID) and displacement damage and disturb their function through single-event effects (SEE) [4,5]. Radiation hardening addresses these mechanisms at the device level, but drives up cost and design complexity and leads to technologies that perform worse than state-of-the-art commercial devices [5]. Software-based measures can correct or bypass soft SEE during operation [4,6], whereas passive shielding reduces part of the incoming radiation load and thereby lowers the probability of radiation-induced failure. Passive shielding therefore remains a relevant complementary strategy for missions using COTS electronics.

From a shielding standpoint, the incident particles divide into three groups with opposing material requirements: high-energy protons, heavy ions, and fast neutrons are moderated most effectively by nuclei of low atomic mass [7]; thermal neutrons are attenuated by capture in elements with a high thermal neutron capture cross section, such as boron [8]; and electrons and photons call for elements of high atomic number [8]. No single material can therefore shield all groups effectively at once. This work focuses on the first group, which contains the high-energy particles that are the most difficult to shield and against which hydrogen-rich materials are the most effective: a low mean atomic mass increases the fragmentation probability per unit mass [7], and hydrogen moderates fast neutrons most efficiently [9]. Hydrogen-rich polymers such as polyethylene consequently outperform aluminium per unit areal density and produce fewer secondary particles [10–12], while carbon fibre reinforced polymer (CFRP) lies between the two [13,14]. The most effective shields, however, are not structural materials, and dedicated shielding mass competes directly with payload capacity. This conflict motivates structural concepts in which the load-bearing structure itself contributes to shielding.

Sandwich panels with CFRP face sheets and an aluminium honeycomb core are an established structural solution on satellites, such as Olympus or space probe Rosetta [15]. Their core occupies a substantial volume that is conventionally filled by a honeycomb of negligible areal density and shielding contribution. Replacing or augmenting this core volume with hydrogen-rich constituents could add a shielding function within the existing structural envelope. On small platforms, where the mass budget is strictly capped, such multifunctionality is particularly attractive: a 1U CubeSat, for example, is limited to 2 kg [16], its electronics are typically COTS, and the enclosing solar panels are conventionally printed circuit boards [17–19]. No studies were found in which they are executed as sandwich panels. Whether a core modification preserves acceptable mechanical performance is, however, an open question, since the core governs the transverse shear behaviour and the separation of the face sheets [20].

This work presents a feasibility study on whether the

core volume of a structural sandwich panel can be converted into a shielding element without compromising its load-bearing function. Two integration routes are investigated: filling the unused volume of a honeycomb core with a hydrogen-rich and structurally weak filler; and replacing the core entirely with a stack of load-bearing layers that are more hydrogen-rich than carbon. Both concepts were manufactured using established composite processing routes and evaluated in four-point bending against a conventional sandwich baseline, with the flexural stiffness *D* as the main comparison criterion. The following sections derive the material selection and specimen design from these two routes, describe the manufacturing and testing, and discuss the mechanical cost at which the shielding function is gained.

2. MATERIALS AND METHODS

2.1. Sandwich concepts

All configurations share the same sandwich architecture: two CFRP face sheets of 1 mm enclosing a core volume of 10 mm. The reference sandwich represents the established spacecraft solution and combines face sheets made of eight plies of IM7/8552 prepreg in a symmetric cross-ply layup $[0,90,0,90]_s$ with an aluminium honeycomb core of type PAMG-XR1-8.1-1/8-20-P-5056, bonded with Redux 312 adhesive film. In this configuration, only the face sheets, with an areal density of about 0.3 g/cm^2, contribute to shielding (Fig. 1a).

The two concepts modify the core volume while keeping the face-sheet thickness unchanged. They are intended for the established prepreg route. For the feasibility question of this study, however, the qualified aerospace prepreg is required only for the reference, representing the established solution, not for the concept specimens themselves. Their face sheets were therefore laid up from four layers of 3K carbon 2x2 twill fabric at 200 g/m^2 and infused with epoxy, reaching approximately the same 1 mm thickness as the prepreg baseline and an equally balanced [0,90] fibre architecture. The concept face sheets thus reproduce the geometry of the reference, while the manufacturing route differs.

The infusion system used, R&G epoxy resin L with hardener GL2, is not space-qualified. Its strength values are comparable to those of the space-qualified infusion system Araldite LY 556 with Aradur 906, which is sufficient to address the feasibility question in this study. Since the L/GL2 resin tolerates only 85 °C, the concept specimens were bonded at room temperature with a two-component adhesive instead of the adhesive film. However, the material selection for the concepts follows the requirements of the intended prepreg route.

The material selection of both concepts rests on two atomic parameters introduced in the shielding literature [7]: the ratio *Z/A* of mean atomic number to mean atomic mass, proportional to the mass stopping power for charged particles, and $A^{-1/3}$, proportional to the fragmentation cross section per unit mass. Tab. 1 compares the candidate materials against polyethylene, consistently the most effective of the considered materials, and carbon, the stiffest constituent. Since *Z/A* varies only weakly across these materials, their shielding differences are governed by the fragmentation parameter, and thus by their hydrogen content. All selected materials lie between the two bounds: they shield less than polyethylene but more than the carbon fibres of the face sheets.

Table 1: Shielding parameters of the candidate materials: density, hydrogen mass fraction, mass stopping power parameter Z/A and fragmentation parameter $A^{-1/3}$ (larger is more effective), computed as atom-fraction weighted means from standard atomic weights

Material	ρ (g/cm^3)	H (wt %)	Z/A	$A^{-1/3}$
HDPE (CH_2)	0.95	14.4	0.570	0.598
PA 11 ($C_{11}H_{21}NO$)	1.04	11.55	0.556	0.570
Epoxy (C_2OH_3)	1.10	7.0	0.534	0.518
para-Aramid ($C_{14}H_{10}N_2O_2$)	1.44	4.2	0.520	0.490
PEEK ($C_{19}H_{12}O_3$)	1.30	4.2	0.520	0.490
PEI ($C_{37}H_{24}O_6N_2$)	1.27	4.1	0.520	0.489
Carbon (C)	1.8	0	0.500	0.437

The first concept fills the honeycomb cells (Fig. 1d) with a relatively hydrogen-rich body, which can preserve its geometric shape at the curing temperatures required by the adhesive film, so that the surrounding sandwich carries the load and the filler is exempt from structural requirements. PA 11, or Nylon 11, was selected as the filler material: with a hydrogen content of 11.55 wt% it approaches polyethylene in fragmentation effectiveness (Tab. 1), but unlike polyethylene it remains form-stable up to 150 °C [21] and therefore can withstand the 120 °C curing step of the aerospace Redux 312 adhesive film, which keeps the concept transferable to the prepreg route. The baseline core provides cells too small (3.18 mm) to be filled efficiently, so a different core was required. It was selected for shielding rather than for mechanics: the lightest available aerospace honeycomb, PAMG-XR1-1.0-3/8-07-P-5056, maximises filler volume through its larger 9.53 mm cells and minimises the aluminium in the shielding path, and, with it, the secondary radiation, through its thinner walls (Fig. 1c,d). The mechanical contribution of the core was deliberately set aside at this stage. The consequences of this

choice are quantified later in Section 3.
The second concept replaces the honeycomb entirely with a layered stack of two load-bearing constituents, epoxy-impregnated aramid fabric and polyetherimide (PEI) plates, both more efficient at shielding against the chosen particle group than carbon (Tab. 1). Aramid 2x2 twill fabric at 170 g/m^2, impregnated with epoxy, retains 80 to 90 % of the shielding efficiency of polyethylene against heavy ions [22] and is established in space applications as debris protection, as in the Columbus shield [23]. In laminate form aramid can also carry load. PEI, an amorphous thermoplastic with a glass transition temperature of 217 °C [24], shields comparably to aramid, since both materials nearly coincide in their fragmentation parameter (Tab. 1). Its selection over the equally shielding polyether ether ketone (PEEK) rests on three properties: it bonds exceptionally well to epoxy systems, forming a gradient interphase during co-curing above 120 °C [25]; its ductility as a thermoplastic, with failure strains exceeding those of epoxy laminates by more than an order of magnitude, mitigates the brittleness of a thick epoxy stack; and its temperature tolerance permits co-curing with aerospace prepregs in the autoclave, which makes the concept adaptable to the established prepreg route. The stack is symmetric and reaches the 10 mm thickness of the replaced core. Two variants with identical PEI content were built: three PEI plates of 2 mm (Layered 3x2) and two plates of 3 mm (Layered 2x3), with 16 aramid layers filling the remaining thickness (Fig. 1e,f).
The face sheets of the concepts and of the reference thus differ in their manufacturing route. Comparing a concept directly against the reference would therefore vary two parameters at once: the core and the face-sheet manufacturing route. Two bridge panels resolve this. Bridge 1 combines the infused face sheets with the baseline 8.1 pcf core and serves as the reference for the layered concept with aramid and PEI, while Bridge 2 combines the infused face sheets with the unfilled 1.0 pcf core, separating the effect of the core exchange from that of the filling. Every comparison in Section 3 is thus made between panels that differ in exactly one parameter. Tab. 2 summarises all six configurations, and Fig. 1 shows their cross-sections.

Table 2: Specimen series with face-sheet route, core configuration and areal density

Series	Face sheets	Core volume	Areal density [g/cm^2]
Baseline	prepreg	8.1 pcf	0.48
Bridge 1	infused	8.1 pcf	0.48
Bridge 2	infused	1.0 pcf	0.40
Filled honeycomb	infused	1.0 pcf + PA 11 inserts	1.16
Layered 3x2	infused	3 PEI plates + aramid	1.59
Layered 2x3	infused	2 PEI plates + aramid	1.56

2.2. Manufacturing

The baseline was produced in two stages. The prepreg face sheets were cured in the autoclave at 180 °C and 7 bar, then ground on the core-facing surfaces and bonded to the honeycomb with Redux 312 film at 120 °C and 2 bar. The concept face sheets were infused and post-cured at up to 70 °C. All concept and bridge sandwiches were then bonded at room temperature with the two-component adhesive Loctite EA 9466 (Section 2.1). For the filled honeycomb, hexagonal inserts, 9 mm across and 8.5 mm high, were laser-sintered from PA 11 powder and placed into the cells before bonding (Fig. 1d).
The filled-honeycomb concept is intended for the prepreg route, in which the assembled sandwich is bonded with the film adhesive under autoclave pressure (Section 2.1). To verify this step, prepreg face sheets were additionally bonded to the 1.0 pcf core with the Redux 312 film. This attempt failed: the core collapsed under the 2 bar consolidation pressure, so the prepreg route is not processable with this core. The consequences are taken up in Section 3.

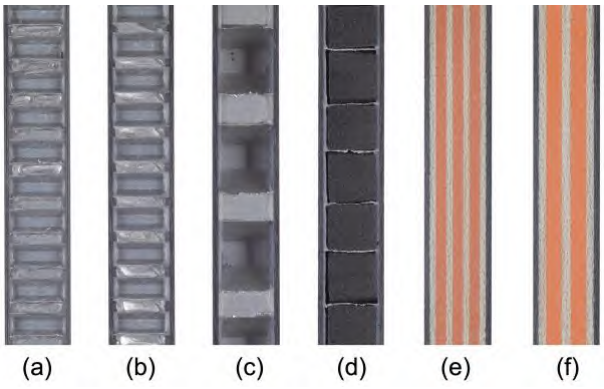

Figure 1: Cross-sections of the manufactured specimen series: (a) Baseline sandwich; (b) Bridge 1; (c) Bridge 2; (d) Filled honeycomb with PA 11 (Nylon) inserts; (e) Layered 3x2; (f) Layered 2x3.

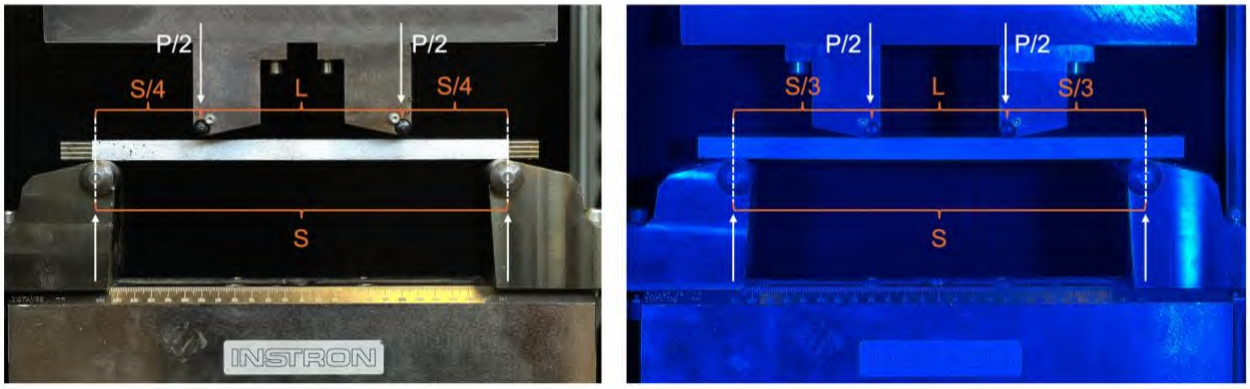

Figure 2: Loading configurations according to ASTM D7250, method 10.2.5: quarter-span (left, L=S/2) and third-span (right, L=S/3). The photo on the right is illuminated by the ARAMIS measurement system.

For the layered concept, the PEI plates were first fused from 0.5 mm PEI-SF Dexnyl© foils (Bieglo GmbH) in a heated press to the required thicknesses. The complete stack, consisting of carbon face-sheet layers, aramid layers and PEI plates, was then infused in a single shot (Fig. 1e,f). Because the PEI plates are impermeable, a linear inlet was used, with flow media wrapped down the sides of the preform so that the resin reaches every aramid layer in-plane. In a prepreg-based version of the concept, where the plies arrive pre-impregnated, this measure would not be necessary.

2.3. Four-point bending tests and data reduction

The mechanical cost of the core modifications was quantified in four-point bending following the standard ASTM D7250 [26], which separates the mid-span deflection of a sandwich beam into a bending and a shear contribution,

$$\Delta = \frac{P\,(2S^3 - 3SL^2 + L^3)}{96\,D} + \frac{P\,(S - L)}{4\,U} \qquad (1)$$

where P is the total force, S is the support span and L is the load span. The flexural stiffness D (the sandwich counterpart of the beam bending stiffness EI) and the transverse shear rigidity U are the two unknowns; from U, the core shear modulus G_c follows. Since the face-sheet modulus of the wet-laid laminates is a process outcome rather than a datasheet value, both unknowns must be determined by testing each specimen in two loading configurations with different L/S ratios and solving the two instances of Eq. 1 simultaneously.

All specimens measure 290x30 mm. The support span of 240 mm is the largest the specimen length permits and simultaneously the smallest that keeps simple beam theory valid ($S/d > 20$ at a panel thickness of 12 mm). Both loading configurations are therefore bound to the same support span and differ only in the load span: 120 mm ($L = S/2$) and 80 mm ($L = S/3$), as shown in Fig. 2. The consequences of this geometric constraint for the shear extraction are shown in Section 3. Tests were run on an Instron 5584 machine at 1 mm/min, within the elastic range, since both configurations must be applied to the same specimen. The mid-span deflection was measured directly on the specimen by digital image correlation (ARAMIS), so that machine compliance does not enter Eq. 1 . For evaluation, the toe region of each record was removed by linear extrapolation to zero force, and D, U and G_c were computed at ten evenly spaced force levels per specimen and averaged, with five to six specimens per series.

3. RESULTS AND DISCUSSION

3.1. Force-deflection response and flexural stiffness

All series respond linearly over the evaluated range. Fig. 3 compares the Baseline with Bridge 1, which share the 8.1 pcf core and differ only in the face-sheet route: the prepreg face sheets respond 55 to 60 % stiffer than the infused ones (751 against 469 N/mm in the quarter-span configuration, Tab. 3) and reproduce within about 1 % against 2 to 3 % for the infused series. This difference quantifies the price of the substitute face-sheet route and defines Bridge 1 as the reference level for the concepts.

Fig. 4 shows the central result. Both layered variants respond 40 to 43 % stiffer than Bridge 1 in both loading configurations: replacing the honeycomb with the PEI/aramid stack increases bending stiffness rather than degrading it. This gain answers whether the shielding layers themselves carry load: a stiffness above the honeycomb reference is only possible if the interfaces between the PEI plates and the aramid laminate transfer shear, so the layered core participates in the load transfer rather than being carried by the face sheets. The two variants respond almost identically (the Layered 3x2 variant about 2 to 3 % stiffer), so the distribution of the PEI through the thickness has only a minor influence, consistent with the identical PEI content of both variants. The Layered 2x3 variant is the most reproducible series of the study, with a scatter below 1 %.

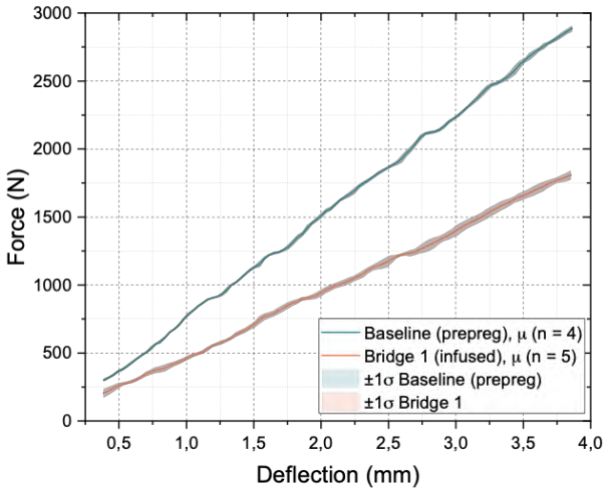

Figure 3: Force-deflection response of the Baseline and Bridge 1 sandwiches in the quarter-span configuration (mean and standard deviation across each series, toe-compensated).

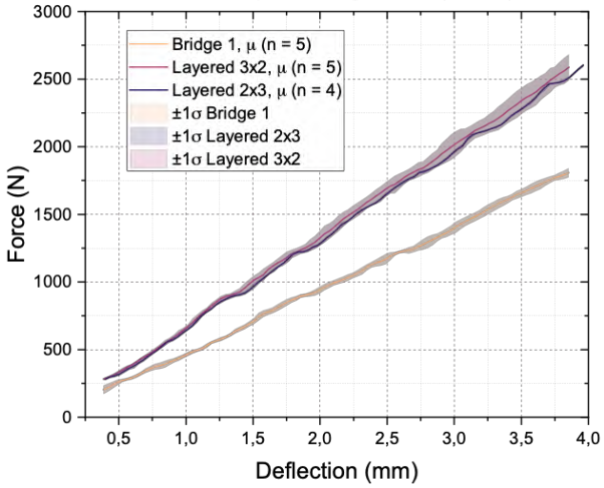

Figure 4: Force-deflection response of the Bridge 1 sandwich and Layered concepts in the quarter-span configuration (representation as in Fig. 3).

Fig. 5 completes the isolation chain for the filled honeycomb. The core exchange dominates: at a given deflection, Bridge 2 carries only about one-quarter of the force of Bridge 1. The PA 11 inserts partially restore this loss: the filled honeycomb carries about 63 % more force than the unfilled Bridge 2 (199 against 122 N/mm). The loss is therefore caused by the core exchange itself, the price of the larger cells and thinner walls selected in Section 2.1, not by the inserts. The soft-core records scatter more than those of the stiff-core series because the fluctuations in the machine load signal, present in all series, become visible against the low forces these specimens carry. The low-density core is, in addition, sensitive to local compressive damage, and both loading configurations are run consecutively on the same specimen. For these two series, the first run therefore provides the only measurement that is certain to represent the unloaded state, and the quarter-span configuration, tested first, is used for the comparison.

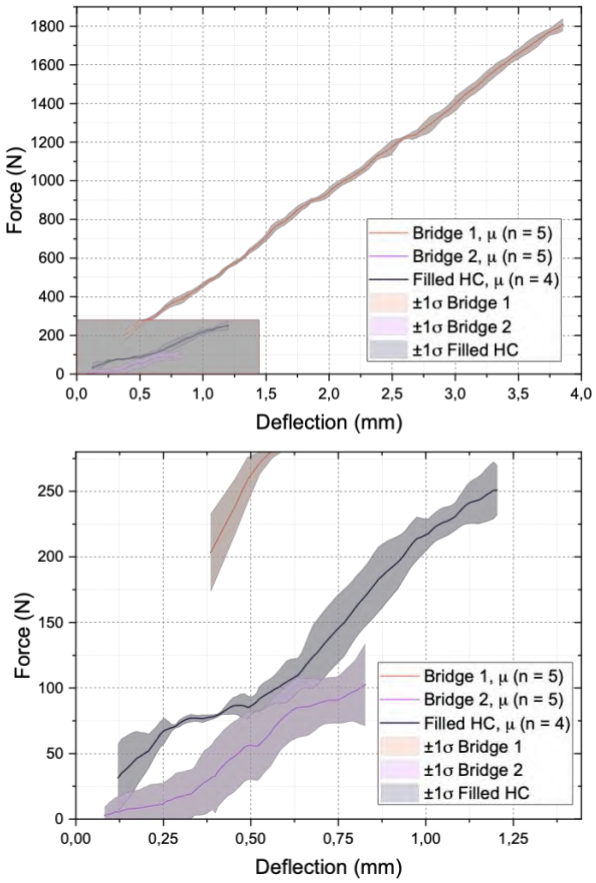

Figure 5: Force-deflection response of the Bridge 1 and Bridge 2 sandwiches and the Filled honeycomb concept in the quarter-span configuration (representation as in Fig. 3).

Table 3: Mean slopes k of the force-deflection records per loading configuration and flexural stiffness D (mean, CV) of the valid specimens. For the soft-core series, only quarter-span configuration is reported

Series	n	*k* quarter (CV) [N/mm]([%])	*k* third (CV) [N/mm]([%])	D (CV) [×10^8 N mm^2]([%])
Baseline	4	751 (0.6)	599 (0.7)	1.79 (24.2)
Bridge 1	5	469 (1.4)	385 (2.3)	0.99 (13.4)
Bridge 2	5	122 (25)	–	–
Filled honeycomb	4	199 (11)	–	–
Layered 3x2	5	672 (2.9)	550 (2.3)	1.19 (18.7)
Layered 2x3	4	656 (0.4)	533 (0.6)	1.13 (3.3)

Tab. 3 summarises the evaluation. The flexural stiffness D confirms the ranking of the slopes for the four stiff-core series. The coefficients of variation of D exceed the scatter of the underlying curves because the data reduction is divided by a term that is only about 0.07 for the present span combination, so a deviation of 1 % in the deflection ratio changes D by about 15 %. The ranking of the series remains unchanged. Only the absolute values carry this amplified uncertainty. With four valid specimens for the Baseline and the Layered 2x3 variant, one below the five recommended by the practice, the absolute values are indicative rather than qualification data.

3.2. Transverse shear extraction

The transverse shear rigidity U, and with it the core shear modulus G_c, could not be reliably determined for any series. The cause is geometric. The specimen length limits the support span to 240 mm, which is simultaneously the minimum span for beam theory, so both loading configurations are bound to the same support span and their shear-to-bending ratios differ by only about 7 %, against a factor of about 16 between the standard configurations the practice recommends. For pure bending, Eq. 1 gives a deflection ratio of exactly 368/297 for this span combination, and the U equation divides by the distance of the measured ratio from this value. The expected shear contribution of the stiff cores raises the ratio by less than about 1 %, while the measurement scatter reaches 1 to 3 %: the equation system becomes nearly singular, and the sign of the extracted U is decided by scatter rather than by the material. The response of all series is thus bending-dominated at the spans accessible to this specimen geometry, which defines a lower bound on U rather than a value: U is at least large enough that its deflection contribution stays below the measurement resolution, so the shear contribution can be neglected for stiffness predictions at comparable spans. A dedicated shear test according to ASTM C273 [27] is the appropriate method for the layered concept, and the only way to obtain G_c for a core that is itself a laminate.

3.3. Trade-off and application perspective

The layered concept does what it was designed to do, using materials and processes available today. Its price is the areal density, which rises from 0.48 g/cm^2 for the baseline sandwich to 1.56 g/cm^2 for the Layered 2x3 variant. This mass, however, is not spent on a single function: it carries a load, attenuates the first particle group, and consists of a material established for space debris protection. Of the two variants, the Layered 2x3 configuration carries forward: it contains fewer bonded interfaces, is the most reproducible series, and is slightly lighter than Layered 3x2. For the intended prepreg route, the stiffness values measured here are a lower estimate, since the prepreg face sheets respond 55 to 60 % stiffer than the infused ones (Fig. 3). The bonding pf the PEI plates may improve as well: gradient interphase between PEI and epoxy [25] forms only during co-curing above 120 °C, which the room-temperature route of this study does not reach.

The filled honeycomb is rejected, for a processing rather than a material reason. The concept was designed for the prepreg route, and the core selected in Section 2.1, with large cells for the filler volume and thin walls for less aluminium in the shielding path, collapsed under the consolidation pressure of the film adhesive (Section 2.2). Between the two tested cores, cell size and wall thickness trade the filler volume against the pressure the core can carry, so a compromise grade, with thicker walls, somewhat smaller cells, or both, might survive the autoclave cycle. The stiffness contribution of the inserts, about 63 % over the unfilled core, suggests that such a configuration could reach a sufficient mechanical performance. The filling effort, however, remains for every core: the cells have to be filled one by one, about 95 cells for a 100 x 100 mm panel and a multiple of that for larger panels, which is difficult to automate reliably at present. The layered concept, in contrast, is compatible with existing prepreg and autoclave infrastructure.

The shielding itself remains to be quantified. The fragmentation parameter of Tab. 1 is a proxy: it contains no information about the energy spectrum, the secondary particles, or the angular distribution of the incident flux. The areal densities reached here, about 1.5 g/cm^2, are one order of magnitude below the 5 to 23 g/cm^2 of the accelerator studies reviewed in the introduction, so an effect on the accumulated dose from trapped particles can be expected, whereas heavy GCR ions are only partly fragmented. Whether the secondary particles increase or decrease the single-event rate requires a radiation transport simulation, which is the necessary next step. For mass-capped platforms, the concept meets a hard boundary: at 1.56 g/cm^2, all six faces of a 1U CubeSat would amount to about 1.0 kg of its 2 kg budget, against about 0.31 kg for the baseline sandwich, so the concept is more attractive for larger satellites, where added mass can be traded for mission reliability.

4. CONCLUSIONS

This work examined whether the core volume of a structural sandwich panel can be converted into a shielding element against protons, heavy ions, and fast neutrons without compromising its load-bearing function. Two concepts, both realised with space-relevant materials and established composite processes, were manufactured and tested in four-point bending against a prepreg baseline and against bridge panels that isolate the effect of the face-sheet route. The layered concept, in which PEI plates and epoxy-impregnated aramid layers replace the honeycomb core, proves feasible. It

responds 40 to 43 % stiffer in bending than the honeycomb reference with the same face sheets, so the shielding layers themselves carry the load. Its price is the areal density, which rises from 0.48 g/cm^2 for the baseline sandwich to 1.56 g/cm^2 for the selected variant with two 3 mm PEI plates, the most reproducible series of this study. This mass serves several functions at once: it carries a load, attenuates the targeted particle group, and consists of a material established for debris protection. The temperature tolerance of PEI permits co-curing with aerospace prepregs, which makes the concept compatible with existing prepreg and autoclave infrastructure.

The filled-honeycomb concept, in which laser-sintered PA 11 inserts fill the cells of a lightweight aluminium core, is not pursued further. The inserts work as intended: they partially restore the stiffness lost by the core exchange, and the material withstands the bonding temperature of the prepreg route. The concept nevertheless fails at the process. The thin-walled core selected for shielding collapsed under the consolidation pressure of the film adhesive, and while a compromise core grade could resolve this, the filling of the cells one by one remains for every core and is difficult to automate for panel quantities.

The transverse shear properties could not be extracted for any series, since the specimen geometry forces both loading configurations onto the same support span, and the shear signal stays below the measurement scatter. A dedicated shear test according to ASTM C273 is the appropriate method for the layered concept. What this study demonstrates is therefore the feasibility, not shielding performance: more effective shielding materials can be integrated into a structural panel without loss of bending stiffness, using materials and processes available today, while the shielding gain itself remains to be quantified by radiation transport simulation.

Abstract

Large Deployable Reflector (LDR) antennas maintain their reflecting surface through the pretension of lightweight cable networks, so the operational configuration is the equilibrium of a tension-stiffened geometrically nonlinear system. Thermal excursions and manoeuvre-induced transients perturb the initial equilibrium: heating reduces cable tension and can cause surface drift and beam depointing, while dynamic loads may temporarily cause members to become slack and impose a recovery time before the design configuration is regained. This work presents a Python-controlled OpenSees workflow for the dynamic assessment of a prescribed LDR design. A new cable finite element is implemented to represent the main thermo-mechanical effects governing tensioned cable networks, including pretension, thermal variation, tension-only behaviour, geometric stiffness and distributed dynamic effects. The formulation is verified through analytical benchmarks and numerical comparisons with commercial finite element software. The pipeline is then used to investigate sensitivity to thermal and dynamic operating conditions, identifying modal changes, loss of tension and operational response shapes. As a proof of concept, a compact feed-forward neural-network classifier trained on the resulting database reproduces the dynamic loss of tension at reduced inference cost, providing a basis for data-driven screening of operating conditions.

1 INTRODUCTION

Large Deployable Reflector (LDR) antennas are used in space applications requiring high-gain, large-aperture radiating systems under severe mass and stowage constraints (Fig. 1). In mesh-reflector architectures, such as AstroMesh-like and tensegrity-based concepts, the reflecting surface is a prestressed assembly of a deployable structure, front and rear cable nets, tensioning ties and a metallic reflective mesh [1,2]. The target paraboloid is therefore an equilibrium configuration whose stiffness and shape accuracy depend primarily on the pretension field. The static design of deployable mesh reflectors is generally addressed through form-finding procedures. The Force Density Method remains a classical tool because it rewrites cable-network equilibrium in terms of force-to-length ratios [3]. Related approaches include dynamic relaxation and other network-based form-finding strategies [4,5], while reflector-specific procedures account for topology, surface accuracy, mesh properties, supporting-truss compliance and shape adjustment [6,7,8,9]. Manufacturing-oriented studies

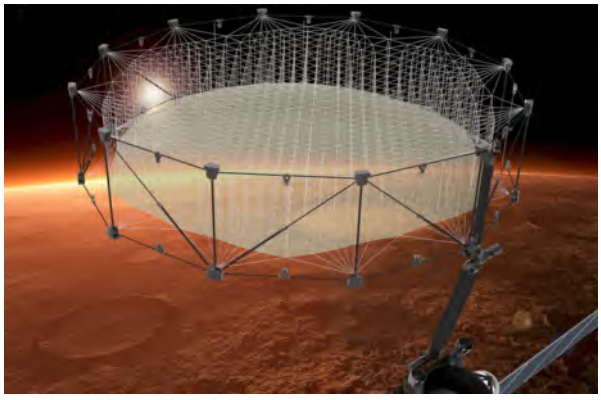

Figure 1: Thales Alenia Space LDR antenna architecture. The reflecting surface is supported by a lightweight prestressed cable-net and mesh assembly.

recover the zero-stress configuration used to define rest lengths, cutting patterns and assembly tolerances [10], and robust-design studies show how manufacturing deviations propagate into surface errors [11]. These contributions provide the static and geometric basis for LDR design.

Cable mechanics provides the reference scale for the dynamic assessment of prestressed cable nets. Taut-string theory gives the dependence of transverse frequencies on axial tension, while sag-extensibility models describe the effects of sag, axial compliance and boundary conditions [12,13]. Thermoelastic extensions show how temperature modifies stress and natural frequencies, providing benchmarks for thermally stressed cables [14]. These models identify the mechanisms that the finite element formulation must reproduce: tension-dependent transverse stiffness, thermal detensioning, local cable-span dynamics and slack to taut transitions.

Operational assessment adds system-level requirements. In orbit, thermal gradients and transient disturbances associated with attitude manoeuvres, deployment events and platform vibrations modify the pretension field and may detension members. Slack locally removes stiffness, alters the modal spectrum, degrades the reflecting surface shape and increases the time needed to recover the operational configuration. Previous reflector studies have addressed form-finding and modal analysis through dedicated dynamic models [15], and recent work has shown that internal cable-member displacements can affect vibration predictions in large reflector networks [16]. Scaling analyses further confirm that mesh-reflector dynamics are tied to geometry, mass distribution and structural layout [17].

Numerical simulation is essential, but the modelling environment must support repeated and reproducible analyses. General-purpose finite element frameworks provide truss, link or cable elements for prestressed structures, and commercial solvers offer cable formulations suitable for numerical comparison [18,19,20]. However, reflector studies often rely on models tailored to one architecture or analysis objective [15,16]. Such models are effective for isolated calculations, but less suited to thermal and load campaigns where the same structure must be generated, solved and post-processed many times while tracking slack, modal changes and operational indicators.

A further difficulty is modal interpretation. Prestressed cable nets contain a few global network modes and many closely spaced local cable modes. Eigenvalue analysis orders all modes by frequency, but does not indicate which modes are excited by a given operational load or which subset is suitable for coupled spacecraft descriptions [21]. Operational deflection shapes (ODSs) extracted from transient frequency-response data describe the actual response pattern, including phase. Their comparison with eigenvectors through the Modal Assurance Criterion (MAC) distinguishes dynamically relevant network modes from local cable-dominated modes [22].

Beyond a single validated model, dense thermal and dynamic campaigns are computationally expensive, which motivates data-driven surrogates that map operating parameters directly to operational indicators such as the onset of dynamic slack. Machine-learning models have recently been applied to deployable reflector antennas and cable-net structures, for example to predict and adjust the reflecting-surface accuracy of cable-net and mesh reflectors [23,24] and to forecast the dynamic behaviour of deployable space mechanisms by combining physics-based and data-driven models [25]. Compact neural networks can therefore provide fast approximations that are retained alongside the high-fidelity model for verification near the operational limits.

This work addresses these issues through an automated OpenSees-based framework for a prescribed prestressed LDR design. A new cable finite element is implemented directly in the solver to represent, at element level, pretension, thermal effects, tension-only response, geometric stiffness, mass modelling and distributed cable dynamics. The formulation is verified through analytical benchmarks and numerical comparisons, and the workflow is used to assess the dynamic sensitivity of the design to thermal and transient operating conditions.

2 CABLE ELEMENT FORMULATION

2.1 Modelling requirements

The cable-net model can be built through different levels of description, depending on which physical effects are represented directly at element level. The starting point is a more conventional approach adopting corotational truss with initial stress, which provides a useful OpenSees baseline for a prestressed configuration but does not treat temperature and slack as native cable-state variables. A two-node prestressed cable element adds assigned pretension, runtime thermoelasticity, tension-only response, geometric stiffness and cable mass within the element formulation. The modal cable element further enriches this description by adding internal transverse coordinates, so that local cable-span dynamics is represented without subdividing each cable into several physical elements. Tab. 1 summarises the modelling routes considered in this work, distinguishing what was already available, what was added, and how each model is used in the validation path. The assigned pretension is denoted by P_0, the cable area by A, Young's modulus by E, the density by ρ, and the thermal-expansion coef-

ficient by α. The uniform temperature change is $\Delta T = T - T_{\text{ref}}$, where T_{ref} is the reference temperature of the prestressed state. The number of internal transverse modes retained per local direction is denoted by N. The objective of the proposed formulation is therefore to combine assigned pretension, runtime thermoelasticity, unilateral tension-only response, smooth slack-to-taut transition, geometric stiffness and distributed dynamic mass in one tangent-consistent finite element.

2.2 Two-node thermo-mechanical kinematics

The reference end positions are $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$, while $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ are the current positions (Fig. 2). The nodal displacements are $\boldsymbol{u}_i = \boldsymbol{x}_i - \boldsymbol{X}_i$, with $i = 1, 2$. The reference and current chord lengths, L_0 and L_n respectively, and the chord direction unit vector $\boldsymbol{n}$ are

$$L_0 = \|\boldsymbol{X}_2 - \boldsymbol{X}_1\|, \quad L_n = \|\boldsymbol{x}_2 - \boldsymbol{x}_1\|, \quad \boldsymbol{n} = \frac{\boldsymbol{x}_2 - \boldsymbol{x}_1}{L_n}. \tag{1}$$

Pretension is assigned as initial strain $\varepsilon_0 = P_0/(EA)$. The mechanical strain used by the two-node element is

Table 1: Cable descriptions considered in the formulation and validation. The table separates the modelling route, the capability available within one cable member, and the role assigned to each model in the paper.

Description	Element-level capability	Role in this work
Corotational truss with initial stress	Initial axial stress imposed through the material state. Temperature is not a native runtime cable parameter and slack is handled indirectly.	Legacy OpenSees baseline for the prestressed configuration at $\Delta T = 0$. Used to check the consistency of the initial modal response.
Two-node prestressed cable	Assigned pretension P_0, temperature update ΔT, tension-only response, geometric stiffness and cable mass are element quantities.	Intermediate formulation used to isolate the effect of native pretension, runtime thermoelasticity and smooth slack treatment.
Modal cable element	Same thermo-mechanical state as the two-node cable, plus internal amplitudes a_k and b_k describing transverse span motion.	Main formulation used in the cable-net campaigns to include local cable dynamics without refining each member.
CABLE280 reference	Independent commercial cable formulation evaluated through the adopted ANSYS linear-perturbation setup.	External numerical reference for modal frequencies, mode-shape correlation and interpretation of residual modelling differences.

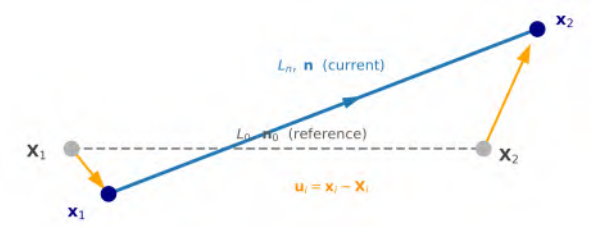

Figure 2: Two-node corotational cable kinematics. Reference and current chord lengths and directions define the geometric stretch used together with assigned pretension and runtime thermal strain.

$$\varepsilon_{\text{m}} = \frac{L_n - L_0}{L_0} + \varepsilon_0 - \alpha \Delta T. \tag{2}$$

In the taut branch the axial force is $P = EA\varepsilon_{\text{m}}$. The linearised tangent contains an axial contribution and the geometric stiffness associated with the current tension is

$$\boldsymbol{K}_{\text{T}} = \boldsymbol{K}_{\text{A}} + \boldsymbol{K}_{\text{G}}, \qquad \boldsymbol{K}_{\text{G}} \propto \frac{P}{L_n}\left(\boldsymbol{I} - \boldsymbol{n} \otimes \boldsymbol{n}\right). \tag{3}$$

The geometric term is the source of lateral stiffness in a pretensioned cable and vanishes when the member detensions. If $L_n = L_0$, the temperature increment that balances the assigned pretension is

$$\Delta T_{\text{crit}} = \frac{\varepsilon_0}{\alpha} = \frac{P_0}{EA\alpha}. \tag{4}$$

2.3 Internal modal enrichment and slack law

The two-node formulation does not represent transverse motion between fixed end nodes. Let $s \in [0, L_0]$ be the material coordinate along the reference chord and let $\boldsymbol{e}_2, \boldsymbol{e}_3$ be the two local transverse directions of the corotational frame. The enriched element approximates the current centreline as

$$\boldsymbol{p}(s) = \boldsymbol{x}_1 + \frac{s}{L_0}(\boldsymbol{x}_2 - \boldsymbol{x}_1) + w_2(s)\boldsymbol{e}_2 + w_3(s)\boldsymbol{e}_3, \tag{5}$$

with

$$w_2(s) = \sum_{k=1}^{N} a_k \sin\frac{k\pi s}{L_0}, \qquad w_3(s) = \sum_{k=1}^{N} b_k \sin\frac{k\pi s}{L_0}. \tag{6}$$

The amplitudes a_k and b_k are internal generalised coordinates associated with the two transverse polarisations (Fig. 3). The sine basis vanishes at the end nodes, so that physical connectivity remains two-node. The generalised state is $\boldsymbol{q} = [\boldsymbol{x}_1^{\mathsf{T}}, \boldsymbol{x}_2^{\mathsf{T}}, \boldsymbol{a}^{\mathsf{T}}, \boldsymbol{b}^{\mathsf{T}}]^{\mathsf{T}}$, with $\boldsymbol{a} = (a_1, \ldots, a_N)$ and $\boldsymbol{b} = (b_1, \ldots, b_N)$. The internal variables add the uniform stretching generated by transverse motion,

$$\varepsilon(\boldsymbol{q}) = \frac{L_n - L_0}{L_0} + \varepsilon_0 - \alpha\Delta T + \frac{\pi^2}{4L_0^2}\sum_{k=1}^{N} k^2(a_k^2 + b_k^2). \tag{7}$$

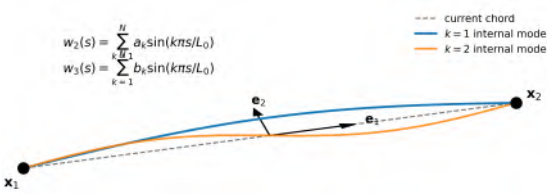

Figure 3: Internal modal enrichment of the cable span. The physical end nodes define the moving chord, while the internal modal amplitudes represent distributed cable motion in the two transverse polarisations.

A smooth unilateral law is used to avoid compression and tangent discontinuities at zero tension, i.e.

$$P(\varepsilon) = \frac{EA}{\beta} \log\left[1 + \exp(\beta\varepsilon)\right], \qquad \frac{\mathrm{d}P}{\mathrm{d}\varepsilon} = EA\, S(\beta\varepsilon), \tag{8}$$

where β is the softplus sharpness and $S(z) = 1/(1 + e^{-z})$ is the logistic function. In the taut regime Eq. 8 tends to the linear elastic law. In slack it keeps the axial force non-negative and preserves a continuous tangent.

2.4 OpenSees implementation

The formulation is implemented in the OpenSees source code as a native finite element. A new C++ element class was added through corresponding header and source files, registered in the element API and exposed to Tcl input files. The implementation is developed in a mixed C++, Tcl and Python workflow: the compiled solver evaluates the element residual, tangent stiffness, mass matrix and response queries, while Python generates the parametric Tcl decks used for the LDR campaigns. The user-level command is

```
element ModalCable3D eleTag iNode jNode A P0
  -modes N -E E -rho rho -alpha alpha
  -Tref Tref -beta beta [-etaSlack eta]
  [-lumped] [-condensed]
```

Here ρ is the material density and N is the number of modes per transverse direction. Setting $N = 0$ recovers the two-node prestressed cable. The optional flags `-etaSlack`, `-lumped` and `-condensed` set, respectively, the smoothing parameter of the unilateral law, a lumped instead of consistent mass matrix, and the static condensation of the internal amplitudes; they are kept at their default settings in the present campaigns. Preliminary checks verified parsing, pretension initialisation, temperature updates, tangent-force consistency, mass assembly and response extraction.

3 VALIDATION STRATEGY AND COMPARISONS

The validation path combines analytical checks, application-scale case studies and external numerical comparisons. The isolated cable span checks elementary cable physics. The complete cable net checks whether the same modelling ingredients remain relevant at reflector scale. The external comparisons separate the benefit over a conventional OpenSees truss baseline from consistency with a commercial cable-element model.

3.1 Isolated-cable comparison

A straight taut cable is analysed using five approaches: the analytical string solution; `ModalCable3D`, `PrestressedCable`, and `corotTruss` with initial stress in OpenSees, and `CABLE280` in ANSYS software. The cable properties were $L_0 = 0.28$ m, $P_0 = 12.6$ N, $A = 5.026548 \times 10^{-7}$ m^2, $E = 72$ GPa, and $\rho = 2200$ kg m^{-3}. Both ends are fixed, gravity and thermal loading are neglected, and consistent mass is used in all numerical models.

The analytical transverse frequencies are

$$f_n = \frac{n}{2L_0}\sqrt{\frac{P_0}{\rho A}}, \qquad n = 1, 2, \ldots \tag{9}$$

A single `ModalCable3D` element with three internal modes per transverse polarisation reproduces the first three analytical frequencies to machine precision. Its internal sine basis represents the distributed cable modes without intermediate physical nodes.

The `PrestressedCable` and `corotTruss` models are discretised with $N = 2, 4, 8, 16, 32,$ and 64 straight elements. Pretension is assigned directly in `PrestressedCable` and through `InitStressMaterial`, with $\sigma_0 = P_0/A$, in `corotTruss`. The two formulations produce identical frequencies at every mesh level, confirming their equivalence in the straight, isothermal, fully taut limit.

Tab. 2 reports the first three transverse frequencies and the corresponding relative errors with respect to the analytical solution. At a fixed discretisation, the error of the straight two-node elements grows with the order of the mode. With 16 elements, the maximum error over the first three modes is 1.451%; with 64 elements, it decreases to 0.090%. `CABLE280` reaches a maximum error of 0.008% with 16 elements, whereas `ModalCable3D` reproduces the same spectrum with one physical element.

All finite-element approaches provide mode shapes. `PrestressedCable` and `corotTruss` return eigen-

Table 2: First three transverse frequencies and relative errors for the representative taut cable.

Approach	Discretisation	f_1	f_2	f_3	e_1	e_2	e_3
		[Hz]			[%]		
Analytical string	continuum	190.6123	381.2246	571.8370	-	-	-
`ModalCable3D`	1 element, 3 modes	190.6123	381.2246	571.8370	0.0000	0.0000	0.0000
`PrestressedCable`	64 elements	190.6315	381.3778	572.3538	0.0100	0.0402	0.0904
`corotTruss`	64 elements	190.6315	381.3778	572.3538	0.0100	0.0402	0.0904
ANSYS `CABLE280`	16 elements	190.6134	381.2327	571.8827	0.0006	0.0021	0.0080

vectors at the physical mesh nodes, with the span-wise field reconstructed by interpolation. `CABLE280` uses quadratic interpolation, while `ModalCable3D` directly returns the amplitudes of the internal sinusoidal modes.

3.2 Complete cable-net application and numerical validation

The second case study applies the formulation to the complete prestressed cable net (Fig. 4), where global nodal motion and local cable-span dynamics coexist within the same frequency range. The model therefore provides a representative benchmark for both the conventional two-node formulation and the enriched modal cable element.

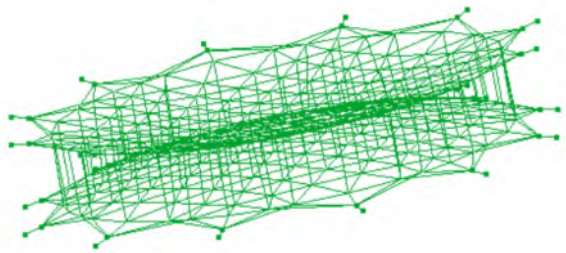

Figure 4: Reference NET-only model used in the modal and transient campaigns, including the prestressed front net, anchor nodes and internal cable coordinates of the enriched formulation.

Three complementary comparisons are performed at the reference thermal state, $\Delta T = 0$, and are summarised in Tab. 3. First, the two-node prestressed cable element is compared with the conventional OpenSees model based on corotational trusses and an initial-stress material. The close modal agreement confirms that both formulations reproduce the same prestressed equilibrium. In the conventional model, however, pretension is embedded in the material state, whereas the native cable element directly updates temperature and axial force during the thermoelastic campaign.

The effect of the internal cable coordinates is then assessed on the NET-only model. Their activation reduces the first twenty frequencies by an almost uniform 9.3%, showing that span-wise inertia and deformation remain relevant at network scale. The enriched model also separates a limited number of global net modes from dense clusters dominated by local cable motion.

Table 3: Numerical comparisons for the complete cable-net application at $\Delta T = 0$.

Comparison	Numerical evidence	Main conclusion
Corotational truss with initial stress versus two-node prestressed cable, ring plus net	Maximum relative frequency difference of 1.3% over the first six modes; 3.4% RMS over the first 35 modes.	Both formulations reproduce the same reference prestressed state; the native element additionally permits runtime thermoelastic updates.
Two-node versus enriched modal cable, NET-only	Almost uniform 9.3% reduction over the first twenty frequencies.	Local span-wise deformation and inertia remain relevant in the complete-network response.
Enriched modal cable versus CABLE280, NET-only	MAC $= 0.9992$ and 0.9993 for modes 1 and 2; ANSYS frequencies approximately 4.4% higher, comprising 1.59% from mass modelling, 2.74% from realised pretension and about 0.07% residual.	The mode shapes coincide and the frequency difference is attributable to modelling assumptions rather than solver disagreement.

Finally, the enriched OpenSees model is compared with an independent ANSYS model using CABLE280 elements and linear-perturbation modal analysis about the prestressed state. The first two mode shapes give MAC values of 0.9992 and 0.9993. The approximately 4.4% higher ANSYS frequencies are explained by the different mass formulation and by the realised front-net pretension. Once these effects are accounted for, the residual discrepancy is approximately 0.07%.

4 AUTOMATED ANALYSIS PIPELINE

The analyses are managed through a Python-controlled OpenSees pipeline. For each parameter combination, Python generates the Tcl model and the required analysis block, launches the locally compiled OpenSees interpreter, and parses the re-

sulting outputs. Input parameters, execution time, timeout status and convergence flags are stored for every run, while the physical quantities recorded depend on the specific campaign.

Three complementary campaigns are considered. The modal thermal campaign, denoted phase M, evaluates 56 temperature offsets between $-180\,^{\circ}$C and $+45\,^{\circ}$C. At each temperature, the prestressed net is re-equilibrated and the static slack count, minimum and maximum cable tensions, and first twenty eigenfrequencies are extracted.

The transient slack-threshold campaign, denoted phase T, samples the $(\Delta T, F_0)$ plane. After thermal re-equilibration, a half-sine impulse with peak amplitude F_0 and duration $T_P = 8$ ms is applied. The stored outputs include the static and transient convergence states, the possible failure step, the initial slack count and the maximum number $N_{\text{slack,max}}$ of simultaneously slack cables. Since the modal state is established before the impulse, the corresponding eigenfrequencies are taken from phase M rather than recomputed for each value of F_0.

A third high-resolution transient campaign, denoted phase H, is performed only at selected operating conditions. A 25 s observation window gives the frequency resolution $\Delta f = 0.04$ Hz. The input force and selected nodal displacement histories are recorded, from which fast Fourier transform (FFT) spectra are computed. Operational deflection shapes and MAC values are evaluated only for the selected all-node datasets. Transient analyses use the average-acceleration Newmark method with $\gamma = 0.5$ and $\beta_N = 0.25$, where γ weights the acceleration contribution in the velocity update and β_N its contribution in the displacement update. This choice was retained after preliminary Hilber–Hughes–Taylor (HHT) analyses showed greater sensitivity near simultaneous taut–slack transitions. Campaign points are executed sequentially because the analyses are memory-bound and unsuccessful runs must be retained in the response map. Non-converged or timed-out cases are stored with their numerical status and are not automatically interpreted as physical slack states. The resulting structured database supports modal interpretation, operational-limit identification and surrogate modelling.

5 MODAL AND OPERATIONAL IDENTIFICATION OF THE CABLE NET

5.1 NET-only model and thermally evolving prestress

The application study focuses on the overall prestressed cable net. The model contains 955 cable members and 302 physical nodes, of which 24 are fixed at the interface with the perimeter structure. Cable properties are uniform: Young's modulus $E = 72$ GPa, area $A = 5.0265 \times 10^{-7}$ m^2, density $\rho = 2200$ kg m^{-3}, and thermal expansion coefficient $\alpha = 10^{-5}\,^{\circ}$C^{-1}. The form-found cable tensions range from approximately 1 N to almost 200 N. This spread of more than two orders of magnitude leads to a global dynamic behaviour not governed only by an average prestress level: the least tensioned members determine the first local cable frequencies and control the approach to slack. The temperature offsets considered below are applied uniformly with respect to the reference temperature. For each thermal state, the net is first re-equilibrated and the tangent stiffness is then evaluated about the resulting prestressed configuration. The corresponding eigenvalue problem therefore provides a linearised modal description of a thermally updated equilibrium state.

5.2 Thermal modal map and slack-sensitive spectrum

The first campaign sweeps 56 uniform temperature offsets and extracts twenty eigenvalues at each re-equilibrated state. In the fully taut regime, the first global frequency decreases monotonically as thermal expansion reduces the cable pretension. Over the investigated interval, the first global frequency decreases from approximately 58 Hz in the cold state to approximately 25 Hz near the warm edge of the taut domain. Fig. 5(a) shows that this evolution remains smooth only while every cable carries a positive tensile force. The transition is abrupt: when the first members detension, near-zero local mechanisms enter the lower part of the spectrum and the lowest computed eigenfrequency collapses. Consequently, the first frequency ceases to be a meaningful indicator of the global network stiffness as soon as the first slack member appears. The minimum cable tension in Fig. 5(b) is a more reliable precursor because it identifies the member that first approaches the unilateral boundary.

Slack is also load-dependent. A second campaign maps the $(\Delta T, F_0)$ plane by applying half-sine impulses and monitoring the maximum number of simultaneously slack cables during each transient. The admissible impulse decreases as the network warms: a disturbance that leaves the cold network fully taut may cause several members to unload when applied close to the warm thermal margin. The thermal state therefore controls not only the linearised modal frequencies but also the available manoeuvre margin.

The modal map and the slack count must conse-

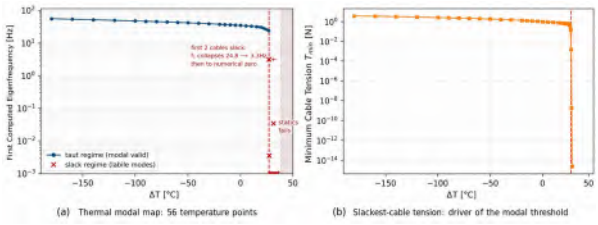

Figure 5: Thermal evolution of the cable-net modal response versus temperature offset. (a) Thermal modal map, showing modal softening along the taut branch and the collapse at cable detensioning. (b) Minimum cable tension, the indicator of the approaching slack transition.

quently be interpreted together. Frequency softening describes the evolution of the tangent dynamics while the net remains taut, whereas the slack count identifies the onset of a different response regime in which the set of active tensile members may change during the motion. Beyond this boundary, a single frequency extracted from the initial tangent system is insufficient to characterise the complete transient response.

5.3 Network modes, cable modes and the slackest-cable threshold

The eigenvectors split into two physically different populations. Global network modes involve appreciable motion of the physical nodes, while the cable spans translate approximately with their end chords. Local cable modes instead leave the physical nodes almost stationary and are dominated by the internal transverse deformation of one or more spans. The resulting spectrum is therefore not a sequence of global reflector modes, but a combination of a small number of network modes and a dense forest of local cable modes. The lower boundary of this forest can be estimated directly from taut-string theory. The first transverse frequency associated with cable e is

$$f_{\mathrm{c},e} = \frac{1}{2L_{0,e}}\sqrt{\frac{P_e}{\rho A}}, \tag{10}$$

and the lowest local-cable frequency in the complete net is therefore

$$f_{\mathrm{c,min}} = \min_{e}\left[\frac{1}{2L_{0,e}}\sqrt{\frac{P_e}{\rho A}}\right], \tag{11}$$

where $L_{0,e}$ and P_e are the reference length and current tension of element e. Since the minimum is generally attained by one of the least tensioned members, Eq. 11 provides a direct connection between the local tension state and the architecture of the global spectrum.

Below $f_{\mathrm{c,min}}$, there is not a first cable that interacts with a network mode, which can therefore remain spectrally isolated. Above this threshold, network modes enter the dense cable-mode population and may hybridise with local span vibrations.

As shown in Fig. 6, the prediction agrees closely with the observed onset of the cable-mode clusters. The predicted and computed thresholds are, respectively, 77.83 and 77.70 Hz in the cold state (Fig. 6(a)), 39.06 and 39.03 Hz at the reference temperature (Fig. 6(b)), and 25.35 and 25.34 Hz close to the warm margin (Fig. 6(c)). The corresponding errors remain below 0.2%. At the same time, the number of spectrally separable network modes decreases from three in the cold state to two at the reference temperature and finally to zero near the warm limit.

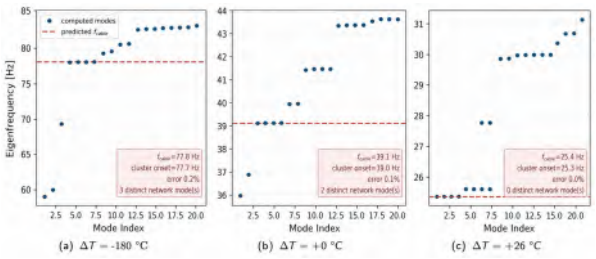

Figure 6: Computed spectra compared with the threshold set by the slackest cable. (a) Cold, $\Delta T = -180\,^{\circ}$C, with three isolated network modes; (b) reference, $\Delta T = 0\,^{\circ}$C, with two; (c) warm, $\Delta T = +26\,^{\circ}$C, with none.

Eq. 11 should be interpreted as a conservative spectral threshold rather than as proof that every mode above it is strongly hybridised. It indicates where interaction with cable modes becomes possible. Whether a particular global mode remains dynamically identifiable must subsequently be assessed from its nodal participation and from the operational response.

5.4 Effective-mass classification

To distinguish global network modes from local cable modes, the first forty eigenvectors of the NET-only model are classified through their effective mass at the reference thermal state, $\Delta T = 0$, after equilibration of the prescribed prestress. For mode i and rigid-body direction d,

$$M_{i,d}^{\mathrm{eff}} = \frac{\left(\boldsymbol{\phi}_i^{\mathsf{T}}\boldsymbol{M}\boldsymbol{r}_d\right)^2}{\boldsymbol{\phi}_i^{\mathsf{T}}\boldsymbol{M}\boldsymbol{\phi}_i}, \tag{12}$$

where $\boldsymbol{\phi}_i$ is the eigenvector, $\boldsymbol{M}$ is the mass matrix and $\boldsymbol{r}_d$ is the dragging vector associated with one of the three global translations or three global rotations. The reported percentages are normalised with

respect to the corresponding total mass or rotational inertia.

As shown in Fig. 7(a), only modes 1 and 2, at approximately 35.71 and 36.64 Hz, exceed the adopted 10% significance threshold. Their translational participation remains below 0.5%, whereas the rotational participation reaches approximately 70.5% about the x-axis for mode 1 and 82.0% about the y-axis for mode 2. Fig. 7(b) shows that the remaining thirty-eight modes have maximum participation below approximately 0.51%, consistently with their classification as local cable modes.

The antisymmetric deformation of modes 1 and 2 produces limited net translation but significant rotational participation. Since the present model contains only the cable net, these values do not represent interface loads transmitted to the spacecraft; they indicate only that these two modes have the greatest potential to couple with rotational motion of the supporting structure.

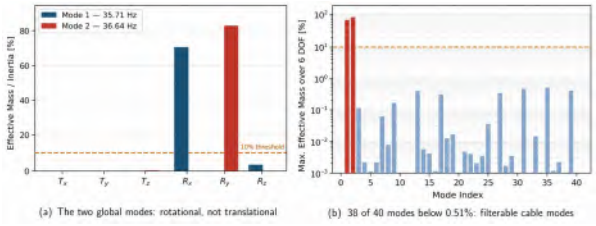

Figure 7: Effective-mass classification of the first forty modes of the NET-only model at $\Delta T = 0$. (a) Modes 1 and 2 across the six rigid-body directions, dominated by rotation. (b) Maximum participation of all forty modes, with only modes 1 and 2 above the significance threshold.

5.5 Transient spectra and operational-shape extraction

Modal analysis identifies the possible vibration patterns of the tangent system, but it does not determine which of them are actually reached by a prescribed disturbance. This distinction becomes essential when many of the lowest-frequency eigenvectors are internal cable modes with negligible displacement at the physical nodes.

A half-sine impulse is applied at one node in the direction normal to the net. Its time history is

$$F(t) = \begin{cases} F_0 \sin\left(\dfrac{\pi t}{T_P}\right), & 0 \le t \le T_P, \\ 0, & t > T_P, \end{cases} \qquad T_P = 8\,\text{ms}. \tag{13}$$

For the all-node identification runs, the response is computed for 5 s with a time step of 10^{-4} s. The

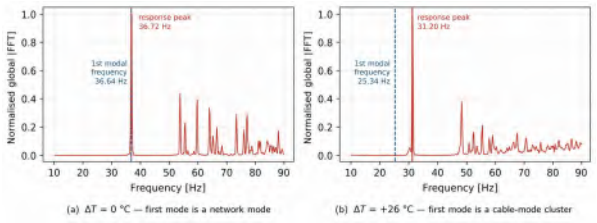

Figure 8: Global FFTs of the all-node impulse responses. (a) Reference, $\Delta T = 0\,^\circ$C, where the dominant peak is a global network mode. (b) Warm, $\Delta T = +26\,^\circ$C, where the dominant peak lies above the cable-mode cluster.

displacement histories of all 302 physical nodes are recorded and subsequently decimated to a sampling frequency of 2 kHz. The reference-state analysis uses $F_0 = 20$ N, whereas the warm-state analysis uses $F_0 = 10$ N to reduce the probability of inducing slack–taut commutations in a configuration already close to detensioning.

For displacement channel j, the discrete Fourier transform is denoted by

$$\widehat{u}_j(f_k) = \sum_{n=0}^{N-1} u_j(t_n) \exp\left(-\mathrm{i}2\pi f_k t_n\right). \tag{14}$$

At a selected response frequency $f^\star$, the complex operational deflection shape is assembled directly from the channel amplitudes and phases,

$$\phi_{\mathrm{ODS}}(f^\star) = \left[\widehat{u}_1(f^\star) \quad \widehat{u}_2(f^\star) \quad \cdots \quad \widehat{u}_{n_{\mathrm{ch}}}(f^\star)\right]^{\mathsf{T}}. \tag{15}$$

The correspondence between the operational shape and eigenmode i is evaluated through the complex modal assurance criterion,

$$\mathrm{MAC}_i(f^\star) = \frac{\left|\phi_{\mathrm{ODS}}^{\mathsf{H}}(f^\star)\phi_i\right|^2}{\left[\phi_{\mathrm{ODS}}^{\mathsf{H}}(f^\star)\phi_{\mathrm{ODS}}(f^\star)\right]\left[\phi_i^{\mathsf{H}}\phi_i\right]}, \tag{16}$$

where the superscript $(\cdot)^{\mathsf{H}}$ denotes the Hermitian transpose. A value close to unity indicates that the measured operational response is approximately proportional to one eigenvector and can therefore be interpreted through a single-mode linear description.

Fig. 8(a) and (b) compare the normalised global spectra obtained at the reference temperature and close to the warm slack margin, respectively. The two spectra illustrate why the lowest eigenfrequency and the dominant operational frequency are not necessarily the same quantity.

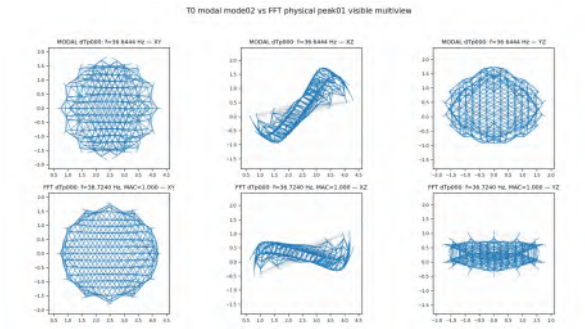

Figure 9: Operational-shape identification at the reference thermal state. The isolated FFT peak at 36.72 Hz produces an ODS that coincides with eigenmode 2 at 36.644 Hz, with complex MAC equal to 0.99997.

5.6 Reference thermal state

At the reference temperature, Fig. 8(a) shows an isolated response peak at 36.72 Hz, approximately 10–17 dB above the surrounding spectral content. The corresponding ODS has a MAC of 0.99997 with eigenmode 2 at 36.644 Hz. The internal-to-nodal motion ratio, defined as the ratio between the Euclidean norm of the internal modal amplitudes and that of the physical nodal displacements of the mode, is approximately 0.16, confirming that the responding shape is a global network mode rather than a local cable mode.

The operational and modal shapes are compared in Fig. 9. Their near-perfect agreement confirms that the response is dominated by one isolated mode and that a linear, time-invariant modal interpretation is accurate at this frequency.

The complex phase also provides information that is absent from a plot of displacement magnitude alone. At the response peak, 168 physical nodes move in one direction while 134 move in antiphase. The transition between the two groups identifies the nodal lines directly from the simulated transient response, rather than imposing them from the eigenvector.

5.7 Operational response near the warm slack margin

Near the warm margin, the modal spectrum changes qualitatively. The first eigenfrequencies form a dense cluster close to 25.34 Hz. These modes have internal-to-nodal motion ratios of approximately 8 and are therefore dominated by transverse cable-span motion. Since a nodal force performs work through physical-node displacement, it cannot efficiently excite modes whose end nodes remain nearly stationary.

Accordingly, Fig. 8(b) does not show its dominant response at the first eigenfrequency. The main operational peak occurs at 31.2 Hz, approximately 5.9 Hz above the lower cable-mode cluster. The ODS extracted at this frequency has a MAC of 0.9999 with mode 20 at approximately 31.16 Hz and negligible correlation with the modes of the 25.34 Hz cluster.

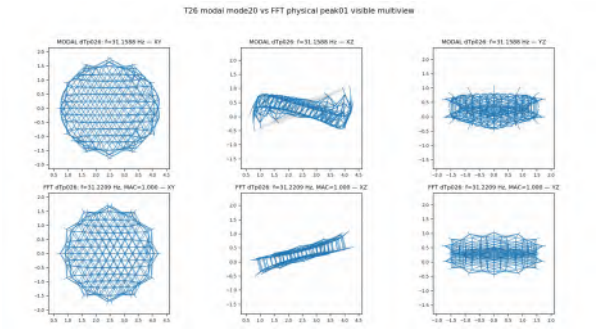

Figure 10: Operational-shape identification near the warm slack margin. The lowest eigenmodes are dominated by internal cable motion, whereas the ODS at the dominant nodal-response peak identifies mode 20 at approximately 31.16 Hz with MAC equal to 0.9999.

Table 4: Operational identification from the all-node transient response.

Thermal state	Spectral response	ODS–mode correspondence
Reference state	Isolated peak at 36.72 Hz	Mode 2 at 36.644 Hz, with MAC $= 0.99997$. The nodal impulse excites a clean global network mode.
Warm margin	Cable-mode cluster near 25.34 Hz; dominant nodal peak at 31.2 Hz	Mode 20 at 31.16 Hz, with MAC $= 0.9999$. The lowest modes are local cable modes, whereas the ODS identifies the higher mode reached by the nodal load.

Fig. 10 confirms that the nodal impulse selects a higher-frequency mode that retains appreciable motion of the physical network. The result demonstrates that frequency ordering alone is insufficient: the first eigenmode is not necessarily the first mode observable or excitable through the spacecraft–net interface.

Tab. 4 summarises the operational identification at the two thermal states.

5.8 Validity of the linear modal interpretation near slack

The eigenvalue analyses are linearisations about thermally re-equilibrated configurations, whereas the transient simulations retain the tension-only

constitutive response and can therefore capture changes in the set of taut members. An FFT–ODS interpretation remains valid only while the motion stays close to one equilibrium state and the response near the selected frequency is dominated by a single eigenvector.

At the reference temperature, the isolated spectral peak and the nearly unit MAC confirm this condition. Near the warm margin, however, the cable-mode forest enters the frequency range of the global modes, the lowest eigenvalues become increasingly dominated by local cable motion, and small changes in temperature or displacement may produce taut–slack commutations and a time-dependent tangent stiffness.

The 5.9 Hz difference between the first eigenfrequency and the dominant warm-state response peak should therefore not be interpreted as a nonlinear resonance shift. In the analysed case, it is primarily an observability effect: the lowest modes are dominated by internal cable motion and are weakly excited by the nodal impulse, whereas mode 20 has sufficient nodal participation. Its MAC of 0.9999 shows that the response at 31.2 Hz is still well represented by a single eigenvector.

The slackest-cable threshold in Eq. 11 and the operational MAC provide complementary information. The former indicates where interaction with local cable modes becomes possible, whereas the latter verifies whether the observed response remains effectively separable. A decreasing MAC, broadband or harmonic content, force-dependent peak shifts, or an increasing slack count would instead indicate departure from the linear time-invariant regime. The combined FFT–ODS–MAC procedure therefore identifies the dynamically active mode rather than simply selecting the lowest eigenvalue, which near the slack boundary may correspond to a local cable mode with negligible nodal observability.

6 SURROGATE MODELLING FOR FAST EVALUATION

The structured database generated by the automated OpenSees campaigns was used to train a compact feed-forward neural-network (FFNN) classifier [25] for the rapid identification of dynamic slack onset,

$$\widehat{p}_{\text{slack}} = \mathcal{N}_{\text{s}}\left(\widetilde{\Delta T}, \widetilde{F}_0\right), \qquad s = \mathbb{I}\left(N_{\text{slack,max}} > 0\right), \tag{17}$$

where $\mathcal{N}_{\text{s}}$ denotes the trained classifier and $\widetilde{\Delta T}$ and $\widetilde{F}_0$ are the standardised temperature offset and impulse amplitude. The binary target is $s = 1$ when at least one cable becomes slack during the transient and $s = 0$ otherwise, with $N_{\text{slack,max}}$ denoting the maximum number of simultaneously slack cables. The sigmoid output $\widehat{p}_{\text{slack}} \in [0, 1]$ is used as a continuous classification score: values close to zero and one indicate conditions classified as no-slack and slack, respectively, whereas the $\widehat{p}_{\text{slack}} = 0.5$ contour defines the estimated decision boundary.

Only simulations for which both the static and transient analyses completed were assigned a physical label. This retained 154 of the 345 phase-T cases, comprising 127 no-slack and 27 slack samples. Static failures and timed-out analyses were retained in the campaign database but excluded from supervised training.

Each classifier contains two hidden layers with 16 neurons and hyperbolic-tangent activations, followed by a sigmoid output. The networks were trained using the limited-memory BFGS algorithm and balanced sample weights. To reduce sensitivity to the random initialisation, 20 classifiers with the same architecture were trained independently and their sigmoid outputs were averaged to obtain the final prediction shown in Fig. 11.

Validation was performed by leaving one complete temperature level out of the training set at each iteration. The resulting out-of-fold predictions achieved a balanced accuracy of 0.900, an F_1 score of 0.863, and an area under the receiver-operating-characteristic curve of 0.951. A further numerical challenge was performed on 25 longer phase-H transients whose exact $(\Delta T, F_0)$ pairs were not included in the training set, giving an accuracy and an F_1 score of 0.960.

The classifier does not remove the cost of generating the original high-fidelity database. Its purpose is to convert the completed simulations into a continuous approximation of the operational taut–slack boundary, allowing interpolation between the sampled conditions and identifying regions in which additional OpenSees analyses are required.

The computational advantage was assessed using the hardware and numerical settings adopted for the present campaigns. Under these conditions, a completed OpenSees transient required a median wall time of approximately 133 s, whereas batched evaluation of the 20-network ensemble required approximately 10 μs per state. These values are specific to the adopted model, solver settings and computational platform, and exclude model-loading and file-management overhead. They nevertheless show the substantial reduction in evaluation cost obtained once the classifier has been trained. Predictions close to the $\widehat{p}_{\text{slack}} = 0.5$ boundary, within sparsely

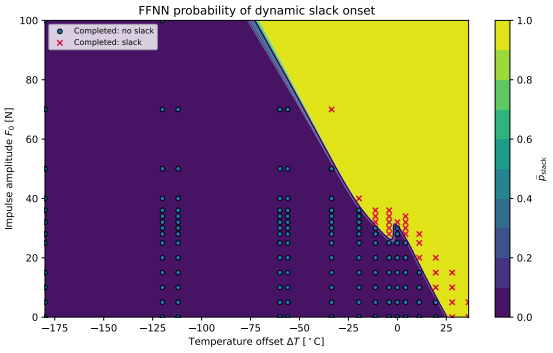

Figure 11: Ensemble-averaged FFNN classification score in the temperature–impulse plane. Symbols denote completed OpenSees simulations, while the $\widehat{p}_{\text{slack}} = 0.5$ contour approximates the predicted taut–slack boundary.

sampled regions, or outside the training domain are returned to the high-fidelity OpenSees model for verification.

7 CONCLUSIONS

This work presented an automated OpenSees-based framework for the dynamic analysis of pre-stressed cable-net reflector antennas. The proposed workflow combines automated model generation with a newly developed cable finite element that directly incorporates pretension, thermoelastic effects, tension-only behaviour, smooth slack–taut transition, geometric stiffness and distributed cable dynamics within a single formulation. The proposed element was successfully validated against analytical cable solutions and commercial finite element models, demonstrating excellent agreement while enabling thermo-mechanical analyses that are difficult to perform with conventional formulations. The enriched element also captures internal cable-span dynamics without requiring mesh refinement, providing an efficient representation of large reflector cable networks. The automated thermal and transient analyses reveal several important physical findings. The key outcomes can be summarized as follows:

- increasing temperature progressively reduces cable pretension, softens the global structural response and eventually causes local cable detensioning;
- transient dynamic loads can also induce slack, with the allowable disturbance level decreasing significantly as the structure approaches its thermal limit;
- the modal spectrum consists of only a few global reflector modes embedded within a dense population of local cable modes, making modal identification based solely on eigenvalue ordering unreliable;
- combining effective modal mass, operational deflection shapes (ODS) and MAC provides a robust procedure for identifying the dynamically relevant modes under operational loading.

Finally, the large database generated through the automated simulations enables efficient data-driven modelling. A compact feed-forward neural network accurately predicts the onset of dynamic slack, providing a computationally inexpensive surrogate for rapid operational screening while preserving the high-fidelity finite element model for verification near critical operating conditions. Future work will extend the methodology to the complete reflector assembly, including the supporting ring and interface dynamics, with the long-term objective of supporting digital-twin applications for large deployable space reflectors.

ABSTRACT

Scientific optical payloads for space observation missions operate at extremely low temperatures, typically below 4K and in some cases down to the millikelvin range. Under such conditions, structural supports must fulfil two conflicting requirements: they must provide high mechanical stiffness and dimensional stability while minimizing conductive heat transfer between stages. This makes the design of compact cryogenic supports particularly challenging.

This paper presents the development of compact hybrid supports based on carbon-fibre-reinforced polymer (CFRP) tubes bonded to metallic end-fittings for cryogenic optical systems. A literature review first confirmed the relevance of CFRP for such applications due to its favourable stiffness-to-thermal-conductivity ratio, low thermal expansion in the fibre direction, and strong potential for thermally efficient structural design. Particular attention was paid to the behaviour of bonded multi-material interfaces at low temperature, since thermoelastic compatibility between CFRP, adhesive and metal end-fittings is a key driver for structural integrity.

A material trade-off was then conducted for the development of very small CFRP tubes. Among the candidate prepreg systems, a high-modulus carbon/epoxy prepreg compatible with out-of-autoclave consolidation was selected as the best compromise between process feasibility, low areal weight, high stiffness and expected low thermal conductivity. The selected material was subsequently characterized on flat samples. The experimental results showed high and consistent mechanical performance with limited scatter, together with a porosity level <1%.

In parallel, a preliminary numerical mechanical analysis and a bonded CFRP/metal micro-struts were carried out on representative cryostrut configurations. The numerical work confirmed the structural relevance of the concept while identifying thermoelastic loading as the main design driver. The experimental results further showed that the CFRP/titanium configuration provided the most favourable overall mechanical behaviour under cryogenic conditions. More generally, the bonded concept remained mechanically robust after cryogenic exposure, with performance levels improving relative to ambient-temperature reference tests.

The combined material, numerical and experimental results support the relevance of bonded CFRP/titanium hybrid supports for compact cryogenic optical structures. Thermal conductivity and outgassing characterization of the selected CFRP material are still ongoing and will complete the validation of the concept for future space applications.

1. INTRODUCTION

Future scientific space missions increasingly rely on optical instruments operating at cryogenic temperatures in order to improve detector sensitivity, reduce thermal noise and preserve dimensional stability. In many architectures, optical subsystems are distributed over several thermal stages, ranging from a few kelvin down to sub-kelvin domain. The structural parts connecting these stages must therefore provide both mechanical continuity and thermal isolation.

This dual requirement is especially demanding for compact structural elements integrated within optical payloads. On the one hand, these supports must withstand launch loads and maintain alignment accuracy during operation. On the other hand, they must limit the conductive heat transfer between thermal stages. The trade-off becomes even more challenging when the available volume is limited and the support geometry must remain very small.

Cryogenic optical systems therefore impose a strong coupling between thermal, mechanical and manufacturing constraints. The support architecture cannot be defined from stiffness considerations alone. It must also account for cooldown-induced deformations, thermal mismatch between materials, manufacturability of parts, interface robustness, and compatibility with space environmental constraints. In practice, these constraints often lead to the development of hybrid structural concepts rather than monolithic metallic designs.

Carbon-fibre-reinforced polymer (CFRP) materials are attractive candidates for such applications because they combine high specific stiffness with low thermal conductivity, especially at low temperature. However, when a structural support includes metallic interfaces, the design challenge extends beyond the CFRP tube itself to the behaviour of the bonded multi-material assembly. The thermal expansion mismatch between the composite, the adhesive and the metallic end-fittings may generate significant thermoelastic stresses during cooldown and thermal cycling.

The present work addresses the development of compact hybrid micro-struts composed of CFRP tubes and metallic end-fittings for cryogenic optical systems. These developments are carried out with ATHENA X-IFU as the targeted application, providing a representative framework for the definition and assessment of compact cryogenic support structures. The approach combines literature review, material trade-off, flat-coupon mechanical characterization, numerical structural analysis and bonded assembly testing under cryogenic-relevant conditions. The objective is not only to identify suitable material system, but also to build a coherent design for compact cryogenic supports compatible with future optical payload architectures.

2. FUNCTIONAL REQUIREMENTS AND DESIGN DRIVERS

The targeted application concerns compact structural supports for optical instruments operating below 4K, with some potential use cases extending down to the sub-kelvin range. In such systems, the support elements are required to ensure a stable mechanical link between stages while avoiding excessive thermal conduction from warmer interfaces to colder functional equipment.
The primary functions of these supports are:

- to ensure the mechanical support of the optical stages (high stiffness and strength),
- to provide thermal decoupling between colder and warmer parts of the structure,
- to maintain dimensional stability over severe thermal excursions.

These functions are directly driven by the operating environment. In orbit, the structure is expected to remain stable under cryogenic conditions for long durations. Before operational use, it must also withstand integration constraints, thermal variations and launch-related mechanical loading. Because the same component must respond to all these situations, its design becomes a multi-criteria optimization problem.

The geometry is constrained by the architecture of the instrument. The study focuses on CFRP tubes with small dimensions:

- inner diameter < 10mm
- thickness <1mm
- length around 200mm

Such small geometries are representative of compact cryogenic structural parts intended for highly integrated optical systems. They are attractive from a thermal standpoint because they reduce conductive paths, but they are also more demanding in terms of manufacturing and local interface design.

In addition to the mechanical and thermal requirements, the selected material system must be compatible with space environmental constraints, including vacuum operation, radiation exposure, low porosity and outgassing compliance. For bonded solutions, special attention must also be paid to the durability of the interface and to the behaviour of the adhesive during thermal cycling and cooldown.

3. DESIGN BASIS AND STATE-OF-THE-ART REVIEW

A literature review was first performed to identify the most relevant material families for cryogenic support structures. This review showed that thermal conductivity is a critical driver for the design of supports connecting cryogenic stages. In the cryogenic temperature range relevant to optical payloads, composite materials offer a better stiffness-to-thermal-conductivity ratio than conventional metals.

Aluminium was rapidly excluded as a candidate material for the structural tube itself because of its excessive thermal conductivity at very low temperatures. Titanium remains attractive for interface parts thanks to its lower thermal conductivity and relatively moderate thermal expansion. CFRP was identified as the most promising candidate for the tube because of its very low thermal conductivity at low temperature, its high longitudinal stiffness, and its near-zero coefficient of thermal expansion along the fibre direction [1,4,6,7]. Contrary to popular belief, GFRP is more thermally conductive than CFRP at temperatures below 15K.

The literature also highlighted the importance of fibre orientation and constituent compatibility [1,2]. In composite materials, thermal and mechanical behaviours are highly anisotropic, and the axial direction of a unidirectional carbon reinforcement is particularly favourable when high stiffness and low thermal expansion are required. This makes high-modulus CFRP especially attractive for small structural components for a cryogenic cooling system.

However, the structure under study cannot be reduced to the composite tube alone. The interface with metallic end-fittings is a critical feature of the design. Bonded joints are attractive because they enable compact integration, optimize mass and avoid local mechanical weakening associated with

drilling or bolted joints on very small tubular geometries. At the same time, bonded interfaces remain sensitive to thermal mismatch and adhesive behaviour at low temperature [8].

The review of low-temperature bonded assemblies suggested that properly selected epoxy adhesives may retain satisfactory mechanical behaviour under cryogenic exposure, although stiffness increases and brittleness may become more pronounced [8,11]. In addition, the thermo-mechanical compatibility between CFRP/titanium appears more favourable than between CFRP/aluminium [9,10].

4. MATERIAL SELECTION STRATEGY FOR CFRP MICRO-TUBES

4.1. Process constraints

For small tubular geometries, manufacturing constraints strongly influence the feasible material and process solutions. Standard liquid moulding routes were considered unsuitable because of the difficulty of setting up consumables and ensuring satisfactory impregnation and compaction in such small diameters.
As a result, prepreg technology was selected as the most realistic route. This choice focuses primarily on simplifying the process by manually draping plies around a mandrel using the roll-wrapping technique. This approach ensures optimal compaction, thereby guaranteeing excellent structural integrity and material health of the tubes.

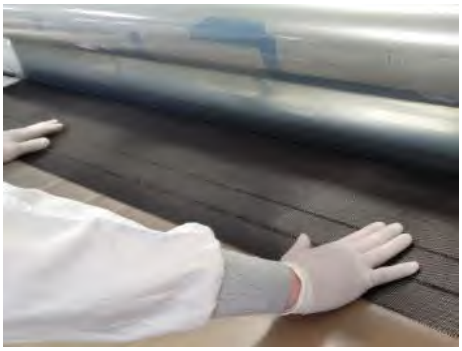

Figure 1: Manual roll-wrapping process

4.2. Trade-off criteria

The targeted prepreg had to satisfy the following criteria:

- high-modulus unidirectional carbon fibres,
- epoxy resin compatible with space applications and high-temperature capability,
- out-of-autoclave consolidation,
- low areal weight,
- compatibility with manual lay-up.

A trade-off was conducted between several candidate prepreg systems. The ranking considered process feasibility, areal weight, technical performance, expected cryogenic thermal behaviour, space qualification potential and recurring cost. This step was essential because material selection could not be driven by stiffness alone. For such compact geometries, processability and robustness of fabrication are equally critical.

Figure 2: Micro-tube CAD design

4.3. Outcome of the trade-off

Among the candidate materials, a high-modulus carbon/epoxy prepreg was selected as the best overall compromise. It combines high stiffness, low areal weight, processability for very small tubular geometries and compatibility with out-of-autoclave consolidation. This material was therefore retained for subsequent characterization.

The outcome of this trade-off illustrates a key point of cryogenic structural development: the best theoretical material is not always the best engineering solution. For very small supports, the selected system must not only deliver good thermomechanical properties but must also be manufacturable with repeatable quality and sufficiently low defect levels.

5. MECHANICAL CHRACTERIZATION OF THE SELECTED CFRP MATERIAL

5.1. Experimental approach

The selected prepreg was characterized using flat laminates in order to obtain representative input data for future structural modelling. Unidirectional and angle-ply laminates were manufactured to investigate the main mechanical properties relevant to the design of small cryogenic supports. The test campaign included:

- micrographic analysis for porosity assessment,
- interlaminar shear testing,
- three-point bending,
- tensile testing in the fibre direction,
- in-plane shear characterization from angle-ply tensile specimens.

This strategy was chosen because flat-coupon characterization provides a robust first database for material selection and early design calculations. Even though the final product is a tube, coupon-level tests remain highly valuable to compare process outcomes, confirm the quality level of the selected material system and provide the first set of engineering properties.

5.2. Experimental results

The mechanical characterization demonstrated a high level of performance together with limited scatter. The unidirectional laminate exhibited:

- a very high longitudinal tensile strength,
- a high tensile modulus and flexural properties,
- and a strong interlaminar shear response for this class of material.

The angle-ply laminate provided in-plane shear properties in line with expectations for a high-modulus carbon/epoxy system. Porosity remained below 1% after process adjustment, which is compliant with the targeted requirement. More generally, the results showed good repeatability, with low dispersion across the different test campaigns. This point is particularly important because the mechanical efficiency of compact cryogenic supports depends strongly on process quality and on the stability of the manufactured microstructure.

5.3. Discussion

These results are consistent with the expected behaviour of a high-modulus carbon/epoxy system. They confirm that the selected prepreg is suitable for small structural supports requiring high axial stiffness and limited material variability. The low porosity levels are also a positive indicator for both structural performance and future environmental compatibility.

From a design perspective, the coupon results support the use of a highly oriented CFRP architecture for the main load-carrying direction. They also provide a basis for estimating the expected behaviour of the tube under axial loading and for feeding the first numerical models of the cryostrut concept.

At this stage, thermal conductivity and outgassing measurements are still in progress and are required to complete the full validation of the material for cryogenic space applications. Nevertheless, the mechanical characterization already confirms that the selected material system is a credible candidate for the targeted application.

6. NUMERICAL MECHANICAL ANALYSIS

In addition to material-level characterization, a preliminary numerical mechanical analysis was performed on a representative cryostrut configuration developed for a cryogenic optical application. The analysed configuration was based on CFRP struts bonded to metallic end-fittings, and the model was used to assess global stiffness, quasi-static behaviour, thermoelastic response and dynamic performance.

The objective of this numerical work was twofold. First, it aimed at verifying whether the proposed structural concept could achieve the required stiffness and general mechanical integrity at assembly level. Second, it aimed at identifying the most critical areas of the design before detailed hardware maturation, especially with respect to cooldown-induced stresses at bonded interfaces.

The numerical assessment showed that the overall stiffness of the structure is compatible with the design intent. The quasi-static behaviour was found to be globally satisfactory, although local stress concentrations were identified in the end-fitting area, indicating that local geometric refinements are required. These results are typical of compact hybrid assemblies, in which the global architecture may be mechanically efficient while still requiring local design optimization near interfaces and geometric transitions.

The thermoelastic load cases appeared to be the most critical, with the highest stress levels located in the bonded regions and in the CFRP close to the glued interfaces. This result is particularly important because it confirms that the main design challenge is not the global load-carrying capability of the concept, but rather the local behaviour of the multi-material interface during cooldown. In this respect, the analysis supports the use of titanium end-fittings rather than aluminium in order to reduce thermo-mechanical mismatch effects.

The modal analysis also confirmed a high level of structural stiffness, with the first global modes located in a frequency range consistent with a mechanically efficient support architecture for compact cryogenic systems. The model therefore supports the overall relevance of the concept not only from a static point of view, but also from a dynamic one.

More generally, the numerical model proved useful for identifying the most critical design areas and for guiding local design improvements, including end-fitting geometry and bonded interface definition. At this stage, the results should nevertheless be regarded as preliminary design guidance, since some cryogenic material properties and interface allowables still require further correlation with dedicated test data. This point is especially relevant for glued interfaces, for which material data at very low temperature often remain limited.

7. BONDED HYBRID MICRO-STRUTS

7.1. Test purpose and justification

In parallel with the coupon-level material characterization, the project investigated bonded hybrid supports composed of CFRP tubes and metallic end-fittings. The objective was to assess the influence of the metallic interface material and thermal exposure on the mechanical performance of the bonded assembly. Two metallic end-fitting materials were considered:

- aluminium,
- titanium.

An aerospace-grade structural adhesive was used for the tested assemblies.

Figure 3: Micro-strut prototype

The choice to compare two metallic partners was motivated by both thermal and mechanical considerations. From a thermal standpoint, titanium is more attractive than aluminium for cryogenic interfaces. From a mechanical standpoint, the question was whether this advantage could be maintained once the full bonded assembly was tested after thermal exposure.

7.2. Results after thermal cycling

A first tensile test series was carried out on bonded micro-struts at room temperature before and after thermal cycling from 300 to 83K. Cycling is not conducted at lower temperature because below 83 K, molecular motion freezes and thermoelastic stresses become negligible. The most significant stresses occur between 300 K and 83 K. Both configurations remained mechanically satisfactory after exposure. However, the CFRP/titanium pairing systematically provided higher bond performance than CFRP/aluminium.

In addition, the bonded assemblies showed an increase in strength after thermal cycling relative to the ambient-temperature reference condition. This trend is consistent with the known evolution of epoxy-based bonded systems at lower temperature, where increased stiffness may contribute to a higher apparent resistance, provided that no premature damage is induced at the interface.

7.3. Results after cooldown to cryogenic temperature

Additional tensile tests were then performed at room temperature after cooldown to 4K on the same bonded concept. The results confirmed the robustness of the bonded architecture and again showed that the CFRP/titanium configuration outperformed the CFRP/aluminium alternative.

The bond stress levels remained in a range consistent with structural use for compact cryogenic assemblies, and the observed scatter was low.

7.4. Discussion

The results indicate that cryogenic exposure does not degrade the bonded concept. On the contrary, an increase in bond strength was observed after thermal cycling and after cooldown to cryogenic temperature. This behaviour is consistent with the known stiffening of epoxy adhesives at low temperature.

Beyond purely mechanical results, titanium is also advantageous thermo-mechanically. The literature review indicates that CFRP and titanium exhibit better compatibility in thermal expansion than CFRP and aluminium, which likely contributes to a reduction in thermoelastic stresses within the bonded interface during cooldown. The combined experimental and bibliographic evidence therefore supports the selection of titanium as the preferred end-fitting material for cryogenic bonded supports.

These results are also coherent with the numerical findings. The latter highlighted thermoelastic loading as the critical case and suggested that interface behaviour would govern design maturity. The experiments confirm that the choice of the metallic partner is indeed decisive and that the CFRP/Ti configuration offers the most favourable balance for further development.

Figure 4: Tensile test setup for the bonded CFRP/metal micro-strut

8. DISCUSSION

The results presented in this work highlight the importance of approaching cryogenic support development as a coupled material-process-interface problem. The final performance of the concept does not depend on a single parameter, but on the consistency of the overall design strategy.

First, the material trade-off and coupon characterization confirm that high-modulus CFRP is well suited for compact cryogenic supports. Its high axial stiffness and favourable expected thermal behaviour make it a strong candidate for low-conductivity structural members. However, the study also shows that process feasibility must be considered at the same level as material performance, especially when the target geometry

is very small.

Second, the numerical mechanical analysis shows that the global structural concept is mechanically relevant, but also that thermoelastic effects remain the main challenge. This point is essential for cryogenic optical structures: the structure may appear satisfactory under conventional mechanical loading while still being driven by local interface behaviour during cooldown. In this context, early numerical analyses are valuable not only to size the structure, but also to orient the choice of materials and local design features.

Third, the bonded assembly tests provide a direct experimental validation of the interface strategy. They demonstrate that the concept is robust under cryogenic exposure and that titanium offers a clear advantage over aluminium for the metallic end-fittings. This advantage is not limited to thermal conductivity considerations; it also improves the overall thermo-mechanical compatibility of the bonded assembly.

Taken together, these three levels of investigation — material, numerical and experimental — define a coherent pathway for the development of compact cryogenic supports. They also show that the proposed concept is already supported by converging evidence, even though some validation tasks remain ongoing.

The main remaining steps concern thermal conductivity quantification and outgassing characterization of the selected CFRP material. These activities are necessary to complete the qualification logic for future space applications. In parallel, additional refinement of the end-fitting geometry and further correlation between analysis and testing will strengthen the maturity of the concept.

9. CONCLUSION

This work presents the development of compact structural supports for cryogenic optical systems based on bonded CFRP/metal hybrid micro-struts. The design challenge arises from the need to simultaneously achieve high stiffness, low thermal conductivity, dimensional stability and robust multi-material interfaces under severe thermal excursions.

A literature review first confirmed the relevance of CFRP for cryogenic support structures and identified titanium as a particularly suitable interface material. A dedicated material trade-off then led to the selection of a high-modulus carbon/epoxy prepreg for the manufacture of small CFRP tubes. Mechanical characterization of this material demonstrated high performance, low scatter and acceptable porosity levels.

In parallel, a preliminary numerical mechanical analysis highlighted the structural relevance of the concept and identified thermoelastic loading as the most critical design case. Experimental testing of bonded hybrid assemblies then showed that the CFRP/Ti configuration consistently outperformed the CFRP/Al alternative and remained mechanically robust after cryogenic exposure.

Overall, the combined material, numerical and experimental results confirm that bonded CFRP/titanium hybrid supports constitute a promising solution for structural applications in cryogenic optical payloads. The ongoing thermal conductivity and outgassing characterization will complete the validation of the selected material system and support future qualification of the concept for space applications.

10. PERSPECTIVES

Beyond the present material, numerical and bonded-interface investigations, the next steps of the development will focus on the maturation of the cryostrut concept at product level. This includes consolidating the tube manufacturing process, refining the end-fitting design and bonded interface geometry, and correlating the numerical models with dedicated experimental results. Early work on the manufacture of small CFRP tubes has already been initiated, as this aspect is considered a key factor for compact cryogenic architectures.

Figure 5: Prototype of a small CFRP tube (inner diameter <5mm)

Further work will also address the assessment of the assembled cryostrut after thermal exposure and extend the analysis to thermo-mechanical performance. The project aims to develop and validate a compact support solution combining structural efficiency, thermal decoupling and compatibility with cryogenic optical payload requirements. This development is conducted with the support of CNES as part of an R&T initiative, aiming for TRL 5 by mid-2027.

11. ACKNOWLEDGEMENTS

MECANO ID would like to thank CNES for supporting this development and the teams involved in material characterization whose contributions supported the maturation of the cryostrut concept.

ABSTRACT

Traditional thermoset composites are widely used in structural applications, including aerospace pressurized and cryogenic tanks, but their inherent brittleness makes them vulnerable to microcracking and damage. CompPair addresses these limitations with HealTech™ products, allowing to build composites that rapidly heal cracks and delamination through localized heating between 100°C and 150°C. CompPair has developed slit-tapes specifically designed for cryogenic tanks. These materials offer high resistance to microcracking and can heal damage caused by thermal cycling, supporting the development of lightweight Type V tanks as an alternative to metallic solutions. CompPair and its partners have also integrated autonomous sensing and heating technologies, allowing composite structures to detect and heal damage without external intervention. This paper highlights the mechanical performance, healing efficiency, and space-environment compatibility of these materials, as well as real-time damage monitoring and autonomous repair capabilities. Developed within ESA programs, these innovations also have promising applications in aeronautics and sustainable mobility.

1. INTRODUCTION

A cost-effective and high-performance space transportation ecosystem for the 2025-2050 horizon is expected to rely on reusable launchers, high-orbit parking strategies, and a “hub-and-spoke” in-space logistics network supporting constellation deployment, exploration missions, orbital servicing, and propellant depots. In this context, lightweight and durable materials are essential. Fibre Reinforced Polymers (FRPs), particularly epoxy-based composites, are widely used in space structures and ideally in particular in cryogenic propellant tanks because of their excellent stiffness-to-weight ratio, high glass transition temperature, and chemical resistance.

In the specific case of cryogenic tanks, despite these advantages, conventional thermoset composites remain vulnerable to manufacturing defects, such as gaps, overlaps, voids, and excess fibre buildup (the typical defects generated by winding and automatic fibre placement) [1], [2], [3], [4], as well as in-service damage caused by thermal cycling, cryogenic conditions, and impacts [5]. Matrix microcracking and delamination can compromise structural integrity and create leakage paths for cryogenic propellants, limiting the adoption of liner-less Type V tanks, which otherwise offer significant weight savings compared to metallic or lined alternatives [3], [5].

To address these challenges, CompPair has developed healable composite technologies capable of repairing microcracks and delamination through controlled heating (100 °C – 150 °C) [6][7], restoring structural performance without additional repair materials. Additionally, this process can be repeated multiple times.
Within the frame of ESA OSIP, CompPair specifically developed slit tapes for cryogenic tanks applications (HealTech™ CS03 slit tapes). Within the scope of a FLPP FIRST! initiative CompPair teamed up with Com&Sens and CSEM to achieve autonomous damage sensing and healing in HealTech™ composites structures by embedding optical fibres sensors [8] and metallic heaters in its composite structures. These innovations are key enablers for sustainable space transportation, in-orbit servicing, and long-duration orbital infrastructure.

2. MATERIALS AND METHODS

2.1. Materials

Two different types of thermoset based healable pre-impregnated textiles (prepregs) from CompPair Technologies were used: HealTech™ CS03 AS7 unidirectional prepregs with a fibre areal weight of 200 g/m^2 and HealTech™ CS01 T700S unidirectional prepregs with a fibre areal weight of 200 g/m^2. AS7 fibres are manufactured by Hexcel, while T700S fibres by Toray.

2.2. Tensile tests

Tensile tests were performed on HealTech™ CS03 AS7 unidirectional laminates in the longitudinal

direction according to standard ISO 527-5 at room temperature. 5 samples per test condition were tested.

2.3. Outgassing

Outgassing tests were performed on HealTech™ CS03 AS7 unidirectional laminates according to standard ECSS-Q-ST-70-02 by Deutsches Zentrum für Luft- und Raumfahrt e.V. (DLR).

2.4. Healing

Quantitative healing tests were performed on HealTech™ CS03 carbon twill laminates with a $[(\pm 45)]_9$ layup. Samples 135x20 mm^2 were mounted on the unsupported impact setup visible in Figure 2 and impacted 18 times with a 10J energy. A part of the samples was healed for 20 minutes at 150 °C. Virgin, damaged and healed samples have been tested in 3-point bending based on ASTM D790 to assess the flexural modulus. Healing efficiency was computed in terms of recovery of flexural modulus:

$$Healing\ efficiency = \frac{E_{healed}}{E_{virgin}}$$

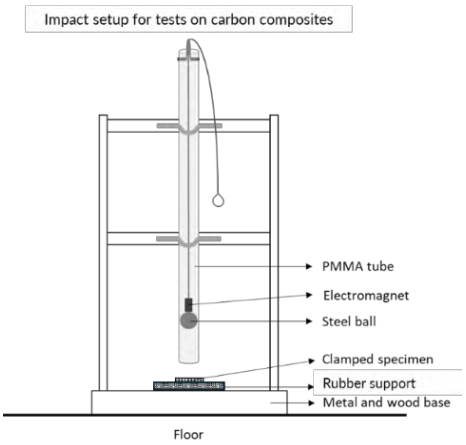

Figure 1: A schematic of the impact setup.

2.5. Cryogenic micro-cracking

3 samples 50x50 mm^2 were obtained cutting HealTech™ CS03 carbon twill laminates with a $[(+-45)/(0/90)]_{4s}$ layup. They were immerged in liquid nitrogen for 2 min and 30 seconds and put on aluminium plates to heat back up at room temperature as fast as possible (between 12 and 17 minutes were necessary). This procedure was repeated 10 times to simulate the typical thermal shock a cryogenic vessel could experience (the thermal history experienced by the samples is visible in
Figure , the thermocouple was placed on the surface of samples which was always in contact either with air or with liquid nitrogen). Optical microscopy (OM) observations were carried out on the 3 samples before and after thermal shock cycling. This enabled to assess the material resistance to microcracking induced by this cycling.

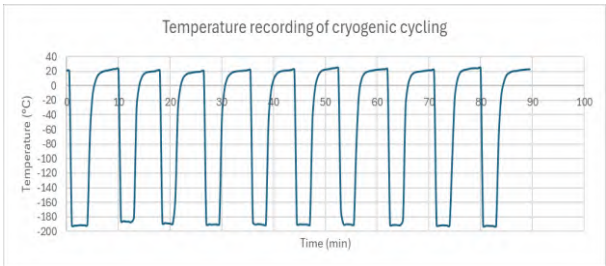

Figure 2: the thermal history experienced by HealTech™ CS03 carbon laminates.

2.6. Breadboard integrating optical fibres and metallic heaters

In order to assess the achievable performances in terms of autonomous damage sensing and healing a flat laminate made of HealTech™ CS01 carbon prepregs was manufactured. The fibres were T700 unidirectional fibres, with an areal weight of 200 g/m^2. The plies were 32 in total. Optical fibres were integrated between ply 27 and 28 and between ply 29 and 30. 3D printed aluminium grids were embedded in between 2 mat glass veils with an areal weight of 30 g/m^2 in the middle of the laminate. Figure 3 depicts the geometry of the laminate as well as the geometry and position of optical fibres and metallic grids in the laminate.

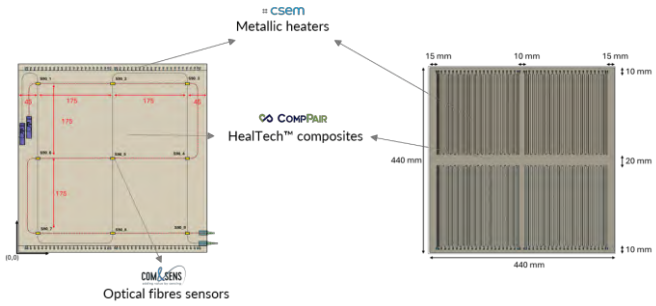

Figure 1: A schematic depicting the geometry of the laminate integrating autonomous damage sensing and healing. The geometry and position of optical fibres and metallic heaters is detailed.

2.7. Breadboard impact test

A Rosand impact tower equipped with a cylindrical impact head with diameter 40 mm and weighing 5,79 kg was used to impact the breadboard integrating autonomous damage sensing and healing in 3 selected locations, depicted in red in Figure 2. The impact test was monitored using optical fibres.

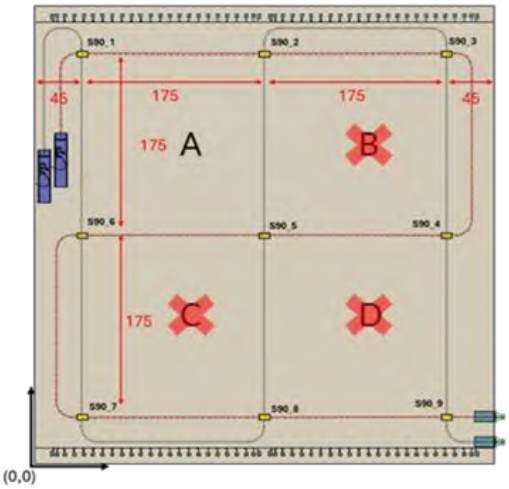

Figure 2: A schematic of the impact locations of the breadboard, highlighted as red crosses.

2.8. Breadboard healing test

In order to perform the autonomous healing, 2 power supplies were connected to the integrated aluminium grids. The power supplies were connected so to each cover a 6 pins distance between the 2 clamps. The current and the voltage were then gradually increased until reaching a 100 °C < T < 140 °C in the whole heated area and then a 15 min timer was started keeping the temperature constant.
This step was also monitored using optical fibres.

2.9. Breadboard quantitative healing test

Samples were made of sixteen layers of HealTech™ CS01 unidirectional T700 prepregs, arranged in a ±45° stacking sequence. The integrated damage sensing and healing systems were integrated in the laminates. A 3D-printed aluminium grid was embedded at the mid-plane, with wires oriented along the 0° direction, serving as the electrical heating element. Glass fibre veils (30 gsm, mat) were placed immediately above and below the grid to ensure electrical insulation and reduce the risk of short circuits. Optical fibres were inserted one ply below the top surface and aligned with the 0° direction. These fibres are non-functional in the present test but included to replicate the full configuration of the final smart composite system. Mechanical testing was performed on a Shimadzu AGS-X 10 kN Universal Testing Machine (UTM). Five-point bending was used, with a load span of 30 mm and a total support span of 60 mm. Support and loading pins were 6 mm in diameter, and the crosshead speed was 1 mm/min. Five samples were tested without any induced damage or healing to establish baseline performance. Seven samples were tested after a single 5 J impact to induce matrix damage. Impact was performed using the setup shown in Figure . Eight samples were tested after a single 5 J impact followed by the healing procedure (20 minutes at 150 °C)

3. RESULTS AND DISCUSSION

3.1. HealTech™ CS03 slit tapes characterization

The longitudinal tensile strength and modulus of HealTech™ CS03 laminates are shown in Figure as compared to standard composite benchmarks [9]. This highlights that HealTech™ CS03 has competitive mechanical performances.

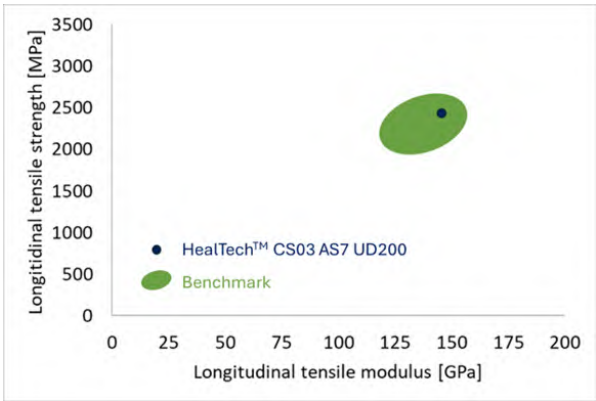

Figure 5: the longitudinal tensile modulus and strength of HealTech™ CS03 laminates as compared to standard composite benchmarks [9].

Outgassing tests on HealTech™ CS03 laminates were performed by DLR according to ECSS-Q-ST-70-02. The total mass loss (TML), the recovered mass loss (RML) and the collected volatile condensable materials (CVCM) (Figure) resulted well below the limits set by the standard, confirming HealTech™ CS03 compatibility with space conditions.

Material	TML [%]	RML [%]	CVCM [%]
HealTech™ CS03 AS7 UD 200 g/m²	0,37	0,18	0,01
ECSS requirements	< 1,00	< 1,00	< 0,10

Figure 6: TML, RML and CVCM for HealTech™ CS03 laminates as compared to the requirements set in the ECSS standards.

A quantitative healing test was performed on carbon twill laminates according to the procedure described in the section 2.4. The damage procedure (18 impacts at 10J) generated a 20.5% loss in flexural modulus (Figure), and a healing efficiency of 92% was achieved heating the samples for 20 minutes at 150°C. This proved the healing capabilities of the developed product, HealTech™ CS03.

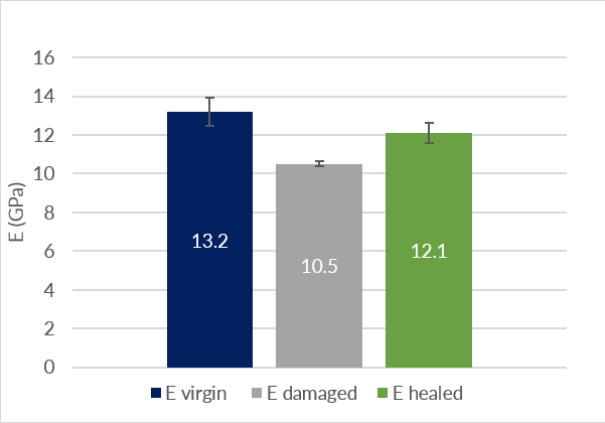

Figure 7: The flexural modulus of virgin, damaged and healed HealTech™ CS03 carbon composite samples.

Figure shows optical microscopy (OM) observations with different magnifications of the cross section of HealTech™ CS03 carbon laminates as produced and after thermal shock cycling between -196 °C and room temperature. No sign of microcracking is visible in any of the samples. This highlights CS03 has a superior cryogenic microcracking resistance, making it a good candidate to be integrated in a cryogenic propellant tank.

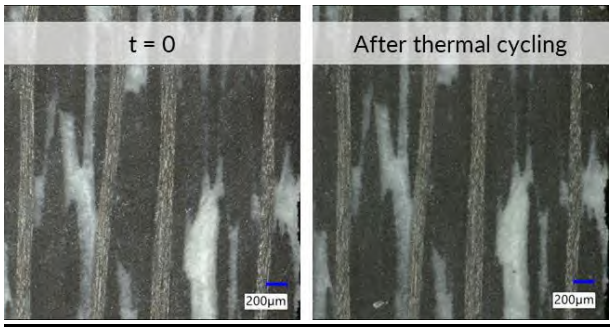

Figure 8: OM observation of the cross section of HealTech™ CS03 carbon laminates as produced and after thermal shock cycling between -196 °C and room temperature.

These tests confirmed the potential of HealTech™ CS03 slit tapes to build cryogenic propellant tanks. Consequently, following the OSIP project that allowed to develop such product, a subsequent activity started within the frame of a FLPP FIRST! initiative, in order to increase the maturity of CS03 for cryogenic tanks applications. This project is currently ongoing in collaboration with Invent GmbH. One of the main results that could be achieved so far is the successful manufacturing of tank shaped structure via slit tape winding. Figure 3 shows the intermediate steps followed to manufacture the part. These tests allowed to proof the compatibility of CS03 slit tapes with the typical processes used to manufacture tanks, like winding, and confirmed the capability to manufacture complex shape parts with a geometry representative of the final application targeted.

3.2. Autonomous damage sensing and healing

The breadboard integrating optical fibres and aluminium heaters was successfully impacted in the 3 targeted locations shown in Figure 2 with a 3.5 J energy without registering any malfunction in the impact machine. The system preventing double rebound of the impact head worked correctly.
For each impact position, the raw data signal collected using the optical fibres and the connected interrogator were used to calculate the impact location considering the 4 sensors with the fastest time of flight. This method allowed to locate the impact location with a maximum error of 40 mm. Figure 4 shows the actual location of the impact damage, as an example for impact location D, as compared to the location computed with the optical fibres sensors.

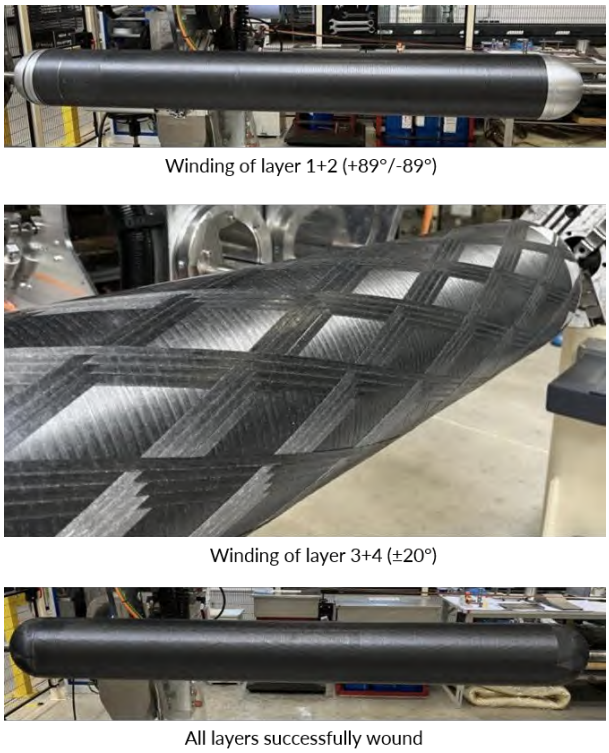

Figure 3: The winding steps to manufacture a tank shaped demonstrator with HealTech™ CS03 slit tapes.

After impacting the breadboard and locating the generated damage, the breadboard was healed via the integrated heating system consisting of aluminium grids. Having 4 independent grids covering the full surface of the breadboard and having several locations to which it was possible to apply current allowed to activate the heating only in the needed area, where damage was located. Figure 5 shows the typical temperature distribution over the breadboard surface that could be obtained. It highlights that temperature was homogeneous over the area heated by joule effect and that the temperature was in the range needed to achieve efficient healing, i.e. between 100 °C and 140 °C.

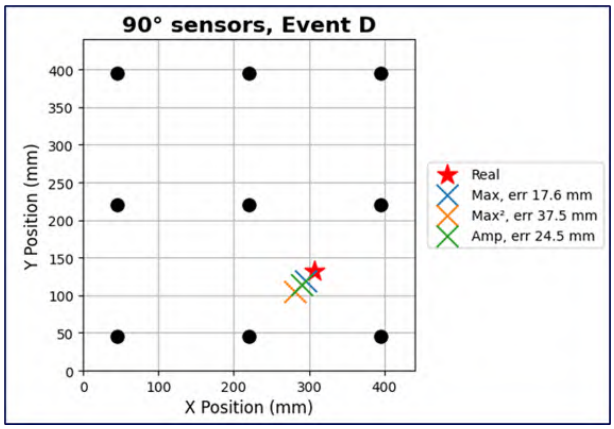

Figure 4: the red star indicates the actual location of the impact in zone D of the breadboard. The other crosses indicate the location computed using the signal from the 4 sensors with the fastest time of flight. Different colours indicate different computation methods.

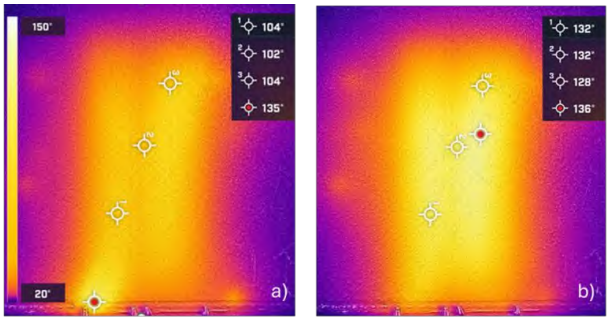

Figure 5: thermal camera images of the surface of the breadboard showing a mapping of the temperature that was achieved connecting the aluminium grids to the power supplies.

The healing capabilities of HealTech™ composites integrating autonomous damage sensing and healing systems were quantitatively assessed via mechanical testing on smaller samples that could be subjected to 5-point bending flexural tests with the methodology described in section 2.9.

To evaluate the performance of the different sample types, the maximum surface stress was considered. According to beam theory, on the surface at midspan the sample experiences the highest tensile or compressive stress during bending. Using the maximum force recorded by the testing machine, the corresponding maximum bending moment experienced by the specimen can be calculated using the following equation:

$$M_{max} = \frac{3}{32} P_{max} L$$

And subsequently, the max compressive and/or tensile stress at the external layers can be calculated as:

$$\sigma_{max} = \frac{9}{8} \frac{PL}{wt^2}$$

5 samples were tested in a virgin state (“virgin”), 7 after impacting once with 5J of energy (“impacted”), and 8 after impacting once with 5J of energy and healing via the integrated metallic grids (“healed”).

The results of the average maximum stress for each sample type are summarized in the graph in Figure 6. The damage procedure induced a 17.7% loss of mechanical performances and the healing procedure with the integrated autonomous damage healing system allowed to achieve a 92% healing efficiency.

An interesting observation during testing was that delamination in the virgin samples did not occur at the mid-plane, in correspondence with the aluminium grids, where the theoretical shear stress is expected to be highest, but rather between the mid-plane and the outer plies (see Figure 7). This suggests that the presence of the aluminium grids and glass veils enhances the samples’ ability to withstand higher levels of interlaminar shear stress.

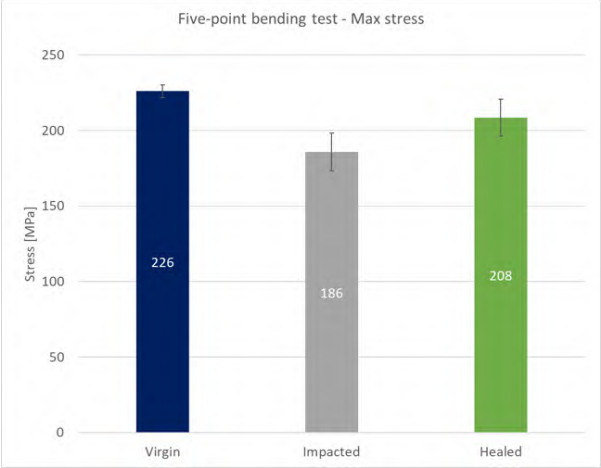

Figure 6: the average maximum stress of virgin, damaged and healed samples integrating optical fibres and metallic grids.

Figure 7: The typical failure mode observed in virgin samples.

4. CONCLUSION

The results demonstrate that HealTech™ CS03 is a promising multifunctional composite material for space and cryogenic applications. The developed slit tapes exhibited mechanical properties comparable to conventional high-performance composites, while meeting ECSS outgassing requirements and showing excellent resistance to cryogenic thermal shock, with no evidence of microcracking after cycling between room

temperature and liquid-nitrogen temperatures.
The self-healing capability of the material was successfully validated, achieving 92% recovery of the initial mechanical performance after impact-induced damage.
The successful manufacture of tank-shaped demonstrators by slit-tape winding confirmed the compatibility of HealTech™ CS03 with industrial processing routes and its suitability for complex aerospace structures.

The integration of optical fibre sensors and embedded metallic heating grids in HealTech™ CS01 composites enabled autonomous damage detection, localization, and localized repair. Impact events were identified with a maximum error of 40 mm, while the integrated heating system provided homogeneous temperatures within the optimal healing range, resulting in a healing efficiency of 92%.

Overall, the combination of structural performance, cryogenic durability, damage sensing, and efficient self-healing highlights the strong potential of HealTech™ materials for next-generation cryogenic propellant tanks and other resilient space structures.

Design for Demise, Structural Joints, Space Debris, Clean Space

ABSTRACT

As part of the Design-for-Demise (D4D) effort of the Zero Debris approach, one area of research and development focuses on the primary structural joints of satellites to improve the break-up behaviour during re-entry. With an early opening of the structure, a better demise of critical components is expected.
This paper presents the demisable joint developments within the ESA-funded D4D SAFER project. Several technologies and joint designs are presented, as well as their current testing and results. With the focus being on the demise performance, extensive testing has been performed as part of a first test campaign in the re-entry chamber of AAC and the L2K plasma wind tunnel facility of the DLR. The results and findings, as well as the conclusions and the next phases of the development, are being presented.

1. STUDY GOAL AND USE-CASE

The number of satellites in Low-Earth-Orbit (LEO) are growing each year, especially due to telecommunication constellations such as Starlink, OneWeb or Iridium. To ensure that orbits remain usable in the long term, satellites must be removed from orbit at the end of their service life, for example by an uncontrolled re-entry due to natural orbit decay. However, as this approach does not allow for control over where the satellite re-enters the Earth's atmosphere, it must be ensured that the satellite burns up completely upon re-entry to prevent the risk of falling debris on the ground. Large and heavy components, such as reaction wheels or fuel tanks, often survive re-entry, thereby creating an on-ground causality risk.
One approach to solving this problem and thereby reducing the risk is to open the outer satellite structure early during re-entry. This allows more heat to reach the critical internal components at an earlier stage, giving them more time to burn up completely. In previous studies [1], the connecting elements of the primary structure were identified as a promising solution. The aim of the ESA study, part of their Design for Demise (D4D) effort, described in this paper is therefore to develop demisable primary structural joints for use in LEO telecommunications satellite up to a Technology-Readiness-Level (TRL) of 4.
To investigate the potential effect of demisable joints on re-entry using simulations, a representative model of a telecommunications satellite was required. This involved conducting an analysis of the designs of current and planned constellations, with the aim of creating a representative model based on the results. The CAD model of this satellite, nicknamed FrankensteinSat, is shown in Fig. 1. It includes all major components of a typical telecom satellite, especially critical components such as the reaction wheels, main payload, and a large tank. The total mass of this satellite is roughly 860 kg, with a dry mass of 700 kg. The primary structure consists of aluminium panels joined by aluminium brackets.

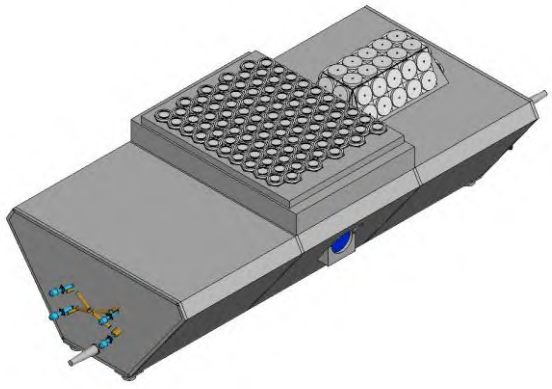

Figure 1: CAD model of FrankensteinSat

This model was used for re-entry simulation to access the demisability of a conventional design

without any demisable technology to get a baseline for later comparison. The simulations were performed by HTG using SCARAB. In total, 15 simulations were done. All simulations started at the initial orbital state (at about 125 km above the equator, inclination 68.4 degrees), but with different initial attitudes. In all simulations, the batteries, main payload, reaction wheels, and the tank survived the re-entry and therefore contributed to a causality risk area. In addition, the temperature profile at two critical joints was examined during re-entry, one at the outer edge of the satellite structure (pos. 1 in Fig. 2), the other in the shielded centre of the structure (pos. 2).

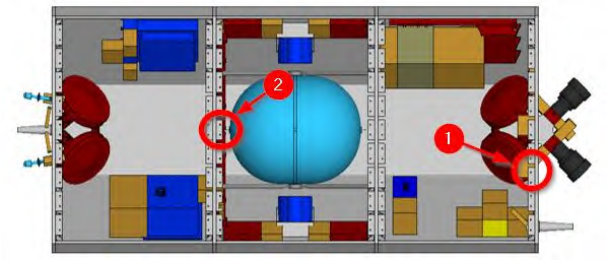

Figure 2: Inside of FrankensteinSat with marked joint positions

Assuming an arbitrary failure temperature of this joint of 450 K, this temperature is reached at the outer edge in an altitude range of 82-110 km. The centre joint reached this temperature at a much lower altitude range of 70-82 km, meaning the structure would only have opened fully at this altitude. This demonstrates the need for demisable joints that allow the structure to be separated at comparatively low temperatures.

2. DEVELOPMENT APPROACH

The development of the joints is taking place in six phases as part of the project. During the first phase, the use case described above was developed, re-entry simulations were carried out to establish the baseline, and the requirements and constraints were defined. In the second phase, feasible joints were then designed based on the requirements provided, and a test plan and sample geometry were prepared. The third phase involves the first test campaign. The aim here was to examine the concepts and understand how they performed, with a particular focus on any potential shortcomings. With the lessons learned, the designs of the joints will be reiterated in phase four, in which the project is currently at the time of writing this paper. The optimisations and improvements will then be verified in a second test campaign in phase five. In phase six, development within the scope of the project will be completed, and outstanding issues for further development and testing will be defined within a roadmap.

3. OVERVIEW OF DEMISABLE JOINT TECHNOLOGIES

The study focused on passive technologies that are activated by the rising temperature during re-entry. There are several options available for implementation. Technologies that can be used for separation at temperatures around 150 °C were of particular interest. Either the technology can be integrated directly into the sandwich panel – for example, in the form of a demisable insert – or the aluminium bracket can be replaced with a demisable version.
Three technologies, which could replace joints, and five support technologies, which could additionally be integrated into demisable joints, were investigated. Those are:

- Demisable Inserts for sandwich panels with a low melting point solder material
- Demisable Anchor Nuts with a low melting point solder material, to be used in combination with standard brackets
- CFRP cleats with a demisable resin system
- Adhesives, which separate at defined temperature

Based on these concepts, multiple joint design variants were created. The demisable insert consists of two aluminium parts, which are interlocked with a third part made from a low-melting point solder. The target separation temperature is between 130 °C and 150 °C. Two variants were designed. The first one is a replacement for conventional face-to-face inserts (also known as spool inserts), which are to be used with cleats to form a panel-to-pan
el joints. When reaching the triggering temperature, the inner part of the insert, connected to the cleat, can separate from the outer part, which remains in the panel. A similar approach is used for the second variant, an edge insert, which are integrated at the corner of the panel. Two edge inserts are directly connected and therefore form the joint without the need of extra hardware like cleats. Both variants are shown in Fig. 3.

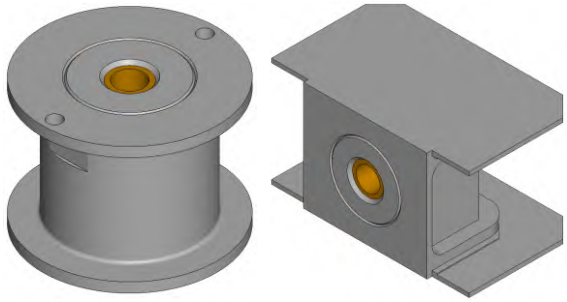

Figure 3: Demisable Inserts - Face-to-Face insert (left) and Edge Insert (right)

The design principle of the demisable insert is also used for the demisable anchor nut. The major difference is the location of the separation mechanism. While the inserts are integrated into the

sandwich panel and therefore need to be selected early in the design and manufacturing process of the satellite structure, the demisable anchor nut is attached to a cleat. This means that, even at a relatively late stage in the design process, a panel-to-panel connection can be changed from a standard design to a demisable design without making any major alterations to the surrounding structure.
The CFRP cleat offers a similar advantage, albeit based on a different operating principle. Tests have shown that standard aerospace epoxy and cyanate ester resins, such as Araldite LY 556 or EX-1515, decompose only with difficulty under re-entry conditions, meaning that CFRP structures are relatively robust. However, there are certain resin systems which have performed significantly better in material tests and have allowed the structure to disintegrate. This observation is now to be examined at component level. Additionally, an extra sample was produced in which 1% aluminium-magnesium particles were mixed into the matrix. This is based on the findings found in [2], which have shown that the additional particles are thought to promote heat transfer in the thickness direction of the laminate and thus accelerate its disintegration. The anchor nut and the CFRP cleat are shown in Fig. 4.

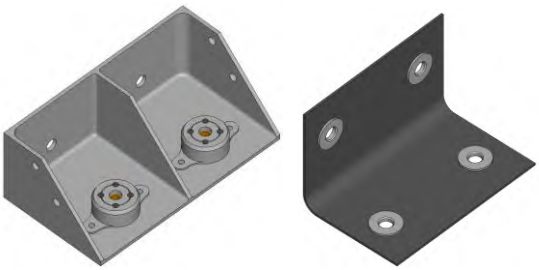

Figure 4: Demisable Anchor Nuts attached to an aluminium cleat (left) and CFRP cleat with demisable matrix (right)

The last joint concept based on adhesives, which separate at a temperature of around 150 °C. To incorporate this technology, the cleat was split into two parts – a base plate and a bracket – and joined together using an epoxy structural adhesive. A total of three different design variants were developed. The basis was a two-part CFRP cleat, which, like the previous cleats, is fitted in the conventional location on the inside of the panel-to-panel joint. In order to investigate the influence of the material on this concept, aluminium was used for the second variant. The position remained unchanged. In the third variant, the position of the CFRP cleat was moved to the outer side of the joint. As a result, the component is directly exposed to heat during the test and degradation occurs sooner. Two of the cleats are shown in Fig. 5.

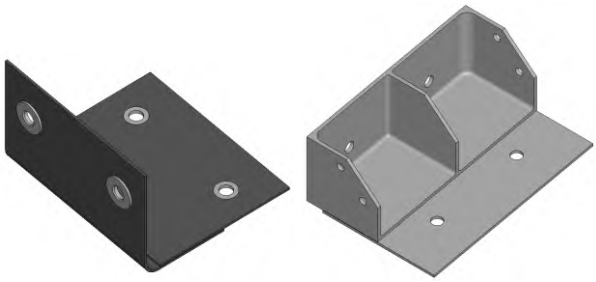

Figure 5: Two-part, bonded cleats made from CFRP (left) and aluminium (right)

4. TESTING

Preliminary testing of the demisable joints was performed at INVENT for mechanical properties as well as at DLR and AAC for demise testing.

4.1. Mechanical Properties

The mechanical investigations were mainly limited to the most significant characteristics, as the focus is on the demise behaviour. Nevertheless, a small number of tests were carried out.
As the material used for the Demisable Inserts had not previously been used in load-bearing structures, several tensile tests were carried out, both at the material level for characterisation and at the component level to verify the design.
The load-bearing capacity of the demisable insert was investigated on the basis of the face-to-face design. Typically, for the test, an insert is fitted into a small section of sandwich panel, which is then mounted in a tensile testing machine. The test setup and procedure are described in [3]. However, in such cases, the panel usually fails significantly before the insert does. For a panel and insert such as those used in the case study mentioned, the failure load would be around 3200 N.
The panel was therefore replaced with a solid piece of aluminium to ensure that any failure occurred in the insert during the test, thereby enabling the maximum load-bearing capacity to be determined. The graph of the tensile test is shown in the Fig. 6. As it was not possible to fit a displacement transducer directly to the insert, the diagram shows only the movement of the crossbeam and, consequently, the deformation of all components in the load path. The insert did not fail during the test; instead, a constant, almost linear displacement was measured until the test machine's maximum load of 20 kN was reached. After the test, the insert was inspected and a permanent displacement of 0.35 mm between the inner and outer component was detected.
The tensile test successfully demonstrated the design's load-bearing capacity at 21 °C, which significantly exceeds that of the surrounding sandwich structure. This allows conventional inserts to be replaced with the demisable variant without the need for structural modifications.

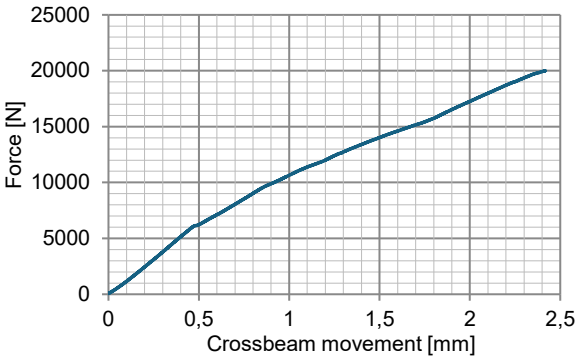

Figure 6: Force/displacement diagram of the out-of-plane tensile test on the demisable face-to-face insert at 21 °C

The second type of mechanical testing concerned the adhesive technology used for the cleats. In this case, single-lap shear samples were used to investigate the mechanical properties at room temperature and following thermal stress. The data was used to design the bonded seams and to determine the operating temperature for this technology.

4.2. Demise Testing

In total, 20 samples were manufactured for testing, with 12 samples for the re-entry chamber (RC) and 8 samples for the plasma wind tunnel (PWT).

4.2.1. Sample Designs

The basic design of all demise samples is always the same. It consists of two sandwich plates connected to one another via the demisable joint. The upper plate is fixed statically in the test setup, whilst the lower plate can detach itself downwards when the joint is triggered, either under its own weight or under additional loads, depending on the test setup. The configuration of the sandwich panels, shown in Tab. 1, corresponded to the design typically used for the outer structure of satellites, such as closure panels.

Table 1: Sandwich Panel Configurations

	Aluminium	**CFRP**
Total Thickness	20 mm	
Facesheet Material	EN AW-2024	EX-1515 / M55J
Facesheet Thickness	0,5 mm	0,3 mm (4 plies)
Honeycomb Material	EN AW-5056	
Honeycomb Density	50 kg/m³	32 kg/m³
Adhesive Film	HexBond 312UL	
Panel Size for RC	200 mm x 200 mm	
Panel Size for PWT	200 mm x 100 mm	

The samples were mounted in the test setup with the corner of the panel-to-panel joint facing in the direction of the heat flux and the panels oriented at a 45° angle to the direction of flow. The temperature distribution during testing on the demisable joint as well as the panels are recorded using multiple thermocouples on the surface as well as integrated into the sample. At least one video camera was used during testing to capture the separation behaviour of the joint. A representative CAD model of the sample (in this case for RC testing) is shown in Fig. 7.

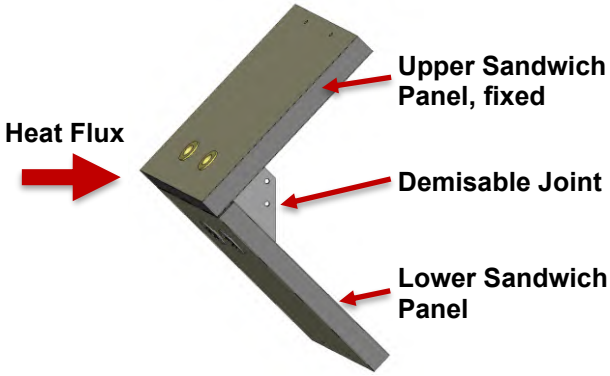

Figure 7: CAD model of demise sample

4.2.2. Re-entry Chamber Testing

The testing was performed in AAC's re-entry chamber (RC). It is a multi-purpose thermal vacuum chamber specifically designed for testing materials and small components under re-entry relevant heat fluxes. The samples are heated using radiation heaters, so heat fluxes up to ~100 kW/m² can be tested. For this test, a gradually increasing heat flux, representing a re-entry trajectory, is used. The heat flux values were determined in the previous D4DBB project using a re-entry simulation; see [1]. The parameters are shown in Tab. 2. The chamber with a mounted sample is shown in Fig. 8.
Using an adjustable pulley system and weights, which attached to the outer edge of the lower panel, the load on the demisable joint was varied during testing.

Table 2: Trajectory Heat Flux

Time [s]	**Heat Flux [kW/m²]**
0	3.2
285	3.2
465	5.0
765	20.0
965	50.0

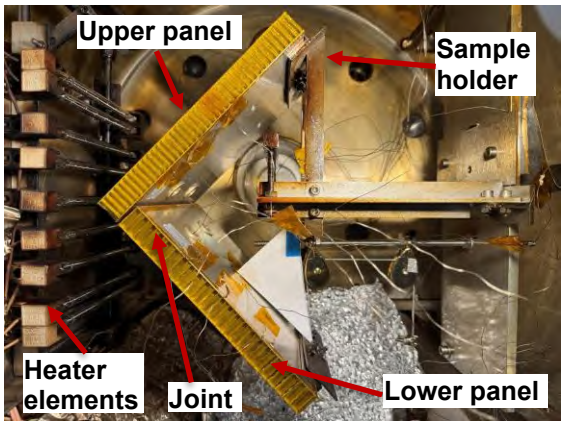

Figure 8: Sample mounted in RC

4.2.3. Plasma Wind Tunnel Testing

The testing was conducted by the DLR in the L2K facility. The test parameters were selected so that tests could be carried out at the lowest possible heat fluxes, whilst at the same time ensuring stable flow conditions around the specimen. These conditions were achieved with a heat flux of 50 kW/m².
A mounting setup similar to the re-entry chamber was used, although with a reduced sample size, since the original panel length of 200 mm resulted in unstable flow conditions. Therefore, the length was reduced to 100 mm. A mounted sample is shown in Fig. 9.

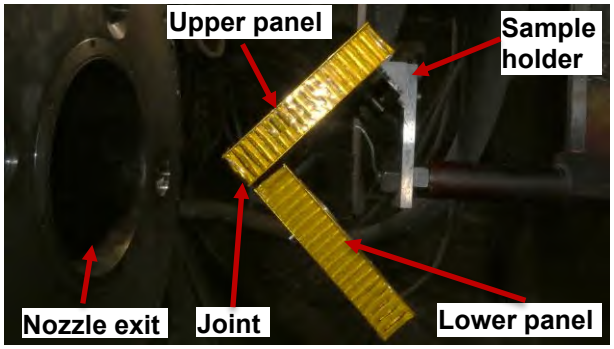

Figure 9: Sample mounted in PWT

4.2.4. Results

The test results depended heavily on the concepts being tested, but were consistent between RC and PWT. Concepts that showed separation in the RC exhibited similar behaviour in the PWT. Similarly, concepts that did not show separation did so in all tests.
In particular, the 'Demisable Insert' concept proved problematic in terms of separation during the trials. A root cause analysis was carried out through repeated tests in the RC using various loads. This identified a specific design feature as the cause, which can lead to the insert becoming jammed under certain loads. This behaviour was subsequently also observed in simplified tests. As the anchor nuts and insert designs were based on a very similar design principle, they also suffered from jamming during the tests.

At the same time, however, the triggering could be reliably demonstrated in all tests. Thermocouples were embedded in the solder material of the two inserts, so that the point at which the phase transition from solid to liquid occurred was clearly visible in the measurement data. This can be seen in the diagram in Fig. 10 from around the 10 min point onwards.

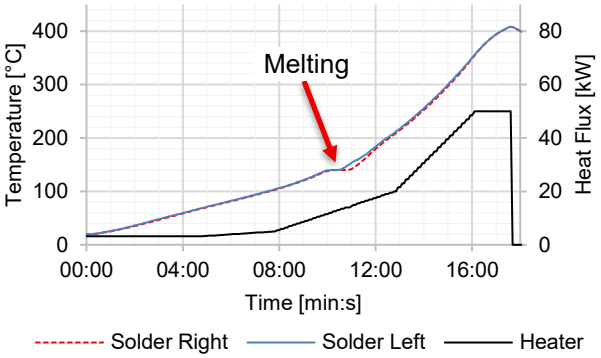

Figure 10: Temperature data of the demisable insert sample in the RC

The concept of the detachable CFRP cleat did not prove successful in the tests. In the re-entry chamber, the cleat material did not reach the temperature required to cause decomposition of the matrix material. One issue encountered was that, at a certain point during the test, the temperature of all the other materials in the sample such as the adhesive in the sandwich panel had risen to such an extent that they began to off-gas heavily and emit smoke. This smoke filled the test chamber, which not only caused the radiation intensity on the sample to decrease significantly, but also posed the risk of combustion residues settling on the sensitive heating elements and damaging them. The test therefore had to be terminated at this time.
In the PWT, this was not an issue, so the sample could be tested until it had completely disintegrated. Here, however, it became apparent that, although the matrix system softened and the cleat deformed, it retained its structural integrity overall. Ultimately, therefore, the sandwich panels collapsed before the cleat did, meaning that the joint did not lead to premature separation. The remnants of the sample after the test in the plasma wind tunnel are shown in Fig. 11. The total test duration was 2:40 min and was stopped after the upper sandwich panel disintegrated and the whole sample detached from the sample holder.

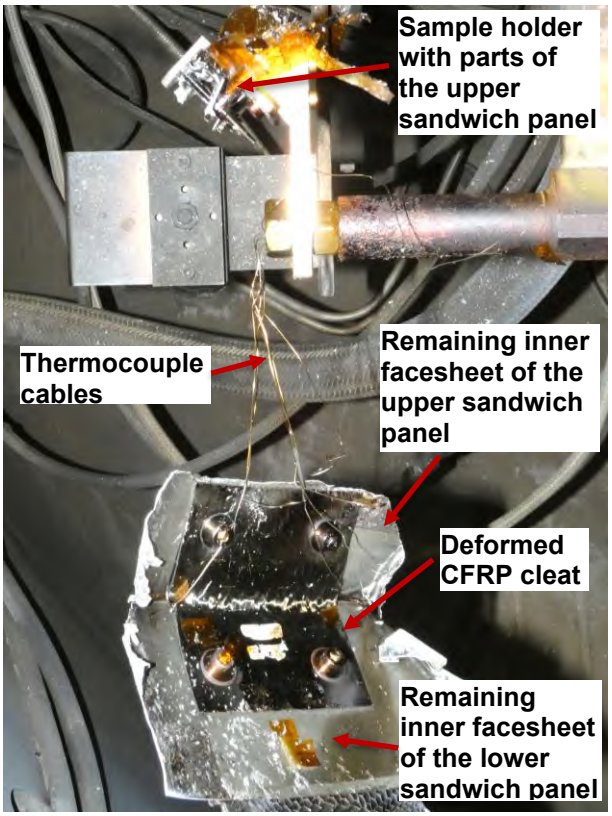

Figure 11: Remnants of the Demisable CFRP Cleat sample

The samples with a two-part, bonded cleat showed in general a similar behaviour. The joint separated in the bond line well before any significant damage occurred to the surrounding structure, such as the panels. A sample after the test in the PWT is shown in Fig. 12, which separated in 12 s.

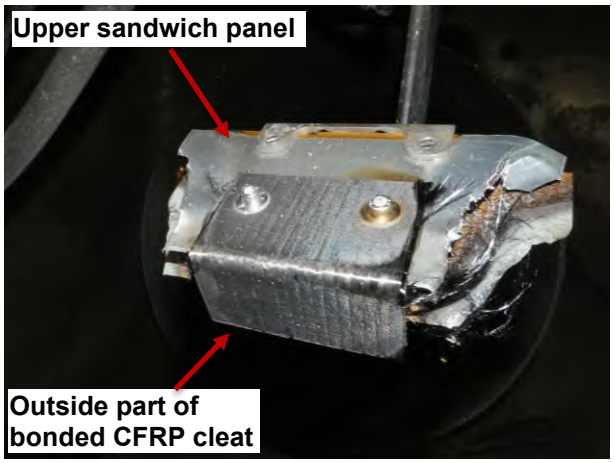

Figure 12: Sample after test with adhesive technology integrated in a two-part CFRP cleat, which separated during the test

The outlier was the test of the bonded CFRP cleat on the inside position in the PWT in which no clear separation was observed. Instead, the lower panel deformed and likely became stuck on the sample holder and therefore did not detach. In post-test investigation a clear debonding of the bond line was found, indicating the adhesive triggered. Nevertheless, it was not possible to determine a definite time to separation.

The difference between the samples lay in the time taken for separation, which depended not only on the specific joint design but also on the test. The samples in which the joint was positioned on the outside generally fragmented more quickly than those in which the joint was on the inside. In addition, the test sample in which aluminium was used for the cleat material instead of CFRP fractured even sooner.

The times required until the joint separates, or – in the case of inserts – until the solder melts, at which point separation would have been possible, are listed in Tab. 3 for the RC and in Tab. 4 for the PWT. The times between the two test set-ups naturally differ due to the different heat fluxes. In the RC test, the radiant heat is gradually increased over several minutes – the full power of 50 kW/m² is only applied after 965 s – whilst the PWT heats the sample immediately at full power. Another difference between the tests is the aerodynamic forces in the PWT, which enable material to be ablated. The difference is also clear from the condition of the sandwich panels after the testing. Whilst the samples in the RC clearly show the effects of the heat – the panels are all slightly deformed and warped following the tests – their fundamental structural integrity remains intact, even after tests lasting 20 minutes. On the other hand, samples in the PWT are usually destroyed after just a few minutes. The facesheets melt and the honeycomb disintegrates, causing the sandwich panels to lose their structural integrity and fall out of the sample holder. This effect is therefore also reflected in the times taken for separation.

Table 3: Results of the RC testing

Sample	Time [s]	Note
Demisable Insert in aluminium panel	590	Only melting of solder
Bonded 2-part CFRP cleat, inside location	751	Full separation
Bonded 2-part CFRP cleat, outside location	626	
Bonded 2-part alu cleat, inside location	596	
Demisable Anchor Nuts	726	Only melting of solder
CFRP cleat with demisable matrix	n/a	No separation
CFRP cleat with demisable matrix and added AlMg particles	n/a	

One anomaly was observed during the tests at the PWT, which affected all samples. The tests revealed that the width of the samples was slightly greater than the homogenous plasma flow core, which resulted in deflection of the flow and instable

flow conditions, shown in Fig. 13 on the left. This resulted in excessive heating by the shear layer at the outer edges of the panels. As a result, within a few seconds of the test beginning, the edges of the sample had melted away, shown in Fig. 14. This meant that the sample now fitted back into the homogeneous flow core and the flow stabilised, shown in Fig. 13 on the right, so the problem effectively resolved itself and the tests could continue.

Figure 13: Deflected flow at the beginning of test at 6 s (left), and stabilised flow at 36 s (right)

Figure 14: Areas of increasing heating on sample and subsequent "cutting" to size

Table 4: Results of the PWT testing

Sample	Time [s]	Note
Demisable Insert in aluminium panel	~55	Only melting of solder
Bonded 2-part CFRP cleat, inside location	n/a	No definite measurement possible
Bonded 2-part CFRP cleat, outside location	12	Full separation
Demisable Insert in CFRP panel	~50	Only melting of solder
CFRP cleat with demisable matrix	n/a	No separation
Demisable Edge Insert	~30	Only melting of solder
Demisable Anchor Nuts	~65	

5. CONCLUSION & OUTLOOK

The re-entry simulations of the FrankensteinSat case study, carried out at the start of the project, demonstrated, firstly, the need for 'design-for-demise' and, secondly, the requirement for the joints to begin to separate as early as possible at low temperatures in order to be effective. As part of the first series of tests, initial mechanical and demise properties were characterised, providing a good understanding of the design's behaviour. Whilst some designs and technologies, such as bonded cleats, have already demonstrated their potential and met the requirements, tests on other technologies, such as inserts and anchor nuts, have revealed design flaws. Only those designs that relied solely on a change of material to a demisable matrix system failed to achieve any observable improvement in the test and will therefore not be considered further in the next phase of the project.
Revising the designs will be the primary task for further development in the next phase of the project. For the inserts, the design issue of jamming must be resolved, whilst at the same time maintaining mechanical performance as far as possible. For the bonded cleats, reliability is to be optimised, and future development will also place greater emphasis on mechanical properties. The design is therefore optimised for stiffness using simulations and verified through testing on samples. These design changes will then be verified as part of the second test campaign, which will again take place in the RC of AAC and PWT of the DLR.
As primary joints, the designs developed must, of course, also meet all other requirements apart from those relating to improved demise, in particular the loads that occur when the satellite is launched into space. Further qualification work is therefore required in this area. These tests include, amongst other things, vibration tests, thermal cycling, shock loading and, where new materials are used, qualification on material level like outgassing.

Design for Demise (D4D), Re-entry technology, Uncontrolled re-entry, SCARAB, Casualty risk, Satellite structures

ABSTRACT

The rapid growth of low Earth orbit activity has increased the importance of end-of-life disposal and the safety implications of uncontrolled atmospheric re-entry. This work develops a methodology for progressively evaluating a representative LEO mid-mass satellite architecture for improved demise. A traceable baseline is used to define a bounded design space in which Design-for-Demise measures and architecture choices are translated into explicit variables. These are evaluated through a SCARAB simulation campaign, first individually and then in selected combinations to assess interactions. Total debris casualty area is used as the main comparison metric, supported by surviving mass and subsystem contributions. The single-variable results show reductions in total debris casualty area of up to 38.0%, while some modifications reduce surviving mass but increase casualty area. Subsystem-level results also show that architecture changes can affect components other than those directly modified, and the preliminary interaction analysis shows that the response to a design change can vary when combined with other architecture modifications. The aim is to provide a structured and traceable methodology for identifying architecture changes that improve demisability and for assessing how their effects change when combined.

1. INTRODUCTION

The increase in the number of objects in Low Earth Orbit (LEO) has increased the attention given to end-of-life disposal [1]. For spacecraft undergoing uncontrolled re-entry, safety requirements are commonly expressed in terms of human casualty risk from surviving debris. Both ESA and NASA adopt a maximum human casualty risk of 10^{-4} per re-entry event [2] [3]. Reducing this risk requires limiting the number and casualty area of fragments surviving to ground impact [4]. Design-for-Demise (D4D) is a method to address this by designing the spacecraft around these requirements, for example by promoting earlier break-up or reducing subsystem survivability during re-entry [5].

D4D is often associated with individual components or technologies, but their effect also depends on the surrounding architecture. Due to shielding and exposure timing, specific D4D technologies can have indirect effects on subsystems they are not directly targeting [6]. As a consequence, the effect of a D4D measure cannot always be inferred from the modified component alone.

Existing work provides D4D concepts at the component or system level and detailed re-entry analyses, but implementing these measures within a complete spacecraft creates a large and coupled architecture design problem. Many possible technologies can be used to improve demisability, with interactions and indirect effects on other subsystems. The effect of combining different measures therefore cannot necessarily be inferred from their isolated performance. The resulting architecture design problem is explored progressively, with the design space reduced through successive evaluation of individual measures and their interactions. Individual measures are first evaluated independently, and the resulting changes in DCA and surviving components are then used to select combinations for the assessment of interactions.

This paper presents a structured methodology for representing and progressively evaluating D4D measures through a bounded variable table. To test this methodology, a representative LEO satellite is used as a baseline, and candidate D4D technologies are converted into explicit variables describing component modelling, accommodation, shielding, and structural openings. The methodology is tested through a SCARAB simulation campaign, with debris casualty area (DCA) used as the main comparison metric. Total DCA, surviving mass, and their distribution among subsystems are used to identify the effects of

individual technologies and to guide subsequent simulation iterations.

2. ARCHITECTURE DESIGN-SPACE METHODOLOGY

2.1. Representative Baseline

To apply the proposed methodology, a baseline satellite architecture is required. To avoid arbitrary geometry and keep the architecture physically plausible, an existing satellite architecture is used as a starting reference. A communication-platform architecture is selected because communication satellites account for more than 80% of recent LEO payload launch traffic, making them particularly representative of current LEO activity [1]. Where public information is insufficient, representative subsystem references and modelling assumptions are used to complete the architecture.

Iridium NEXT and the ELiTeBUS 1000 documentation are used as the main spacecraft and platform references. The latter provides the broad platform configuration and subsystem list [7], while the first provides information on the communication payload and antenna functions [8]. More information is taken from public references to define individual subsystems. Where the required geometry, material, or accommodation information is not available, modelling assumptions are introduced. The resulting baseline therefore combines platform information, subsystem references, and assumptions to provide a physically realistic and representative starting architecture for the simulation campaign.

2.2. Design-variable Table

After running the re-entry simulation of the baseline model, the main demise-critical subsystems and surviving components can be identified. These results are then used to select relevant D4D measures and possible architecture changes for the components of interest, which are translated into explicit design variables. For the representative baseline used in this study, the critical components identified are the propellant tank, reaction wheels, magnetorquers, and the Solar Array Drive Mechanisms (SADM) so dedicated variables are defined for their design and accommodation. Additional variables are used to represent architecture changes that can influence shielding, exposure, and structural break-up.

For the present study, the design space is bounded to the variables implemented in the simulation campaign and those required for the selected interaction cases. Each variable defines a baseline condition and one or more implemented variants that can be represented directly in the re-entry model. The resulting design variables are summarized in Tab. 1.

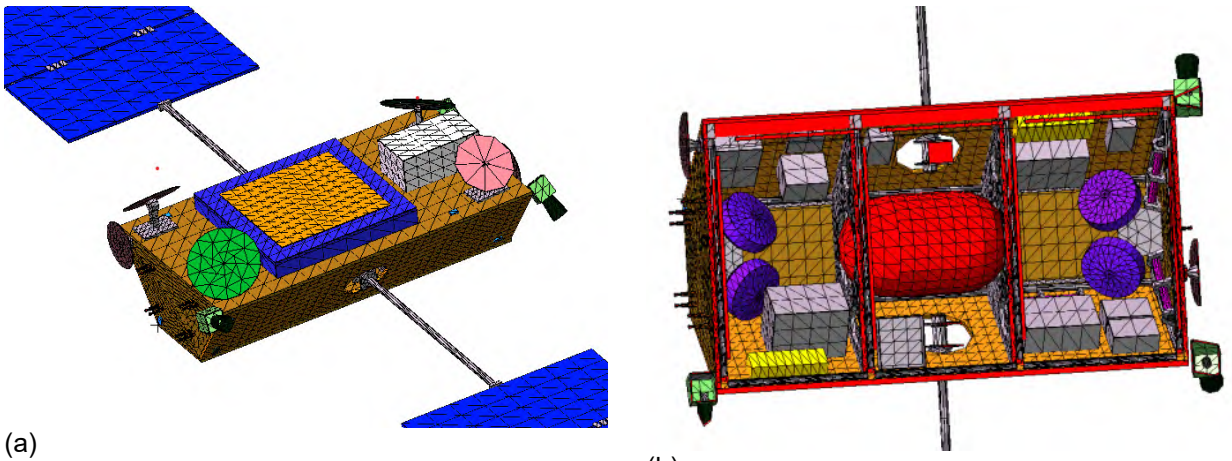
The variable identifiers are retained from the broader design space to maintain consistency with the simulation campaign. Missing identifiers correspond to variables that are not included in the analysis presented here.

Table 1: Architecture design variables

ID	Design variable	Baseline state	Implemented variants	Intended effect
V1	Tank material and construction	Titanium tank	**B:** Aluminium tank; **C:** Al/carbon-fibre-reinforced polymer overwrapped tank	Reduce the heat required for tank demise and modify its break-up behaviour
V2	Reaction wheel accommodation	Two reaction wheels mounted on each side of the platform	**B:** Alternative accommodation with separated reaction wheel pairs	Modify shielding and exposure timing
V3	Reaction-wheel construction	Baseline Al housing with steel internal components	**B:** Aluminium flywheel; **C:** early-release baseline construction; **D:** Al flywheel and early-release	Reduce the survivability of dense components and promote earlier separation
V5	Magnetorquer construction	Steel core, full housing and baseline support configuration	**B:** Hiperco core; **C:** segmented core; **D:** exposed core; **E:** demisable fastener	Reduce survival of the dense core and increase its thermal exposure
V9	Local panel opening	No local openings	**B:** Local break-out patches placed near selected critical subsystems	Increase local exposure with minimal intervention
V10	Demisable panel joints	Baseline structural panel connections	**B: T**op-panel release; **C:** front/back-panel release; **D:** side-panel release	Promote earlier structural opening and exposure of internal subsystems
V12	Solar Array Drive Mechanism release interface	Baseline SADM connections	**B:** Demisable interface between the SADM and its support	Promote early separation of the SADM and solar array assemblies

2.3. Design-space Reduction and Interaction Logic

The design variables reported in Tab. 1 can be combined into a large number of possible spacecraft configurations. Testing every possible combination would require an equally large number of re-entry simulations. The design space is therefore explored progressively, starting from isolated variable changes before introducing selected combinations.



The first stage consists of a single-variable campaign. In each case, one design variable is modified with respect to the baseline while the remaining architecture and simulation conditions are kept unchanged. The resulting changes are used to identify the effect of each variable when applied independently and the subsystems that remain critical after the modification.

The single-variable results are then used to guide the selection of subsequent interaction cases. Particular attention is given to variables whose effect may depend on shielding, exposure timing, or structural break-up. A D4D modification applied to an internal component, for example, may have a limited effect if the component remains shielded until late in the re-entry, while its effect may change when combined with an architecture modification that promotes earlier exposure [6]. The interaction cases are therefore selected based on the remaining critical subsystems and the expected physical interaction between the corresponding design variables, rather than by testing all possible combinations.

3. RE-ENTRY MODEL AND SIMULATION SETUP

3.1. Re-entry Model

The destructive re-entry simulations are carried out in SCARAB, where the spacecraft model is constructed from simple primitive shapes such as boxes, cylinders and spheres. The geometry is simplified while preserving properties relevant to demise, including component envelope, mass, relevant material properties, accommodation, shielding relationships, and hard-to-demise internal hardware. Smaller details that are not relevant to break-up or exposure are omitted. Changes to the reference model are then made according to the D4D measure under investigation, while all other model features are kept unchanged, to create the modified geometric model. The resulting baseline model is shown in Fig. 1, including the external configuration and the internal subsystem accommodation.

(a) (b)

Figure 1: Representative SCARAB baseline model: (a) external spacecraft configuration; (b) internal subsystem accommodation.

In addition to the reference baseline (BL), a second baseline configuration (BL2) is defined with a more detailed battery representation. In BL, each battery module is represented as a single uniform component. In BL2, the same battery inventory is instead resolved into the module housing and its internal cells as separate modelled components. This changes the way the battery can heat, fragment, and contribute surviving objects during re-entry, while the remaining spacecraft architecture is kept unchanged. BL2 is therefore used as an alternative reference configuration for part of the simulation campaign.

3.2. Simulation Setup and Evaluation Metrics

All baseline and variant simulations use the same initial state, environmental models, and numerical settings, so that differences between cases can be attributed to the implemented architecture changes. The initial conditions are summarized in Tab. 2.

Table 2: Common initial conditions used for all simulations

Semi-major axis	6510 km
Eccentricity	0.001
Inclination	84.5°
RAAN, argument of perigee, and true anomaly	0°
Geodetic Altitude	125.35 km
Velocity	7.8 km/s

The primary evaluation metric is the total DCA, with the change relative to the baseline used to compare the individual variants. Additional outputs, including surviving mass, number of surviving fragments, and DCA and surviving mass by subsystem, are used to support the interpretation of the results.

Since the DCA calculation depends on the representation of the surviving fragments, a specific post-processing treatment is applied to the small electronic units modelled within the L-band antenna and hosted payload. These units are represented with explicit internal cards, consistent with the electronics-box approach described in the DIVE guidelines [9]. However, details such as their mass, dimensions, and internal card layout are not available from public information, and the resulting representation can therefore vary significantly depending on the assumptions adopted. More recent ESA SARA guidance instead recommends representing small and medium electronic components as an aluminium housing containing a generic electronics material, while explicit GFRP cards are reserved for large components as an exception [10]. To approximate this coarser representation, surviving cards belonging to the same small electronic unit are grouped in post-processing for the DCA calculation. Their masses are summed, while the group DCA is taken as the maximum DCA of its constituent cards. This aggregation rule is an assumption introduced in the present study and is not prescribed by the SARA guidance.

Casualty risk is retained as the wider compliance context but is not used as the architecture-comparison metric, since it additionally depends on the population distribution associated with the re-entry case.

3.3. DCA Interaction Metric

For the selected combination cases, the interaction between two design changes is evaluated relative to a common background configuration. The DCA of the common background is denoted by D_0, while D_A, D_B, and D_{AB} denote the DCA obtained after applying change A, change B, and both changes together, respectively. The effect of a change is measured as the difference between the DCA with and without that change:

$$\Delta D_A = D_A - D_0;\ \Delta D_B = D_B - D_0 \quad (1)$$

The interaction term between two changes is then calculated as

$$\Delta D_{int} = \Delta D_{B|A} - \Delta D_B \quad (2a)$$

$$\Delta D_{int} = D_{AB} - D_A - D_B + D_0 \quad (2b)$$

where the interaction is defined as the difference between the effect of B when A is present, and the effect of B on the background. An interaction term equal to zero therefore indicates that the effect of B is unchanged by the presence of A.

A value of $\Delta D_{int} = 0$ indicates an additive response, which means that the changes do not interact. Negative values ($\Delta D_{int} < 0$) indicate a favourable interaction, for which the combined DCA is lower than expected from the isolated effects. Positive values ($\Delta D_{int} > 0$) indicate an interaction that is less favourable than the additive expectation.

The sign of the interaction alone, however, does not indicate whether the combined configuration is beneficial compared with the individual changes. For this reason, the combined DCA is also compared with the best individual case. Three responses are distinguished:

$$D_{AB} < D_A + D_B - D_0 \quad (3a)$$

Indicates a favourable interaction, for which the combined DCA is lower than the additive expectation;

$$D_A + D_B - D_0 \leq D_{AB} < \min(D_A, D_B) \quad (3b)$$

indicates that the combination improves upon the best individual change, but the DCA is higher than or equal to the additive expectation; and

$$D_{AB} \geq \min(D_A, D_B) \quad (3c)$$

indicates that the combination does not improve upon the best individual change.

The resulting interaction is dependent on the background used for the comparison. The same pair of changes can therefore be evaluated around either BL or BL2, provided that the same background is used for all four cases. For example, for an interaction evaluated around BL2, the comparison is made between BL2, BL2+A, BL2+B, and BL2+A+B.The interaction obtained for the same pair A and B can therefore change when evaluated around a different background.

The resulting interaction is dependent on the background used for the comparison. The same pair of changes can therefore be evaluated around either BL or BL2, provided that the same background is used for all four cases. For example, for an interaction evaluated around BL2, the comparison is made between BL2, BL2+A, BL2+B, and BL2+A+B. The interaction obtained for the same pair A and B can therefore change when evaluated around a different background.

4. RESULTS

4.1. Baseline

The baseline simulation establishes the reference case for the subsequent architecture variants and allows the critical surviving components to be identified. The baseline results are also used to refine the design-variable table presented in Section 2.2 towards the components that remain relevant after re-entry.

The baseline model has a starting mass of 634.13 kg, of which 134.12 kg survives to ground impact, corresponding to 21.15% of the initial mass. The baseline total DCA is 14.00 m². The surviving mass and DCA are not distributed uniformly across the spacecraft, with the main contributions associated with the propellant tank, reaction wheels, magnetorquer, SADM and the payload and electronic assemblies. The subsystem-specific baseline results are summarized in Tab. 3.

The surviving components are consistent with those expected from the initial design-space definition. The propellant tank survives as a single large fragment, while the reaction wheels retain 37.74 kg across six surviving fragments. The SADM and solar arrays, and the magnetorquer, also remain present at ground impact. The L-band antenna and hosted payload contain surviving internal electronic units, resulting in DCA contributions of 2.07 m² and 0.68 m², respectively.

Table 3: Baseline surviving fragment results by subsystem

Subsystem	Surv. mass [kg]	Surv. fragments	DCA [m²]
Antennas	44.79	2	2.07
Hosted Payload	7.69	1	0.68
Reaction wheels	37.74	6	3.29
Electronic boxes	19.20	6	3.45
Propellant tank	17.57	1	1.63
SADM + solar arrays	4.52	4	1.79
Magnetorquers	1.75	1	0.5
Multiple	0.87	1	0.59

The breakup sequence shows that these internal assemblies remain shielded until comparatively late in the re-entry. This behaviour is supported by the subsequent architecture variants. The baseline therefore identifies both the main demise-critical components and a strong dependence of the surviving-fragment burden on the exposure timing of the internal electronics.

4.2. Single-variable Results

The single-variable cases are first compared through the percentage change in total DCA relative to the baseline, as shown in Fig. 2. The greatest reduction is produced by the top-panel release (V10B), with a decrease of 38.0%. The side-panel release (V10D) reduces the total DCA by 20.9%, followed by the aluminium tank (V1B), with a reduction of 15.6%. Smaller reductions are obtained with V2B, V3B and the magnetorquer variants V5C–V5E. Several variants instead increase the total DCA, with the largest increases obtained for the aluminium flywheel with early release (V3D), the Al/CFRP overwrapped tank (V1C), and the front/back-panel release (V10C), with increases of 17.3%, 15.6%, and 8.4%, respectively.

The absolute DCA and its distribution among the spacecraft subsystems are shown in Fig. 3.

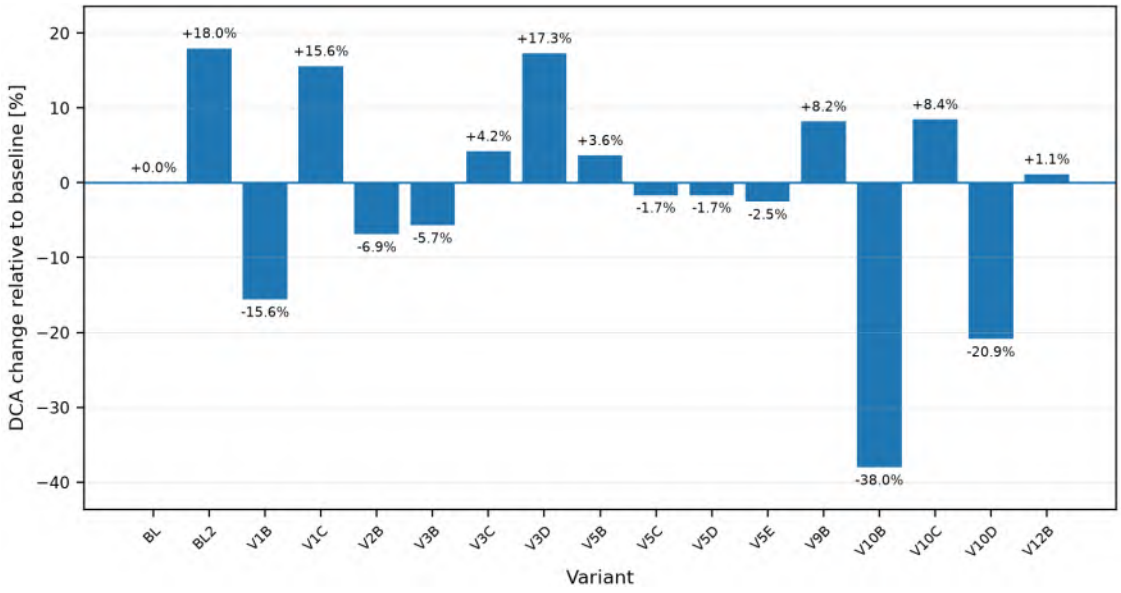


Figure 2: Percentage change in total debris casualty area relative to the baseline for the single-variable cases.

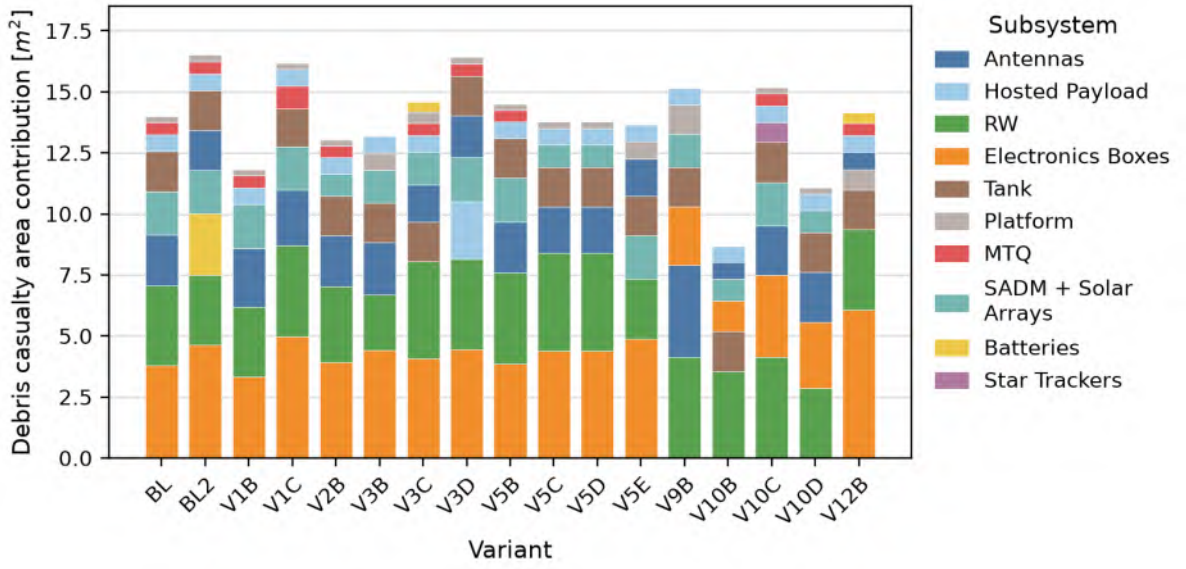

Figure 3: Total debris casualty area for the baseline and single-variable cases.

The change in each subsystem contribution relative to the baseline is shown in Fig. 4. For the top-panel release, the largest reductions come from the electronic boxes and antennas, whose DCA contributions decrease by 2.5 m² and 1.4 m², respectively. The SADM and solar-array contribution is reduced by 0.9 m² and the magnetorquer no longer survives, while the tank remains unchanged and the reaction-wheel contribution increases slightly. The reduction is therefore mainly associated with the earlier exposure of the internal electronics and antenna assemblies. The local break-out patches (V9B) instead reduce the electronic-box, magnetorquer, and SADM contributions, but these reductions are outweighed by increases in the antennas, reaction wheels, and platform, resulting in an overall DCA increase of 8.2%. The side-panel release produces a more distributed reduction, mainly through the electronic boxes, SADM and solar arrays, magnetorquer, and reaction wheels. The propellant tank remains unaffected in both panel-release cases.

The aluminium tank (V1B) instead produces a more direct response, with its reduction in total DCA resulting primarily from the complete demise of the tank. This result should be treated with caution when assessing the realistic behaviour of the variant. The aluminium tank completely demises in the present model, whereas Grassi et al. found that an aluminium-lithium tank fragmented into several surviving pieces and increased the casualty area in their re-entry analysis [6].

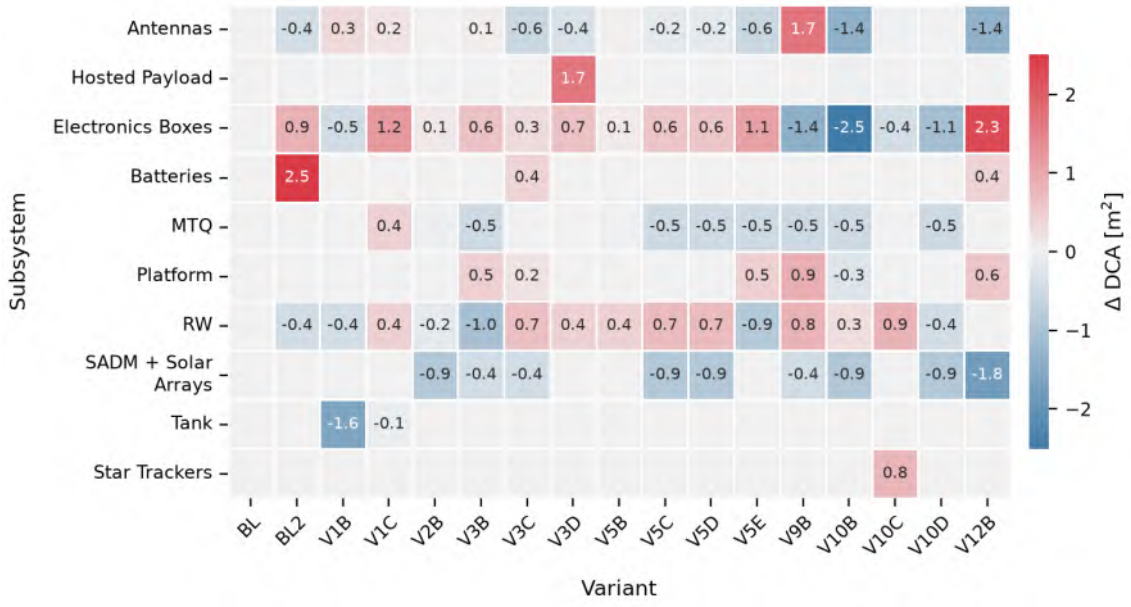

Figure 4: Change in debris casualty area by subsystem relative to the baseline for the single-variable cases.

The subsystem results also show cases where the change in total DCA is not driven primarily by the component being modified. The alternative reaction-wheel accommodation (V2B) reduces the total DCA by 6.9%, while the reaction-wheel contribution decreases by only 0.2 m². Most of the reduction instead comes from the SADM and solar arrays, whose contribution decreases by 0.9 m². Conversely, the aluminium flywheel with early release (V3D) increases the total DCA by 17.3%, while the reaction-wheel contribution increases by only 0.4 m². The hosted-payload and electronic-box contributions increase by 1.7 m² and 0.7 m², respectively. A substantial part of the overall response therefore occurs outside the subsystem directly modified.

Surviving mass provides an additional comparison, as shown in Fig. 5. The top-panel release again gives the largest reduction, decreasing the surviving mass from 134.12 kg to 60.26 kg. However, surviving mass and DCA do not always follow the same trend. The front/back-panel release (V10C) and the aluminium flywheel with early release (V3D) reduce the surviving mass to 121.73 kg and 104.99 kg, respectively, while increasing total DCA by 8.4% and 17.3%. Reducing the amount of surviving material therefore does not necessarily reduce the casualty area, since the number, size, and distribution of the surviving fragments also change.

These results show why total DCA needs to be considered together with subsystem contributions and surviving mass. Some modifications mainly affect the component they target, while others produce larger changes elsewhere in the spacecraft or alter the surviving-fragment population in ways that are not reflected by surviving mass alone. Surviving-mass reduction can nevertheless help identify design changes that improve the demise of specific subsystems, particularly when a clear reduction is observed in their surviving mass. The single-variable results are therefore used to identify the remaining critical components and select the interactions investigated in the following section.

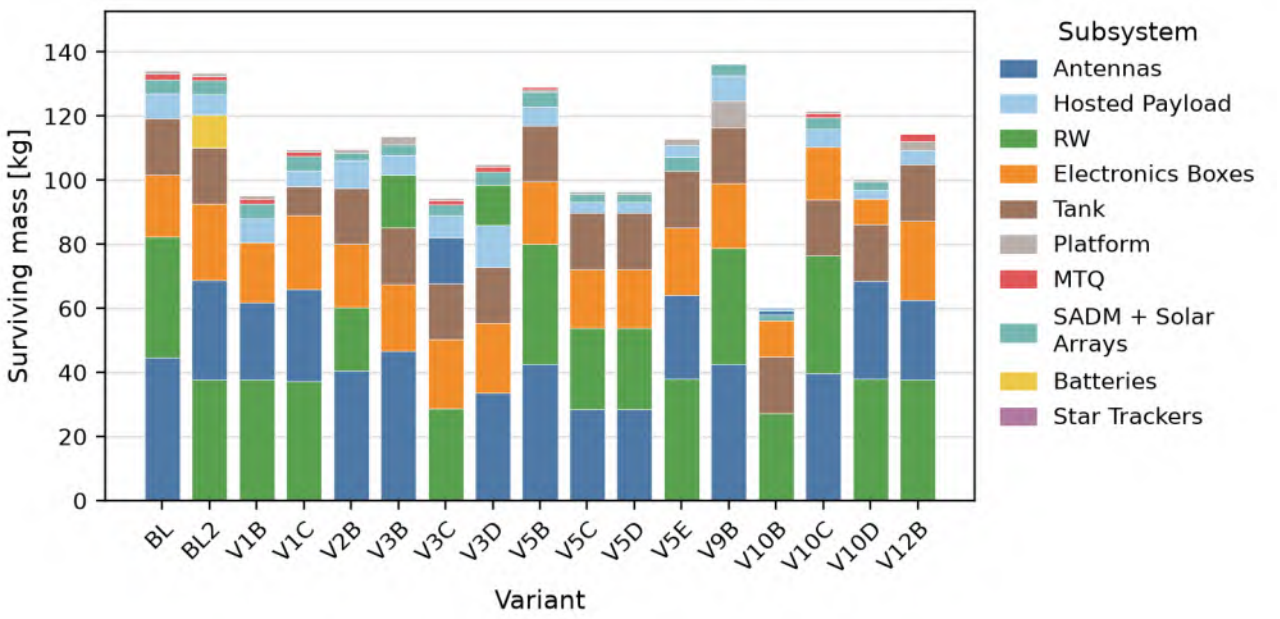

Figure 5: Absolute surviving mass by subsystem.

4.3. Preliminary Combination Results

The wider optimization campaign is still ongoing. Rather than drawing conclusions from an incomplete interaction matrix, one completed interaction is considered here to demonstrate the analysis method and examine the resulting subsystem behaviour. The interaction between the top-panel release (V10B) and the aluminium reaction-wheel flywheel (V3B) is evaluated around BL2. This pair combines a change to the spacecraft opening and exposure sequence with a modification to a critical internal component. The four configurations required for the interaction analysis are summarized in Tab. 4.

Table 4: DCA and surviving mass for the V10B–V3B interaction cases around BL2

Configuration	Total DCA [m²]	ΔDCA	Surviving mass [kg]
BL2	16.51	-	133.34
BL2 + V10B	8.43	-49.0%	74.73
BL2 + V3B	14.93	-9.6%	117.30
BL2+V10B+V3B	7.18	-56.5%	52.30

V10B produces the dominant isolated effect, reducing DCA by 8.09 m², while V3B reduces it by 1.58 m². When V3B is added to a configuration already containing V10B, the DCA decreases from 8.43 m² to 7.18 m², corresponding to an effect of −1.24 m². The interaction term is therefore:

$$\Delta D_{int} = (-1.24) - (-1.58) = 0.34 m^2 \qquad (4)$$

This case falls within the response defined by Eq. 4b: the interaction is less favourable than additive, while the combined configuration still achieves a lower DCA than either individual change.

The subsystem contributions show that the mechanism also changes between the isolated and combined cases. When V3B is applied independently to BL2, the reaction-wheel DCA decreases by only 0.35 m², while the largest reduction occurs in the electronic boxes, at 1.48 m². The platform contribution simultaneously increases by 0.37 m². When V3B is instead added with V10B already present, the reaction-wheel contribution decreases by 0.77 m², while the antenna and magnetorquer contributions decrease by 0.53 m² and 0.49 m², respectively. The electronic-box contribution, however, increases by 0.54 m². The effect of V3B is therefore smaller in total DCA when V10B is present, despite producing a larger reduction in the subsystem it directly modifies.

This case shows why the mechanism behind the interaction cannot be interpreted from total DCA alone. A change in the surrounding architecture can alter both the magnitude and the subsystem distribution of the response to a component-level modification.

The present case is one selected pair from a broader interaction campaign that is still in progress. The interaction values currently available for the BL2 background are assembled in Fig. 6. As the campaign is completed, separate interaction matrices will be constructed for BL and BL2 and interpreted together with the corresponding subsystem DCA and surviving-mass changes. A positive interaction indicates that the combined effect is less favourable than an additive response, but does not necessarily mean that the combined configuration performs worse than the individual modifications. Cases where the combined configuration does not outperform the best

individual modification are therefore outlined in black.

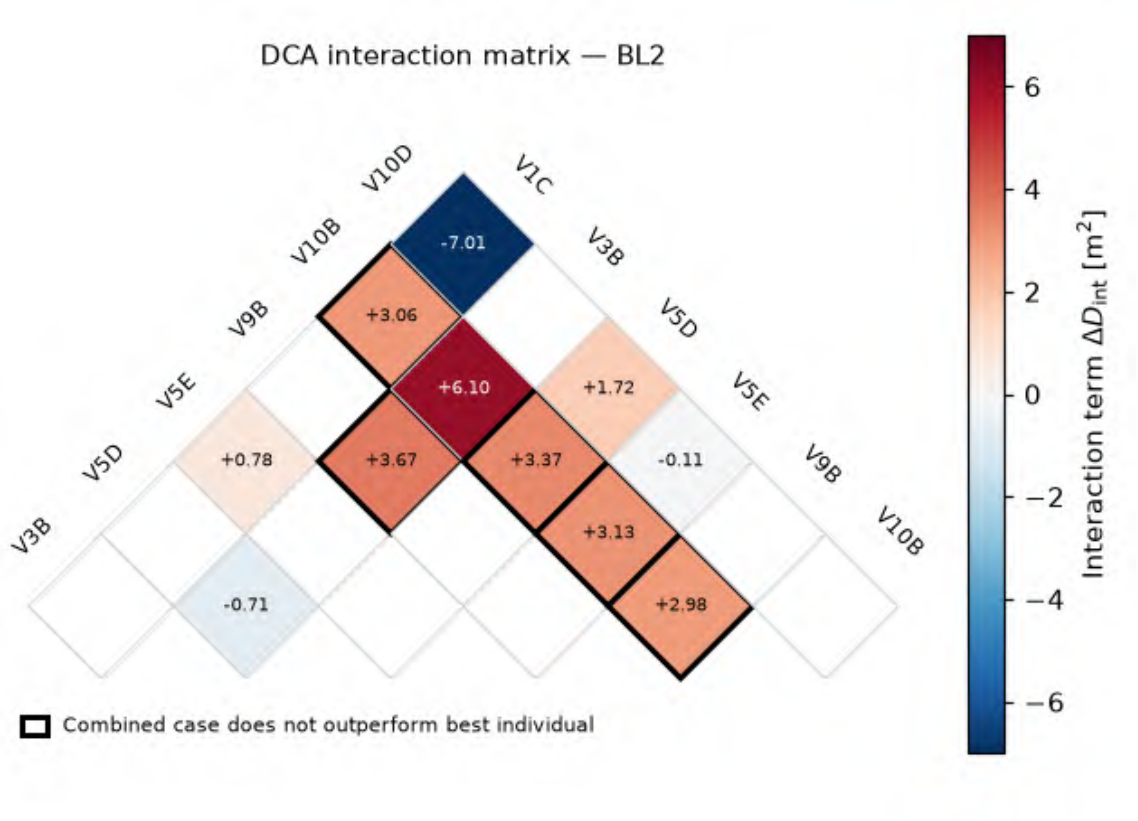

Figure 6: Preliminary normalized DCA interaction matrix for the BL2 background.

5. DISCUSSION

The single-variable results show that the effect of a D4D measure is not limited to the subsystem directly modified. Changes in shielding, exposure and break-up sequence can also affect other parts of the spacecraft. This is most evident for the panel-release cases: the top- and side-panel releases reduce DCA, while the front/back-panel release increases it despite reducing the surviving mass. The effectiveness of an early-release concept therefore depends on where the release occurs and which components are subsequently exposed or released. More generally, reducing surviving mass does not necessarily reduce DCA, since the resulting number, size and distribution of surviving fragments can also change.

The selected interaction between the top-panel release and the aluminium reaction-wheel flywheel shows that the effect of a design change can depend on the surrounding architecture. Although the interaction in total DCA is small, the subsystem response of the reaction-wheel modification changes when the top-panel release is already present. The preliminary interaction matrix in Fig. 6 also shows that the magnitude and direction of the interactions vary between different variable pairs. Interaction effects therefore need to be considered together with both the resulting combined DCA and the corresponding subsystem response, rather than being interpreted from the interaction term alone. Evaluating D4D measures as architecture variables rather than as isolated component modifications is supported by this.

The results also highlight the importance of the adopted modelling representation. For components whose detailed internal architecture is not publicly available, different assumptions can change the resulting surviving-fragment population and therefore the calculated DCA. This is particularly relevant for the small electronic units considered in this study, for which a specific aggregation treatment is applied in post-processing. The absolute DCA values should therefore be interpreted together with the assumptions used to represent these components.

More generally, destructive re-entry predictions are subject to modelling uncertainty. SCARAB has been validated against in-flight measurements, re-entry observations and wind-tunnel experiments, and has been compared with other international re-entry prediction tools [11]. The present study therefore focuses primarily on relative differences between

consistently modelled configurations rather than exact predictions of absolute DCA.

6. CONCLUSION

This work develops a progressive method for evaluating D4D measures as spacecraft architecture variables using destructive re-entry simulations. The investigated combinations already achieve substantial reductions in total DCA, with the lowest value obtained so far by combining the aluminium reaction-wheel flywheel (V3B), local break-out patches (V9B), and top-panel release (V10B) around the BL2 configuration. This combination reduces the DCA from 16.51 m² to 6.943 m², corresponding to a reduction of 57.9%. The results show that modifications can affect subsystems other than the one directly targeted and that lower surviving mass or earlier release does not necessarily result in lower DCA.

A normalized interaction metric is also introduced to quantify how the effect of one D4D measure changes when combined with another relative to a common background configuration. The interaction results show that these combined responses can differ in both magnitude and subsystem distribution from the corresponding isolated effects.

The interaction campaign will be continued around both baseline configurations, with the completed pairwise interactions used to select further multi-variant configurations and progressively reduce the design space towards architecture optimization.

KEYWORDS
Bio-based materials; wood materials; CubeSat; spacecraft structures; in-orbit demonstrator; sustainability.

ABSTRACT
This work develops a 3U CubeSat concept to obtain in-orbit data on bio-based materials. The mission uses the International Space Station (ISS) orbit and exposes twelve samples for 8 to 12 months. The selected payload uses four internal cameras with 30 mm deployable mirrors at a 40° angle and forty-eight thermocouples. Structural analyses based on the NanoRacks CubeSat Deployer (NRCSD) loads show stress results below the material strengths in all evaluated cases, with a first natural frequency of 888.74 Hz. Thermal analyses show material-dependent sample temperatures; balsa reaches -60 to 18°C in the longest-eclipse mixed-material case, while degraded optical properties increase internal temperatures by about 3 to 4°C and exposed-wood temperatures by about 8 to 30°C. An engineering model confirms that the selected mirror geometry images the full sample height.

1. INTRODUCTION

The increasing number of spacecraft in low Earth orbit (LEO) and the associated growth in re-entry mass have increased interest in the environmental impact of space activities [1]. Spacecraft structures primarily use aluminium alloys, titanium alloys, and carbon-fibre reinforced polymers because of their structural performance and flight heritage [2]. At the same time, supply and sustainability concerns are increasing for several raw materials used by European industry [3].

Wood and other bio-based materials are being investigated for selected spacecraft applications. Their advantages include low density, low thermal conductivity, renewable origin, and improved demisability, but their behaviour in space is still poorly characterised [4]. A recent ISS exposure experiment tested three hardwood species for about ten months. The specimens were installed on a different port after an accident at the originally planned port, which placed them opposite to the intended flight direction and reduced the atomic-oxygen (AO) exposure. Visible surface and colour changes were still observed [5].

The German Aerospace Center (DLR) Institute of Structures and Design has been investigating wood and other bio-based materials for spacecraft structures within the DLR Bio Strux project [6,7]. Previous work assessed the structural and space environment feasibility of wooden satellite concepts [8], followed by life cycle assessment and plasma wind tunnel demisability testing of wood-aluminium laminated panels [9]. The mission proposed here extends this work by evaluating how these materials could be monitored directly in orbit.

For this purpose, a 3U CubeSat in-orbit demonstrator is developed. The experiment focuses on visible surface degradation, thermal cycling, dimensional changes, ultraviolet (UV) and atomic oxygen (AO) exposure, and moisture loss in vacuum. The work covers the mission and payload definition, CubeSat system design, structural and thermal analyses, and an engineering model of the camera and mirror system.

2. EXPERIMENT DEFINITION

2.1. Mission Definition

The main objectives are to monitor surface changes, including erosion, cracking, and colour changes, relate these effects to UV and AO exposure, evaluate thermo-mechanical behaviour during thermal cycling, assess shrinkage caused by moisture loss in vacuum, and assess surface charging effects.

The mission requirements are divided into orbit, environment, performance and design. The orbit parameters are summarised in Tab. 1. The nominal mission duration is 10 months, within an acceptable range of 8 to 12 months. The ISS wood experiment measured visible surface changes after a similar exposure time [5]. The actual orbital lifetime remains uncertain because it is mainly influenced by atmospheric drag, which varies with solar activity [10].

Table 1: Baseline mission orbit and deployment parameters.

Parameter	Selected value
Orbit type	Circular, ISS-like
Deployment	Release from ISS
Altitude	420 km
Inclination	51.6°
Period	88 min
Maximum eclipse	35.5 min

The orbit is kept in LEO because AO is one of the main degradation mechanisms of interest. ISS deployment provides the selected altitude and inclination and allows comparison with the previous ISS exposure experiment. The CubeSat is transported to the ISS as pressurised cargo and deployed through the NanoRacks CubeSat Deployer (NRCSD), which is used as the baseline 3U dispenser [11,12].

The mission scenario is divided into six phases, including the pre-launch phase. Phase 0 covers sample preparation, bake-out, and integration into the NRCSD. Phase 1 covers cargo launch to the ISS, ISS handling, and deployment. Phase 2 is the early-orbit phase, where survival, first contact, and solar-panel deployment are checked. Phase 3 is commissioning, including subsystem checks and mirror deployment. Phase 4 is nominal operation and lasts about nine months. Images and sensor data are stored and downlinked during this phase. Phase 5 starts after the exposure campaign, when payload operations stop, final data are downlinked, and the spacecraft is passivated before natural orbital decay.

2.2. Material Selection

A material trade-off was used to select representative bio-based candidates. Two candidate groups were created based on their intended use. Load-bearing candidates were evaluated mainly on mass, stiffness, strength, and dimensional stability. The second group included candidates for other applications, such as thermal insulation or energy absorption, and was evaluated on mass, thermal performance, dielectric performance, energy absorption, and dimensional stability. Space compliance, availability, and sustainability were considered for both groups [4,13-15]. The candidates and selected materials are summarised in Tab. 2.

Table 2: Material trade-off summary.

Group	Candidates	Selected
1: load-bearing	Scots pine; Norway spruce; Douglas-fir; European larch; European beech; oak; birch; flax; hemp	Scots pine; birch
2: other uses	Radiata pine; balsa; poplar; black alder	Balsa; poplar

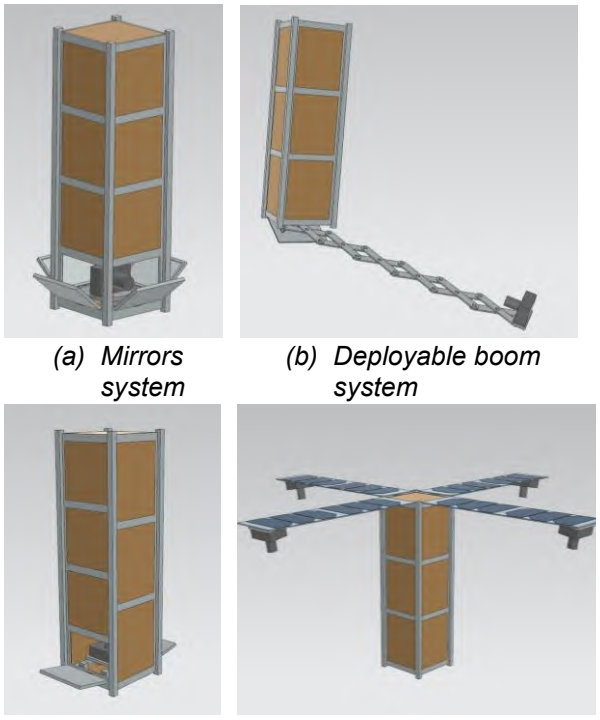
Scots pine performed well because of its low density, availability, and sustainability, whereas birch was stronger in stiffness and strength. In Group 2, balsa stood out for its very low density and thermal conductivity and high specific energy absorption, while poplar performed well in dielectric behaviour, dimensional stability, availability, and sustainability. These four materials obtained the highest overall scores and were selected for the later design and analysis phases.

2.3. Sensor Selection

The payload must capture the main material responses to the space environment. Vacuum can remove absorbed water and other volatiles, causing shrinkage; thermal cycling produces temperature gradients and dimensional changes; UV and vacuum-UV radiation can degrade the surface; AO can oxidise and erode organic materials; and charging is relevant because wood is electrically insulating [4,16,17].

The subject trade is summarised in Tab. 3. The subjects were ranked using relevance to material behaviour, measurability, integration complexity, data usefulness, power and data demand, and risk. Relevance to material behaviour received the highest weight.

Table 3: Sensor subject trade outcome.



Subject	Measurement location
Temperature	Samples, frame and electronics
Strain	Samples and frame
Acceleration	Near CubeSat center-of-gravity (CG)
Visual degradation (images, colour metrics)	External sample surface
Radiation exposure (ionising, UV and AO)	External samples
Pressure	CubeSat cavity
Radio-frequency (RF) and magnetic transparency	Internal antenna and magnetometer
Spacecraft charging	External samples to spacecraft ground

Temperature, strain, visual inspection, UV and AO exposure were classified as primary subjects.

In this work, only the camera and temperature measurement systems are developed in detail. A Raspberry Pi Camera Module V2 was selected, with the Raspberry Pi 4 Model B and the Arducam B012001 as the board and multi-camera adapter, respectively. Four images per day, one from each lateral side, are used as the reference imaging rate. Type-T thermocouples were selected for the expected temperature range, with MCC 134 boards used for data acquisition. Strain gauges remain relevant for a future flight model, but vacuum testing is needed first to determine the required measurement range.

2.3.1. Camera Mechanism

Four camera concepts were investigated, as shown in Fig. 1: an internal camera with mirrors (a), a deployable boom (b), a rail-mounted camera (c), and cameras on deployable solar panels (d). The mirrors concept was divided into three variants: one with adjustable mirrors with one rotating camera, one with deployable mirrors with one rotating camera, and one with deployable mirrors with four fixed cameras. The boom concept is similar to the WISA WoodSat camera configuration [18]. The solar-panel concept was inspired by the Orion camera system, which uses cameras on the solar arrays for external inspection [19,20].

(a) Mirrors system *(b) Deployable boom system*

(c) Rails system *(d) Solar-panel system*

Figure 1: Camera-mechanism concepts.

The mirror system candidate was selected, specifically the concept with four cameras and deployable mirrors. Out of its variants, it is the simplest because the cameras remain fixed and no stepper motor for camera rotation is required.

A MATLAB geometric model was then used to define the mirror length and deployment angle. The model represents the camera, the mirror, and the upper and lower limits of the exposed sample section. For each tested geometry, the real camera position was reflected across the mirror plane to create an equivalent virtual camera. Rays were then drawn from the upper and lower limits of the samples towards this virtual camera. It was then calculated where both rays crossed the mirror surface. A configuration is feasible when both intersection points fall within the mirror boundaries, meaning that light from both the top and bottom of the sample section reaches the camera through the mirror. The geometry used for this calculation is shown in Fig. 2.

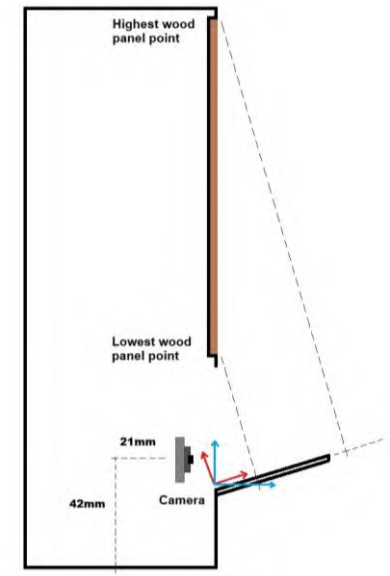


Figure 2: Geometric model of the mirror concept.

The feasible mirror length and deployment angle combinations are shown in Fig. 3. Below approximately 30°, no tested mirror length captures both sample limits. A 20° feasible deployment range was used as the design target. A 30 mm mirror provides a feasible range from 33.59° to 53.85°, and 40° was selected for the final design.

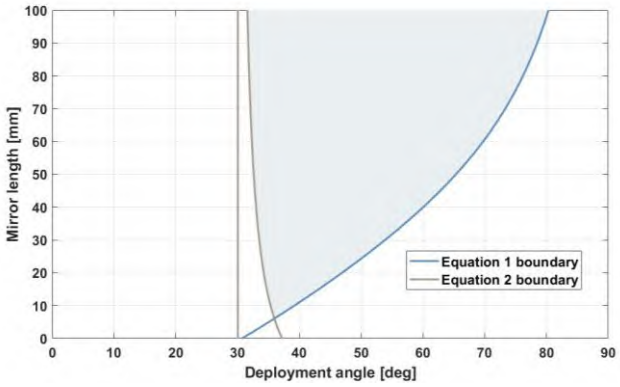

Figure 3: Feasible mirror geometries.

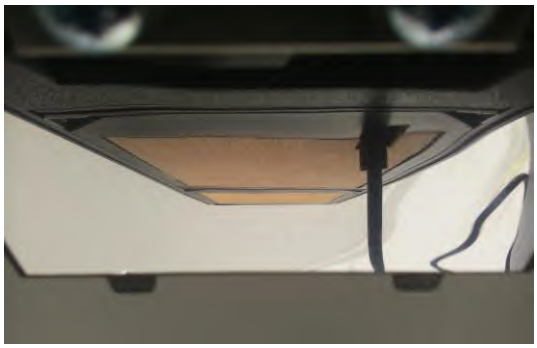
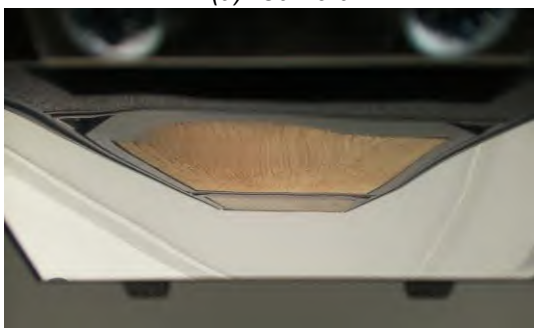
3. ENGINEERING MODEL

A physical engineering model was built to check the selected mirror and camera geometry. The imaging system uses the Raspberry Pi components previously discussed. The mirror supports, camera mounts, and sample interfaces were printed in polylactic acid (PLA) using a Bambu Lab H2D printer. Reflective aluminium foil was applied to the

mirror surfaces. The complete model is shown in Fig. 4.

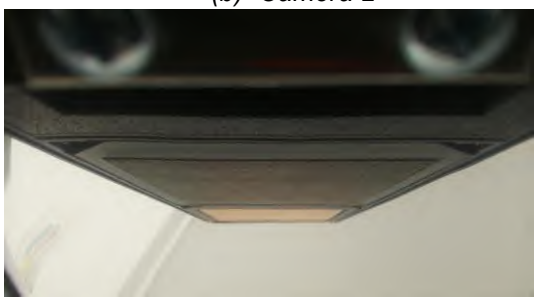


(a) Side view

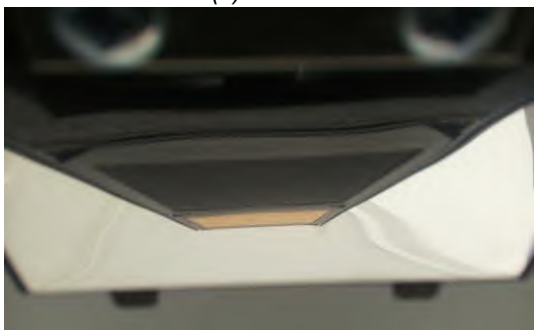


(b) Front view

Figure 4: Physical engineering model.



The four cameras were operated sequentially. The images in Fig. 5 confirm that a 30 mm mirror at 40° allows the complete height of the material samples to be imaged. The regions farther from the mirror occupy fewer pixels and contain less detail. Local distortion is also visible because the aluminium foil follows the roughness of the 3D-printed surface.



(a) Camera 1

(b) Camera 2

(c) Camera 3

(d) Camera 4

Figure 5: Engineering-model images obtained from the four cameras.

4. CUBESAT SYSTEM DESIGN

The imaging architecture tested in the engineering model is also used for the CubeSat design. Regarding the amount of data produced, 1.7 MB per image and four images per day give 6.8 MB/day. The temperature system uses four thermocouples per sample, sampled once per minute. Thus, the temperature data produced is 0.55 MB/day.

For the attitude determination and control system (ADCS), passive magnetic stabilisation is selected. Four permanent magnets create a fixed magnetic dipole that tends to align the CubeSat with the local geomagnetic field, while four hysteresis strips dissipate rotational energy. The layout follows the AstroBio 3U CubeSat reference [21]. A MATLAB script was used to visualise the CubeSat orientations throughout one orbit, with its Z-axis aligned with the magnetic field, as shown in Fig. 6.

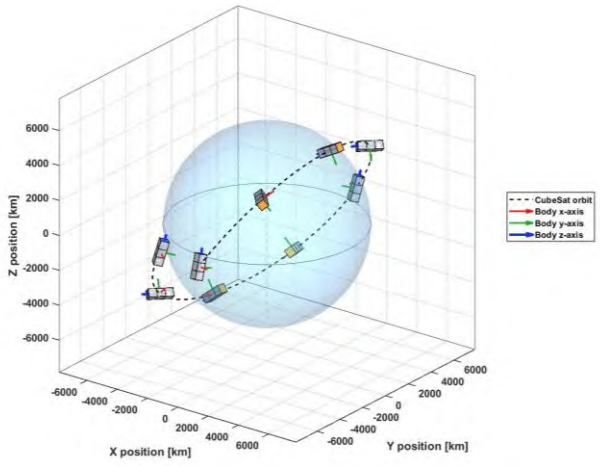


Figure 6: Visualisation of CubeSat attitude behaviour.

The Structure and Mechanisms System (SMS) uses separate aluminium 6061-T6 corner rails and removable sample panels. The design was inspired by available 3U CubeSat structures from 2NDSpace, NPC Spacemind, ISISpace, AAC Clyde Space, Serenum Space, and EnduroSat, together with university reference designs. The mirrors and solar panels use the EXA Hinge Nano+ and Hold-Down and Release Mechanism (HDRM) Nano as reference deployment hardware. Silicon carbide is used as the reference mirror substrate.

The Electrical Power System (EPS) uses four laterally deployable AAC Clyde Space PHOTON-SIDE solar panels, a GomSpace NanoPower P60 Power Conditioning and Distribution Unit (PCDU), and a NanoPower BPX 100 Wh battery. The Communication System (CS) uses a GomSpace NanoCom AX100 ultra-high-frequency transceiver and an ISISpace deployable very-high/ultra-high-frequency antenna. The Command and Data Handling System (C&DHS) uses an AAC Clyde Space Q7S as the main on-board computer (OBC), with separate Raspberry Pi, thermocouple acquisition, and deployables control boards for payload functions, together with an inertial measurement unit (IMU).

The preliminary mass distribution is given in Tab. 4. For the margins, 5% is used on commercial-off-the-shelf (COTS) components and 10% on components that need to be manufactured. The operating temperature limits used for thermal verification are listed in Tab. 5, while the main power consumption values used in the design are given in Tab. 6.

Table 4: Preliminary mass distribution.

System	Component	Qty.	Mass (g)
SMS	Primary structure	–	393.3
SMS	Secondary structure	–	419.8

The internal components were arranged to balance the CubeSat and keep the wiring simple. From top to bottom, the main stack contains the battery, PCDU, transceiver, main OBC and IMU, thermocouple boards, camera adapter, camera control board, passive ADCS strips, cameras, mirror assembly, ADCS magnets, deployables control board, and antenna. The battery is placed near the top to balance the payload mass at the lower end, while the IMU is kept near the spacecraft centre and away from the permanent magnets. The final deployed and stowed layouts are shown in Fig. 7. The final internal stack is shown in Fig. 8.

(a) Deployed *(b) Stowed*

Figure 7: Final CubeSat assembly.

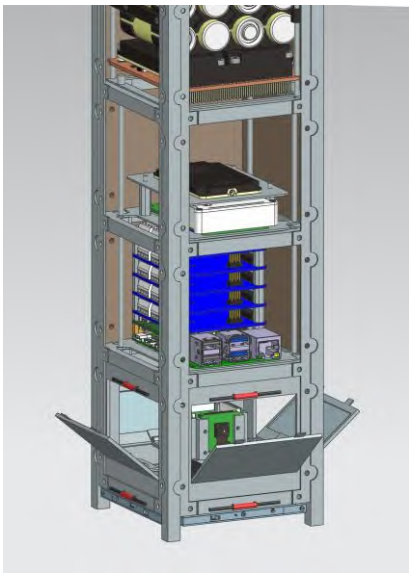

Figure 8: Final CubeSat internal stack.

5. SIMULATION CAMPAIGN

5.1. Structural Simulations

The structural model is based on the stowed assembly. The rails, braces, plates, samples, mirrors, mirror supports, hinges, and HDRMs are maintained, while electronic subsystems are replaced by point masses. The 4 mm wood panel samples are shell elements defined as orthotropic Scots pine, with the longitudinal grain direction aligned with the CubeSat Z-axis. The simplified finite-element model is shown in Fig. 9.

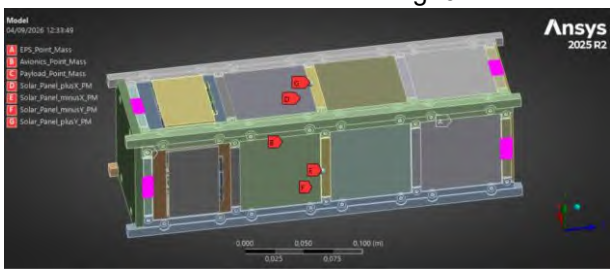

Figure 9: Simplified structural model.

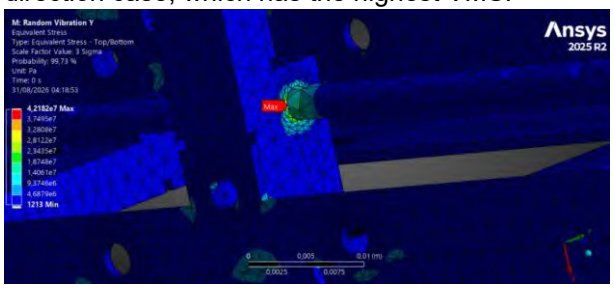
Bolted interfaces are represented by bonded annular washer regions with frictional contact on the remaining overlap. Adhesive interfaces are bonded, free contact surfaces are frictionless, and interfaces that must remain closed use no-separation contact. The EPS, avionics, payload, and solar-panel groups are represented by point masses at their respective centres of mass. The rail faces parallel to the XZ plane are constrained in X, the faces parallel to the YZ plane in Y, and the four lower rail ends in Z.

The structural cases follow the NRCSD launch requirements [12]. The most critical quasi-static load case applies +7 g in X and -1.8 g in Z together with angular accelerations of +13.5 rad/s² about X, Y, and Z. An integrated rail load case applies 1200



N compression across the rail ends. Modal analysis is followed by random-vibration analyses in X, Y, and Z using the 20 to 2000 Hz soft-stow profile at 5.76 g root-mean-square. The monitored outputs are total deformation, metallic von Mises stress, and longitudinal, radial, and longitudinal-radial (LR) shear stresses in the wood.

Metallic von Mises stress (VMS) is compared with the corresponding yield strength. For Scots pine, the values used for direct comparison are 102.0 MPa longitudinal tensile strength, 50.0 MPa longitudinal compressive strength, 3.0 MPa radial tensile strength, 4.7 MPa radial compressive strength and 9.2 MPa LR shear strength [13,22,23]. The main results are summarised in Tab. 7.

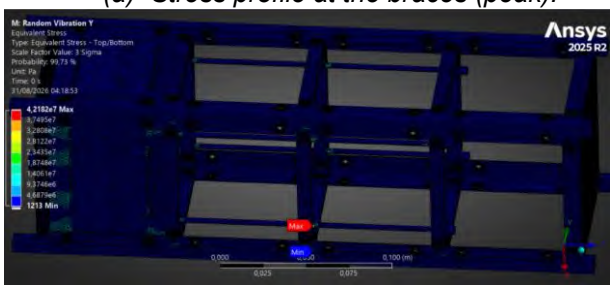


Table 7: Structural simulation results.

Case	Max. def. (mm)	Max. VMS (MPa)	Max. stress L / R / LR (MPa)
Quasi-static load	0.008	5.6	0.108 / 0.026 / 0.031
1200 N rail load	0.031	26.3	0.855 / 0.335 / 0.225
Random vibration X	0.037	37.8	1.211 / 0.292 / 0.316
Random vibration Y	0.037	42.2	1.220 / 0.378 / 0.283
Random vibration Z	0.040	33.5	2.884 / 0.468 / 0.428

All reported stresses remain below the material strengths. The Y-direction random-vibration case gives the highest metallic stress, while the Z-direction case gives the highest wood longitudinal and LR shear stresses. The first natural frequency is 888.7 Hz. Fig. 10 shows the random vibration Y-direction case, which has the highest VMS.

(a) Stress profile at the braces (peak).

(b) Stress profile in the entire CubeSat.

Figure 10: Random vibration Y-direction case, von Mises stress distribution.

5.2. Thermal Simulations

The thermal model is developed in ESATAN-TMS. The 4 mm wood panels use an isotropic conductivity equal to the longitudinal wood value. This represents heat transfer along the vertical grain direction but overestimates radial, tangential, and through-thickness conduction. Thin structural parts are represented by shell elements, hinges are replaced by conductive interfaces, and two lumped nodes represent the payload and internal bus. The simplified thermal model is shown in Fig. 11.

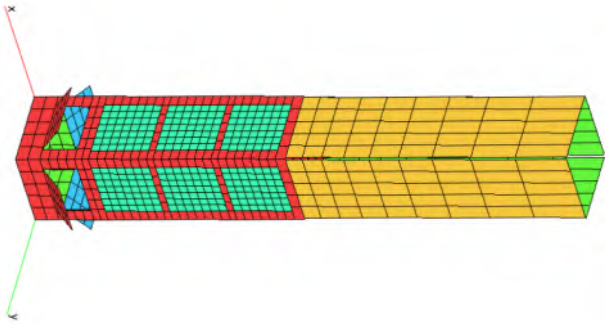

Figure 11: Simplified ESATAN model.

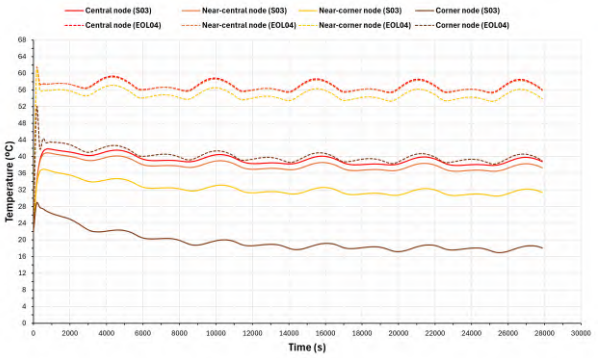
The beginning-of-life (BOL) wood surface uses a solar absorptivity of 0.49 and an emissivity of 0.91. For the end-of-life (EOL) sensitivity case, wood absorptivity is increased to 0.64. No measured EOL optical properties are available for the selected wood species over an 8 to 12 month LEO mission, so the +0.15 change is used as a conservative estimate based on spacecraft contamination data [24]. Smaller changes are applied to the white coating, mirror, and solar cells. White paint is retained on the aluminium surfaces because of its low solar absorptivity and high infrared emissivity [25,26].

The wood-aluminium interface was also evaluated. Removing the conductive interface increases the hot and cold extremes of the wood samples and makes the payload and internal-bus nodes about 2 to 4°C warmer than in the conductive cases. In contrast, changing the contact conductance from 328.95 to 740.1 W/(m²K) produces almost identical profiles.

The nominal operations case uses 0.885 W at the payload node and 10.035 W at the internal bus. The transient model is run for five orbits. Radiative cases use the 420 km, 51.6° ISS-like orbit and evaluate no-eclipse and longest-eclipse conditions. Fixed-face, 2.5°/s first-day rotation and 0.25°/s nominal rotation cases were defined.

A black-versus-white coating comparison was first used to select the aluminium surface finish. With white paint, the no-eclipse payload remains at about 12 to 14°C and the internal bus at 2 to 5°C; under the longest eclipse, they reach about -2 to 2°C and

-22 to -8°C, respectively. White paint is therefore chosen and used for the remaining analyses.



The main BOL/EOL comparisons are grouped in Fig. 12. Across the evaluated eclipse and pointing cases, the EOL payload and internal-bus temperatures are about 3 to 4°C higher than the corresponding BOL values. The exposed wood shows larger differences of about 8 to 30°C, depending on face and orbital condition. This temperature change is large enough to be measured by the selected thermocouples. Visible wood darkening after about ten months of ISS exposure has already been reported, although that experiment did not measure the corresponding change in solar absorptivity [5].

The 0.25°/s mixed-material configuration is the main nominal material comparison. The temperature ranges are summarised in Tab. 8, and the corresponding Poplar, Scots pine and Balsa profiles are grouped in Fig. 13 and Fig. 14. Balsa has the largest temperature extremes because it has the lowest thermal conductivity and density of the four materials. The corner node has a narrower range than the interior nodes because it is more strongly coupled to the aluminium frame.

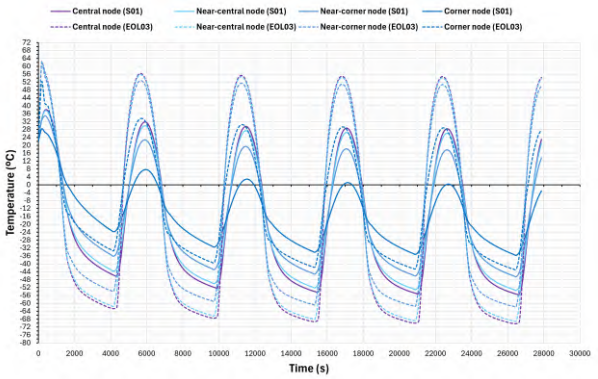


Table 8: Mixed-material sample temperature ranges under nominal 0.25°/s rotation.

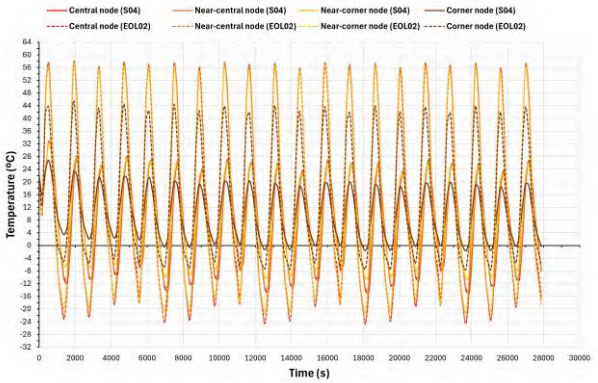
Material	No eclipse (°C)	Longest eclipse (°C)
Poplar	-12 to 30	-44 to 6
Balsa	-32 to 44	-60 to 18
Scots pine	-14 to 28	-44 to 16
Birch	-12 to 24	-42 to 8



For the mixed-material no-eclipse case, the payload remains at about 16 to 18°C and the internal bus at 8 to 10°C. Under the longest eclipse, the payload reaches about -2 to 4°C, and the internal bus reaches -21 to -8°C.

6. CONCLUSIONS

This work defines a 3U CubeSat concept that can extend DLR bio-based material development from ground-based characterisation toward in-orbit testing. The mission uses an ISS-like orbit and an 8 to 12 month exposure period, with Scots pine, birch, balsa, and poplar as the main wood candidates. The selected payload focuses on two main measurements: visual monitoring and temperature. The four-camera deployable mirror concept provides full four-side coverage while keeping the cameras inside the CubeSat. The geometric study selected a 30 mm mirror and 40° deployment angle, and the engineering model confirmed that this geometry captures the complete sample height. The structural analyses remain below the material strengths used for the evaluated NRCSD load cases, with a first natural frequency of 888.7 Hz. The thermal analyses define the expected operating ranges and show clear material-dependent behaviour. Balsa gives the widest nominal temperature range, while the EOL sensitivity cases increase internal temperatures by about 3 to 4°C and exposed-wood temperatures by about 8 to 30°C.

The concept therefore provides a practical way to collect temperature and image data that can be compared with ground tests and thermal predictions during a long-duration LEO exposure. This is directly relevant to the Bio Strux objective of developing bio-based materials for satellite structures.

Future work should extend the numerical verification with thermo-elastic and solar-panel deployment analyses. A representative test campaign should then cover thermal cycling, outgassing, atomic oxygen, radiation, vibration, electrical behaviour, mechanical properties and deployment mechanisms. These tests can be used to qualify the final sensor attachments and mechanisms before moving from the current concept toward a flight demonstrator.

ABSTRACT

Deployable composite booms are seeing increasing interest as solar array wings, antenna supports, and drag sail structures on small satellites, where mass and stowage volume are at a premium. SpaceMast, a motorised collapsible tubular mast developed at DLR's Institute of Lightweight Systems, achieves this through a coilable CFRP lenticular cross-section that can be repeatedly deployed and retracted. Repeated coiling induces large strains and, as observed in demonstration models, can lead to premature fatigue failure after relatively few cycles, raising concerns for missions requiring reliable, repeated actuation.

This paper investigates the underlying fatigue damage mechanisms through coupon-level and full-scale deployment testing. The results point to a dominant failure mode: transverse cracking on the compression side, driven by localised strain concentrations from compressive buckling during coiling, and accelerated by manufacturing imperfections, friction, and boom tension. These findings inform recommendations for coupon test design and highlight the value of full-scale deployment testing for reliable fatigue characterisation.

1. INTRODUCTION

Deployment mechanisms are widely used in spacecraft design to fold oversized components for launch and unfold them once in orbit, from the deployable antennae and solar array wings of large missions such as ESA's Jupiter Icy Moons Explorer [1] to the smaller instruments, antennae, and drag sails used on individual CubeSats and constellations. The growing use of deployable structures on small satellites has created demand for reliable, affordable deployment mechanisms.

Within research done by NASA, its Deployable Composite Boom (DCB) project began with the Storable Tubular Extendible Member (STEM), a slit-overlapped circular tube developed for the antenna of Canada's Alouette 1 satellite, which flattens and coils onto a reel much like a self-straightening steel measuring tape [2, 3]. Later designs, such as the Triangular Rollable and Collapsible (TRAC) boom, adopted open Λ-, N-, or M-shaped cross-sections built from bonded circular arcs [4]. Both the STEM and TRAC families share open cross-sections, which suffer from low torsional stiffness. DLR addressed this with a closed lenticular cross-section, the Collapsible Tubular Mast (CTM) [5], which is the design underlying the SpaceMast project. The adoption of fibre-reinforced polymer composites, and CFRP in particular, in place of metals has since become the dominant trend in deployable boom design, owing to their favourable stiffness-to-weight ratio, low coefficient of thermal expansion, and the tailorability of ply sequence and orientation to further limit thermal distortion in orbit [6, 7]. Deployable boom research has grown rapidly in recent years, but has concentrated on mechanical behaviour such as buckling, vibration, creep, and thermal distortion for a small number of established cross-sections [6]; to the authors' knowledge, no fatigue characterisation of deployable booms has previously been published, likely reflecting the low cycle counts typical of space operations.

SpaceMast booms, a spin-off project and technology plattform of DLR's Institute of Lightweight Systems, are manufactured from a single ply of plain-weave CFRP, reducing mass relative to metallic alternatives while allowing tailoring of the laminate for thermoelastic stability. Motorised actuation gives these booms the ability to be deployed and stowed repeatedly and in a controlled manner, simplifying functional testing and enabling operational concepts such as retracting the boom in orbit to reduce the spacecraft's angular mass moment of inertia. However, the high strains induced in the boom during coiling mean that repeated deployment and stowage cycles can lead to fatigue damage of the CFRP material, and failures have already been observed in SpaceMast demonstration units after a comparatively small number of deployment cycles.

Due to the absence of prior fatigue research on deployable composite booms, expectations for their low-cycle fatigue (LCF) behaviour must be drawn from the broader composites' literature. LCF of composites, defined as cyclic loading at a peak stress high relative to the material's static failure stress and limited to fewer than approximately 10^4 cycles, produces a markedly steeper stress-life relationship than high-cycle fatigue, reflected in a bilinear or knee-shaped S-N curve with the transition typically located between 10^3 and 10^4 cycles [8]. Harik and Bogetti attribute much of this steepened degradation to non-cyclic damage accumulated within roughly the first 20 cycles, arising not from progressive crack growth but from pre-existing manufacturing and material imperfections (weak fibre-matrix interfaces, micro-voids, fibre waviness, and thermally induced micro-cracking) at which local fibre stresses exceed their strength once load approaches the failure stress [9]. Woven single-ply CFRP shells further complicate this picture: because the fibre tows in a plain-weave laminate behave as individual beams bending about their own neutral axes rather than as a homogeneous plate, surface strain measured on such shells underestimates true fibre strain, allowing single-ply woven flexures to sustain considerably higher bending strains than standard tension or compression coupon failure strains would suggest [10]. The compressive response of thin CFRP shells is additionally nonlinear, governed by fibre misalignment and matrix shear rather than simple elastic buckling, with very thin shells (below roughly 350 μm) tending to fail by tensile fibre fracture and thicker shells transitioning toward compressive micro-buckling and discrete damage events such as fibre blistering [11].

Buckling behaviour is of particular relevance to SpaceMast, since the boom must repeatedly coil onto a spool. DLR's own finite-element modelling of coiled lenticular boom sections shows that local buckles form on the compression side during coiling, each acting as a localised strain concentration and creating gaps between adjacent layers of the reeled boom [12]. Separately, DLR's assessment of the boom's manufacturing quality identified waviness in the flanges connecting the two halves of the lenticular cross-section, an imperfection expected to further lower the critical buckling load [13]. Taken together, this prior work motivates buckling-induced strain concentration, amplified by manufacturing imperfections, as a plausible driver of fatigue damage in the coiled boom - but because no fatigue testing of a lenticular cross-section composite boom has previously been performed, whether this mechanism actually governs failure under repeated cyclic deployment, and how it compares with material-level fatigue behaviour, remained unknown prior to this work.

This paper reports the results of an experimental campaign combining coupon-level material characterisation with full-scale cyclic deployment testing of the SpaceMast boom and derives design and testing recommendations from a comparison of the two datasets. Section 2 describes the two testing methodologies; Section 3 presents the results; Section 4 discusses the failure mechanism and the discrepancy between coupon and full-scale behaviour; and Section 5 concludes with recommendations for future work.

2. METHODOLOGY

2.1. Coupon Testing

Flat coupons of the single-ply plain-weave CFRP material were subjected to pure bending on a custom column-bending jig, adapted from the counter-weight balanced column bending fixture developed by Fernandez and Murphey [14] and later adopted by Meyer et al. [15] for compliant-mechanism flexure testing. As in the original design, the jig converts a vertical displacement applied by the testing machine into pure bending at the clamped coupon ends, while a load cell measures reaction force and a Digital Image Correlation (DIC) system captures surface strain and jig rotation.

Figure 1: Column-bending coupon testing jig used in this study, adapted from Fernandez and Murphey's design [14].

Because CAD files for the original jig in [14] are not publicly available, the jig used in this study was redesigned from scratch and manufactured by Fused Deposition Modelling (FDM) and by Stereolithography (SLA) 3D printing, following the same general fabrication approach as the original. Said jig can be seen in Figure 1. The initial coupon size matched that used by Fernandez and Murphey [14] (1.5 in × 2 in, giving a bendable length of 10 mm between clamps), but trial tests showed that this geometry could not reach the curvature needed to fracture the coupons even at the jig's maximum rotation - consistent with the original jig having been used to characterise large-deformation bending response rather than to deform specimens to failure. The bendable coupon length was therefore reduced to 3 mm, based on a breaking curvature estimated from a simple platen test. This shorter length caused the clamps to interfere with one another at large bend angles, requiring the clamp geometry to be modified by thinning the lower clamp profile to eliminate the interference. Static tests were performed to characterise the force-displacement and strain-rotation response up to failure; fatigue tests cyclically loaded coupons to 95%, 90%, and 80% of the static failure load to characterise stiffness degradation and crack initiation under repeated bending.

2.2. Deployment Testing

Full-scale cyclic deployment testing was performed using the SpaceMast mechanism itself, consisting of an enclosed spool driven by a motor that reels and unwinds the boom, deployed vertically to represent realistic operating conditions.

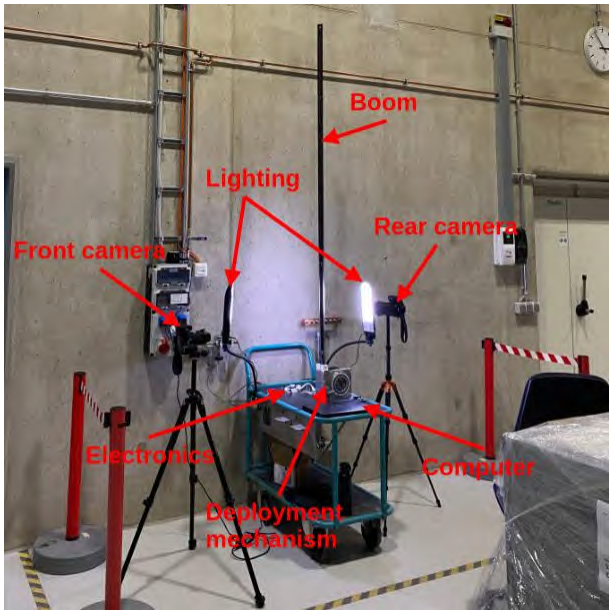

Figure 2: Full-scale deployment testing setup, showing the SpaceMast mechanism mounted for vertical cyclic deployment.

Since the mechanism did not natively support automatic direction switching, physical end-stops were added: a tab on the boom tip actuates a switch at full retraction, and a string-actuated switch triggers at full extension, avoiding the drift that a timer-based switching scheme would introduce over many cycles. Because the region of the boom most likely to fail - inside the coiled spool - is enclosed by an opaque casing, DIC and strain gauges could not be used to monitor strain directly. Instrumentation was therefore limited to two cameras recording both faces of the deployed boom to visually track the appearance of damage, and continuous logging of motor current, voltage, and state by the mechanism's Arduino controller, providing an indirect measure of mechanical resistance and cycle count. The boom was manually inspected for new damage at fixed cycle intervals throughout each test.

Three booms were tested under these conditions. Boom 1 served as the baseline test. Boom 2

experienced an unplanned failure of the retraction end-stop partway through testing, which allowed the boom to over-retract; the resulting tension, transmitted through the electronic harness and the coiled boom onto the spool, produced a substantial increase in compressive tensioning of the coil. Boom 3 was manufactured using a modified process resulting in a rougher inner surface compared with the smoother, matte surface of Booms 1 and 2. Because tensioning of the coiled boom against itself is controlled by the mechanism's disk brake and, in Boom 2's case, was further altered by the end-stop failure, the three tests together provide a basis for comparing damage accumulation and current draw across different tensioning conditions.

3. RESULTS

3.1. Coupon Testing

As shown in Fugure 3, static bending tests showed the compressive softening effect, with compressive surface strain reaching approximately 5-6% at failure, notably higher than the roughly 3% failure strain on the tension side. Additionally, the bending modulus could be computed using a kinematic model of the jig. This had an initial rise to 15 GPa before decreasing steadily with increasing deflection - well below the 48 GPa axial elastic modulus obtained from tensile coupon testing.

Fatigue coupon tests at 95%, 90%, and 80% of the static failure load produced unexpectedly long lives: most coupons did not reach complete fracture even after several thousand cycles, with only two of the eighteen tested specimens failing at all, - one after 439 cycles and another after 141 cycles. Partial edge damage was observed in many coupons but could not be reliably related to applied load level, and was attributed largely to non-uniform clamping rather than representative material fatigue behaviour.

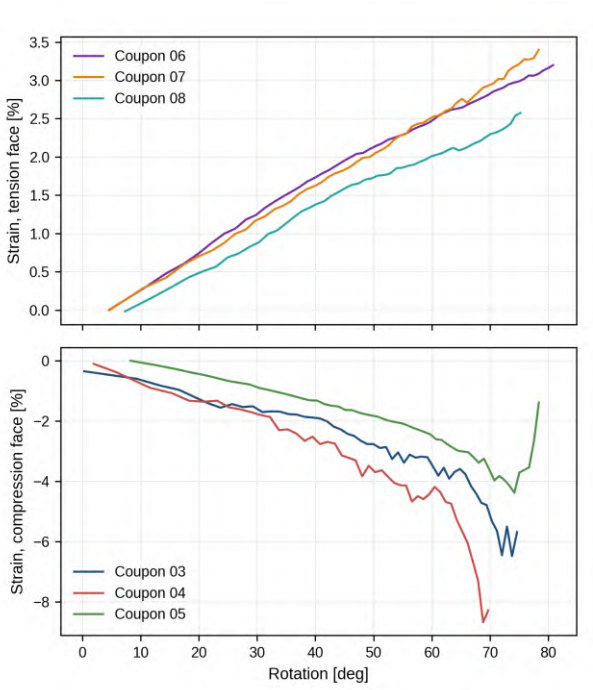

Figure 3: Coupon-level strain-rotation response in pure bending, showing tension-face strain (top) and compression-face strain (bottom) for three coupons per condition, used to characterise material behaviour.

3.2. Deployment Testing

All three booms failed exclusively by transverse fracture on the compression side of the boom, typically at the boundary between transverse strands where longitudinal strands cross over. The number of cycles to first observable damage differed sharply across the three tests and was closely tied to boom tensioning.

Figure 4 shows the motor current trends for the three tested booms, separated by deployment and retraction modes. Damage count was tracked only for the booms 2 and 3, with data shown in Figure 5. Boom 1 accumulated resistance gradually, with increasing motor current draw over roughly twelve hours of testing (approximately 90 cycles) before the test was terminated by repeated over-current stops. Boom 2, following the end-stop failure and associated over-tensioning at cycle 40, showed an abrupt surge of new damage: thirteen new transverse fractures were counted immediately after the failure, followed by eighteen more over the next ten cycles, after which no further damage appeared up to cycle 80 - indicating a finite, geometry-limited number of damage sites that saturates once populated. Boom 3, tensioned nominally throughout, began accumulating damage from the first ten cycles, peaked at twenty cycles, and ceased entirely by sixty cycles, over a test extended to 100 cycles. An example of the damage is shown in

Figure 6, where a transverse crack is underlined with a white marker.

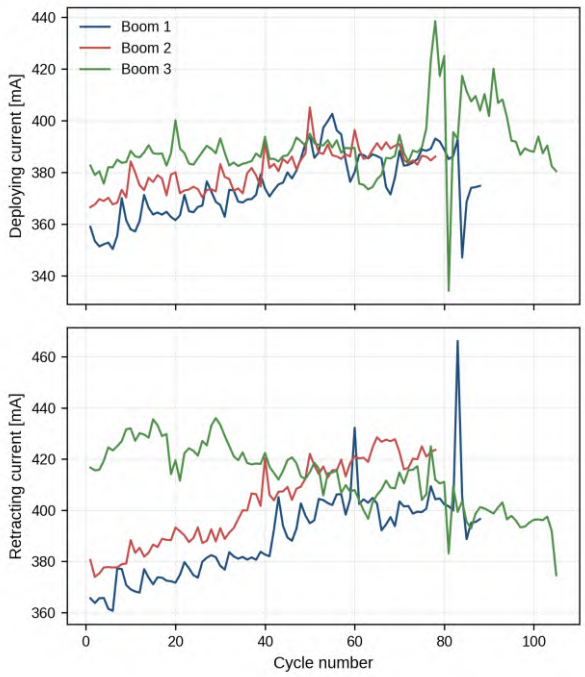

Figure 4: Mean deployment and retraction motor current per cycle for Booms 1-3, showing the differing friction trends associated with manufacturing surface finish and mechanical resistance.

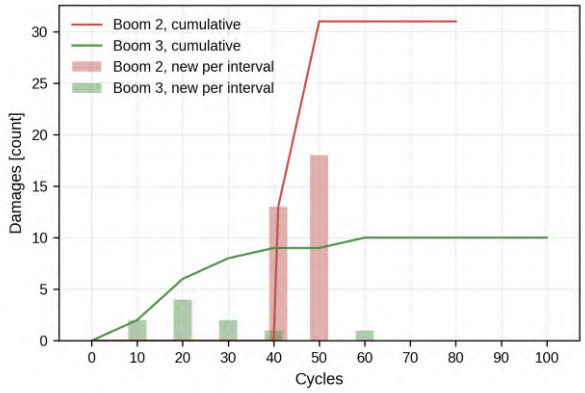

Figure 5: Damage accumulation per cycle interval for Booms 2-3, showing the saturating damage count and the effect of the Boom 2 tensioning event.

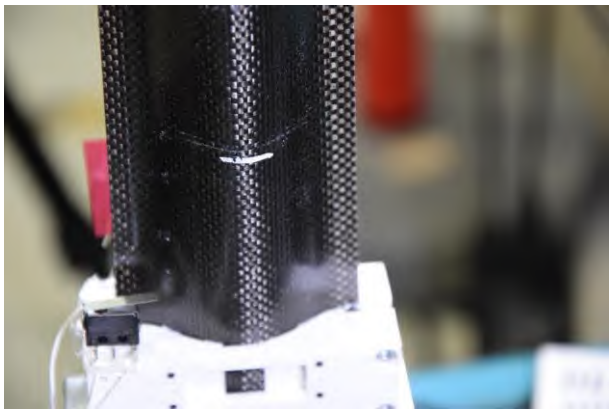

Figure 6: Representative transverse fracture damage observed on the compression side of the boom after cyclic deployment testing.

Motor current trends also diverged between booms. Booms 1 and 2 showed a general increase in both deployment and retraction current over the course of testing, consistent with growing mechanical resistance from crack accumulation, loose manufacturing residue collecting at the mechanism hub, and gearbox wear (confirmed by powder accumulation observed inside the gearbox at the end of testing). Boom 3, by contrast, showed a decreasing retraction current trend, attributed to its rougher as-manufactured inner surface being progressively abraded smooth by repeated cycling - an effect that outweighed any resistance increase from crack accumulation over the tested range.

4. DISCUSSION

The deployment tests point to a single, geometry-governed failure mechanism: fatigue damage on the SpaceMast boom occurs as transverse fractures on the compression side, at locations that plausibly coincide with the local buckles that form when the lenticular cross-section is coiled onto the spool. The saturation of new damage after a fixed number of sites are populated, most clearly seen in Boom 2, where damage stopped appearing entirely once thirty-one fractures had accumulated across two 10-cycle intervals, supports the interpretation that the number and spacing of buckle-induced high-strain sites is fixed by boom geometry rather than by continued cycling.

Boom tensioning, controlled by the disk brake that prevents the coiled boom from unrolling under its own elasticity, is the dominant driver of damage rate and extent. The unplanned over-tensioning of Boom 2 produced immediate, extensive damage that would otherwise have accumulated far more gradually, directly demonstrating that the compressive pressure the coiled layers exert on one another, rather than cycle count alone, governs how quickly the fixed set of damage sites is populated. This is consistent with the eventual cessation of new damage in all three tests: once tensioning-driven local strain has activated every available site,

further cycling under the same tensioning condition produces no additional first-time damage, though it may still contribute to wear-related effects such as the rising motor current in Booms 1 and 2.

The manufacturing-related divergence in motor current trend between Boom 3 and the first two booms further indicates that surface finish and residual manufacturing debris measurably affect mechanical resistance independent of fatigue damage, and should be controlled for in future comparative testing.

A central finding of this study is the substantial discrepancy between coupon-level and full-scale fatigue behaviour. Coupon specimens subjected to pure bending survived, in most cases, several thousand cycles, whereas the full-scale boom showed extensive damage within roughly fifty cycles, - two to three orders of magnitude sooner. This discrepancy is attributed to the loading condition applied at coupon level: pure bending does not reproduce the complex, biaxial strain state generated by local buckling and by the compressive pressure the coiled boom exerts on itself inside the mechanism. Because the exact strain state at the buckle, and specifically whether cracking initiates at the buckle peak or valley, remains unknown, and finite-element simulations do not yet account for coil-on-spool pressure, coupon-level pure-bending tests cannot presently be used to predict the fatigue life of the SpaceMast boom or, by extension, similar DCB designs. Full-scale or representative-loading testing is therefore necessary until a coupon-level loading condition that reproduces the governing strain state can be identified.

5. CONCLUSION & RECOMMENDATIONS

This study investigated the low-cycle fatigue behaviour of the SpaceMast deployable composite boom through coupon-level pure-bending tests and full-scale cyclic deployment tests of three boom units. The results show that fatigue failure in the full-scale boom occurs exclusively as transverse fracture on the compression side, at a fixed number of locations plausibly linked to coiling-induced local buckling, and that the rate and extent of damage accumulation are strongly governed by the tensioning applied by the deployment mechanism's disk brake. Coupon-level pure-bending tests, by contrast, do not reproduce this failure mode or timescale and cannot presently be used to predict full-scale fatigue life, indicating that the strain state driving failure is dominated by buckling and coil-on-coil pressure rather than simple bending.

Two categories of recommendations follow from these findings.

Design recommendations for the SpaceMast mechanism and similar DCB deployment systems: (i) disk brake pressure should be reduced to the minimum level needed to retain the boom in its stowed state, since excess tensioning directly accelerates damage formation; and (ii) end-stops should be permanently integrated into the mechanism, both for improved fatigue performance predictability and because timer-based direction switching is prone to drift and consequent mechanical damage over extended cyclic operation.

Research-methodology recommendations for future fatigue characterisation of DCBs: (i) full-scale or otherwise representative-loading deployment testing should be prioritised over coupon-level pure-bending characterisation as the primary means of establishing fatigue life, since it requires no assumptions about the governing loading condition and is comparatively inexpensive to perform; and (ii) if coupon-level testing is retained for material property characterisation, the clamping method should be revised, for example by bonding coupons to expendable end blocks rather than relying on thin, deformable clamp lips, and DIC strain measurement accuracy improved through reduced lens aperture, before coupon data is used to inform fatigue predictions.

6. ACKNOWLEDGEMENTS

The authors thank the colleagues at DLR's Institute of Lightweight Systems who supported the testing campaign, and the thesis committee at Delft University of Technology for their guidance throughout this research.
This research was funded by the German Aerospace Center (DLR) through the Executive Board department “Innovation, Transfer and Research Infrastructure” and by the German Federal Ministry for Economic Affairs and Energy (BMWE) through the EXIST Transfer of Research programme.

ABSTRACT

This paper investigates vibration attenuation for in-plane vibrations of the annular support ring (Secondary Holddown and Release Mechanism - SHRM) of the Large Deployable Reflector (LDR) developed by Thales Alenia Space. The paper combines dispersion and frequency response analyses to characterize the generation of a bandgap, i.e. a frequency region where waves are attenuated. The role of curvature is critically discussed, and the limitation of linear metamaterials is highlighted. This work sheds light on the dynamics of curved metastructures in the context of vibration attenuation.

1. INTRODUCTION

The continuous demand for increased payload capacity and reduced launch costs is driving the development of increasingly lightweight spacecraft structures. This trend is particularly evident for large deployable components, such as reflector antennas, solar arrays and instrument-supporting panels, whose dimensions must be maximized while satisfying stringent mass and stowed-volume requirements. However, the reduction of structural mass and stiffness generally results in low natural frequencies and increased sensitivity to dynamic loading. During launch, spacecraft are exposed to a combination of broadband acoustic excitation, random and sinusoidal vibrations and transient mechanical loads, which may induce significant dynamic amplification and represent a critical design condition for large deployable reflectors [1] as well as other space systems and sub-systems.

Traditional vibration-mitigation strategies are commonly based on structural stiffening, additional damping treatments or tuned vibration absorbers. Although effective, these solutions may introduce a considerable mass penalty or require substantial modifications to the primary structure. These drawbacks are especially relevant in space applications, where the available mass budget is limited and any added component must comply with demanding integration and qualification requirements. Consequently, major research effort has recently been devoted to lightweight periodic devices for passive vibration attenuation.

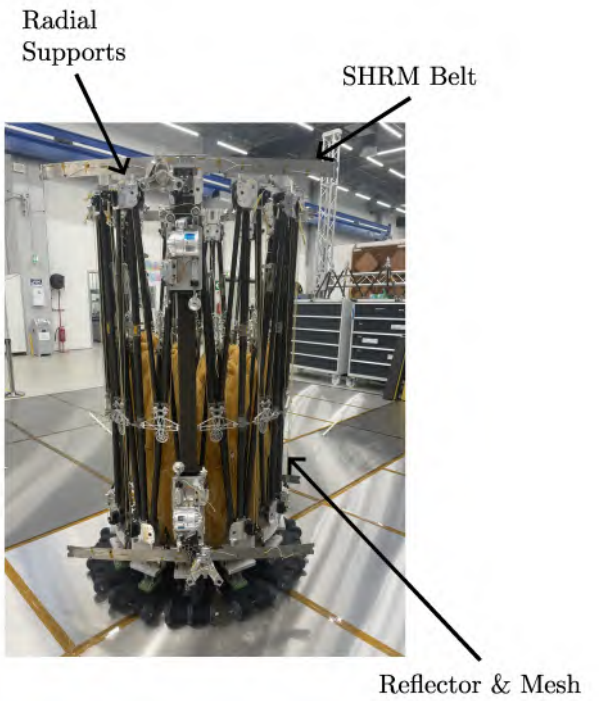

Figure 1: Image of the LDR in the stowed configuration, with the SHRM belts yet to be closed on the radial supports.

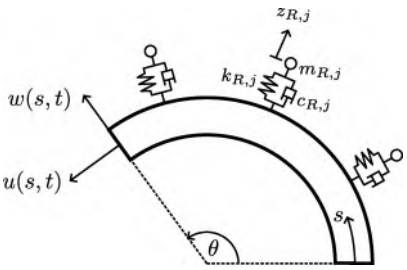
Phononic crystals and mechanical metamaterials provide a promising framework for controlling elastic-wave propagation [2]. This new family of materials allows to inhibit wave propagation within selected frequency intervals, generally referred to as bandgaps. In classical phononic crystals, bandgaps are predominantly generated by Bragg scattering mechanism and therefore occur when the structural pe-

riodicity is comparable with the wavelength. This condition generally requires large unit cells when low-frequency vibrations are targeted, limiting the applicability of Bragg-based solutions to compact aerospace structures.

Locally resonant metamaterials overcome this limitation by embedding resonant substructures whose characteristic dimensions are substantially smaller than the wavelength. The interaction between the host structure and the local resonators generates an effective dynamic inertia and can produce attenuation bands in the vicinity of the resonator natural frequency. This mechanism has been investigated extensively for rods, beams and plates, demonstrating that periodically distributed resonators can suppress flexural and longitudinal wave propagation and reduce the vibration response of finite structures [3, 4]. Furthermore, the resonance suppression observed in the finite metastructure is related to the dispersion diagram of the corresponding infinite medium [5, 6].

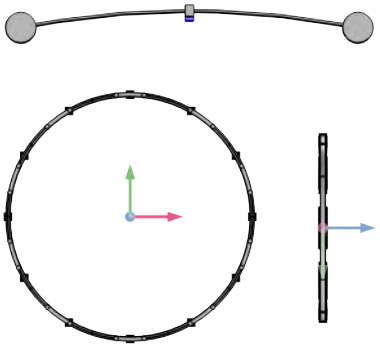
Despite these advantages, low-frequency locally resonant metamaterials remain subject to important practical limitations. For a prescribed tuning frequency, the attainable bandgap width is strongly influenced by the ratio between the resonator mass and the mass of the host structure [5]. Therefore, obtaining a broad attenuation region at very low frequencies may require large additional masses, which is undesirable for spacecraft applications.

Electromechanical resonators exploiting piezoelectric patches, and hybrid mechanical–electromechanical concepts have been proposed to increase tunability and broaden the attenuation bandwidth without relying exclusively on added mechanical mass [7]. Recent investigations have also demonstrated the potential of vibroacoustic metamaterials for representative launcher and satellite components, highlighting their compatibility with lightweight structural design [8, 9].



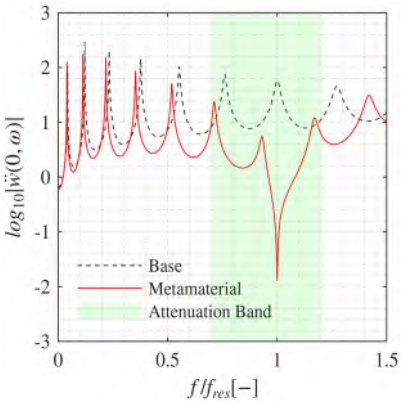
Nevertheless, most analytical studies of locally resonant metastructures focus on straight beams, rods, or flat plates [10–12]. Application of these concepts to curved members is nontrivial because curvature couples deformation mechanisms that are uncoupled in the corresponding straight geometry. Previous studies have addressed locally resonant curved panels and actively controlled curved beams and rings [13, 14]. However, the role of wave polarization in passive locally resonant closed rings, and its relation to the attenuation achieved in the corresponding finite structure, remains insufficiently understood. For the in-plane motion of an annular beam, radial bending and circumferential extension are intrinsically coupled, and the polarization of the propagating branches varies with frequency. Consequently, resonators acting only in the radial direction may attenuate bending-dominated waves while leaving a circumferentially polarized propagation channel unaffected.

This work investigates locally resonant vibration attenuation in the annular support ring of the large deployable reflector reported in Fig. 1. The figure shows the reflector in the stowed configuration and the Secondary Holddown and Release Mechanism (SHRM) in the open configuration. The radial supports hosting the SHRM before deployment of the Large Deployable Reflector (LDR) are also visible. The ring is modeled as an extensible curved beam, and two resonator layouts are compared under the same total added-mass constraint: a radial-only configuration and a configuration containing both radial and circumferential resonators. A complex-wavenumber analysis of the homogenized periodic medium is used to identify propagating and evanescent branches and to compute their polarization. The response of the corresponding finite ring is then evaluated using an assumed-modes formulation and validated against finite-element simulations. The results are compared with those of an equivalent straight beam to isolate the effects of curvature-induced coupling and stiffness. Finally, a realizable flexural resonator is implemented in a detailed finite-element model. The study therefore links dispersion, wave polarization, and finite-structure attenuation, while assessing the extent to which locally resonant concepts developed for straight members retain their effectiveness in annular structures.



1.1. Analytical model of the system

The analysis starts with the analytical model of the system, limited to in-plane vibrations, thereby including radial and tangential vibrations of the ring, as shown in Fig. 2a. Wave propagation and in-plane vibrations of thin ring are well documented subjects [15–17], hence the governing equations can be easily written (Eq. 1). Here $w = w(s,t)$ and $u = u(s,t)$ denote the radial and circumferential displacements, respectively, as functions of the position along the arclength and of time. $(\cdot)^{(i)}$ indicates the *i–th* derivative with respect to s, while $\dot{(\cdot)}$ indicates derivative with respect to time.



$$\begin{cases} \dfrac{EI}{R}\left(u^{(3)} - Rw^{(4)}\right) - \dfrac{EA}{R}\left(\dfrac{w}{R} + u^{(1)}\right) = \rho A\ddot{w} & \text{(1a)} \\ \dfrac{EI}{R}\left(\dfrac{u^{(2)}}{R} - w^{(3)}\right) + \dfrac{EA}{R}\left(w^{(1)} + Ru^{(2)}\right) = \rho A\ddot{u} & \text{(1b)} \end{cases}$$

(a) Schematic of the extensible thin-ring model with periodically distributed local resonators. The radial and circumferential displacements of the ring are denoted by $w(s,t)$ and $u(s,t)$, respectively, while $z_{R,j}$ represents the relative displacement of the j-th radial resonator located at $s = s_j$.

(b) Final design of the single resonator (top), front view of the metamaterial ring (bottom left) side view of the metamaterial ring (bottom right).

(c) Comparison between the frequency response function of a base structure (black dashed line), and the one of a metastructure (red solid line). The attenuation band is highlighted in green. Results are reported in terms of normalized frequency f/f_{res}.

Figure 2: Overview of the analysis and design workflow for metamaterials in annular structures:

The curved beam has radius $R = 0.3761$ m, height $h = 12$ mm, depth $b = 20$ mm, elastic modulus $E = 70$ GPa and density $\rho = 2700\,\mathrm{kg/m^3}$. Being the section of the beam rectangular, the value of the area moment of inertia can be computed as $I = bh^3/12$. The correspondence between the mode shapes of the analytical model and those of the SHRM was assessed through the modal assurance criterion applied to the mode shapes obtained from the finite element models of the systems; however, a detailed analysis is beyond the scope of the present work.

Since the aim of the current study is to assess the influence of discrete resonators, their contribution can be added to Eq. 1, yielding Eq. 2.

$$\begin{cases} \frac{EI}{R}\left(u^{(3)} - Rw^{(4)}\right) - \frac{EA}{R}\left(\frac{w}{R} + u^{(1)}\right) + \\ \quad + \sum_j k_{Rj} z_{Rj} \delta(s - s_j) = \rho A \ddot{w} \end{cases} \tag{2a}$$

$$\begin{cases} \frac{EI}{R}\left(\frac{u^{(2)}}{R} - w^{(3)}\right) + \frac{EA}{R}\left(w^{(1)} + Ru^{(2)}\right) + \\ \quad + \sum_j k_{Aj} z_{Aj} \delta(s - s_j) = \rho A \ddot{u} \end{cases} \tag{2b}$$

$$m_{Rj}\ddot{z}_{Rj} + k_{Rj} z_{Rj} + m_{Rj}\ddot{w}(s_j, t) = 0 \tag{2c}$$

$$m_{Aj}\ddot{z}_{Aj} + k_{Aj} z_{Aj} + m_{Aj}\ddot{u}(s_j, t) = 0 \tag{2d}$$

In Eq. 2, the subscripts R and A refer respectively to radial and axial resonators, the symbol z describes the relative displacement of resonators, δ is Dirac delta function, and s_j is the arclength coordinate of the $j-th$ attachment. Moreover, damping is neglected for dispersion analysis, while a lightly damped structure is considered in the analysis of the finite system (Sec. 3).

The governing equations are solved to study the underlying dynamics. In the present work, two cases will be studied: a first case in which the resonators are purely radial, and a second case in which resonators can act both in radial and circumferential (also referred to as axial) direction.

2. INFINITE STRUCTURE

2.1.Dispersion relation computation

The dispersion relation can be computed starting from a unit cell by imposing a wave solution and assuming long-wavelength conditions. A comparison of the two cases with the equivalent beam-like case is provided. Note that the study has been conducted at constant added mass ratio $\mu = 0.1$ and at constant unit cell length $a_{UC} = \frac{2\pi R}{N_{res}}$, where $N_{res} = 20$.

Starting from Eq. 2, the governing equations for the unit cell can be found considering a single radial resonator, while the stiffness is considered distributed into the entire domain, since the wavelength is larger than spatial periodicity. This yields Eq. 3 if the first case is considered.

$$\begin{cases} \frac{EI}{R}\left(u^{(3)} - Rw^{(4)}\right) - \frac{EA}{R}\left(\frac{w}{R} + u^{(1)}\right) + & \text{(3a)} \\ + \frac{k_R}{a_{UC}} z_R = \rho A \ddot{w} & \\ \frac{EI}{R}\left(\frac{u^{(2)}}{R} - w^{(3)}\right) + \frac{EA}{R}\left(w^{(1)} + Ru^{(2)}\right) = & \text{(3b)} \\ = \rho A \ddot{u} & \\ m_R \ddot{z}_R + k_R z_R + m_R \ddot{w}(s_R, t) = 0 & \text{(3c)} \end{cases}$$

The *ansatz* is reported in Eq. 4, and can be substituted into Eq. 3, yielding Eq. 5.

$$\begin{aligned} w(s,t) &= \hat{w}_0 e^{i(\kappa s - \omega t)}, \\ u(s,t) &= \hat{u}_0 e^{i(\kappa s - \omega t)}, \\ z_R(t) &= \hat{z}_0 e^{-i\omega t} \end{aligned} \tag{4}$$

$$\begin{cases} \frac{EI}{R}\left(-i\kappa^3 \hat{u}_0 - R\kappa^4 \hat{w}_0\right) - \frac{EA}{R}\left(\frac{\hat{w}_0}{R} + i\kappa \hat{u}_0\right) + & \text{(5a)} \\ + \frac{k_R}{a_{UC}} \hat{z}_0 + \omega^2 \rho A \hat{w}_0 = 0 & \\ \frac{EI}{R}\left(-\frac{\kappa^2}{R} \hat{u}_0 + i\kappa^3 \hat{w}_0\right) + & \text{(5b)} \\ + \frac{EA}{R}\left(i\kappa \hat{w}_0 - R\kappa^2 \hat{u}_0\right) + \omega^2 \rho A \hat{u}_0 = 0 & \\ -m_R \omega^2 \hat{z}_0 + k_R \hat{z}_0 - \omega^2 m_R \hat{w}_0 = 0 & \text{(5c)} \end{cases}$$

Notice that Eq. 5 can be written as the polynomial eigenvalue problem in Eq. 6 by defining the matrix $\mathbf{P}(\kappa, \omega) = \mathbf{A_0}(\omega) + \kappa \mathbf{A_1} + \kappa^2 \mathbf{A_2} + \kappa^3 \mathbf{A_3} + \kappa^4 \mathbf{A_4}$.

$$\mathbf{P}(\kappa, \omega)\nu = \mathbf{0}, \text{ where } \nu = [\hat{w}_0, \hat{u}_0, \hat{z}_0]^T \tag{6}$$

By prescribing the frequency ω the polynomial eigenvalue problem can be solved for the eigenvalues κ and eigenvectors ν. This is referred to as inverse problem and yields complex eigenvalues $\kappa(\omega)$.

Solutions characterized by $\Im[\kappa] = 0$ are propagating modes, whereas branches with $\Im[\kappa] \neq 0$ are representative of spatially attenuated waves. Generally, an attenuating solution may have both nonzero real and imaginary part.

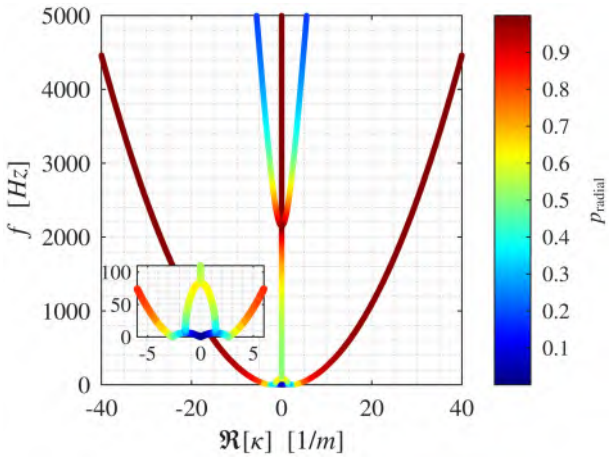
Conversely, the direct dispersion problem is solved by prescribing a real wavenumber κ and solving for the corresponding frequencies ω and eigenvectors. This formulation provides a more immediate representation of the dispersion branches and facilitates the identification of complete bandgaps. When no complete band gap is present, the eigenvectors can be used to identify frequency intervals in which radial or circumferential waves are selectively suppressed.

The relative amplitude of each eigenvector can be used to infer the polarization of the corresponding branch. For the *j–th* eigenvector, the radial displacement polarization factor can be computed as:

$$p_{radial} = \frac{|\hat{w}_{0j}|^2}{|\hat{w}_{0j}|^2 + |\hat{u}_{0j}|^2} \tag{7}$$

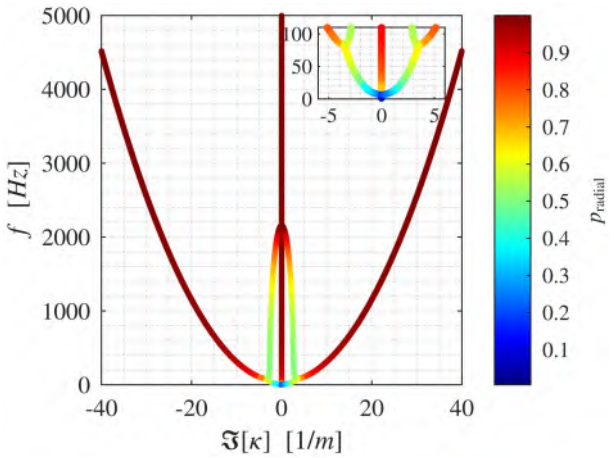
A polarization factor equal to 1 is representative of a radially dominated motion, while a polarization factor close to 0 means that axial motion is predominant.

2.2.Results



The dispersion relation of the bare ring is shown in Fig. 3. Each forward-propagating wave with positive wavenumber ($+\kappa$) is paired with a backward-propagating wave with opposite wavenumber ($-\kappa$). Depending on the frequency, either one or two pairs of propagating waves exist.

Consistently with [17], three frequency regions can be identified. For our choice of parameters, below approximately 7 Hz, the propagating waves exhibit a predominantly axial polarization. Between 7 Hz and 2150 Hz, only the flexural branch supports propagation, whereas the axial-dominated solutions are evanescent. Above 2150 Hz, an additional pair of axial-dominated propagating waves appears.



This frequency-dependent polarization is a consequence of the coupling between axial and radial motion introduced by the curvature of the ring.

By targeting bending-dominated branches, resonators can be employed to alter the dispersion diagram, creating a frequency range in which the corresponding wave becomes evanescent. In terms of the polynomial eigenvalue problem in Eq. 6, a bandgap is identified as a frequency interval in which no purely real wavenumber solutions exist for the bending-dominated branches.

Fig. 4 shows a comparison of the computed dispersion relations for the equivalent straight beam and the two cases. Notice that only the propagating branches, i.e. those with $\Im[\kappa] = 0$ have been reported for the sake of clarity. Fig. 4 shows that no bandgap is created in the first case. However, a frequency range in which only axial waves can propagate exists. We observe that: below the resonator tuning frequency, the relation is mostly unaffected by the resonators; at the target frequency, a propagative axial branch is found, while the branch supporting bending displacement becomes complex (i.e. both $\Re[\kappa] \neq 0$ and $\Im[\kappa] \neq 0$) as shown in Fig. 5; at higher frequency, the propagative axial branch supports flexural waves. On the other hand, the second case shows the nucleation of a bandgap, where

(a) Real part.

(b) Imaginary part.

Figure 3: Complex dispersion relation of the bare ring represented in the $(\Re[\kappa], \Im[\kappa], f)$ space. The color scale indicates the radial polarization factor p_{radial}.

wave propagation is prohibited for both polarizations, as shown in the rightmost column of Fig. 4.

The bandwidth of the spectral gap is also a key performance metric, and can be directly evaluated from the dispersion relation. The resulting bandgap widths are summarized in Tab. 1. Since the first case does not exhibit a well-defined bandgap, its upper bound was defined as the frequency at which the bending and axial components contribute equally to the wave polarization, corresponding to ($p_{radial} = 0.5$). Above this threshold, the branches become predominantly bending-dominated.

Finally, the relative bandwidth can be computed as $\delta f = \Delta f / f_{res}$. Its value is constant and related to the added mass ratio μ. For the straight beam computation of the aforementioned indicator yields $\delta_f = 0.05$, consistently with [5], where $\delta f = \sqrt{1+\mu} - 1 = 0.0488$. On the other hand, for the ring structure,

Table 1: Summary of bandgap widths Δf for the equivalent beam and the two cases. In parentheses the natural frequency f_n, which is also the resonator tuning frequency f_{res} is reported for each mode.

Mode	Beam	Case 1	Case 2
–	Δf (f_n) [Hz]	Δf (f_n) [Hz]	Δf (f_n) [Hz]
4	14.6 (279)	12.2 (467)	11.6 (467)
3	7.6 (150.1)	8.4 (289)	7.7 (289)
2	3.0 (60.8)	3.9 (150.5)	3.8 (150.5)
1	0.6 (11.3)	1.4 (53.2)	1.3 (53.2)

$\delta_f \approx 0.025$, suggesting that bandgaps span a much lower frequency range in the curved case. Another consequence of δf being constant is the fact that, for a given mass ratio, targeting lower frequencies leads to lower absolute bandgap width, confirmed by Tab. 1.

To check whether the bandgap leads to any major improvement in vibration attenuation of the structure, the finite structure has been analyzed as detailed in Sec. 3.

3. FINITE STRUCTURE

To investigate the effect of resonators on the finite structure, the Frequency Response Function (FRF) is computed with two different methods: Assumed Modes Method (AMM), and Finite Element Method (FEM). The former is discussed in detail within Sec. 3.1, while the latter has been implemented in COMSOL Multiphysics, where resonators are modeled as lumped mechanical systems, while the ring is modeled as a linear elastic aluminum solid.

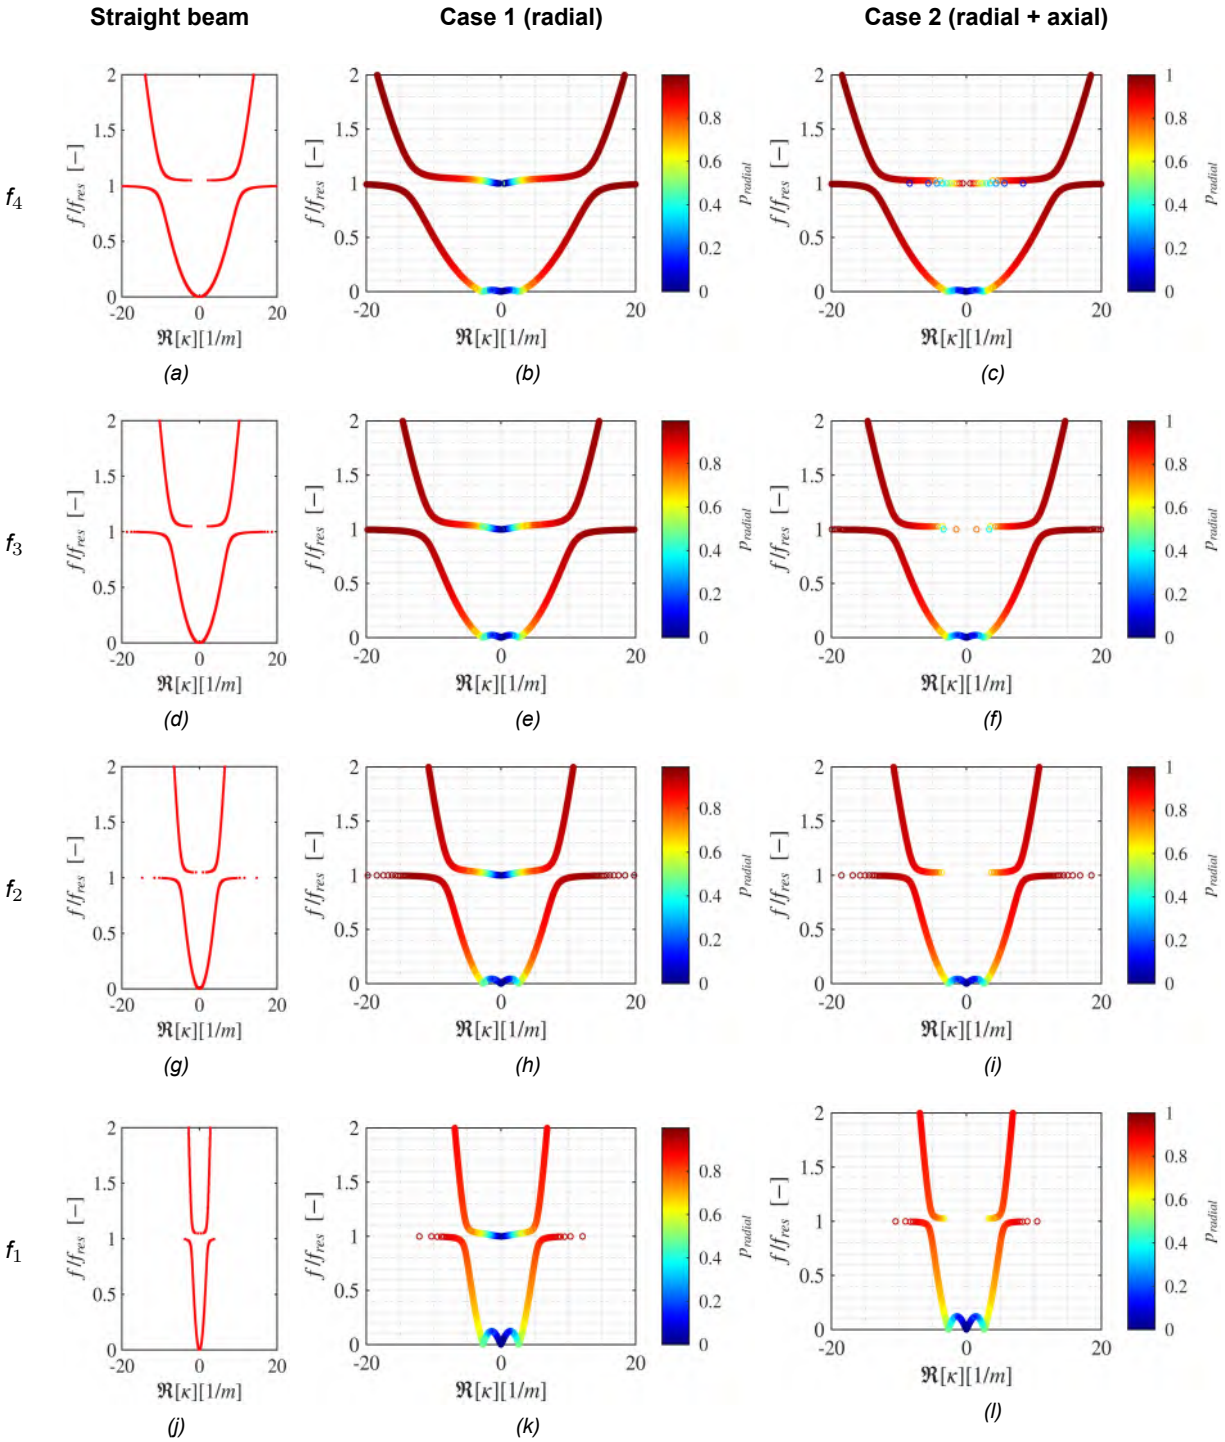
The ring is forced by a radial point force on one side, and the response is measured in terms of acceleration of the opposite side ($\ddot{w}(0,\omega)$).

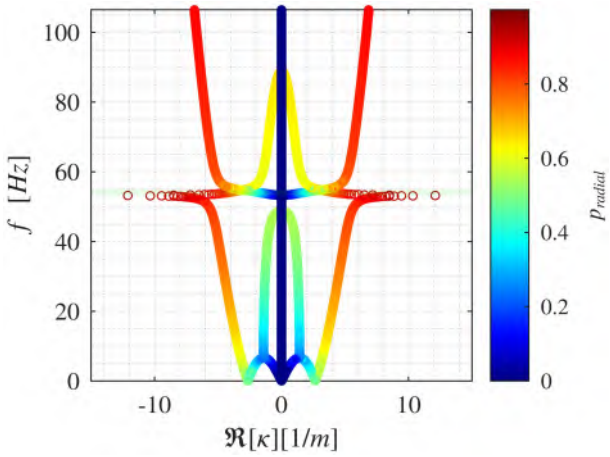
3.1.FRF via assumed modes method

In the AMM, radial and tangential displacements are written as a sum of comparison functions:

$$\begin{aligned} w(s,t) &= \sum_{m=-M}^{M} \eta_m(t)\phi_m(s), \\ u(s,t) &= \sum_{m=-M}^{M} \xi_m(t)\phi_m(s) \end{aligned} \tag{8}$$

The functions $\phi_m(s), m = -M, ..., M$ must be compliant with boundary conditions. These, in case of a free closed ring, require 2π-periodic displacements in θ (Eq. 9), allowing to choose the exponential functions reported in Eq. 10.





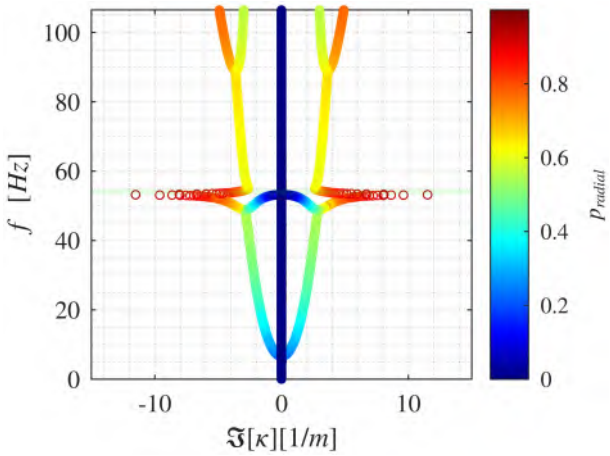


Figure 4: Comparison of the real-wavenumber dispersion diagrams for the equivalent straight beam and the two cases. From top to bottom, the rows correspond to resonator tuning at f_4, f_3, f_2, and f_1. For the ring configurations, the color scale indicates the radial polarization factor p_{radial}.

(a) Real part.

(b) Imaginary part.

Figure 5: Complex dispersion relation of the first case in the $(\Re[\kappa], \Im[\kappa], f)$ space. The color scale indicates the radial polarization factor p_{radial}. The green shaded area indicates the attenuation zone.

$$\begin{aligned} w(s,t) &= w(s+2\pi R,t), \\ u(s,t) &= u(s+2\pi R,t) \end{aligned} \tag{9}$$

$$\phi_m(s) = \frac{e^{i(sm/R)}}{\sqrt{2\pi R}}, m = -M, ..., M \tag{10}$$

The expansions in Eq. 8 are substituted into the governing equations before multiplying by the complex conjugate mode shape ϕ_r^*. Integrating along the entire domain, and exploiting orthogonality of the exponential functions, yields the coupled system in Eq. 11.

$$\begin{cases} \frac{EI}{R}\left(-i\frac{r^3}{R^3}\xi_r - \frac{r^4}{R^3}\eta_r\right) - \frac{EA}{R}\left(\frac{\eta_r}{R} + i\frac{r}{R}\xi_r\right) + \\ -\sum_{j=1}^{N_{res}} m_j \ddot{z}_j \phi_r^*(s_j) + \\ -\sum_{j=1}^{N_{res}} m_j \sum_{m=-M}^{M} \phi_m(s_j)\phi_r^*(s_j)\ddot{\eta}_m + q_r = \rho A \ddot{\eta}_r \end{cases} \tag{11a}$$

$$\begin{cases} \frac{EI}{R}\left(-\frac{r^2}{R^3}\xi_r + i\frac{r^3}{R^3}\eta_r\right) + \\ + \frac{EA}{R}\left(i\frac{r}{R}\eta_r - \frac{r^2}{R}\xi_r\right) = \rho A \ddot{\xi}_r \end{cases} \tag{11b}$$

$$\begin{cases} m_j \ddot{z}_j + k_j z_j + \\ + m_j \sum_{m=-M}^{M} \phi_m(s_j)\ddot{\eta}_m = 0, j = 1, \ldots, N_{\text{res}} \end{cases} \tag{11c}$$

In Eq. 11, q_r is the modal forcing term, that for a point force of amplitude F_0 applied at location s_{force} can be computed as $q_r = F_0\phi_r^*(s_{force})$.

Writing Eq. 11 for each mode $r = -M, ..., M$, and accommodating the coefficients in $\mathbf{x} = [\eta_{-M}, ..., \eta_M, \xi_{-M}, ..., \xi_M, z_1, ..., z_{N_{res}}]^T$, yields:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{F} \tag{12}$$

Where the damping matrix **C** includes two different contributions: structural damping of the host structure and lumped damping of the resonators. Structural dissipation is represented through a Rayleigh damping model,

$$\mathbf{C}_s = \alpha\mathbf{M}_s + \beta\mathbf{K}_s,$$

with $\alpha = 1.1\,\text{s}^{-1}$ and $\beta = 2.8 \times 10^{-6}$s. These coefficients were selected to provide a low damping, representative of the actual structure in the frequency range of interest. Resonator damping is instead modeled by a discrete viscous element acting on the relative motion between the resonator and the ring. This representation is consistent with the localized nature of the resonator dissipation and allows its contribution to be introduced independently of structural damping.

Notice that, in the absence of resonators, the structural stiffness matrix K_s is block diagonal, with each block coupling the modes η_r, ξ_r.

Eq. 12 can be solved in the frequency domain for the response of the entire structure.

3.2.Results

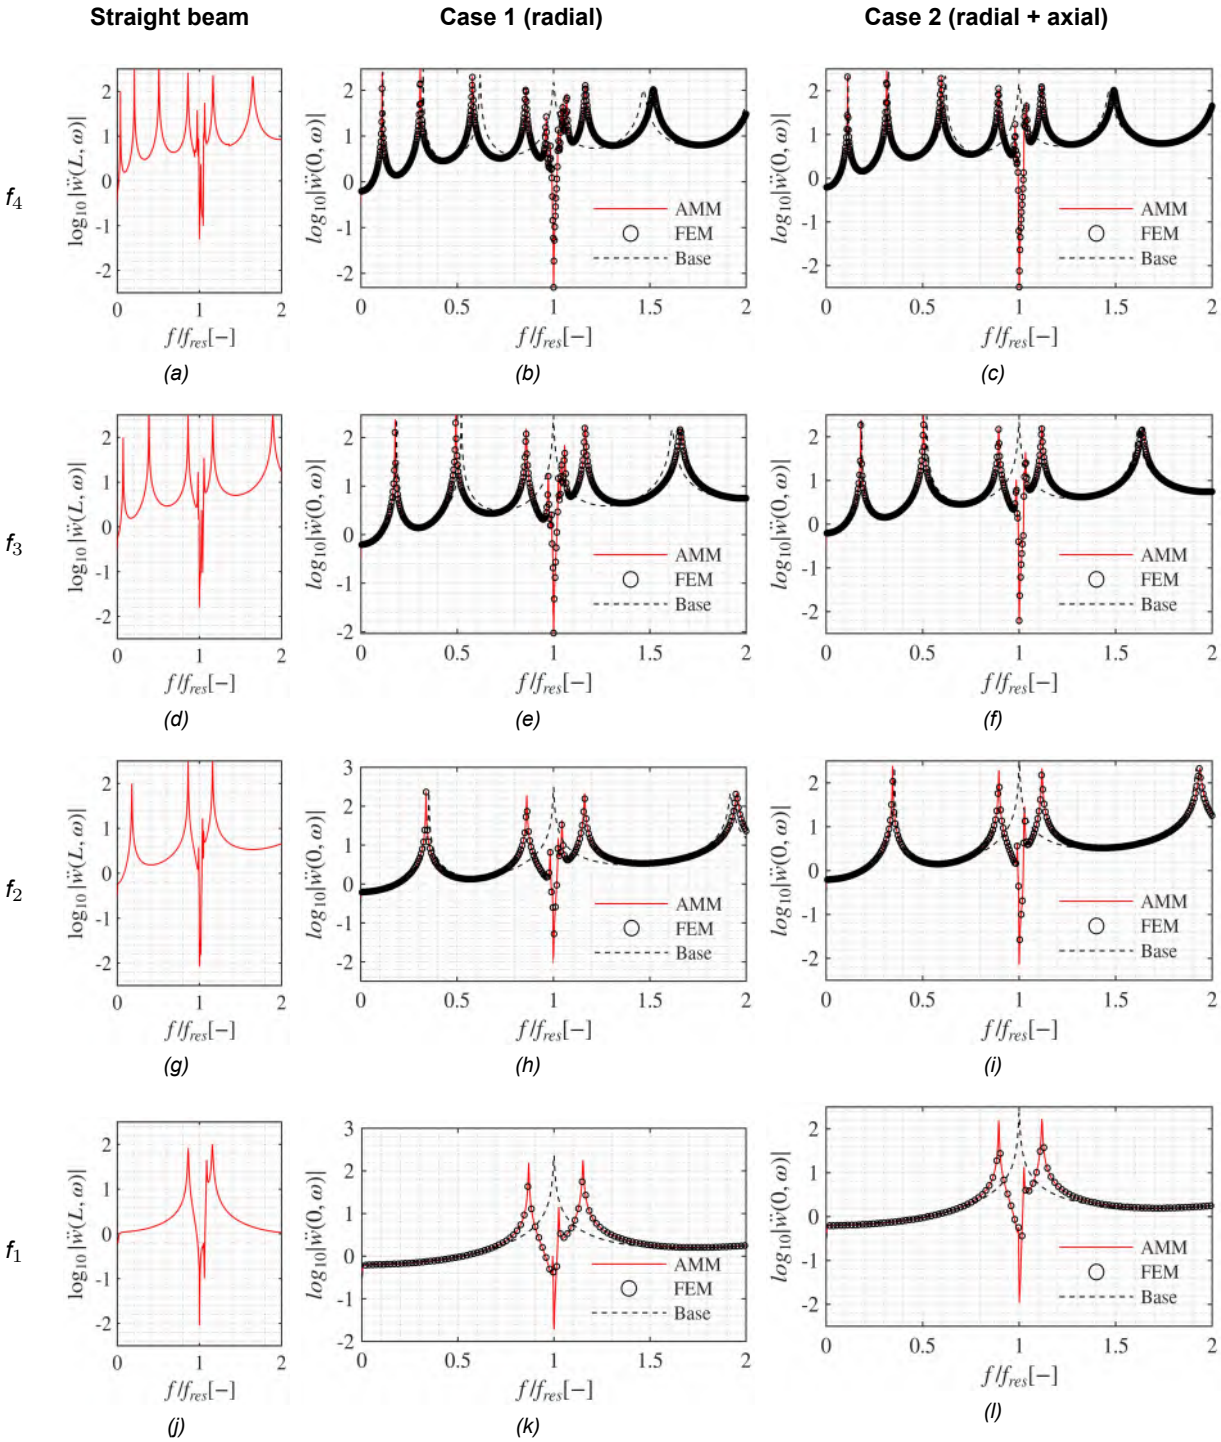
Fig. 6 shows a comparison of the FRFs for the different cases, plotted as a function of the normalized

frequency f/f_{res}, where f_{res} is the resonator tuning frequency, selected as one of the eigenfrequencies of the ring. The first conclusion that can be highlighted is that, in both cases, resonators are able to suppress the target resonance peak, creating an attenuation band. The width of the attenuation band decreases for lower target modes, consistently with Sec. 2.2. Moreover, two additional peaks appear before and after the bandgap, although with smaller amplitude than the case without resonators. In the distribution of the modes outside the bandgaps also lies the main difference between the cases, since performance in terms of vibration isolation is only mildly improved by axial resonators. Moreover, the bandgap in the case of the beam is sharper, with well defined start and end frequency. The same does not happen in the case of the ring, due to the coupling between the axial and radial degrees of freedom.

Fig. 7a shows the spatial distribution of the ring acceleration as function of frequency for $N_{res} = 20$. Within the bandgap, the response is strongly attenuated over the entire structure, indicating that the periodically distributed resonators inhibit wave propagation throughout the ring. By contrast, when a single resonator (i.e. a tuned mass damper) is employed, the reduction in dynamic response is primarily localized in the vicinity of the attachment point, located at $\theta = 0$ in Fig. 7b. This comparison highlights a key advantage of periodically distributed resonators: rather than providing only local vibration mitigation, they enable attenuation of the response in the entire structure.

Finally, Fig. 8 shows, for three different modes, the radial acceleration response as a function of the excitation frequency for different values of the number of resonators N_{res} and of the total added-mass ratio μ. For $N_{res} < 5$, the frequency response remains strongly dependent on the number of attachments, irrespectively of the targeted mode. In this regime, the resonators are too sparsely distributed for the finite ring to reproduce the dynamics predicted by the periodic model. Conversely, for $N_{res} > 5$, the response becomes insensitive to increase in the number of resonators, indicating the establishment of an attenuation region consistent with bandgap behavior.

The added-mass ratio mainly influences the width of the attenuation region. Increasing μ strengthens the interaction between the host structure and the local resonators, resulting in a larger separation between resonances and, consequently, a broader bandgap width.



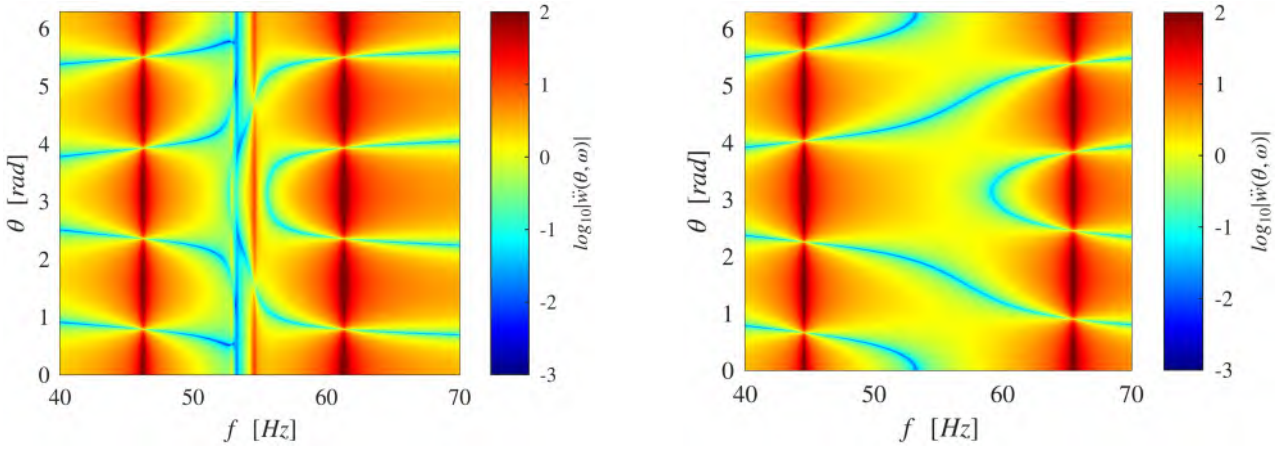


Figure 6: Point-to-point radial acceleration frequency-response functions for the equivalent straight beam and the two ring configurations. From top to bottom, the rows correspond to tuning at f_4, f_3, f_2, and f_1. Solid red lines denote the assumed-modes results, open circles denote the finite-element results, and dashed black lines represent the corresponding bare structures. Frequencies are normalized by the resonator tuning frequency f_{res}.

4. NUMERICAL VALIDATION WITH COMSOL

In order to validate the proposed framework, design of the resonators is carried out using a more realistic model. The ring is equipped with 20 radial resonators, for a total added mass ratio $\mu = 0.1$. The resonators are realized exploiting the bending stiffness of a slender beam, which hosts a total resonating mass of $m_{res} = 0.0076\,\text{kg}$, made in aluminum. Fig. 2b shows the final design of the single resonator. Notice that the beam has been slightly curved to follow the ring geometry, and that the resonating mass has been divided at the extremes of the beam. The structural parameters of the beam, made of the same material as the ring have been tuned to ensure that the first natural frequency is located at $f_{res} = 53.2\,\text{Hz}$, yielding: length $L_{beam} = 73.2\,\text{mm}$, thickness $t_{beam} = 1\,\text{mm}$, width $b_{beam} = 5\,\text{mm}$.

The final design consists of 20 such resonators, 10 for each side of the ring, connected through a rigid element, as shown in Fig. 2b.

Results in terms of frequency response, reported in Fig. 9 show that acceleration amplitude is reduced by up to two orders of magnitude at the measurement point, confirming the effectiveness of the metamaterial in reducing vibration amplitude in a narrow frequency range. Moreover, we find good agreement between the theoretical framework and the final design. Small differences are attributed to the deviation from the ideal conditions assumed for the theoretical approach, mainly: the resonating mass being not perfectly lumped to the attachment, hence the displacement not perfectly radial; damping, which is assumed lumped in the theoretical model while it is distributed in the numerical one.

5. CONCLUSION

This work investigates the use of locally resonant metamaterials for the attenuation of in-plane vibrations in the annular support ring of a large deployable reflector. An extensible curved-beam model is developed to account for the coupling between radial bending and circumferential extension. Complex-wavenumber dispersion analysis, an assumed-modes formulation, and finite-element simulations are combined to relate wave propagation in the associated periodic medium to the forced response of the finite ring.

The radial-only resonator layout produces a bending-polarized partial bandgap: the bending-dominated solutions become evanescent near the tuning frequency, while a circumferentially polarized branch remains propagative. Introducing resonators in both the radial and circumferential directions affects polarization and opens a complete bandgap. However, comparison with the equivalent straight beam shows that curvature substantially modifies both the dispersion characteristics and the finite-structure response. In particular, the relative attenuation bandwidth decreases from approximately 0.05 for the straight beam to approximately 0.025 for the ring, and the boundaries of the attenuation region become less distinct. This reduction in performance is attributed to curvature-induced coupling between radial and circumferential motion and to the higher effective stiffness of the annular configuration.

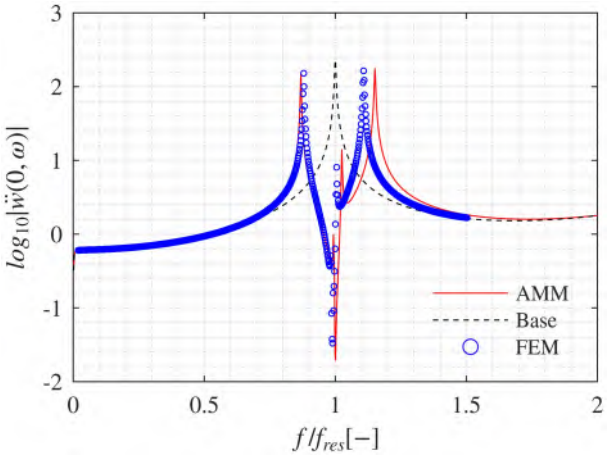

Figure 9: Validation of the designed resonator configuration through the radial acceleration frequency-response function. The response of the bare ring (black dashed line) is compared with the idealized assumed-modes model (red solid line) and with the detailed finite-element model containing the flexural resonators (blue circles).

The assumed-modes and finite-element results are in good agreement. In all the investigated configurations, the distributed resonators suppress the targeted structural resonance and split it into two resonances bounding an attenuation region. The absolute width of this region decreases when lower-frequency modes are targeted. Moreover, although the radial-circumferential configuration generates a complete bandgap in the periodic model, it produces only a moderate improvement in the point-to-point frequency response relative to the radial-only configuration. For the considered configuration, the spatial response map also shows that periodically distributed resonators provide a more uniform attenuation around the ring if compared with a tuned mass damper.

Finally, a realizable flexural resonator is implemented in finite-element model. The configuration containing 20 resonators, with an added-mass ratio $\mu = 0.1$ and a tuning frequency of $53.2\,\text{Hz}$, reduces the acceleration response by up to two orders of

magnitude. These results demonstrate the potential of locally resonant concepts for annular space structures, while also showing that designs for straight members cannot be directly transferred to curved elements. Further improvements will address the use of more exotic dynamical mechanisms with the aim of improving the low-frequency performance of the curved metastructure.

ABSTRACT

Future satellite missions increasingly demand compact, lightweight, and high-performance antennas capable of covering multiple frequency bands for Positioning-Navigation-Timing (PNT) applications. Traditional antenna systems are limited by rigid structures and size constraints, which can impair deployment feasibility and RF performance in small satellite platforms.

In this context, the research for versatile solutions with high compaction ratios becomes particularly interesting, being the structure explored in this paper especially attractive, as it studies the possibility of housing three antennas for three different bands in a single deployable structure.

1. INTRODUCTION

This project, developed within the framework of the ESA Contract Nº 4000143515/23/NL/AS, [DD-STRA], focuses on the design, analysis, and validation of a stacked tri-band deployable antenna operating in the UHF, L, and S bands, optimized for use in low Earth orbit (LEO) missions. The solution is based on a single-body deployable coilable boom structure that integrates all three bands in a stacked configuration, enabling compact stowage and robust deployment. This structure is composed of four flexible longerons and 20 custom-designed mounts manufactured of space validated plastic, providing both mechanical strength and guidance for the helical antenna elements.

The antenna mechanism deployment is passive, and it is controlled by a motorized system that ensures non-violent and controlled deployment. The deployment mechanism includes a non-pyrotechnic Hold Down and Release Actuator (HDRA) that triggers the self-deployment of the boom using the elastic energy stored in the longerons. The mechanism design eliminates the need for post-deployment locking systems due to the inherent stiffness and cable tension of the deployed structure. Each antenna band is supported by its own coaxial cable feed and PCB.
A comprehensive RF simulation was performed using FEKO software, incorporating detailed geometry, coaxial feeds, and platform effects. The results show compliance with most RF specifications, including gain patterns, return loss, and axial ratio. The antenna achieves a deployed length of 3.25 m and a mass of 4.3 kg, fitting within the LEO mission requirements.

The Manufacturing, Assembly, Integration, and Testing (MAIT) plan includes procurement, mechanical assembly, and RF integration steps, along with a detailed test campaign covering frictional deployment, S-parameters, radiation pattern verification, and mechanical qualification. The finalization of these activities will allow a TRL4 maturity achievement and demonstrate the feasibility of the concept as a modular, efficient, and space-compatible multi-band antenna system.

The project represents a major step forward in deployable antenna technology for small satellites and is the result of a successful collaboration between industry, academia, and the European Space Agency.

2. DESIGN AND ANALYSIS

Mechanical Design

The designed solution consists of a single deployable structure capable of compacting and positioning three antennas of UHF-, L- and S-bands. The deployable structure is based on a coilable boom architecture which can transition from a stowed state, forming the longerons a low-pitch helix, to a deployed state where they are completely straight, providing stiffness and stability to the structure.

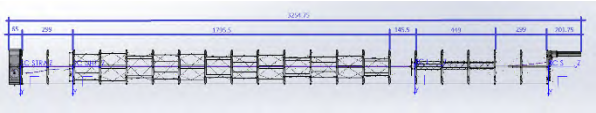

Fig. 1. Deployed STRA.

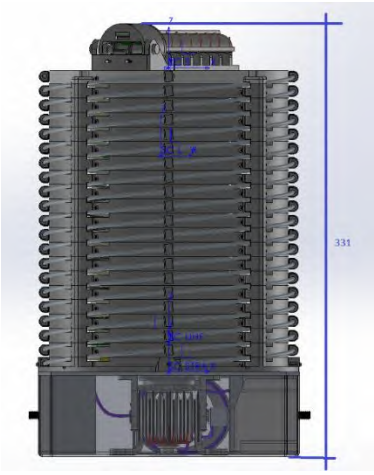

Fig. 2. Stowed STRA.

From the mechanical structure point of view, it consists of four GFRP (Glass Fiber Reinforced Plastic) longerons which are responsible for the passive motorisation of the antenna due to their ability to store elastic strain potential energy in the stowed state, and 20 Ultem mounts that spaced at a length that ensures geometric compatibility between the stowed and deployed states.

The structure is braced by a set of p-aramid tensors with a triple purpose (see Fig. 3).

- Red: deployment control tensors which prevent violent deployment of the structure.
- Green: counter-tensors which stiffen and latch the antenna in the final stage of deployment.
- Yellow: fixed tensors which form St. Andrew's crosses together with the counter-tensors, to brace the structure.

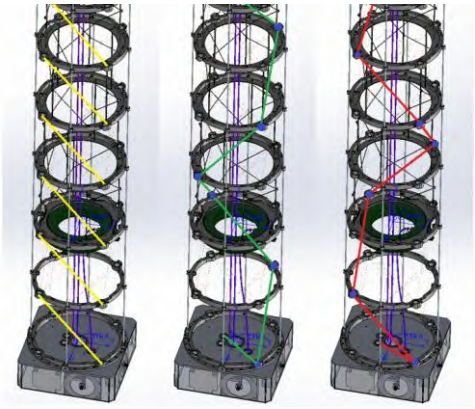

Fig. 3. Antenna control and bracing tensors

The structure remains stowed thanks to the action of an HDRA (Hold Down and Release Actuator). This device has a dual function: on the one hand, it is responsible for releasing the antenna, allowing it to deploy passively; on the other hand, it has the mission of compressing the structure with enough force to ensure that its stiffness in the stowed situation is adequate and to prevent loss of contact (and subsequent bumping) between any of its parts during launch. To withstand this preload, the upper antenna mount (top disc) is made of fibreglass and it is connected by a hollow titanium rod to the HDRA screw, housed in the metal box under the structure.

The deployment control system is driven by a stepper motor. When the HDRA releases the antenna, it tends to deploy explosively, but its movement is controlled by the speed imposed by the motor.

Finally, detailed described the supporting structure, the location of the three antennas on it is shown in Fig. 4.

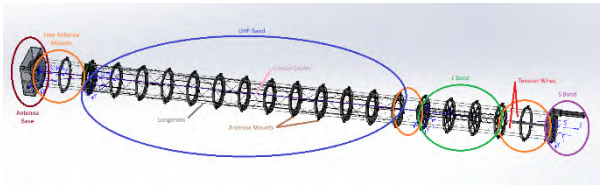

Fig. 4. STRA parts.

The UHF band antenna consists of four wires forming a conical helix with a base diameter of 162 mm, a top diameter of 120 mm, a pitch of 450 mm, and a total height of 1795.5 m. It is housed within 13 of the first mounts, which are connected between them with four non-structural p-aramid threads holding the wires in the approximated helix shape.
The L-band antenna is housed in a similar way to the previous one, consisting of four wires forming a straight helix with 50 mm diameter, 145 mm pitch and a total height of 452 mm. This antenna is comprised in the space between four mounts, after the UHF-band antenna.

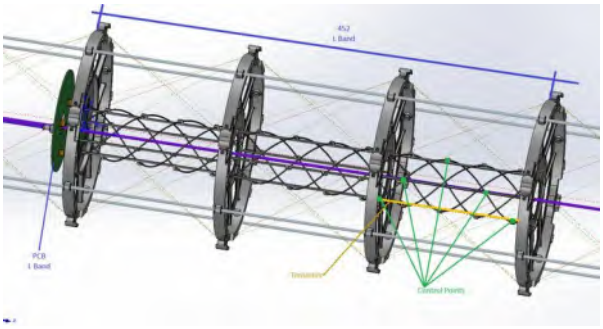

Fig. 5. L-band antenna housing.

The S-band antenna is too small to maintain the deployable concept of the previous two. Therefore, this antenna, consisting of four helical wires with 25 mm diameter, 70 mm pitch and a total height of 140 mm; is embedded in a plastic structure connected to the top disc by means of a hinge and a spring that brings it into position during the deployment manoeuvre.

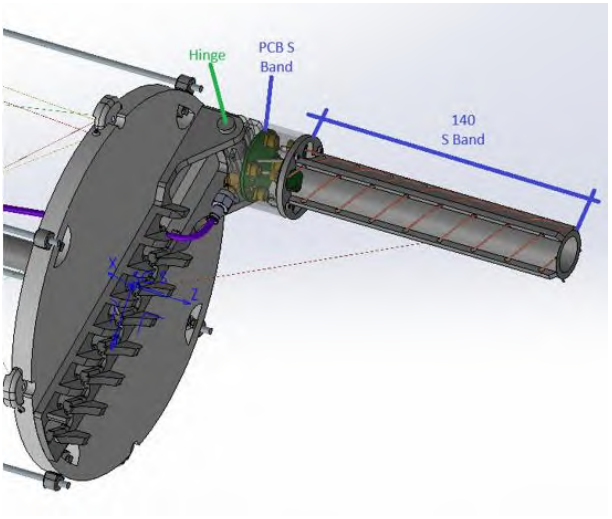

Fig. 6. S-band antenna housing.

Mechanical analysis

Two FEM (Finite Element Model) are built to analyse two different scenarios: stowed structure (preload case and launch load case analyses) and deployed structure (flight case analyses).

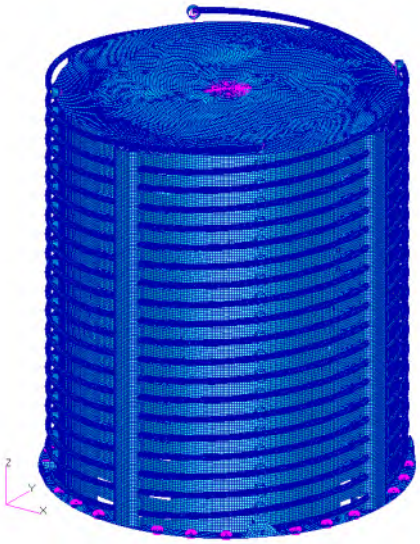

Fig. 7. STRA stowed FEM.

Preload analysis

Employing the stowed FEM, the HDRA is sized on the premise that the compression exerted by the device is enough to prevent separation and bumping of any part of the antenna during launching. To do this, axial (V) and shear (S) forces are recovered at all interfaces of the stowed structure in all launch load cases. The preload required at each interface, knowing the insertion angle of the tongue and groove joint that allows the mounts to fit together when stowed (θ), is calculated as shown below.

$$Preload_{Min} = (V + S \cdot \tan(\theta)) \cdot SF \qquad (1)$$

The effective load distribution of the HDRA preload between the interfaces is calculated using a unit case which, combined with the above information, defines that the minimum device preload required is 14366 N.

Known this value, it is introduced in the stowed model to verify that the structure can withstand it, obtaining the maximum Von Mises stress and the minimum MoS (Margin of Safety) in each part.

Table 1: Preload analysis strength results

	σ_{VM} (MPa)	MoS
Ultem (mounts)	42.66	0.68
GFRP (longeron)	34.06	>5.00
Prepreg glass fabric (top disc)	308.01	0.43

Launch loads analyses

Natural frequencies of the stowed FEM are analysed to better understand its dynamic behaviour under launch loads. The structure has been designed with the aim of achieving a 1st natural frequency greater than 100 Hz (outside the sine specification). As a result, the 1st mode of the structure is at 130.34 Hz.

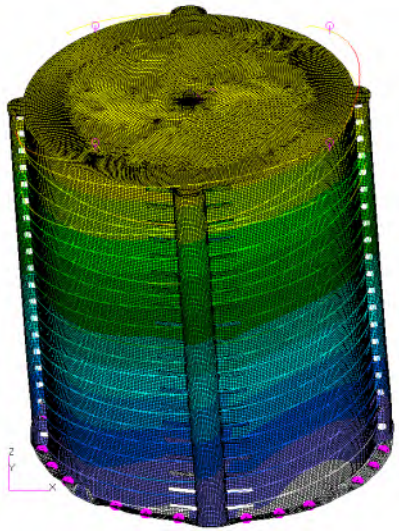

Fig. 8. Stowed FEM 1st vibration mode.

The stowed FEM is analysed under each of the launch loads (Quasi-Static, Sine, Random and Shock), combining the obtained stress results with those from the preload analysis, resulting in the Table 2. It is verified that the random load case is the most critical.

Table 2: Launch load analyses MoS results

	Ultem MoS	GFRP MoS	Prepreg MoS
Pr. + QS	0.28	>5.00	0.41
Pr. + Sine	0.34	>5.00	0.43
Pr. + Random	0.02	>5.00	0.43
Pr. + Shock	0.25	3.96	0.31

Analyses in flight situation

The deployed FEM is built from the previous one, expanding its mounts and adding the tensors that brace the structure.

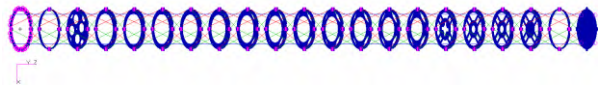

Fig. 9. STRA deployed FEM.

In this situation, only the stiffness and thermoelastic stability of the structure are analysed. The modal analysis shows vibration modes very similar to those of a cantilever beam, being the 1st frequency of 1.76 Hz; while the thermoelastic analysis concludes that both the geometric distortion of the antenna and the stresses derived from the temperature are negligible.

RF Design

The presented triband antenna is basically comprised of three quad-helix antennas, one per frequency band, placed along a deployable boom. Each antenna generates a circularly polarized isoflux pattern that maximizes the uniform power distribution for a global coverage.
Each of the antennas is fed by its own feeding network which is placed just under each one of the helixes. The signal distribution until each feeding network is done through coaxial cables located in the middle of the antenna. The long cables that are required to reach the feeding points of L band and the S band antennas lead to high insertion losses. Fortunately, the application link budget has a large margin, and they can be tolerated.
Many key aspects have been considered in the design, such as the adequate materials selection, the custom shaped feeding networks and the optimized placement of each helix inside the boom.

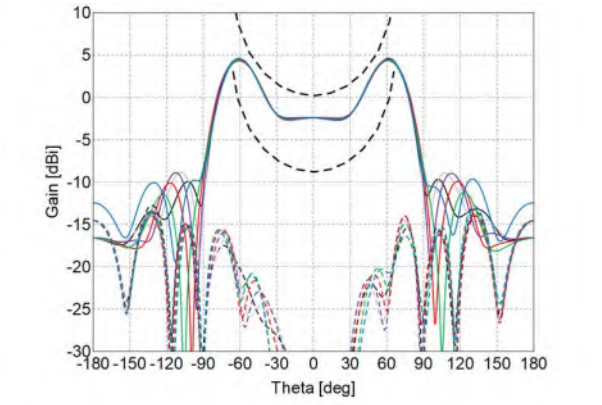

Fig. 10. UHF band isoflux radiation pattern

RF Analysis

The antenna has been modelled in FEKO software for its RF simulation. The electrical model simplification has been key to improve the simulation speed and reduce the required computational resources while maintaining high precision results. This simplification allows the simulation of the antenna including the boom, the support structure, the satellite platform, the feeding network and the cables. This complete electrical model ensures precise RF simulation results.
The copolar and crosspolar radiation patterns (See *Fig. 10* UHF radiation pattern as example), the gain, the axial ratio, the return loss, the phase centre variation, the phase centre stability, the group delay and some more parameters have been simulated and calculated.
The following *Table 3* summarizes some of the most important electrical parameters that define the antenna:

Table 3. Electrical performance summary

Parameter	Value
Frequency band	UHF band, L band and S band
Pattern shape	Isoflux
Polarization	Right-handed circular
Field of view	132º
Bandwidth	50 MHz per frequency band
Return loss	> 10 dB

3. CRITICAL BREADBOARD MANUFACTURING AND TESTING

Mechanical CBB

A mechanical critical breadboard of the structure with dummy electrical parts is manufactured and assembled to verify its mechanical performance and serve as a derisking model.

As the objective is the functional check of the structure, materials used have representative characteristics for this purpose, but they do not necessarily have to be the final ones. Furthermore, different manufacturing and assembly procedures are evaluated to select the best method for building the future final breadboard.

Fig. 11. STRA deployed CBB.

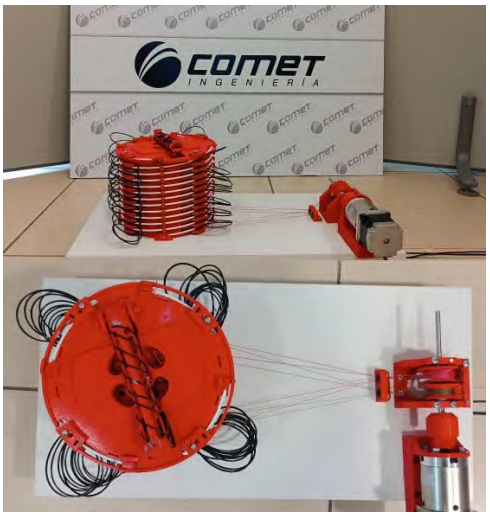

Fig. 12. STRA stowed CBB.

Having finalised the CBB manufacturing, 30 folding and deployment cycles are performed to assess the robustness of the solution. This process starts with the CBB in its stowed state when the stepper motor begins to rotate at a controlled speed, allowing longerons to gradually release elastic potential energy and transition to their nominal position. When the longerons have exhausted their energy, the structure is almost fully deployed, so the last step consists of reversing the rotation direction of the motor to pulling the corresponding tensors (green in Fig. 3) and latching the antenna.

The following lessons are extracted from these experiences:

- The kinematic operation of the structure is correct, and it is able to stow and deploy passively without becoming stuck. There are certain points with slight geometric incompatibilities (Fig. 13) at intermediate stages of the manoeuvre which are corrected in the final model.

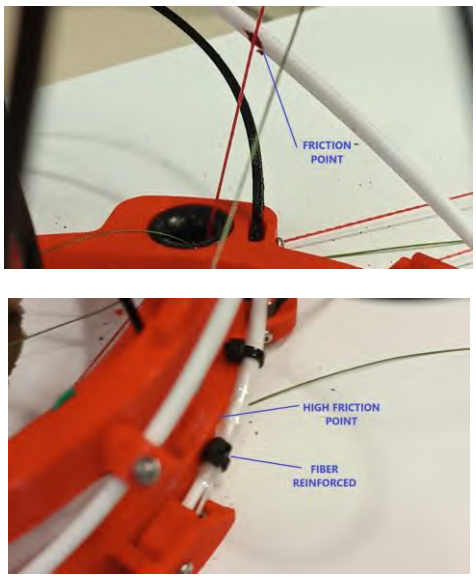

Fig. 13. CBB Collision points.

- The manufacturing methods and 3D printing orientations are correct and suitable for the intended purpose of the structure. No strength issues have been detected in the functional operation, and manufacturing procedures, such as the embedding of the low-friction washers through which the tensors run, have been validated.
- The use of TPU material for the fixed tensors (yellow in Fig. 3) is discarded. The decision to use this material was based on the idea of having threads with adaptive flexibility, all manufactured to the same length using 3D printing; however, it has been concluded that its advantages do not justify its disadvantages and, for the BB, rigid tensors manufactured using a tool will be considered.
- There is enough stowed volume to accommodate the radiating wires that comprise antennas.

RF CBB

In parallel, in the frame of this project, electrical models and feeding networks CBBs are also manufactured and tested.

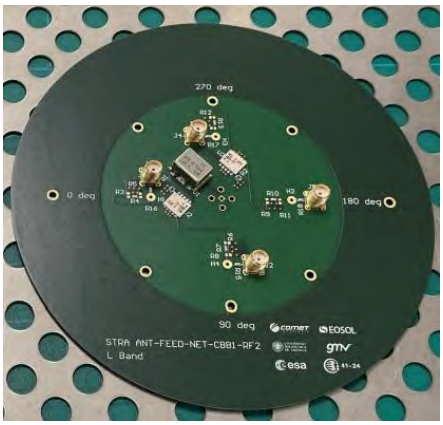

Fig. 14. Manufactured PCB of the CBB L-Band antenna.

There are key parameters that must be verified to validate the design and the manufactured antenna. The isoflux copolar and crosspolar radiation pattern in amplitude and phase, the gain and the return loss are the most important parameters that will be measured over the frequency bands. Many other important parameters such as the phase center related parameters will be calculated from the mentioned ones and compared with simulations.
The antenna will be tested in an anechoic chamber that is able to measure it with a reasonable accuracy even at the UHF frequency band, allowing the validation of the antenna.

4. BREADBOARD MANUFACTURING

After the reduced-scale CBB, a BB of nominal dimensions is manufactured and assembled. The BB measures 200 mm in diameter, 266 mm in height when stowed and 3190 mm when deployed.

Fig. 15. STRA deployed and stowed BB.

The BB manufacture is aligned with the objectives of a TRL 4 project; consequently, the materials of the structure are mechanically representative (and in many cases, conservative), but not necessarily qualified for spatial applications. This includes, for example, the use of UHMWPE tensors, or PLA for the 3D printed parts. Furthermore, the HDRA is omitted as no vibration test campaign is planned, and the motor and electrical components are not space-qualified.

Fig. 16. UHF wire positioning tensors (left top), base (left bottom), L wire positioning tensors (right).

The process is handmade and it begins with the purchase of the raw materials and the manufacturing of the components that comprise the deployable structure (longerons, mounts and tensors). All of these are assembled onto a metal base, which supports the deployable mechanism and houses the harnesses that feed the PCBs.

The wires of the three antennas are measured and installed. Each one is attached to the structure using a slightly different method. The UHF band antenna is supported at its intersections with the mounts, forming a “helix” of straight segments between the mounts and the only support point between each pair of them. The L-band antenna uses a similar system, but due to its smaller size, there are four fixing points between each pair of mounts, which confers its radiating wires a more helical shape. Finally, the S-band antenna is not deployable due to its dimensions, so it is embedded into a plastic fixture that folds 90º and deploys by means of a torsion spring.

The PCBs and their corresponding harnesses, which are housed in the base and deploy at the same time as the structure, are installed and, at this point, the BB is fully assembled and operational.

Before to the test campaign, preliminary deployments are performed to check the BB mechanism works properly.

It is verified that the BB has enough motorisation to deploy against gravity force, without the need for equipment which compensate for this. However, in the stages of the manoeuvre prior to final tensioning (when the longerons are not vertical yet) the flexural stiffness of the assembly is significantly low. Therefore, to prevent buckling due to the gravity action, the deployment takes place inside a methacrylate tube (Fig. 15 right) which acts as an MGSE.

5. MECHANICAL TEST PROCEDURES

Mechanical and radio-electrical tests are performed on both the BB and some of its components. Specifically, on the mechanical side, motorisation and deployment tests are conducted on the complete BB. On the RF side, S-parameters of the complete antenna, the feeding networks, their harness and the SMA connectors are measured; and radiation pattern and gain tests of the complete BB are obtained. In addition, dimensional and mass inspections are also done.

This paper focuses on the mechanical aspects of the project, so procedures of mechanical tests are described in detail below.

Motorisation test

The motorisation test aims to obtain an initial estimation of the axial force exerted by the structure at each moment of the deployment manoeuvre, to assess its motorisation margin.

It is identified that the motorisation force comes from the stored elastic energy of the longerons, while the resistive forces arise from friction at the joints of the structure, friction of the tensors, the resistance exerted by the radiating wires that comprise the antennas, and the resistance of the harness that supplies the PCBs. The deployment mechanism introduces no resistance, as the brake consists of a stepper motor, which is an active element.

Due to the nature of the structure, it is extremely speculative to establish a formulation for estimating the friction of each element at each moment of the manoeuvre. The structure deploys sequentially, with each segment being in a different position to the rest, and the overall configuration being unique at every instant. For this, the experimental approach has been adopted.

Grouping, in one side, as the internal friction of the antenna (R_{Fric}) the resistance originated in joints, tensors and radiating wires; and in the other, the resistance of the harness (R_{Harn}), it is agreed that the motorisation margin of the structure for each deployment % can be expressed as follows.

$$MM(\%) = \frac{F_{Mot}(\%)}{R_{Fric}(\%) + R_{Harn}(\%)} \qquad (2)$$

By analysing the nature of each term in the above expression and assuming that the internal frictions are symmetrical (same magnitude and opposite direction when folding and deploying), the following diagram of forces depending on the movement direction is obtained.

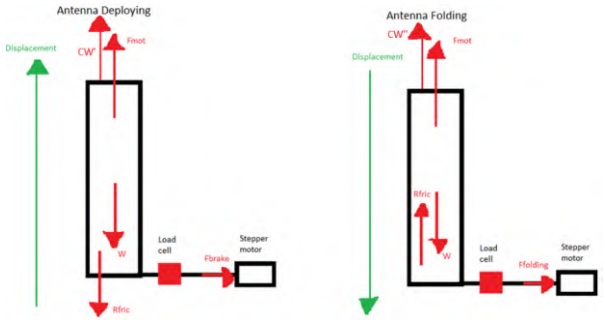

Fig. 17. Force diagram of the BB in deployment and folding.

Where F_{mot} is the motorisation force of the structure, W is the weight of the BB, R_{fric} represents the internal friction, F_{brake}/$F_{folding}$ are the forces reaching the stepper motor and read by the load cell, and CW'/CW'' are the forces exerted by the counterweight (a different value when folding and deploying). It is decided to use a counterweight to prevent the structure from buckling due to the force of gravity instead of the MGSE, so as not to introduce noise into the measurement caused by friction between the BB and the MGSE.

To determine F_{mot}, R_{fric} and R_{Harn}, it is decided to measure the axial force of the BB in three scenarios.

a) Deployment force test without harness.
b) Folding force test without harness.
c) Deployment force test with harness.

In each of which, the load cell measurement can be expressed as a combination of the terms above.

$$F_{a)}(\%) = F_{mot}(\%) - W(\%) - R_{Fric}(\%) + CW' \qquad (3)$$

$$F_{b)}(\%) = F_{mot}(\%) - W(\%) + R_{Fric}(\%) + CW'' \qquad (4)$$

$$F_{c)}(\%) = F_{a)}(\%) - R_{Harn}(\%) \qquad (5)$$

And combining these three measurements it is possible to obtain the variables involved in the calculation of the motorisation margin.

$$R_{Fric}(\%) = \frac{F_{b)}(\%) - F_{a)}(\%) - (CW'' - CW')}{2} \qquad (6)$$

$$R_{Harn}(\%) = F_{a)}(\%) - F_{c)}(\%) \qquad (7)$$

Deployment test

The deployment test aims to demonstrate that the structure is robust enough to withstand 30 deployment manoeuvres without compromising the antenna performance. Along these deployments, the repeatability of the manoeuvre and the deviations and distortions of the structure that could affect the antennas are assessed.
The possible distortions that the structure allows without any of its components evident breaking are as follows.

- Deformation of the structure due to global bending or torsion, resulting in the three antennas being displaced from their nominal position.
- Local diameter reduction of the UHF and L-band antennas due to loss of tension in the positioning threads (Fig. 18 left)
- Random local distortion of the radiating wires of the UHF and L-band antennas between control points (particularly in the UHF-band antenna).

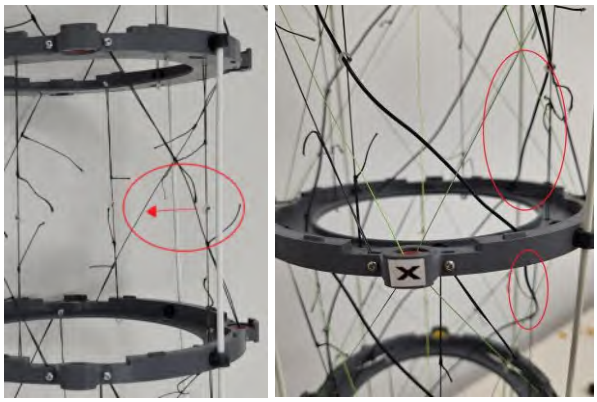

Fig. 18. Unrestricted movement direction of the control points (left), radiant wires with random local distortions (right).

A different measurement strategy will be followed for each of the possible distortions.
To determine the global deformation of the structure, which is expected to be minimal, the position and angle of the top disc is measured by a laser every 15 deployments, extrapolating this measurement linearly to the rest of the length.
To determine the reduction in the diameter of the antennas due to a loss of tension in the threads, the distance between each pair of opposing washers is measured every 15 deployments.
To determine the effect of random local distortions, different models of the UHF and L-band antennas with curvatures of the order of those seen in the BB are randomly generated, and their RF parameters are obtained.

Finally, after the completion of the test campaign, a wear study is performed to identify which areas of the BB suffer more.

6. MECHANICAL TEST RESULTS

Motorisation test results

The axial force exerted by the BB is measured three times for each of the three scenarios described and the mean value is calculated. The graphs obtained from the raw deploying and folding measurements appear as follows.

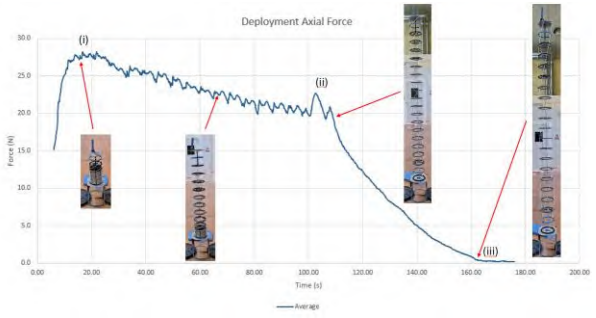

Fig. 19. BB deploying axial force graph shape and phases.

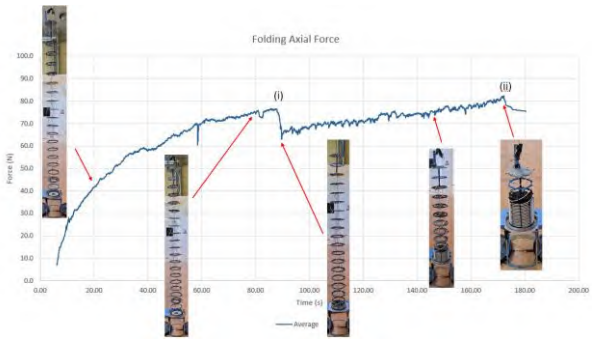

Fig. 20. BB folding axial force graph shape and phases.

Next, the BB mass and the contribution of the counterweight are compensated analytically and by means of auxiliary tests, so that the results represent only the motorisation minus the internal friction and harness resistances. The blue curve corresponds to scenario a), the orange one to b) and the grey one to c).

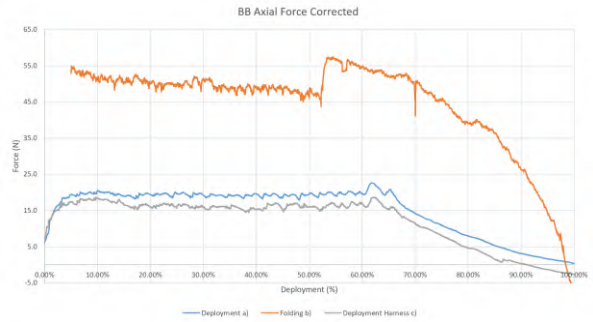

Fig. 21. BB axial force corrected in scenarios a), b) and c).

Operating with the system of equations formed by (3), (6) and (7), the terms F_{mot}, R_{fric} and R_{harn} are obtained. These are calculated along the uniform section of the graph (approximately between 3% and 65% of the deployment). This is because in the final phase of deployment the axial force of the BB tends towards 0; however, the counter-tensioning system starts to operate, providing the extra energy necessary to complete the manoeuvre.

$$\boldsymbol{F_{mot} \in [32.2;\ 36.8]\ N}$$
$$\boldsymbol{R_{fric} \in [12.8;\ 17.7]\ N}$$
$$\boldsymbol{R_{harn} \in [0.9;\ 5.0]\ N}$$

To calculate the motorisation margin, the most appropriate safety factors specified in [1] are applied.

$$MM(\%) = \frac{F_{Mot}(\%)}{2R_{Fric}(\%) + 3R_{Harn}(\%)} \qquad (8)$$

Resulting in an MM in the uniform section of:

$$\boldsymbol{MM \in [0.77;\ 1.02]}$$

In accordance with the ECSS recommendation, the motorisation margin obtained is low, as the standard recommends a margin of 2 once safety factors have

been applied. However, it should not be forgotten that the BB's manufacturing methods are in line with the scope and budget of a TRL4 project; consequently, the surface quality of parts with relative motion between them has significant margin for improvement, so R_{fric} may be reduced. Furthermore, it has been found that the measurement setup introduces some additional friction, which adds a degree of conservatism to the results.

Deployment test results

At the time of the elaboration of this paper, 20 of the 30 planned deployments of the BB campaign have been done; consequently, some results are preliminary, but certain conclusions can already be extracted.

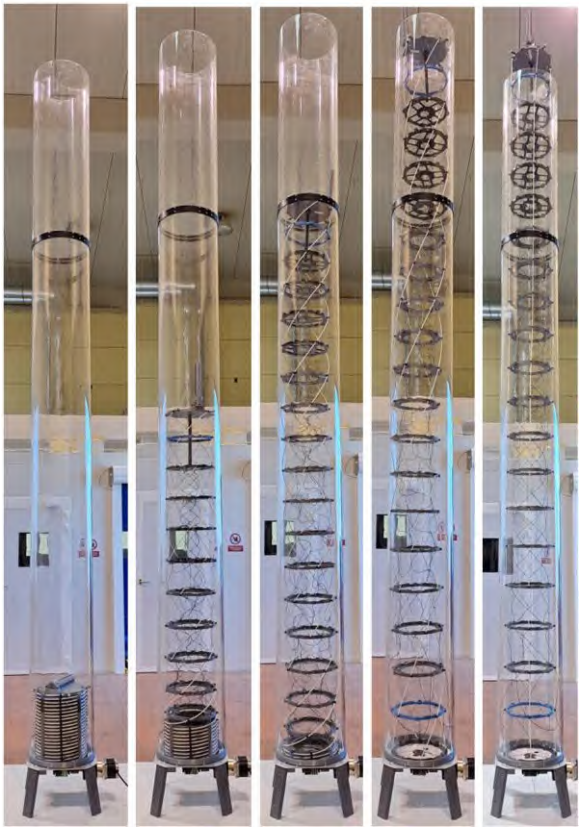

Fig. 22. BB deployment sequence.

First, there is no apparent loss of motorization in the structure due to a possible gradual deterioration. Furthermore, the final position reached by the BB can be forced to be always the same (with a margin of error of a few millimetres), as this is controlled by the tensioning system.

The global deviation of the BB has been measured after manufacture and after 15 deployments. The structure exhibits an approximate deflection of 20 mm and torsion of 16° at its free end, with similar results for both measurements done. The immediate conclusion is that the deviations are caused by manufacturing inaccuracies and tolerances in the model, rather than deterioration by operation. The residual torsion appears to be of some significance, but it has been verified that it has no appreciable impact on the performance of the antennas. The reason for this distortion is that the tensioning by the stepper motor takes place at the base, reducing the latching torque as the height increases due to friction.

Local diameter reduction has increased by around 3 – 4 mm comparing measurements at the start and halfway of the campaign on the UHF band antenna. This distortion is negligible in the L-band antenna. The test campaign needs to continue to determine if this phenomenon worsens with the remaining manoeuvres, or if it has already reached its limit. The impact of this distortion at RF level has not yet been assessed.

The RF impact of random local distortions in radiating wires has not yet been assessed.

7. CONCLUSIONS AND FURTHER STEPS

Conclusions extracted at this stage of the project are listed below:

- An antenna solution has been proposed to satisfy the need identified in the project framework.
- Satisfactory compliance with mechanical and electrical requirements has been verified by analysis.
- It has been confirmed that the solution proposed is feasible and that its deployable structure is functional
- The in-house manufacturing processes for building this type of helical structures have been validated and refined.
- The BB is perfectly capable of deploying against gravity, but the calculated motorisation margin is lower than ECSS recommendation. However, it is considered that there is margin for improvement by removing conservatism.
- It has been verified that the deployment system is robust enough to ensure that the global position of the structure remains unchanged despite the number deployments.
- There are indicators that the reduction in the diameter of the UHF-band antenna local distortions is affected by the number of deployments, but their impact at RF level has not yet been assessed.
- At this stage of the project, it is considered that a robust BB resulting from a design that fulfils the requirements has been achieved; with some areas to improve but leaving a positive impression.

Further steps to mature the technology presented up to TRL4 within the framework of this project are:

- Complete the deployment test campaign and ensure the repeatability and robustness of the structure can be deployment.
- Measure the BB in an anechoic chamber and correlate the results to validate its RF performance.
- Quantify the positional deviations of the radiating elements to assess their impact at RF level is acceptable.

After achieving a design that fulfils the requirements at TRL4 level, the next steps would be:

- Eliminate the conservatism observed regarding motorisation test and study the MM in greater detail.
- Consider flight-grade materials in the manufacturing so that the structure can be tested in representative mechanical environments and under TVAC conditions.
- To frame the antenna within a project involving flight projections that provides more mature requirements and a framework for the development of the solution.

KEYWORDS

Composite material, Deployable structure, Bistable, Viscoelasticity, Temperature-dependence

ABSTRACT

A thin-walled semi-cylindrical boom made of Carbon Fiber Reinforced Plastic (CFRP) with appropriate fiber orientation angles and their stacking sequence has two stable shapes. This CFRP bistable boom is expected to be applied to deployable structures on spacecraft. From the design perspective, this boom requires evaluation of the effects of long-term storage and high-temperature environments due to its flexibility and the presence of resin in CFRP. In this study, the test on bistable booms was conducted to examine the influence of storage temperature and duration on the re-deployed boom shape. Also, the analytical method corresponding to the test conditions was proposed to evaluate the test data.

Figure 1: CFRP Bistable Boom
(Upper: deployed configuration, lower: coiled configuration)

1. INTRODUCTION

Carbon Fiber Reinforced Plastic (CFRP) is increasingly being adopted in the aerospace sector because of its high specific strength and stiffness, as well as the ability to design the mechanical properties by choosing fiber directions and their stacking. Especially, a properly designed CFRP open-section semi-cylindrical boom keeps the shape in both deployed and coiled configuration as shown in Fig. 1. This CFRP bistable boom is expected to be used as deployable components on spacecraft because of its lightweight and the easiness of storage and deployment. For example, in Japanese space projects, the use of CFRP bistable booms is being considered for the storable support columns of solar array paddles on a crewed pressurized rover on the moon [1]. Also, the boom considered here is made of woven CFRP, which leads to less twisting deformation in the coiled configuration than the boom made of unidirectional (UD) laminate [2].

Deployable structures on spacecraft are exposed to the long-term storage until their deployment and to the harsh temperature environment in space. From the point of material properties, it is essential to consider time- and temperature-dependent properties called thermoviscoelasticity and the effect of it on the structural behavior. Deployable structures are subjected to deformation during the storage period, and the resulting stress relaxation causes the shape change in both coiled and re-deployed configuration. Regarding the temperature dependence of viscoelastic properties, time-temperature superposition (TTS) principle was widely used and the accelerated testing of booms based on this principle is considered.

Previous studies focused on the resin thermoviscoelasticity and calculated the relaxation properties of woven CFRP by finite element analysis [3]. They dealt with the difficulty to experimentally obtain all the viscoelastic properties for the structural analysis by using numerical method. However, discrepancy between the experimental and numerical values was observed, and the long-term properties were not fully

evaluated. Other studies investigated the shape change of booms with deformation history experimentally and numerically considering the base material thermoviscoelasticity [4,5]. Test conditions for storage time and temperature were insufficient for actual spacecraft applications and accelerated testing.

This study aims to examine the effect of storage time and temperature conditions on shape changes of CFRP bistable booms through boom tests and analyses. In the boom tests, the booms were stored under multiple storage and temperature conditions, and the time-dependent changes in their coiled and re-deployed configurations were measured. In particular, the master curve for storage time and re-deployed shape were created by shifting the test data based on TTS principle. Besides, approximation methods and numerical analyses were conducted under conditions corresponding to the test.

2. BASE MATERIAL CHARACTERIZATION

2.1. Constitutive Equations

A bistable boom in the deployed configuration and the boom coordinate system is shown in Fig. 2. The *x*-axis is defined as the longitudinal direction and the *y*-axis as the circumferential direction of the cross-section. Due to the anisotropy of the boom base material, the constitutive equations are expressed using the stiffness matrices in this coordinate system.

The constitutive equations combine classical lamination theory and linear viscoelasticity and are shown in Eq. 1.

$$\begin{Bmatrix} \boldsymbol{N}(t) \\ \boldsymbol{M}(t) \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A}(t) & \boldsymbol{B}(t) \\ \boldsymbol{B}(t) & \boldsymbol{D}(t) \end{bmatrix} \begin{Bmatrix} \boldsymbol{\varepsilon}(0) \\ \boldsymbol{\kappa}(0) \end{Bmatrix} + \int_0^t \begin{bmatrix} \boldsymbol{A}(t-s) & \boldsymbol{B}(t-s) \\ \boldsymbol{B}(t-s) & \boldsymbol{D}(t-s) \end{bmatrix} \begin{Bmatrix} \dot{\boldsymbol{\varepsilon}}(s) \\ \dot{\boldsymbol{\kappa}}(s) \end{Bmatrix} ds \quad (1)$$

where: {***N***(*t*)} and {***M***(*t*)} are resultant force and moment, {***ε***(*t*)} and {***κ***(*t*)} are middle surface in-plane strain and curvature, and [***A***(*t*)], [***B***(*t*)] and [***D***(*t*)] are the relaxation stiffness matrices.

Previous studies [6] revealed the coupling matrix [***B***(*t*)] and 16 and 26 components of matrices affect the torsion deformation in the coiled configuration. Thus, the woven textile CFRP that can be regarded to have macroscopically four-fold rotational symmetry is used with a fiber orientation angle of ±45°. Then, relaxation stiffness matrices are expressed as Eq. 2.

$$[\boldsymbol{A}(t)] = \begin{bmatrix} A_{11}(t) & A_{12}(t) & 0 \\ & A_{11}(t) & 0 \\ \text{sym.} & & A_{66}(t) \end{bmatrix}$$
$$[\boldsymbol{B}(t)] = [\boldsymbol{O}] \quad (2)$$
$$[\boldsymbol{D}(t)] = \begin{bmatrix} D_{11}(t) & D_{12}(t) & 0 \\ & D_{11}(t) & 0 \\ \text{sym.} & & D_{66}(t) \end{bmatrix}$$

Note that each component is expressed as a linear combination of a constant term and exponential functions with relaxation time τ_k as shown in Eq. 3.

$$A_{ij}(t) = A_{ij,0} + \sum_{k=1}^{n} A_{ij,k} e^{-t/\tau_k}$$
$$D_{ij}(t) = D_{ij,0} + \sum_{k=1}^{n} D_{ij,k} e^{-t/\tau_k} \quad (3)$$

2.2. Time-Temperature Superposition Principle

The temperature dependence of viscoelasticity is described by an empirical law known as the time-temperature superposition (TTS) principle [7]. TTS allows stress relaxation at any given temperature to be represented by shifting that at a reference temperature along the time axis as shown in Fig. 3.

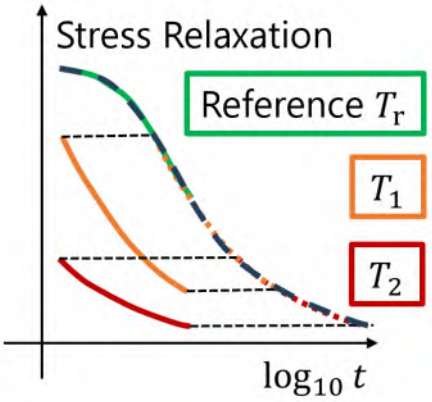

Figure 3: Schematic Diagram of TTS

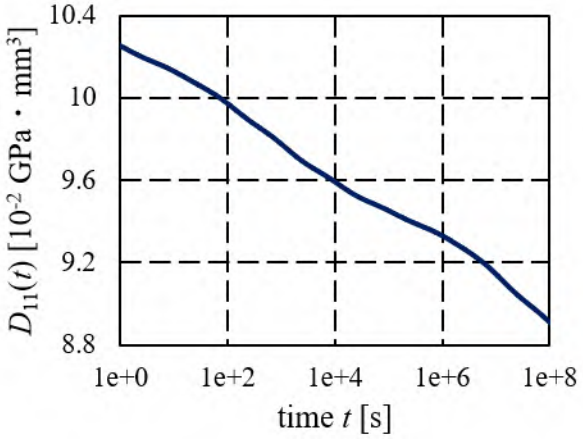

Figure 4: Relaxation Out-of-Plane Stiffness of the Base Material 2-ply 2/2 Twill CFRP

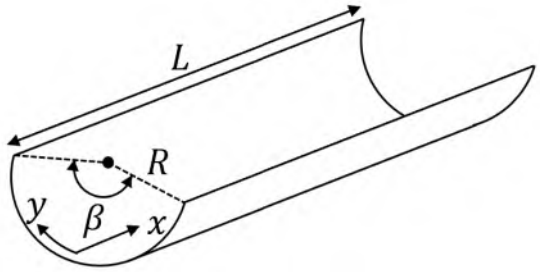

Figure 2: Bistable Boom in the Deployed Configuration and the Coordinate System

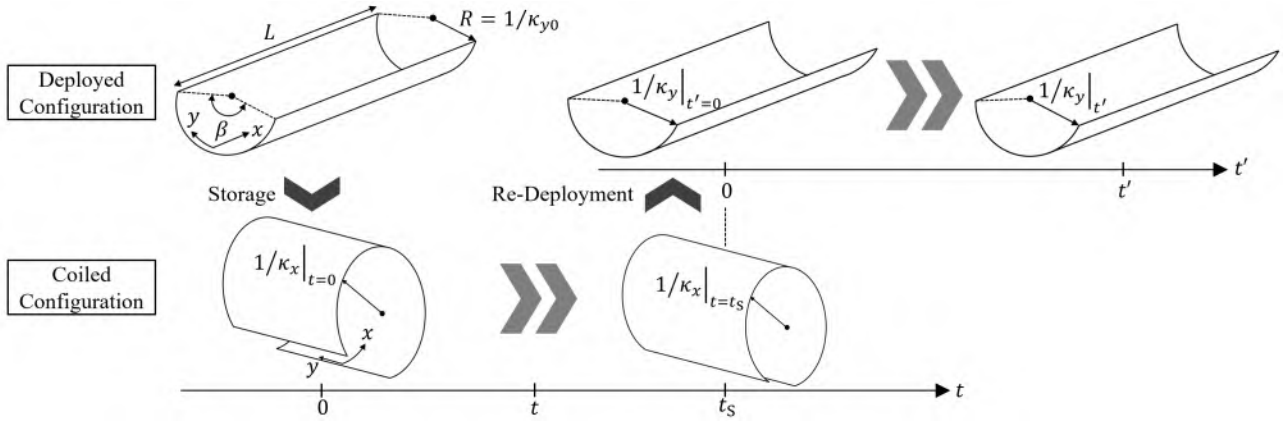

Figure 5: Overview of Boom Deformation

Using the TTS-based time shift factor a(T), the time increment *dt* at temperature *T* is converted to the time increment *dξ* at the reference temperature according to Eq. 4.

$$d\xi = \frac{dt}{a(T)} \tag{4}$$

2.3. Base Material Properties

In this paper, the base material is 2-ply CFRP 2/2 twill weave textile composite. The properties required for the boom shape prediction described later are the relaxation out-of-plane stiffness $D_{11}(t)$ and $D_{12}(t)$. As for $D_{11}(t)$, parameters estimated from DMA test results [8] are used, and the relationship between time and relaxation stiffness is shown in Fig. 4. Note that the relaxation stiffness is expressed with the fiber orientation angle of ±45°, which is the same as bistable booms. Regarding $D_{12}(t)$, the limited temperature dependence was revealed [2], so it is assumed to be expressed by Eq. 5.

$$D_{12}(t) = 0.71 \times D_{11}(0) \tag{5}$$

3. APROXIMATE SOLUTION

3.1. Boom Deformation Flow

This study deals with the boom shape change resulting from the long-term storage and re-deployment, which accounts for the deformation history anticipated for flexible deployable structures on spacecraft. The schematic diagram of the boom deformation is shown in Fig. 5. First, the boom without any deformation history is instantaneously coiled. Next, it keeps its coiled configuration for the given storage duration t_S. During this period, no external force acts on it, and its shape changes over time. Then, it is instantaneously re-deployed, and the boom shape changes over time. As shown in Fig. 5, *t'* represents the elapsed time since the re-deployment.

3.2. Boom Deformation Flow

Previous studies [9,10] derived the analytical method to calculate the coiled shape change based on the principle of minimum potential energy. However, this approach does not cover the re-deployed shape prediction because of the difficulty to analytically jump between the two stable configurations. In this study, the principle of virtual work was adopted to calculate both coiled and re-deployed shape. No external force condition and the integral through the thickness direction yield the following Eq. 6, which is the formulation of the principle.

$$\iint_A \left(N_x\delta\varepsilon_{x0} + N_y\delta\varepsilon_{y0} + N_{xy}\delta\gamma_{xy0} + M_x\delta\kappa_x + M_y\delta\kappa_y + M_{xy}\delta\kappa_{xy}\right)dxdy = 0 \tag{6}$$

To solve boom stable shape change over time using Eq. 6, boom shape approximation is considered. Here, the curvature distribution is assumed to be uniform and the curvature changes during the storage duration and after the re-deployment are expressed in Eqs. 7-8.

Storage duration ($0 \leqq t \leqq t_S$)

$$\begin{cases} \kappa_x(t) = C_0 - \sum_{i=1}^{n} C_i\left(e^{-t/\tau_i} - 1\right) \\ \kappa_y(t) = 0 \\ \kappa_{xy}(t) = 0 \end{cases} \tag{7}$$

After re-deployment ($0 \leqq t'$)

$$\begin{cases} \kappa_x(t') = 0 \\ \kappa_y(t') = C_0' - \sum_{i=1}^{n} C_i'\left(e^{-t'/\tau_i} - 1\right) \\ \kappa_{xy}(t') = 0 \end{cases} \tag{8}$$

Resultant moment components at each time can be calculated using Eqs. 1-3 and Eqs. 7-8. Substituting them into Eq. 6 yields equations to be solved. In this study, the conditions under which the equation holds immediately after the deformation and after the relaxation time τ_k has passed are calculated. This allows the constants C_i and C_i' in Eqs. 7-8 to be determined via a system of n+1 linear equations.

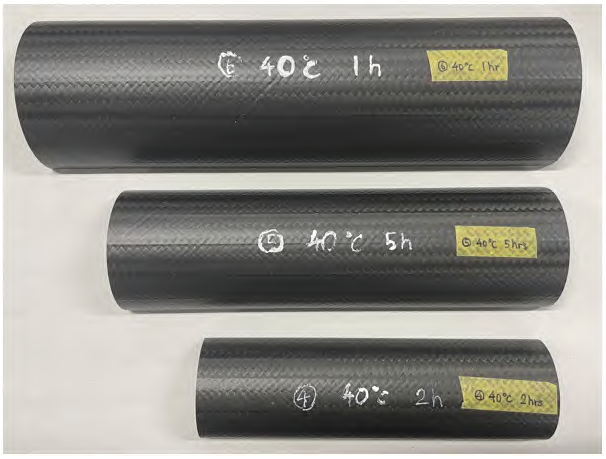

Figure 6: Boom Specimens in the Deployed Shape

Table 1: Boom Specimen Dimensions

Specimen	Radius R [mm]	Length L [mm]
A	20	140
B	25	175
C	30	210

4. BOOM TEST

Tests on bistable booms made of 2-ply 2/2 twill CFRP (See Fig. 6) were conducted to obtain the coiled and re-deployed boom shape data. Among the dimensions determining the initial boom shape shown in Fig. 2, the subtended angle β is 180° in common, while the others are listed in Tab. 1. Tests were performed under multiple conditions of storge time t_S and storage temperature T to evaluate the effects of thermoviscoelasticity. Storage time t_S was set to 10, 20 and 40 minutes, 1, 2 and 5 hours, and 1, 4 and 14 days. Storage temperatures were set to 25 (room temperature), 40, 60, 80 and 100℃. Note that boom specimens were exposed to the room temperature environment except for the storage duration.

Measurement items are the boom cross-section shape before the storage and immediately after the re-deployment. Considering the flexibility of the boom, the boom shape was determined using the cross-section image and the processing software GIMP.

5. RESULTS AND DISCUSSION

5.1. Uniformity of the Cross Section Curvature

In deriving the approximate solution, it was assumed that the curvature distribution of the boom is uniform for both stable configurations. Fig. 7 and Fig. 8 are the cross-section images of coiled and re-deployed boom respectively with the yellow circular arc. As shown in Fig. 7, the most area of the coiled boom almost follows the circular arc, but deviations from it are observed around both ends. This is due to the free-edge effect resulting from the boundary conditions that external forces are zero. Fig.8 shows that the free-edge effect is limited and that the re-deployed boom cross-section can be regarded as

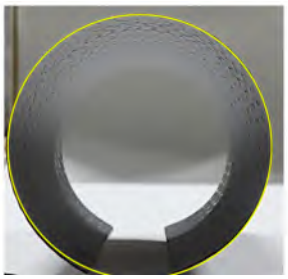

Figure 7: Coiled Boom Cross-Section and Circular Arc Approximation

Figure 8: Re-Deployed Boom Cross-Section and Circular Arc Approximation

the circular arc. Based on this observation, the test data are examined by the cross-section curvature in the following sections.

5.2. Re-Deployed Boom Shape

Fig. 9 shows the relationship between storage time and the cross-section shape immediately after re-deployment. The horizontal axis represents the storage time t_S, and the vertical axis represents the curvature of re-deployed boom cross section (See Fig. 8) κ_y. To compare the re-deployed boom shape recovery of different boom size, the curvature κ_y is normalized by its initial one $1/R$ (See Fig. 2). The test results are presented as a scatter plot, with the prediction results from the approximate solution indicated by dashed and dash-dotted lines. Considering the time lag between re-deployment and shape measurement, prediction results are shown as curves indicating the shape at 1 minute and 10 minutes after re-deployment for each storage time.

Test data indicate the decrease in the cross-section curvature in accordance with rise in storage time and temperature. Also, more than half of the test data at the room temperature condition fall within the predicted range of boom shapes from the approximate solution. However, the discrepancy between test results and the predicted range increases under long-term storage conditions. The reason for this is supposed to be the test method to obtain the relaxation out-of-plane stiffness. The DMA test [8] was conducted with a specimen that is neither sufficiently large relative to the woven CFRP unit cell nor slender. Bending tests with larger specimens are expected to improve the prediction accuracy of relaxation stiffness and boom shape.

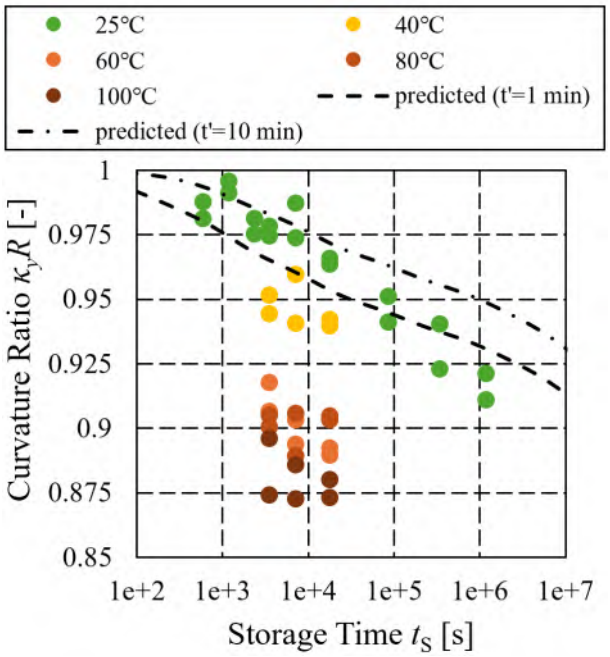

Figure 10: Test and Predicted Results of the Re-Deployed Bistable Boom Shape

5.3. TTS of Boom Test Results

From the practical aspect, the boom shape prediction at the full-scale level is expected using a master curve generated from test data under multiple temperature conditions, which is based on the TTS principle. The master curve of the re-deployed boom shape based on the boom test results and the time shift factors determined from the DMA test [8] is shown in Fig. 10. The equivalent storage time at the reference temperature 25℃ is obtained from dividing the actual storage time by the time shift factor at the storage temperature. There is some variability in the test data, but their distribution allows for fitting with a single curve. This result suggests the validity of acerated testing for bistable booms using the time shift factor of the base material. This master curve can be modified by adding the storage time and temperature conditions so that the shifted data partially overlap.

6. CONCLUSIONS

In this paper, the analytical prediction and sub-scale test were conducted based on the deformation history anticipated for CFRP bistable booms on spacecraft. Test results for room temperature storage conditions were consistent with the analysis. Besides, it was implied that the acceleration under high temperature storage conditions can be characterized by the thermoviscoelastic properties of the boom base material.

ABSTRACT

Future satellite missions increasingly demand compact, lightweight, and high-performance antennas capable of covering multiple frequency bands for Positioning-Navigation-Timing (PNT) applications. Traditional antenna systems are limited by rigid structures and size constraints, which can impair deployment feasibility and RF performance in small satellite platforms.

In this context, the research for versatile solutions with high compaction ratios becomes particularly interesting, being the structure explored in this paper especially attractive, as it studies the possibility of housing three antennas for three different bands in a single deployable structure.

1. INTRODUCTION

This project, developed within the framework of the ESA Contract Nº 4000143515/23/NL/AS, [DD-STRA], focuses on the design, analysis, and validation of a stacked tri-band deployable antenna operating in the UHF, L, and S bands, optimized for use in low Earth orbit (LEO) missions. The solution is based on a single-body deployable coilable boom structure that integrates all three bands in a stacked configuration, enabling compact stowage and robust deployment. This structure is composed of four flexible longerons and 20 custom-designed mounts manufactured of space validated plastic, providing both mechanical strength and guidance for the helical antenna elements.

The antenna mechanism deployment is passive, and it is controlled by a motorized system that ensures non-violent and controlled deployment. The deployment mechanism includes a non-pyrotechnic Hold Down and Release Actuator (HDRA) that triggers the self-deployment of the boom using the elastic energy stored in the longerons. The mechanism design eliminates the need for post-deployment locking systems due to the inherent stiffness and cable tension of the deployed structure. Each antenna band is supported by its own coaxial cable feed and PCB.
A comprehensive RF simulation was performed using FEKO software, incorporating detailed geometry, coaxial feeds, and platform effects. The results show compliance with most RF specifications, including gain patterns, return loss, and axial ratio. The antenna achieves a deployed length of 3.25 m and a mass of 4.3 kg, fitting within the LEO mission requirements.

The Manufacturing, Assembly, Integration, and Testing (MAIT) plan includes procurement, mechanical assembly, and RF integration steps, along with a detailed test campaign covering frictional deployment, S-parameters, radiation pattern verification, and mechanical qualification. The finalization of these activities will allow a TRL4 maturity achievement and demonstrate the feasibility of the concept as a modular, efficient, and space-compatible multi-band antenna system.

The project represents a major step forward in deployable antenna technology for small satellites and is the result of a successful collaboration between industry, academia, and the European Space Agency.

2. DESIGN AND ANALYSIS

Mechanical Design

The designed solution consists of a single deployable structure capable of compacting and positioning three antennas of UHF-, L- and S-bands. The deployable structure is based on a coilable boom architecture which can transition from a stowed state, forming the longerons a low-pitch helix, to a deployed state where they are completely straight, providing stiffness and stability to the structure.

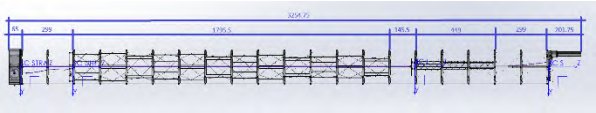

Fig. 1. Deployed STRA.

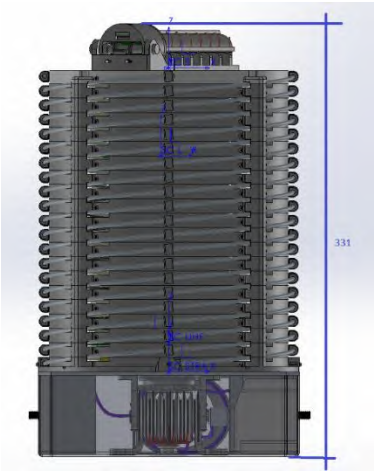

Fig. 2. Stowed STRA.

From the mechanical structure point of view, it consists of four GFRP (Glass Fiber Reinforced Plastic) longerons which are responsible for the passive motorisation of the antenna due to their ability to store elastic strain potential energy in the stowed state, and 20 Ultem mounts that spaced at a length that ensures geometric compatibility between the stowed and deployed states.

The structure is braced by a set of p-aramid tensors with a triple purpose (see Fig. 3).

- Red: deployment control tensors which prevent violent deployment of the structure.
- Green: counter-tensors which stiffen and latch the antenna in the final stage of deployment.
- Yellow: fixed tensors which form St. Andrew's crosses together with the counter-tensors, to brace the structure.

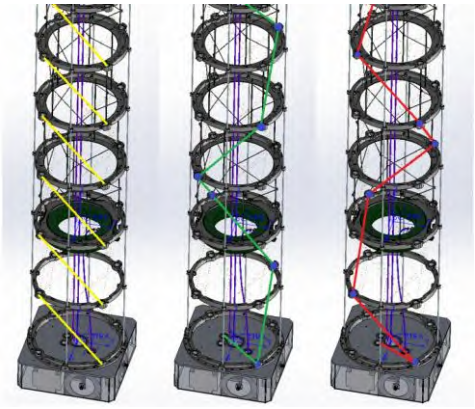

Fig. 3. Antenna control and bracing tensors

The structure remains stowed thanks to the action of an HDRA (Hold Down and Release Actuator). This device has a dual function: on the one hand, it is responsible for releasing the antenna, allowing it to deploy passively; on the other hand, it has the mission of compressing the structure with enough force to ensure that its stiffness in the stowed situation is adequate and to prevent loss of contact (and subsequent bumping) between any of its parts during launch. To withstand this preload, the upper antenna mount (top disc) is made of fibreglass and it is connected by a hollow titanium rod to the HDRA screw, housed in the metal box under the structure.

The deployment control system is driven by a stepper motor. When the HDRA releases the antenna, it tends to deploy explosively, but its movement is controlled by the speed imposed by the motor.

Finally, detailed described the supporting structure, the location of the three antennas on it is shown in Fig. 4.

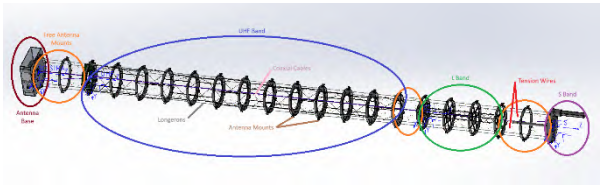

Fig. 4. STRA parts.

The UHF band antenna consists of four wires forming a conical helix with a base diameter of 162 mm, a top diameter of 120 mm, a pitch of 450 mm, and a total height of 1795.5 m. It is housed within 13 of the first mounts, which are connected between them with four non-structural p-aramid threads holding the wires in the approximated helix shape.
The L-band antenna is housed in a similar way to the previous one, consisting of four wires forming a straight helix with 50 mm diameter, 145 mm pitch and a total height of 452 mm. This antenna is comprised in the space between four mounts, after the UHF-band antenna.

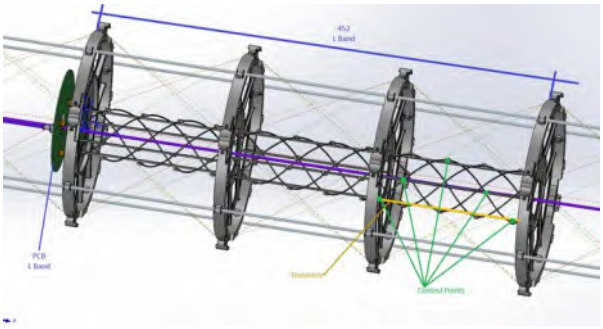

Fig. 5. L-band antenna housing.

The S-band antenna is too small to maintain the deployable concept of the previous two. Therefore, this antenna, consisting of four helical wires with 25 mm diameter, 70 mm pitch and a total height of 140 mm; is embedded in a plastic structure connected to the top disc by means of a hinge and a spring that brings it into position during the deployment manoeuvre.

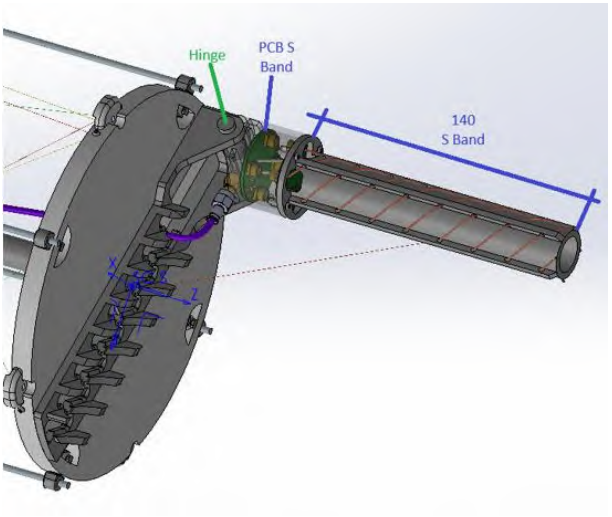

Fig. 6. S-band antenna housing.

Mechanical analysis

Two FEM (Finite Element Model) are built to analyse two different scenarios: stowed structure (preload case and launch load case analyses) and deployed structure (flight case analyses).

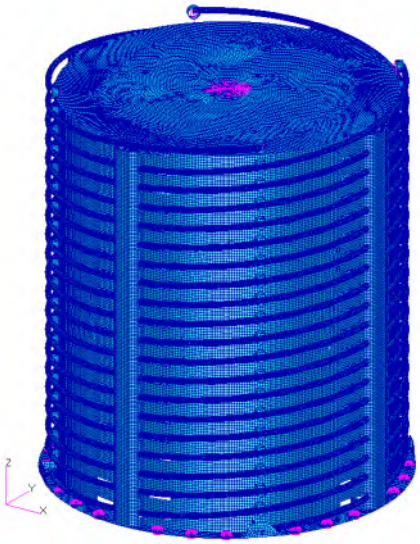

Fig. 7. STRA stowed FEM.

Preload analysis

Employing the stowed FEM, the HDRA is sized on the premise that the compression exerted by the device is enough to prevent separation and bumping of any part of the antenna during launching. To do this, axial (V) and shear (S) forces are recovered at all interfaces of the stowed structure in all launch load cases. The preload required at each interface, knowing the insertion angle of the tongue and groove joint that allows the mounts to fit together when stowed (θ), is calculated as shown below.

$$Preload_{Min} = (V + S \cdot \tan(\theta)) \cdot SF \qquad (1)$$

The effective load distribution of the HDRA preload between the interfaces is calculated using a unit case which, combined with the above information, defines that the minimum device preload required is 14366 N.

Known this value, it is introduced in the stowed model to verify that the structure can withstand it, obtaining the maximum Von Mises stress and the minimum MoS (Margin of Safety) in each part.

Table 1: Preload analysis strength results

	σ_{VM} (MPa)	MoS
Ultem (mounts)	42.66	0.68
GFRP (longeron)	34.06	>5.00
Prepreg glass fabric (top disc)	308.01	0.43

Launch loads analyses

Natural frequencies of the stowed FEM are analysed to better understand its dynamic behaviour under launch loads. The structure has been designed with the aim of achieving a 1st natural frequency greater than 100 Hz (outside the sine specification). As a result, the 1st mode of the structure is at 130.34 Hz.

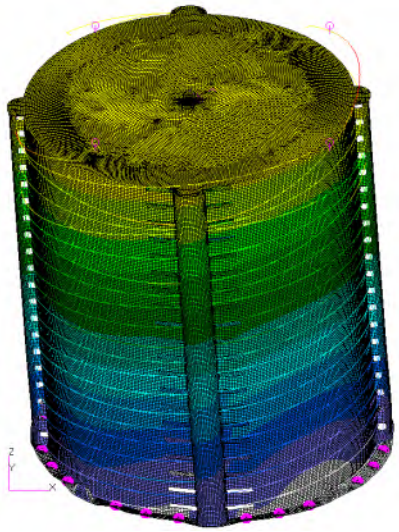

Fig. 8. Stowed FEM 1st vibration mode.

The stowed FEM is analysed under each of the launch loads (Quasi-Static, Sine, Random and Shock), combining the obtained stress results with those from the preload analysis, resulting in the Table 2. It is verified that the random load case is the most critical.

Table 2: Launch load analyses MoS results

	Ultem MoS	GFRP MoS	Prepreg MoS
Pr. + QS	0.28	>5.00	0.41
Pr. + Sine	0.34	>5.00	0.43
Pr. + Random	0.02	>5.00	0.43
Pr. + Shock	0.25	3.96	0.31

Analyses in flight situation

The deployed FEM is built from the previous one, expanding its mounts and adding the tensors that brace the structure.

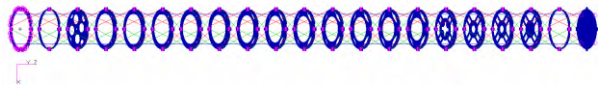

Fig. 9. STRA deployed FEM.

In this situation, only the stiffness and thermoelastic stability of the structure are analysed. The modal analysis shows vibration modes very similar to those of a cantilever beam, being the 1st frequency of 1.76 Hz; while the thermoelastic analysis concludes that both the geometric distortion of the antenna and the stresses derived from the temperature are negligible.

RF Design

The presented triband antenna is basically comprised of three quad-helix antennas, one per frequency band, placed along a deployable boom. Each antenna generates a circularly polarized isoflux pattern that maximizes the uniform power distribution for a global coverage.
Each of the antennas is fed by its own feeding network which is placed just under each one of the helixes. The signal distribution until each feeding network is done through coaxial cables located in the middle of the antenna. The long cables that are required to reach the feeding points of L band and the S band antennas lead to high insertion losses. Fortunately, the application link budget has a large margin, and they can be tolerated.
Many key aspects have been considered in the design, such as the adequate materials selection, the custom shaped feeding networks and the optimized placement of each helix inside the boom.

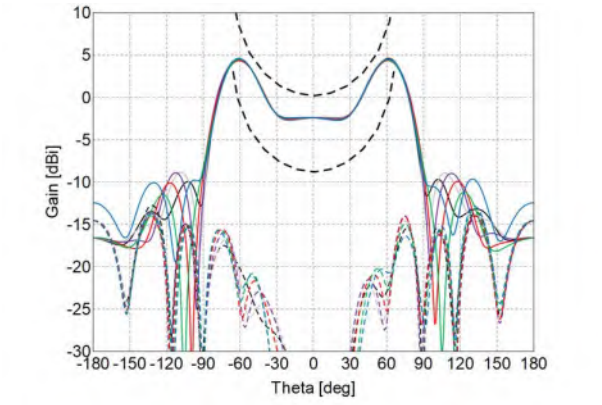

Fig. 10. UHF band isoflux radiation pattern

RF Analysis

The antenna has been modelled in FEKO software for its RF simulation. The electrical model simplification has been key to improve the simulation speed and reduce the required computational resources while maintaining high precision results. This simplification allows the simulation of the antenna including the boom, the support structure, the satellite platform, the feeding network and the cables. This complete electrical model ensures precise RF simulation results.
The copolar and crosspolar radiation patterns (See *Fig. 10* UHF radiation pattern as example), the gain, the axial ratio, the return loss, the phase centre variation, the phase centre stability, the group delay and some more parameters have been simulated and calculated.
The following *Table 3* summarizes some of the most important electrical parameters that define the antenna:

Table 3. Electrical performance summary

Parameter	Value
Frequency band	UHF band, L band and S band
Pattern shape	Isoflux
Polarization	Right-handed circular
Field of view	132º
Bandwidth	50 MHz per frequency band
Return loss	> 10 dB

3. CRITICAL BREADBOARD MANUFACTURING AND TESTING

Mechanical CBB

A mechanical critical breadboard of the structure with dummy electrical parts is manufactured and assembled to verify its mechanical performance and serve as a derisking model.

As the objective is the functional check of the structure, materials used have representative characteristics for this purpose, but they do not necessarily have to be the final ones. Furthermore, different manufacturing and assembly procedures are evaluated to select the best method for building the future final breadboard.

Fig. 11. STRA deployed CBB.

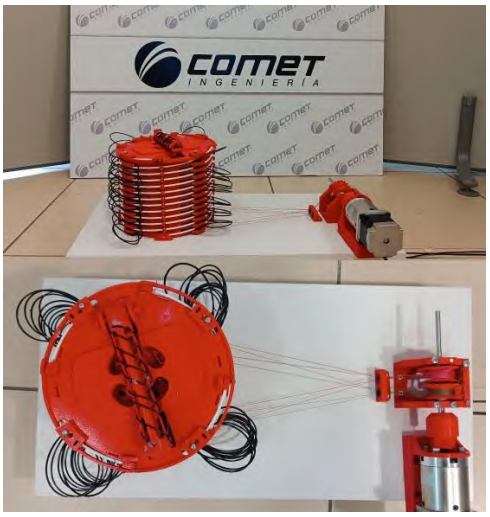

Fig. 12. STRA stowed CBB.

Having finalised the CBB manufacturing, 30 folding and deployment cycles are performed to assess the robustness of the solution. This process starts with the CBB in its stowed state when the stepper motor begins to rotate at a controlled speed, allowing longerons to gradually release elastic potential energy and transition to their nominal position. When the longerons have exhausted their energy, the structure is almost fully deployed, so the last step consists of reversing the rotation direction of the motor to pulling the corresponding tensors (green in Fig. 3) and latching the antenna.

The following lessons are extracted from these experiences:

- The kinematic operation of the structure is correct, and it is able to stow and deploy passively without becoming stuck. There are certain points with slight geometric incompatibilities (Fig. 13) at intermediate stages of the manoeuvre which are corrected in the final model.

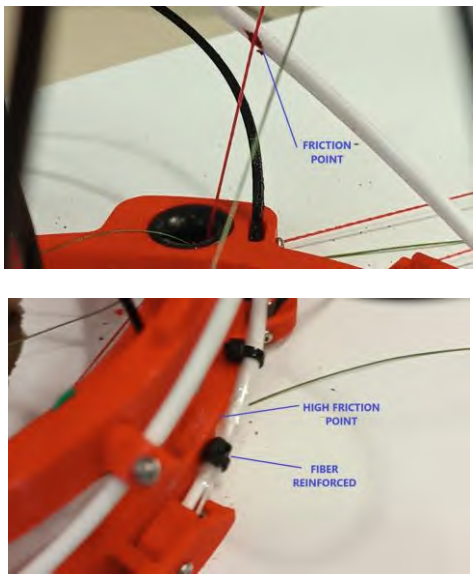

Fig. 13. CBB Collision points.

- The manufacturing methods and 3D printing orientations are correct and suitable for the intended purpose of the structure. No strength issues have been detected in the functional operation, and manufacturing procedures, such as the embedding of the low-friction washers through which the tensors run, have been validated.
- The use of TPU material for the fixed tensors (yellow in Fig. 3) is discarded. The decision to use this material was based on the idea of having threads with adaptive flexibility, all manufactured to the same length using 3D printing; however, it has been concluded that its advantages do not justify its disadvantages and, for the BB, rigid tensors manufactured using a tool will be considered.
- There is enough stowed volume to accommodate the radiating wires that comprise antennas.

RF CBB

In parallel, in the frame of this project, electrical models and feeding networks CBBs are also manufactured and tested.

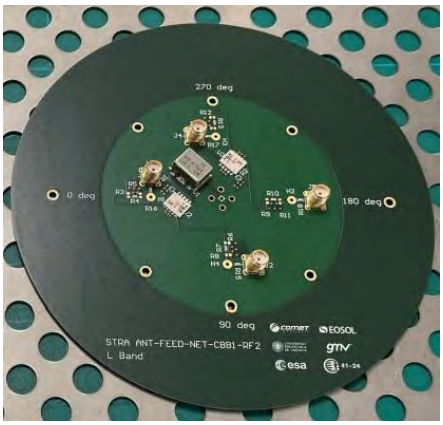

Fig. 14. Manufactured PCB of the CBB L-Band antenna.

There are key parameters that must be verified to validate the design and the manufactured antenna. The isoflux copolar and crosspolar radiation pattern in amplitude and phase, the gain and the return loss are the most important parameters that will be measured over the frequency bands. Many other important parameters such as the phase center related parameters will be calculated from the mentioned ones and compared with simulations.
The antenna will be tested in an anechoic chamber that is able to measure it with a reasonable accuracy even at the UHF frequency band, allowing the validation of the antenna.

4. BREADBOARD MANUFACTURING

After the reduced-scale CBB, a BB of nominal dimensions is manufactured and assembled. The BB measures 200 mm in diameter, 266 mm in height when stowed and 3190 mm when deployed.

Fig. 15. STRA deployed and stowed BB.

The BB manufacture is aligned with the objectives of a TRL 4 project; consequently, the materials of the structure are mechanically representative (and in many cases, conservative), but not necessarily qualified for spatial applications. This includes, for example, the use of UHMWPE tensors, or PLA for the 3D printed parts. Furthermore, the HDRA is omitted as no vibration test campaign is planned, and the motor and electrical components are not space-qualified.

Fig. 16. UHF wire positioning tensors (left top), base (left bottom), L wire positioning tensors (right).

The process is handmade and it begins with the purchase of the raw materials and the manufacturing of the components that comprise the deployable structure (longerons, mounts and tensors). All of these are assembled onto a metal base, which supports the deployable mechanism and houses the harnesses that feed the PCBs.

The wires of the three antennas are measured and installed. Each one is attached to the structure using a slightly different method. The UHF band antenna is supported at its intersections with the mounts, forming a “helix” of straight segments between the mounts and the only support point between each pair of them. The L-band antenna uses a similar system, but due to its smaller size, there are four fixing points between each pair of mounts, which confers its radiating wires a more helical shape. Finally, the S-band antenna is not deployable due to its dimensions, so it is embedded into a plastic fixture that folds 90º and deploys by means of a torsion spring.

The PCBs and their corresponding harnesses, which are housed in the base and deploy at the same time as the structure, are installed and, at this point, the BB is fully assembled and operational.

Before to the test campaign, preliminary deployments are performed to check the BB mechanism works properly.

It is verified that the BB has enough motorisation to deploy against gravity force, without the need for equipment which compensate for this. However, in the stages of the manoeuvre prior to final tensioning (when the longerons are not vertical yet) the flexural stiffness of the assembly is significantly low. Therefore, to prevent buckling due to the gravity action, the deployment takes place inside a methacrylate tube (Fig. 15 right) which acts as an MGSE.

5. MECHANICAL TEST PROCEDURES

Mechanical and radio-electrical tests are performed on both the BB and some of its components. Specifically, on the mechanical side, motorisation and deployment tests are conducted on the complete BB. On the RF side, S-parameters of the complete antenna, the feeding networks, their harness and the SMA connectors are measured; and radiation pattern and gain tests of the complete BB are obtained. In addition, dimensional and mass inspections are also done.

This paper focuses on the mechanical aspects of the project, so procedures of mechanical tests are described in detail below.

Motorisation test

The motorisation test aims to obtain an initial estimation of the axial force exerted by the structure at each moment of the deployment manoeuvre, to assess its motorisation margin.

It is identified that the motorisation force comes from the stored elastic energy of the longerons, while the resistive forces arise from friction at the joints of the structure, friction of the tensors, the resistance exerted by the radiating wires that comprise the antennas, and the resistance of the harness that supplies the PCBs. The deployment mechanism introduces no resistance, as the brake consists of a stepper motor, which is an active element.

Due to the nature of the structure, it is extremely speculative to establish a formulation for estimating the friction of each element at each moment of the manoeuvre. The structure deploys sequentially, with each segment being in a different position to the rest, and the overall configuration being unique at every instant. For this, the experimental approach has been adopted.

Grouping, in one side, as the internal friction of the antenna (R_{Fric}) the resistance originated in joints, tensors and radiating wires; and in the other, the resistance of the harness (R_{Harn}), it is agreed that the motorisation margin of the structure for each deployment % can be expressed as follows.

$$MM(\%) = \frac{F_{Mot}(\%)}{R_{Fric}(\%) + R_{Harn}(\%)} \qquad (2)$$

By analysing the nature of each term in the above expression and assuming that the internal frictions are symmetrical (same magnitude and opposite direction when folding and deploying), the following diagram of forces depending on the movement direction is obtained.

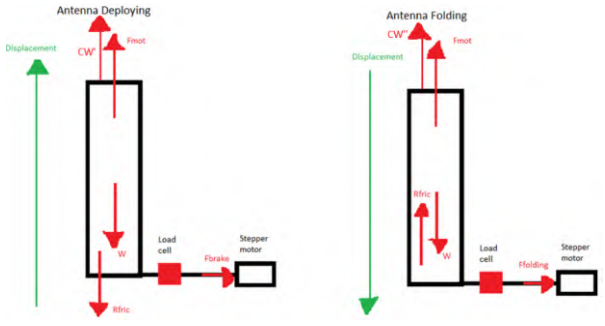

Fig. 17. Force diagram of the BB in deployment and folding.

Where F_{mot} is the motorisation force of the structure, W is the weight of the BB, R_{fric} represents the internal friction, F_{brake}/$F_{folding}$ are the forces reaching the stepper motor and read by the load cell, and CW'/CW'' are the forces exerted by the counterweight (a different value when folding and deploying). It is decided to use a counterweight to prevent the structure from buckling due to the force of gravity instead of the MGSE, so as not to introduce noise into the measurement caused by friction between the BB and the MGSE.

To determine F_{mot}, R_{fric} and R_{Harn}, it is decided to measure the axial force of the BB in three scenarios.

a) Deployment force test without harness.
b) Folding force test without harness.
c) Deployment force test with harness.

In each of which, the load cell measurement can be expressed as a combination of the terms above.

$$F_{a)}(\%) = F_{mot}(\%) - W(\%) - R_{Fric}(\%) + CW' \qquad (3)$$

$$F_{b)}(\%) = F_{mot}(\%) - W(\%) + R_{Fric}(\%) + CW'' \qquad (4)$$

$$F_{c)}(\%) = F_{a)}(\%) - R_{Harn}(\%) \qquad (5)$$

And combining these three measurements it is possible to obtain the variables involved in the calculation of the motorisation margin.

$$R_{Fric}(\%) = \frac{F_{b)}(\%) - F_{a)}(\%) - (CW'' - CW')}{2} \qquad (6)$$

$$R_{Harn}(\%) = F_{a)}(\%) - F_{c)}(\%) \qquad (7)$$

Deployment test

The deployment test aims to demonstrate that the structure is robust enough to withstand 30 deployment manoeuvres without compromising the antenna performance. Along these deployments, the repeatability of the manoeuvre and the deviations and distortions of the structure that could affect the antennas are assessed.
The possible distortions that the structure allows without any of its components evident breaking are as follows.

- Deformation of the structure due to global bending or torsion, resulting in the three antennas being displaced from their nominal position.
- Local diameter reduction of the UHF and L-band antennas due to loss of tension in the positioning threads (Fig. 18 left)
- Random local distortion of the radiating wires of the UHF and L-band antennas between control points (particularly in the UHF-band antenna).

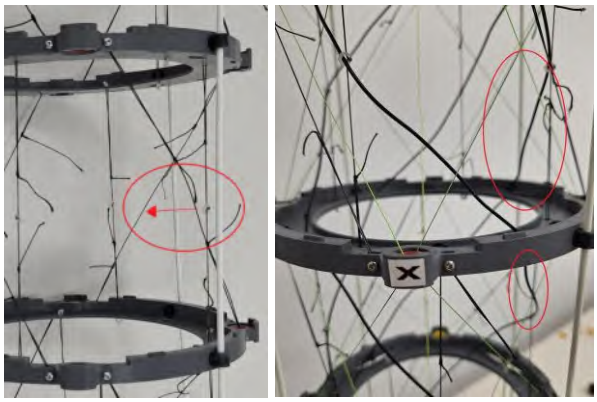

Fig. 18. Unrestricted movement direction of the control points (left), radiant wires with random local distortions (right).

A different measurement strategy will be followed for each of the possible distortions.
To determine the global deformation of the structure, which is expected to be minimal, the position and angle of the top disc is measured by a laser every 15 deployments, extrapolating this measurement linearly to the rest of the length.
To determine the reduction in the diameter of the antennas due to a loss of tension in the threads, the distance between each pair of opposing washers is measured every 15 deployments.
To determine the effect of random local distortions, different models of the UHF and L-band antennas with curvatures of the order of those seen in the BB are randomly generated, and their RF parameters are obtained.

Finally, after the completion of the test campaign, a wear study is performed to identify which areas of the BB suffer more.

6. MECHANICAL TEST RESULTS

Motorisation test results

The axial force exerted by the BB is measured three times for each of the three scenarios described and the mean value is calculated. The graphs obtained from the raw deploying and folding measurements appear as follows.

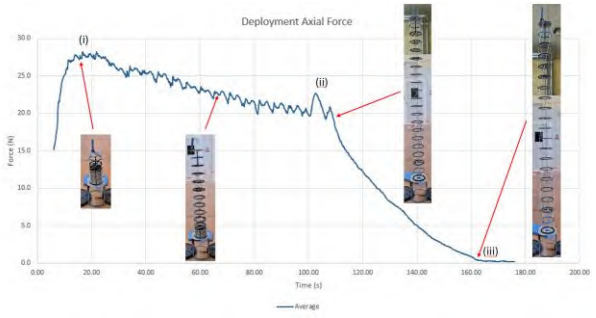

Fig. 19. BB deploying axial force graph shape and phases.

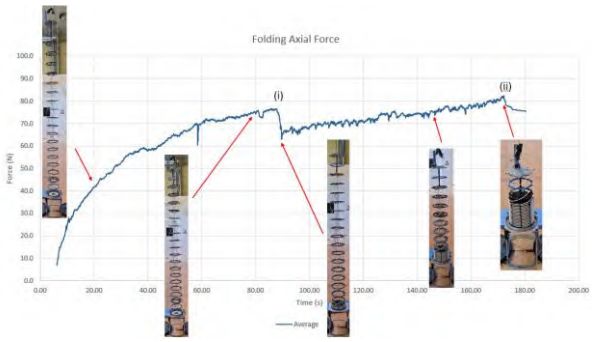

Fig. 20. BB folding axial force graph shape and phases.

Next, the BB mass and the contribution of the counterweight are compensated analytically and by means of auxiliary tests, so that the results represent only the motorisation minus the internal friction and harness resistances. The blue curve corresponds to scenario a), the orange one to b) and the grey one to c).

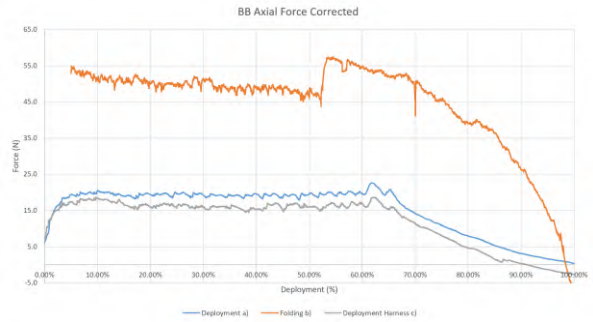

Fig. 21. BB axial force corrected in scenarios a), b) and c).

Operating with the system of equations formed by (3), (6) and (7), the terms F_{mot}, R_{fric} and R_{harn} are obtained. These are calculated along the uniform section of the graph (approximately between 3% and 65% of the deployment). This is because in the final phase of deployment the axial force of the BB tends towards 0; however, the counter-tensioning system starts to operate, providing the extra energy necessary to complete the manoeuvre.

$$\boldsymbol{F_{mot} \in [32.2;\ 36.8]\ N}$$
$$\boldsymbol{R_{fric} \in [12.8;\ 17.7]\ N}$$
$$\boldsymbol{R_{harn} \in [0.9;\ 5.0]\ N}$$

To calculate the motorisation margin, the most appropriate safety factors specified in [1] are applied.

$$MM(\%) = \frac{F_{Mot}(\%)}{2R_{Fric}(\%) + 3R_{Harn}(\%)} \qquad (8)$$

Resulting in an MM in the uniform section of:

$$\boldsymbol{MM \in [0.77;\ 1.02]}$$

In accordance with the ECSS recommendation, the motorisation margin obtained is low, as the standard recommends a margin of 2 once safety factors have

been applied. However, it should not be forgotten that the BB's manufacturing methods are in line with the scope and budget of a TRL4 project; consequently, the surface quality of parts with relative motion between them has significant margin for improvement, so R_{fric} may be reduced. Furthermore, it has been found that the measurement setup introduces some additional friction, which adds a degree of conservatism to the results.

Deployment test results

At the time of the elaboration of this paper, 20 of the 30 planned deployments of the BB campaign have been done; consequently, some results are preliminary, but certain conclusions can already be extracted.

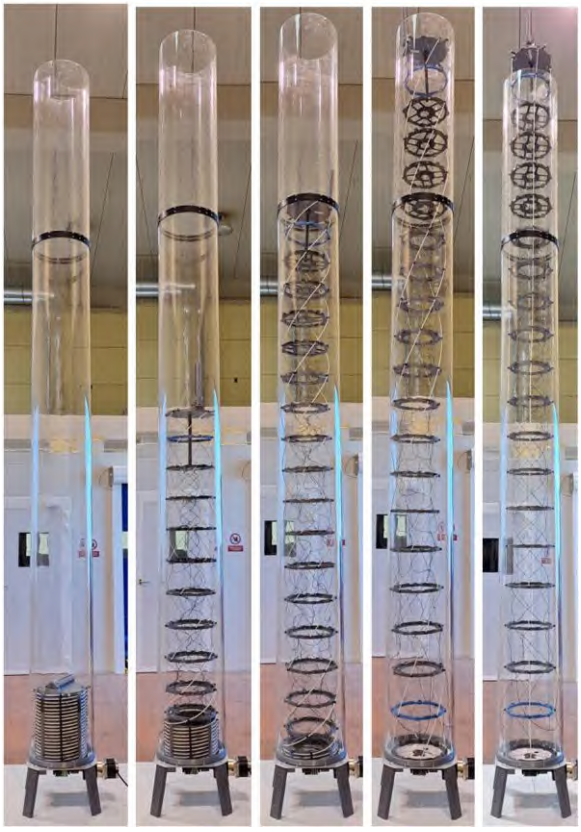

Fig. 22. BB deployment sequence.

First, there is no apparent loss of motorization in the structure due to a possible gradual deterioration. Furthermore, the final position reached by the BB can be forced to be always the same (with a margin of error of a few millimetres), as this is controlled by the tensioning system.

The global deviation of the BB has been measured after manufacture and after 15 deployments. The structure exhibits an approximate deflection of 20 mm and torsion of 16° at its free end, with similar results for both measurements done. The immediate conclusion is that the deviations are caused by manufacturing inaccuracies and tolerances in the model, rather than deterioration by operation. The residual torsion appears to be of some significance, but it has been verified that it has no appreciable impact on the performance of the antennas. The reason for this distortion is that the tensioning by the stepper motor takes place at the base, reducing the latching torque as the height increases due to friction.

Local diameter reduction has increased by around 3 – 4 mm comparing measurements at the start and halfway of the campaign on the UHF band antenna. This distortion is negligible in the L-band antenna. The test campaign needs to continue to determine if this phenomenon worsens with the remaining manoeuvres, or if it has already reached its limit. The impact of this distortion at RF level has not yet been assessed.

The RF impact of random local distortions in radiating wires has not yet been assessed.

7. CONCLUSIONS AND FURTHER STEPS

Conclusions extracted at this stage of the project are listed below:

- An antenna solution has been proposed to satisfy the need identified in the project framework.
- Satisfactory compliance with mechanical and electrical requirements has been verified by analysis.
- It has been confirmed that the solution proposed is feasible and that its deployable structure is functional
- The in-house manufacturing processes for building this type of helical structures have been validated and refined.
- The BB is perfectly capable of deploying against gravity, but the calculated motorisation margin is lower than ECSS recommendation. However, it is considered that there is margin for improvement by removing conservatism.
- It has been verified that the deployment system is robust enough to ensure that the global position of the structure remains unchanged despite the number deployments.
- There are indicators that the reduction in the diameter of the UHF-band antenna local distortions is affected by the number of deployments, but their impact at RF level has not yet been assessed.
- At this stage of the project, it is considered that a robust BB resulting from a design that fulfils the requirements has been achieved; with some areas to improve but leaving a positive impression.

Further steps to mature the technology presented up to TRL4 within the framework of this project are:

- Complete the deployment test campaign and ensure the repeatability and robustness of the structure can be deployment.
- Measure the BB in an anechoic chamber and correlate the results to validate its RF performance.
- Quantify the positional deviations of the radiating elements to assess their impact at RF level is acceptable.

After achieving a design that fulfils the requirements at TRL4 level, the next steps would be:

- Eliminate the conservatism observed regarding motorisation test and study the MM in greater detail.
- Consider flight-grade materials in the manufacturing so that the structure can be tested in representative mechanical environments and under TVAC conditions.
- To frame the antenna within a project involving flight projections that provides more mature requirements and a framework for the development of the solution.

ABSTRACT

The manufacturing of Large Deployable Mesh Reflectors (LDRs) requires the zero-stress geometry of the cable-mesh assembly, which form finding procedures do not deliver directly. This work presents a geometrically nonlinear, incremental-iterative finite element procedure recovering the unstressed configurations of the front net, rear net and reflective mesh, starting from the deployed prestressed state obtained through an extended Force Density Method. A total Lagrangian description is adopted to release the pretension by progressive load reduction; at each increment the strain and stress states are consistently updated, while rigid body modes are removed via spectral decomposition of the singular tangent stiffness matrix. Cable slackening, reactivation and mesh orthotropy are consistently handled. For a 12.25 m case study, the recovered cable rest lengths match the analytical prediction within 0.01%, and the strongly nonlinear stiffening response observed during unloading confirms the relevance of geometric nonlinearity for an accurate determination of the unstressed state.

1. INTRODUCTION

Modern satellite communication, Earth observation and science missions demand antennas with ever larger apertures and tighter surface accuracy, while keeping mass and stowed volume to a minimum. Large Deployable Reflectors (LDRs) address these competing requirements and have become a cornerstone of next-generation spaceborne antenna systems [1,2]. Among them, mesh reflectors stand out for their lightness, compactness when stowed and scalability [3]. The state-of-the-art architecture in deployable reflector antennas is the the one introduced with AstroMesh [4,5]: a deployable ring truss is coupled with two cable networks, front and rear nets, connected by a system of tensioning ties, while a reflective metallic mesh, beneath the front net, realizes the effective reflecting surface. The same architecture underlies the LDR design developed by Thales Alenia Space Italia (TAS-I), taken as reference in this work (Fig. 1).

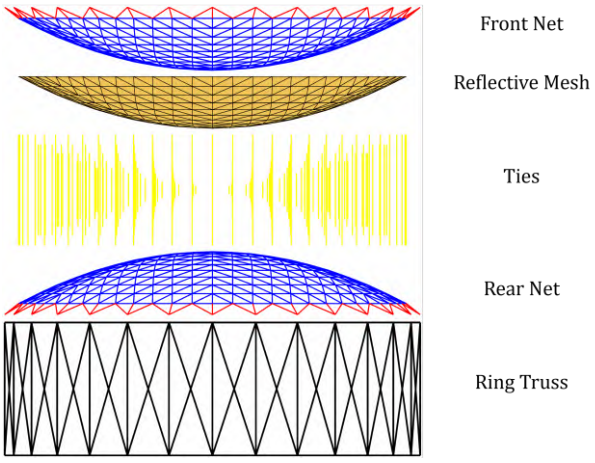

Figure 1: Exploded view of the TAS-I mesh reflector architecture considered in this work..

Cable-mesh structures are tensile structures: their members possess negligible compression and bending stiffness, so their shape is kinematically indeterminate and strongly affected by the member stress levels. Thus, the form-finding process, i.e. the identification of the ideal prestress and the corresponding deployed shape [6], is governed by strong geometric and physical nonlinearities [7,8, 9,10] and is highly sensitive to the zero-stress configuration of the constituent elements [11,12]. The form-finding problem has been extensively investigated [13,14]: Schek introduced the Force Density Method (FDM) [15] as a tool for the linearization of the nonlinear equilibrium equations through the prescription of force-to-length ratios; later developments include the Dynamic Relaxation

Method [16], the Updated Reference Strategy [17], the Natural Force Density Method [18] and the Surface Stress Density Method [19]. Tang et al. [20,21] decompose the membrane stresses into axial and transverse force densities, representing the mesh equilibrium within a nonlinear solution scheme, while Zhang et al. [22] include the compliance of the supporting truss in the cable-network solution.

The equilibrium configuration delivered by most form-finding approaches is not directly related to the unstressed state, which is essential for manufacturing, since cutting patterns, cable rest lengths and assembly tolerances are all defined on the zero-stress geometry. Zero-stress determination for membranes and cable structures has been studied mainly in the civil and architectural literature. Chen et al. [23] propose a least squares treatment of compatibility to handle indeterminacy, releasing selected boundary constraints under minimum-constraint principles, so that the recovered zero-stress state depends on the release scheme. Fan et al. [24] address symmetric cable-strut systems via a Newton iteration method progressively reducing the forces in active members identified by an importance index, while Zhang et al. [25] unify zero-stress form-finding, construction sequencing and prestress force-finding within a single Newton-Raphson loop. Being tailored to civil construction, such techniques translate poorly to spaceborne mesh reflectors, which combine multiple cable nets, a fine reflective mesh and a compliant ring truss; their high static indeterminacy also rules out strategies based on activating individual members or driving selected boundaries.

The present work addresses the recovery of the zero-stress configuration of the cable nets and reflective mesh of a mesh reflector. The deployed, pre-stressed state used as input is obtained through an extended FDM tailored to cable-mesh reflectors [26]. From this balanced reference, a geometrically nonlinear incremental-iterative finite element (FE) procedure gradually reduces the prestress, driving the nodal residual forces to zero. Whenever an element reaches its stress-free length, it is excluded from the equilibrium (and re-admitted if tensioned again), while rigid-body motions are filtered at every step through a modal decomposition of the tangent stiffness matrix. Rather than activating members one by one or replaying a construction sequence, the procedure operates at the structural level, minimizing the nodal residual over each unloaded substructure.

This paper is organized as follows. Section 2 summarizes the equilibrium of the cable-mesh assembly with flexible ring truss, which defines the input of the FE procedure. Section 3 details the geometrically nonlinear FE formulation for the cable and membrane elements and the unstressing algorithm. Section 4 reports the results for the selected case study, and Section 5 draws the conclusions.

2. EQUILIBRIUM OF THE CABLE-MESH ASSEMBLY

This section recalls the equilibrium relations that define the reference (deployed) configuration feeding the FE unstressing procedure. The full derivation of the extended FDM and of the associated multi-objective optimization is given in [26].

2.1. Equilibrium of the cable net

The reflector surface is obtained by cutting a parent paraboloid with an offset cylinder, see Fig. 2. Their intersection curve, called rim, marks the outermost circumferential section of the reflector and is attached to the ring truss through the links, as shown in Fig. 3.

For a cable net made of n_c cables connected by n nodes, the connectivity matrix $\mathbf{C} \in \mathbb{R}^{n_c \times n}$ expresses its topology: the k-th row, associated with a cable joining nodes i and j, has entries +1 and −1 in columns i and j and zero elsewhere [15]. Here, a single quasi-geodesic connection pattern [27] is adopted for both the front and the rear net. Denoting by $\mathbf{q}_c \in \mathbb{R}^{n_c}$ the force density vector of the cables and by $\mathbf{Q}_c \in \mathbb{R}^{n_c \times n_c}$ its corresponding diagonal matrix, the equilibrium equations read

$$\mathbf{I}_3 \otimes (\mathbf{C}^{\mathrm{T}}\mathbf{Q}_c\mathbf{C})\mathbf{r} = \mathbf{f}_c \qquad (1)$$

where $\mathbf{r} = [\mathbf{x}^{\mathrm{T}}, \mathbf{y}^{\mathrm{T}}, \mathbf{z}^{\mathrm{T}}]^{\mathrm{T}} \in \mathbb{R}^{3n}$ collects the nodal coordinates in the global Cartesian frame $(\mathrm{x}, \mathrm{y}, \mathrm{z})$, $\mathbf{f}_c \in \mathbb{R}^{3n}$ is the vector of the external forces acting on the nodes, $\mathbf{I}$ is the identity matrix (with the subscript indicating its dimension) and $\otimes$ denotes the Kronecker product.

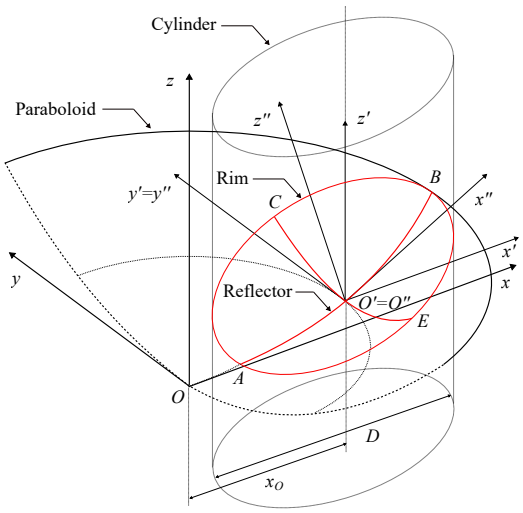

Figure 2: Construction of the offset parabolic surface: a parent paraboloid is intersected with a cylinder of diameter D at an offset distance x_O from the origin of the global reference frame O, yielding the ideal parabolic surface of the reflector [26].

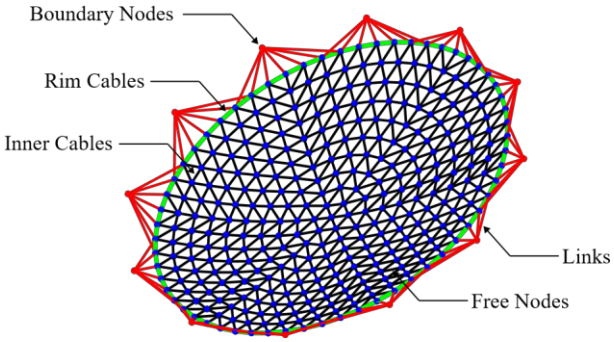

Figure 3: Example of front net topology: free (blue) and boundary (red) nodes; internal cables in black, rim cables in green, links (connecting the net to the ring truss) in red [26].

2.2. Equilibrium of the reflective mesh

Unlike cables, membrane elements work in a plane-stress regime. Their stress state can be described through equivalent axial and transverse forces acting at the element edges, $\mathbf{f}_\mathbf{i}^\tau$ and $\mathbf{f}_\mathbf{i}^\mathbf{n}$ respectively (see Fig. 4). These components are obtained by projecting the equivalent edge tension, and the corresponding force densities can be computed as [21]

$$\mathrm{q}_{\mathrm{m_i}} = \frac{\mathbf{f}_\mathbf{i}^\tau}{|\mathbf{l}_\mathbf{i}|^2} = \frac{1}{2} t_o \mathbf{T}_{\mathbf{q}_\mathbf{i}} \overline{\boldsymbol{\sigma}}, \quad \mathrm{p}_{\mathrm{m_i}} = \frac{\mathbf{f}_\mathbf{i}^\mathbf{n}}{|\mathbf{l}_\mathbf{i}|^2} = t_o \mathbf{T}_{\mathbf{p}_\mathbf{i}} \overline{\boldsymbol{\sigma}} \qquad (2)$$

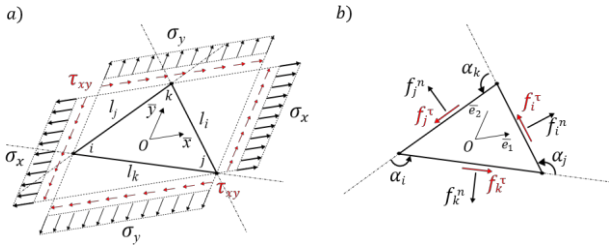

Figure 4: Schematic representation of the a) nominal and b) equivalent tensions in a triangular membrane element [26].

where $\mathbf{l}_\mathrm{i}$ and $\overline{\boldsymbol{\sigma}}$ denote the triangle edge vectors and the Cauchy stress components (in Voigt notation) in the local element frame, and t_o is the membrane thickness. Introducing the shorthand $s_i = sin\,\theta_i = \frac{y_k - y_j}{|l_i|}$, and $c_i = cos\,\theta_i = \frac{x_k - x_j}{|l_i|}$

$$\mathbf{T}_{\mathbf{q}_\mathbf{i}} = \begin{bmatrix} s_i c_i & -s_i c_i & s_i^2 - c_i^2 \\ s_j c_j & -s_j c_j & s_j^2 - c_j^2 \\ s_k c_k & -s_k c_k & s_k^2 - c_k^2 \end{bmatrix} \qquad (3)$$

$$\mathbf{T}_{\mathbf{p}_\mathbf{i}} = \begin{bmatrix} s_i^2 & c_i^2 & -2 s_i c_i \\ s_j^2 & c_j^2 & -2 s_j c_j \\ s_k^2 & c_k^2 & -2 s_k c_k \end{bmatrix} \qquad (4)$$

The choice of the local reference frame is arbitrary. In this work, the origin of each mesh element's local frame is located at the centre of the facet plane; denoting by $\bar{\mathbf{z}}$ the element unit normal vector, directed toward the concavity of the paraboloid, the in-plane axes are defined as $\bar{\mathbf{x}} = (\bar{\mathbf{z}} \times \mathbf{y})/||\bar{\mathbf{z}} \times \mathbf{y}||$ and $\bar{\mathbf{y}} = (\bar{\mathbf{z}} \times \bar{\mathbf{x}})/||\bar{\mathbf{z}} \times \bar{\mathbf{x}}||$ completing a right-handed Cartesian frame.

Similarly to the cable-net case, for a mesh made of n_m triangular elements the topology is described by the matrices $\mathbf{G}, \mathbf{B} \in \mathbb{R}^{3n_m \times n}$: for the generic element m_s connecting the nodes i, j, k sorted counterclockwise ($i \to j \to k$). The rows $3(m_s - 1) + 1, \ldots, 3m_s$ of $\mathbf{G}$ contain the $(+1, -1)$ pairs associated with the ordered edges $(i,j), (j,k)$ and (k,i), while the corresponding rows of $\mathbf{B}$ contain $+1$ in the columns of both nodes of each edge. The mesh equilibrium equations in the edge axial direction then read

$$\mathbf{I}_3 \otimes (\mathbf{B}^\mathrm{T} \mathbf{Q}_\mathrm{m} \mathbf{G}) \mathbf{r} = \mathbf{f}_{\mathrm{m}\tau} \qquad (5)$$

where $\mathbf{Q}_\mathrm{m} \in \mathbb{R}^{3n_m \times n_m}$ collects the membrane axial force densities on its diagonal and $\mathbf{f}_{\mathrm{m}\tau}$ is the vector of the external loads acting along the edge axial direction. The transverse counterpart reads

$$\mathbf{I}_3 \otimes \left(\frac{1}{2} \mathbf{B}^\mathrm{T} \mathbf{P}_\mathrm{m} \boldsymbol{\Gamma}_\mathrm{m} \mathbf{G}\right) \mathbf{r} = \mathbf{f}_{\mathrm{mn}} \qquad (6)$$

where $\mathbf{P}_\mathrm{m} \in \mathbb{R}^{3n_m \times 3n_m}$ is the diagonal matrix of the transverse force densities, $\mathbf{f}_{\mathrm{mn}}$ represents the external loads along the edge transverse direction and $\boldsymbol{\Gamma}_\mathrm{m}$ is the $3n_m \times 3n_m$ block matrix composed of the 3×3 matrices $\boldsymbol{\Gamma}_\mathrm{m}^\mathrm{i}$ relating the transverse force densities to the global frame:

$$\boldsymbol{\Gamma}_\mathrm{m}^\mathrm{i} = \begin{bmatrix} \frac{\cos\alpha_k}{\sin\alpha_k} & -\frac{d_{ij}}{\sin\alpha_k} & 0 \\ 0 & \frac{\cos\alpha_i}{\sin\alpha_i} & -\frac{d_{jk}}{\sin\alpha_i} \\ -\frac{d_{ki}}{\sin\alpha_j} & 0 & \frac{\cos\alpha_j}{\sin\alpha_j} \end{bmatrix} \qquad (7)$$

where for the i-th facet, $\alpha_i, \alpha_j, \alpha_k$ denote the internal angles and d_{ij}, d_{jk}, d_{ki} the edge lengths.

2.3. Ring-truss flexibility and coupled assembly

The cable-net nodes can be partitioned into n_f free and n_g boundary nodes, so that $\mathbf{r} = [\mathbf{r}_\mathbf{f}^\mathrm{T}, \mathbf{r}_\mathbf{g}^\mathrm{T}]^\mathrm{T}$. Denoting by $\mathbf{K}_\mathbf{g} \in \mathbb{R}^{3n_g \times 3n_g}$ the ring-truss stiffness matrix, the ring-truss equilibrium reads

$$\mathbf{K}_\mathbf{g}(\mathbf{r}_\mathbf{g} - \mathbf{r}_\mathbf{g}^\mathbf{0}) = \mathbf{f}_\mathbf{g} \qquad (8)$$

with $\mathbf{r}_\mathbf{g}^\mathbf{0}$ the unstressed boundary-node coordinates. Here, $\mathbf{K}_\mathbf{g}$ is treated as a user-supplied input, obtainable through condensation methods, as done in [28], or via finite element software. Coupling the three sets of equilibrium equations, cable net, mesh and ring truss, through the action-reaction forces exchanged at the interface, and recalling that the

mesh extends only up to the last internal ring, the overall equilibrium of the assembly can be rewritten as:

$$\begin{aligned}\mathbf{I_3}\otimes\left(\mathbf{C}_\mathrm{f}^\mathrm{T}\mathbf{Q}_\mathrm{c}\mathbf{C}_\mathrm{f}+\mathbf{B}_\mathrm{f}^\mathrm{T}\mathbf{Q}_\mathrm{m}\mathbf{G}_\mathrm{f}+\frac{1}{2}\mathbf{B}_\mathrm{f}^\mathrm{T}\mathbf{P}_\mathrm{m}\boldsymbol{\Gamma}_\mathrm{m}\mathbf{G}_\mathrm{f}\right)\mathbf{r}_\mathrm{f}\\ +\mathbf{I_3}\otimes\left(\mathbf{C}_\mathrm{f}^\mathrm{T}\mathbf{Q}_\mathrm{c}\mathbf{C}_\mathrm{g}\right)\mathbf{r}_\mathrm{g}=0\\ \mathbf{I_3}\otimes\left(\mathbf{C}_\mathrm{g}^\mathrm{T}\mathbf{Q}_\mathrm{c}\mathbf{C}_\mathrm{f}\right)\mathbf{r}_\mathrm{f}+\mathbf{I_3}\otimes\left(\mathbf{C}_\mathrm{g}^\mathrm{T}\mathbf{Q}_\mathrm{c}\mathbf{C}_\mathrm{g}\right)\mathbf{r}_\mathrm{g}\\ +\mathbf{K}_\mathrm{g}\left(\mathbf{r}_\mathrm{g}-\mathbf{r}_\mathrm{g}^0\right)=0\end{aligned}\qquad(9)$$

where $\mathbf{C_f}\in\mathbb{R}^{n_c\times n_f}$ and $\mathbf{C_g}\in\mathbb{R}^{n_c\times n_g}$ denote the free- and boundary-node partitions of the cable-net connectivity matrix, and $\mathbf{G_f}$, $\mathbf{B_f}\in\mathbb{R}^{3n_m\times n_f}$ are the analogous partitions for the mesh. Solving Eq. 9 yields the deployed configuration and the prestress field used as the reference state in the following sections. In addition, several strategies for node placing and gradient-based multi-objective optimization can be considered while solving Eq. 9 to obtain a constrained deployed configuration [26].

3. GEOMETRICALLY NONLINEAR FE FORMULATION

The unstressed geometry is retrieved by progressively reducing the forces that the ring truss, as sized in the design stage, applies to the cable-mesh assembly in the deployed state. Two features specific to this class of structures deserve attention before detailing the procedure.

3.1. General assumptions and methodology

Both the mesh and the cable net lack bending and compressive stiffness, thus, infinitely many spatial configurations share the same (null) stress state, differing by zero-strain motions. For manufacturing it is enough to determine one sufficiently regular representative of this family, which legitimizes simplifying assumptions on the path itself: the tensioning forces of net and mesh are taken as fixed in direction and decreasing in magnitude, so that the residual forces are minimized with respect to a known term. Under this assumption the coupling forces arising between mesh and net during unloading can be neglected, and the two subsystems can be unloaded independently. A full Newton-Raphson scheme [29,30] is therefore adopted, linearly reducing the magnitude of the tensioning forces while keeping their direction constant; for each load decrement, an iterative procedure minimizes the balance residual forces until convergence.

A final consideration concerns matrix inversion. Once net and mesh are separated from the ring truss, their tangent stiffness matrices become singular. Rigid-body content is therefore removed at every iteration through a spectral decomposition [29,31]. Let $\boldsymbol{\Phi}\in\mathbb{R}^{k\times k}$ and $\boldsymbol{\Lambda}\in\mathbb{R}^{k\times k}$ denote the orthonormal eigenvectors ($\boldsymbol{\Phi}^\mathrm{T}\boldsymbol{\Phi}=\mathbf{I}$) and the diagonal eigenvalue matrix of $\mathbf{K}\in\mathbb{R}^{\mathrm{k}\times\mathrm{k}}$. The nodal displacements are mapped to modal coordinates $\mathbf{p}=\boldsymbol{\Phi}\,\hat{\mathbf{p}}$ and only the $k-m$ modes with non-zero eigenvalue are in the reduced basis $\boldsymbol{\Phi}_\mathrm{r}\in\mathbb{R}^{k\times(k-m)}$, free of rigid-body modes. In this reduced space, $\boldsymbol{\Lambda}_\mathrm{r}$ denotes the diagonal stiffness and $\hat{\mathbf{f}}_\mathbf{r}$, $\hat{\mathbf{p}}_\mathbf{r}$ the reduced force and displacement vectors. Thus, the (invertible) reduced system reads

$$\hat{\mathbf{p}}_\mathrm{r}=\boldsymbol{\Lambda}_\mathrm{r}^{-1}\,\hat{\mathbf{f}}_\mathrm{r}\qquad(10)$$

and the displacement field is finally reconstructed as $\mathbf{p}=\boldsymbol{\Phi}_\mathrm{r}\,\hat{\mathbf{p}}_\mathrm{r}$.

3.2. Kinematics of the cable net

Following Fig. 5, in the global frame, let the reference position, the displacement and the current position of the nodes be denoted, respectively, by

$$\mathbf{r}^\mathrm{T}=[\mathrm{x},\mathrm{y},\mathrm{z}],\quad \mathbf{p}^\mathrm{T}=[\mathrm{u},\mathrm{v},\mathrm{w}],\quad \mathbf{h}=\mathbf{r}+\mathbf{p}\qquad(11)$$

where u, v and w are the displacement components along the global x, y and z directions. For a generic cable element connecting nodes i and j, the nodal coordinate and displacement vectors read $\mathbf{r}_\mathrm{e}^\mathrm{T}=[x_i,\ x_j, y_i, y_j,\ z_i,\ z_j]$ and $\mathbf{p}_\mathrm{e}^\mathrm{T}=[u_i,\ u_j,\ v_i,\ v_j,\ w_i,\ w_j]$, henceforth denoted by $\mathbf{r}$ and $\mathbf{p}$ dropping the $[\cdot]_e$ subscript for clarity. From these, the support entities $\mathbf{r}_\delta^\mathrm{T}=[x_{ji},\ y_{ji},\ z_{ji}]$ and $\boldsymbol{p}_\boldsymbol{\delta}^T=[u_{ji},\ v_{ji}, w_{ji}]$ are defined, with $x_{ji}=x_j-x_i$ and analogous expressions for the remaining components. The reference and actual squared lengths of the element are $\mathrm{l}_0^2=4\alpha_0^2=\mathbf{r}_\delta^\mathrm{T}\mathbf{r}_\delta$, and $\mathrm{l}^2=(\mathbf{r}_\boldsymbol{\delta}+\mathbf{p}_\boldsymbol{\delta})^\mathrm{T}(\mathbf{r}_\boldsymbol{\delta}+\mathbf{p}_\boldsymbol{\delta})$ so that the Green Lagrange expression of the element strain reads [32]

$$\varepsilon=\frac{1}{\mathrm{l}_0^2}\left(\mathbf{r}_\delta^\mathrm{T}\mathbf{p}_\delta+\frac{1}{2}\mathbf{p}_\delta^\mathrm{T}\mathbf{p}_\delta\right)=\mathbf{b}_1^\mathrm{T}\mathbf{p}+\frac{1}{2\alpha_0^2}\mathbf{p}^\mathrm{T}\mathbf{A}\mathbf{p}\qquad(12)$$

where the following supporting variables were used:

$$\mathbf{b}_1^\mathrm{T}(\mathbf{r})=\frac{1}{4\alpha_0^2}\left[-\mathrm{x}_{\mathrm{ji}},\ \mathrm{x}_{\mathrm{ji}},\ -\mathrm{y}_{\mathrm{ji}},\ \mathrm{y}_{\mathrm{ji}},\ -\mathrm{z}_{\mathrm{ji}},\ \mathrm{z}_{\mathrm{ji}}\right]\qquad(13)$$

$$\mathbf{A}=\frac{1}{4}\begin{bmatrix}1&-1&0&0&0&0\\-1&1&0&0&0&0\\0&0&1&-1&0&0\\0&0&-1&1&0&0\\0&0&0&0&1&-1\\0&0&0&0&-1&1\end{bmatrix}\qquad(14)$$

An increment (or, as here, a decrement) of the external load produces an element displacement variation: $\Delta\mathbf{p}^\mathrm{T}=[\Delta u_i,\ \Delta u_j,\ \Delta v_i,\ \Delta v_j,\ \Delta w_i,\ \Delta w_j]$. The corresponding strain variation is

$$\Delta\varepsilon=(\mathbf{b}_1+\mathbf{b}_2)^\mathrm{T}\boldsymbol{\Delta}\mathbf{p}+\frac{1}{2\alpha_0^2}\boldsymbol{\Delta}\mathbf{p}^\mathrm{T}\mathbf{A}\boldsymbol{\Delta}\mathbf{p}\simeq\mathbf{b}^\mathrm{T}\boldsymbol{\Delta}\mathbf{p}\qquad(15)$$

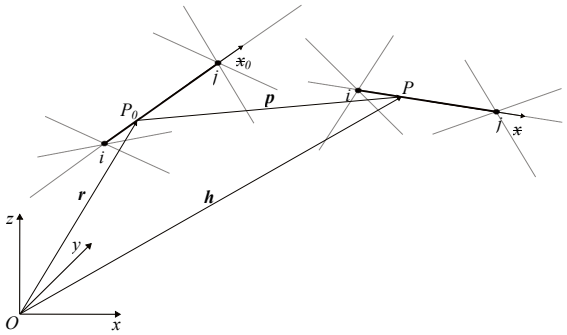

Figure 5: Reference and current configuration of a cable-net element [26].

where

$$\mathbf{b}_2^{\mathrm{I}}(\mathbf{p}) = \frac{1}{4\alpha_0^2}\left[-u_{ji},\, u_{ji},\, -v_{ji},\, v_{ji},\, -w_{ji},\, w_{ji}\right] \qquad (16)$$

so that $\mathbf{b} = \mathbf{b}_1 + \mathbf{b}_2$. For small displacements, the quadratic term in Eq. 15 can be neglected. With linearly elastic, isotropic cables of Young's modulus E, the Second Piola-Kirchhoff stress increment is $\Delta\sigma = \mathrm{E}\,\Delta\varepsilon$. Following the standard full Newton-Raphson scheme [29], after each load update the displacement corrections $\mathrm{d}\mathbf{p}$ are iterated to reduce the balance residual, with the associated strain and stress corrections $\mathrm{d}\varepsilon \simeq \mathbf{b}^{\mathrm{T}}\mathrm{d}\mathbf{p}$ and $\mathrm{d}\sigma = \mathrm{E}\,\mathrm{d}\varepsilon$.

3.3. Tangent stiffness matrix of the cable net

The principle of virtual work for the cable element, written in terms of the internal force vector $\mathbf{f}$ and of virtual displacement $\delta\mathbf{p}$ reads

$$\begin{aligned}\sum_{\mathrm{e}} \delta\,\mathbf{p}^{\mathrm{T}}\mathbf{f} &= \sum_{\mathrm{e}} \int_{\mathrm{V_0}} \sigma\,\delta\varepsilon \mathrm{dV} \\ &\simeq \sum_{\mathrm{e}} \delta\,\mathbf{p}^{\mathrm{T}} \int_{\mathrm{V_0}} \sigma\,\mathbf{b}\mathrm{dV}\end{aligned} \qquad (17)$$

where $\sum_{\mathrm{e}}$ denotes summation over elements. Since Eq. 17 must hold for any $\delta\mathbf{p}$

$$\begin{aligned}\mathbf{f} &= \int_{\mathrm{V_0}} \sigma\,\mathbf{b}\mathrm{dV} = 2\alpha_0 \mathrm{A}_0 \sigma(\mathbf{b}_1(\mathbf{r}) + \mathbf{b}_2(\mathbf{p})) \\ &= \mathbf{f}_1(\mathbf{r}) + \mathbf{f}_2(\mathbf{p})\end{aligned} \qquad (18)$$

with A_0 the cable cross-section area. Introducing the out-of-balance element force vector $\mathbf{g} = \mathbf{f} - \mathbf{f}_{\mathrm{c}}$, with $\mathbf{f}_{\mathrm{c}}$ the element external forces (assumed constant), the tangent stiffness matrix is defined as [32]

$$\mathbf{K_t}(\mathbf{r},\mathbf{p}) = \frac{\partial \mathbf{g}}{\partial \mathbf{p}} = \frac{\partial \mathbf{f}}{\partial \mathbf{p}} = 2\alpha_0 \mathrm{A}_0 \left(\mathbf{b}\frac{\partial \sigma}{\partial \mathbf{p}} + \frac{\partial \mathbf{b}}{\partial \mathbf{p}}\sigma\right) \qquad (19)$$

Since $\partial\sigma/\partial\mathbf{p} = \mathrm{E}\,\partial\varepsilon/\partial\mathbf{p} = \mathrm{E}\,\mathbf{b}^{\mathrm{T}}$, the first term of Eq. 19 becomes $2E\alpha_0 A_0 \mathbf{b}\mathbf{b}^{\mathrm{T}} = \mathbf{K_{t1}} + \mathbf{K_{t2}}$, where

$$\mathbf{K_{t1}}(\mathbf{r}) = 2\mathrm{E}\mathrm{A}_0\alpha_0 \mathbf{b_1}\mathbf{b_1}^{\mathrm{T}} \qquad (20)$$

$$\begin{aligned}&\mathbf{K_{t2}}(\mathbf{r},\mathbf{p}) \\ &= 2\mathrm{E}\mathrm{A}_0\alpha_0\left(\mathbf{b_1}\mathbf{b_2}^{\mathrm{T}} + \mathbf{b_2}\mathbf{b_1}^{\mathrm{T}} + \mathbf{b_2}\mathbf{b_2}^{\mathrm{T}}\right)\end{aligned} \qquad (21)$$

while the second term, exploiting the fact that only $\mathbf{b}_2$ depends on $\mathbf{p}$ and that $\mathbf{A}$ is as in Eq. 14, yields the geometric (stress) contribution

$$\mathbf{K_{t\sigma}}(\mathbf{r},\mathbf{p}) = 2\alpha_0 \mathrm{A}_0 \frac{\partial \mathbf{b_2}}{\partial \mathbf{p}}\sigma = \frac{2\mathrm{A}_0\sigma}{\alpha_0}\mathbf{A} \qquad (22)$$

The contribution $\mathbf{K_{t1}}(\mathbf{r})$ is the linear stiffness involving only the initial geometry of the net and is therefore unchanged throughout the unloading. Summing the terms, the element tangent stiffness matrix is

$$\mathbf{K_t} = \mathbf{K_{t1}} + \mathbf{K_{t2}} + \mathbf{K_{t\sigma}} \qquad (23)$$

3.4. Kinematics of the mesh

Consider now a triangular element with vertices i, j and k, whose global positions and displacements are collected in $\mathbf{r}^{\mathrm{T}} = [x_i, x_j, x_k, y_i, y_j, y_k, z_i, z_j, z_k]$ and $\mathbf{p}^{\mathrm{T}} = [u_i, u_j, u_k, v_i, v_j, v_k, w_i, w_j, w_k]$ (Fig. 6).
Adopting an isoparametric formulation in the local element frame $(\bar{x}, \bar{y})$, the position and displacement fields are interpolated as $\bar{x} = [\bar{x}_i, \bar{x}_j, \bar{x}_k]\boldsymbol{\chi}^{\mathrm{T}}$, $\bar{y} = [\bar{y}_i, \bar{y}_j, \bar{y}_k]\boldsymbol{\chi}^{\mathrm{T}}$, $\bar{u} = [\bar{u}_i, \bar{u}_j, \bar{u}_k]\boldsymbol{\chi}^{\mathrm{T}}$ and $\bar{v} = [\bar{v}_i, \bar{v}_j, \bar{v}_k]\boldsymbol{\chi}^{\mathrm{T}}$ $\bar{w} = [\bar{w}_i, \bar{w}_j, \bar{w}_k]\boldsymbol{\chi}^{\mathrm{T}}$, where $\boldsymbol{\chi} = [\xi, \eta, 1 - \xi - \eta]^{\mathrm{T}}$ is the shape-function vector, defined as the ratios between the areas of the three sub-regions identified by the element vertices and its centre and the total element area. The Jacobian matrix of the element in the local frame is

$$\bar{\mathbf{J}} = \begin{bmatrix} \frac{\partial \bar{x}}{\partial \xi} & \frac{\partial \bar{y}}{\partial \xi} \\ \frac{\partial \bar{x}}{\partial \eta} & \frac{\partial \bar{y}}{\partial \eta} \end{bmatrix} = \begin{bmatrix} (\overline{x_i} - \overline{x_k}) & (\overline{y_i} - \overline{y_k}) \\ (\overline{x_j} - \overline{x_k}) & (\overline{y_j} - \overline{y_k}) \end{bmatrix} \qquad (24)$$

The displacement derivative vector $\mathbf{d}$, collecting the six in-plane gradients $u_x, u_y, v_x, v_y, w_x, w_y$ (where $(\cdot)_x$ denotes $\partial(\cdot)/\partial x$), is obtained as,

$$\mathbf{d} = \mathbf{G}\mathbf{p} \qquad (25)$$

with $\mathbf{G}$ the block diagonal operator built from

$$\mathbf{G}_{\mathrm{b}} = \begin{bmatrix} \bar{\mathbf{J}}_{1,1}^{-1}\boldsymbol{\chi}_{\xi}^{\mathrm{T}} + \bar{\mathbf{J}}_{1,2}^{-1}\boldsymbol{\chi}_{\eta}^{\mathrm{T}} \\ \bar{\mathbf{J}}_{2,1}^{-1}\boldsymbol{\chi}_{\xi}^{\mathrm{T}} + \bar{\mathbf{J}}_{2,2}^{-1}\boldsymbol{\chi}_{\eta}^{\mathrm{T}} \end{bmatrix} \qquad (26)$$

with $\boldsymbol{\chi}_{\xi} = [1, 0, -1]^{\mathrm{T}}$ and $\boldsymbol{\chi}_{\eta} = [0, 1, -1]^{\mathrm{T}}$ the shape-function derivatives. The Green-Lagrange nonlinear deformations, expressed in engineering form via Voigt notation, read [32]

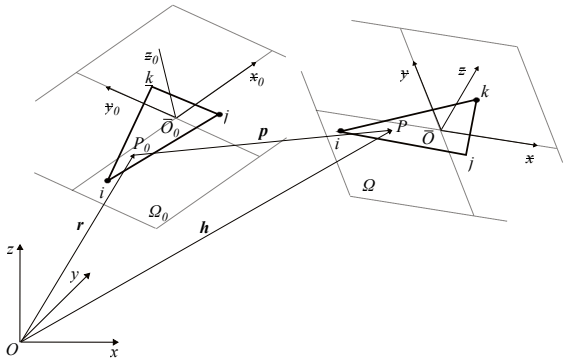

Figure 6: Reference and current configuration of a triangular mesh element [26].

$$\bar{\boldsymbol{\varepsilon}} = \begin{bmatrix} \bar{\varepsilon}_{xx} \\ \bar{\varepsilon}_{yy} \\ \bar{\gamma}_{xy} \end{bmatrix} = \left[\mathbf{H} + \frac{1}{2}\bar{\mathbf{A}}\right]\bar{\mathbf{d}} = \bar{\boldsymbol{\varepsilon}}_1 + \bar{\boldsymbol{\varepsilon}}_2 \qquad (27)$$

where the constant Boolean-like matrix $\mathbf{H}$ extracts the linear part,

$$\mathbf{H} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \end{bmatrix} \qquad (28)$$

and the displacement-dependent matrix collects the quadratic terms,

$$\bar{\mathbf{A}}(\bar{\mathbf{d}}) = \begin{bmatrix} \frac{\partial \bar{u}}{\partial \bar{x}} & 0 & \frac{\partial \bar{v}}{\partial \bar{x}} & 0 & \frac{\partial \bar{w}}{\partial \bar{x}} & 0 \\ 0 & \frac{\partial \bar{u}}{\partial \bar{y}} & 0 & \frac{\partial \bar{v}}{\partial \bar{y}} & 0 & \frac{\partial \bar{w}}{\partial \bar{y}} \\ \frac{\partial \bar{u}}{\partial \bar{y}} & \frac{\partial \bar{u}}{\partial \bar{x}} & \frac{\partial \bar{v}}{\partial \bar{y}} & \frac{\partial \bar{v}}{\partial \bar{x}} & \frac{\partial \bar{w}}{\partial \bar{y}} & \frac{\partial \bar{w}}{\partial \bar{x}} \end{bmatrix} \qquad (29)$$

The corresponding element local stress is $\bar{\sigma} = [\bar{\sigma}_{xx}, \bar{\sigma}_{yy}, \bar{\sigma}_{xy}] = \bar{\mathbf{Q}}\bar{\boldsymbol{\varepsilon}}$, where $\bar{\mathbf{Q}}$ is the membrane local stiffness matrix. $\bar{\mathbf{Q}}$ accounts for the deposition angle θ of the reflective mesh: a counterclockwise rotation about the local normal describing how far the element axes deviate from the material isotropy axes (Fig. 7). For an orthotropic membrane with isotropy axes L (longitudinal) and T (transverse), the stiffness matrix in the LT frame is, with $\Delta = 1 - \nu_{LT}\,\nu_{TL}$,

$$\boldsymbol{C}^{(LT)} = \frac{1}{\Delta}\begin{bmatrix} E_L & \nu_{TL}E_L & 0 \\ \nu_{LT}E_T & E_T & 0 \\ 0 & 0 & G_{LT}\kappa \end{bmatrix} \qquad (30)$$

Introducing the Reuter matrix, $\mathbf{R}$, and the in-plane rotation matrix $\mathbf{T}(\theta)$ relating the true and engineering strains as

$$\mathbf{R} = \mathrm{diag}(1, 1, 2) \qquad (31)$$

$$\mathbf{T}(\theta) = \begin{bmatrix} c^2 & s^2 & 2sc \\ s^2 & c^2 & -2sc \\ -sc & sc & c^2 - s^2 \end{bmatrix} \qquad (32)$$

with $s = sin\ \theta$ and $c = cos\ \theta$, the local stresses read

$$\bar{\boldsymbol{\sigma}} = \mathbf{T}_\sigma \mathbf{C}^{\mathrm{LT}} \mathbf{T}_\varepsilon \bar{\boldsymbol{\varepsilon}},\ \mathbf{T}_\sigma = \mathbf{T}^{-1}, \mathbf{T}_\varepsilon = \mathbf{R}\mathbf{T}\mathbf{R}^{-1} \qquad (33)$$

so that $\bar{\mathbf{Q}} = \mathbf{T}_\sigma \mathbf{C}^{(\mathrm{LT})} \mathbf{T}_\varepsilon$.

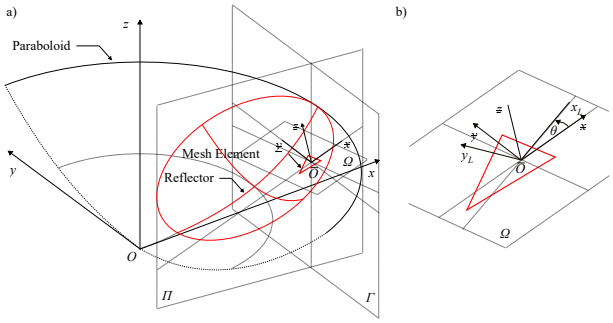

Figure 7: Local frame $\bar{x}$, $\bar{y}$ and the isotropy frame x_L, y_L, the latter rotated counterclockwise by an angle θ: a) overall and b) close-up view [26].

3.5. Tangent stiffness matrix of the mesh

Similarly, the tangent stiffness matrix for the mesh case can be evaluated from the virtual work principle. For a single element,

$$\bar{\mathbf{f}}^{\mathrm{T}} \delta\bar{\mathbf{p}} = \int_{\mathrm{V_o}} \bar{\boldsymbol{\sigma}}^{\mathrm{T}}\, \delta\bar{\boldsymbol{\varepsilon}} \mathrm{dV} \simeq \int_{\mathrm{V_o}} \bar{\boldsymbol{\sigma}}^{\mathrm{T}}\, \bar{\mathbf{B}}\, \delta\bar{\mathbf{p}} \mathrm{dV} \qquad (34)$$

where $\mathbf{f}$ denotes the element internal force vector and

$$\bar{\mathbf{B}} = \bar{\mathbf{B}}_1 + \bar{\mathbf{B}}_2 = \mathbf{H}\bar{\mathbf{G}} + \bar{\mathbf{A}}\,\bar{\mathbf{G}} \qquad (35)$$

so that the internal forces read

$$\bar{\mathbf{f}} = \int_{\mathrm{V}} \bar{\mathbf{B}}^{\mathrm{T}} \bar{\boldsymbol{\sigma}}\, \mathrm{dV} \qquad (36)$$

Introducing the out-of-balance element force vector $\mathbf{g} = \mathbf{f} - \mathbf{f}_{\mathrm{m}}$, the local tangent stiffness matrix is

$$\bar{\mathbf{K}}_{\mathrm{t_m}} = \frac{\partial \bar{\mathbf{g}}}{\partial \bar{\mathbf{p}}} = \int_{\mathrm{V_o}} \frac{\partial \bar{\mathbf{B}}^{\mathrm{T}}}{\partial \bar{\mathbf{p}}} \bar{\boldsymbol{\sigma}}\, \mathrm{dV} + \int_{\mathrm{V_o}} \bar{\mathbf{B}}^{\mathrm{T}} \frac{\partial \bar{\boldsymbol{\sigma}}}{\partial \bar{\mathbf{p}}} \mathrm{dV} \qquad (37)$$

The first term on the right-hand side is the geometric contribution, representing the internal stress effect:

$$\bar{\mathbf{K}}_{\mathrm{t}\sigma_{\mathrm{m}}} = \left(\bar{\mathbf{G}}^{\mathrm{T}} \bar{\boldsymbol{\Sigma}}\, \bar{\mathbf{G}}\right) \mathrm{t_o S_o} \qquad (38)$$

with $\boldsymbol{\Sigma}$ the 6×6 block diagonal matrix built from the 2×2 blocks of the local stress components, and S_o and t_o the element reference surface and thickness, respectively. The second term, using $\mathrm{d}\bar{\boldsymbol{\sigma}} = \bar{\mathbf{Q}}\bar{\mathbf{B}}\, \mathrm{d}\mathbf{p}$, provides the material contributions $\bar{\mathbf{K}}_{\mathbf{t1_m}}$ and $\bar{\mathbf{K}}_{\mathbf{t2_m}}$. Integrating over the reference configuration of the element,

$$\overline{\mathbf{K}}_{\mathrm{t1_m}} = \left(\overline{\mathbf{B}}^{\mathrm{T}}\overline{\mathbf{Q}}\,\overline{\mathbf{B}}_1\right)\mathrm{t_o S_o}$$
$$\overline{\mathbf{K}}_{\mathrm{t2_m}} = \left(\overline{\mathbf{B}}^{\mathrm{T}}\overline{\mathbf{Q}}\,\overline{\mathbf{B}}_2\right)\mathrm{t_o S_o} \qquad (39)$$

The global tangent stiffness matrix is assembled from the individual contributions expressed in the global frame,

$$\mathbf{K_{t_m}} = (\mathbf{R}_{\mathrm{G}}^{\mathrm{L}})^{-1}\,(\overline{\mathbf{K}}_{\mathbf{t1_m}} + \overline{\mathbf{K}}_{\mathbf{t2_m}} + \overline{\mathbf{K}}_{\mathbf{t\sigma_m}})\mathbf{R}_{\mathrm{G}}^{\mathrm{L}} \qquad (40)$$

with $\mathbf{R}_{\mathrm{G}}^{\mathrm{L}}$ the 9×9 rotation matrix mapping global into local components.

3.6. Evaluation of the zero-stress state

The zero-stress state of net and mesh is computed with the incremental-iterative Newton-Raphson algorithm sketched in Fig. 8, taking the optimized equilibrium configuration as the starting point. At each increment the load is lowered by a fixed amount and the displacement field is obtained from the current tangent stiffness, purged of rigid-body modes, as in Eq. 10. Strains and stresses are then updated with the expressions of Sections 3.2 and 3.4 and the unstrained elements are removed from the equilibrium or restored if re-tensioned later. The force densities are recomputed in the current configuration and, whenever the residual exceeds the tolerance, the Newton corrector loop is entered. In the present formulation, strains and stresses in the reference configuration are expressed in terms of the Green-Lagrange tensor $\mathbf{E}$ and of the Second Piola-Kirchhoff tensor $\boldsymbol{\sigma}$. The equilibrium, instead, must be evaluated in the current configuration of the system, implying that the force densities entering the equilibrium equations must be mapped from the reference stress state through the Cauchy stresses $\boldsymbol{\tau}$,

$$\boldsymbol{\tau} = \frac{1}{\mathrm{J}}\,\boldsymbol{F}\,\boldsymbol{\sigma}\,\boldsymbol{F}^{\mathrm{T}}, \qquad \mathrm{J} = \det(\boldsymbol{F}) \qquad (41)$$

with $\mathbf{F}$ the deformation gradient. Because each element frame is body-fixed, the rotation embedded in $\boldsymbol{F}$ is the identity, and $\boldsymbol{F}$ reduces to

$$\boldsymbol{F} = (2\mathbf{E} + \mathbf{I})^{1/2} \qquad (42)$$

4. RESULTS AND DISCUSSION

The case study reproduces the architecture of the TAS-I reflector,, shown in Fig. 9. Its main geometric parameters are taken from the literature as a representative benchmark for this class of antennas:$D = 12.25\,m$ and $\mathcal{F}/D = 0.45$ [33], $\mathcal{F}$ being the focal length. The number of triangular elements is determined by the number of circumferential subdivisions (rings) and zones (sectors), N and M respectively, set to satisfy the minimum requirements imposed by the target operating frequency of 4 GHz [27,34]:

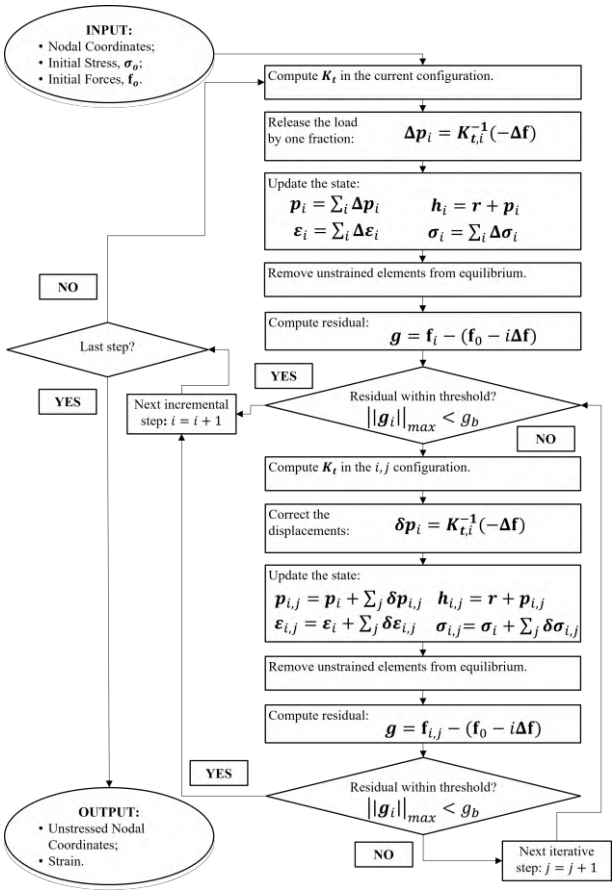

Figure 8: Flow chart of the nonlinear FE unstressing algorithm for cable net and mesh [26].

$$N = max(2, \lceil D/(2L_{max,0})\rceil)$$
$$M = max(3, \lceil (\pi D)/(NL_{max,0})\rceil) \qquad (43)$$

where $L_{max,0} = \eta\sqrt{\lambda\mathcal{F}/\psi}$ is the maximum cable length and λ the wavelength. The parameters ψ and η are set to 50 and 7.872 respectively, ensuring the gain loss of the faceted surface is below 0.3 dB [27]. Material parameters are taken from the literature: Kevlar for the cables [35], and an orthotropic fabric for the mesh [36]. Due to the orthotropic mesh properties, different tensile loads are prescribed in the longitudinal and transverse material directions [37], N_L and N_T respectively, within the $5 - 20\,N/m$ range typical of mesh reflectors [4]. The detailed design of the ring truss falls outside the scope of this study: $\mathbf{K_g}$ is entered as a diagonal matrix, letting the boundary nodes act independently; in general, the reduced $3n_g \times 3n_g$ matrix could be obtained via static condensation of a full ring-truss FE model. Tab. 1 collects the geometric and constitutive parameters of the form-finding and unstressing procedures, and Tab. 2 maps node and cable IDs to the portions of the cable net, to help the reading of the figures. The reference (deployed) configuration is the optimized output of the form-finding stage, for which a final nodal RMS of $2.58 \times 10 - 4\ \mu m$ with respect to the ideal paraboloid is achieved.

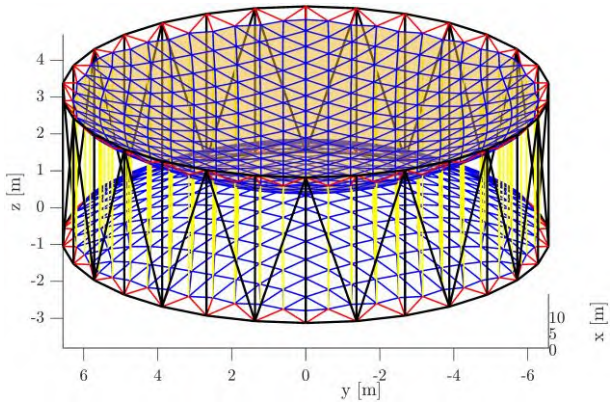

Figure 9: Balanced configuration of the reflector considered in the case study.

Table 1: Geometric and material parameters of the form-finding and unstressing procedures for the cable net and mesh.

Geometry	
Aperture diameter, D [m]	12.25
Focal length, $\mathcal{F}$ [m]	5.52
Clearance [m]	3.06
Ring-truss diameter [m]	13.2
Number of boundary nodes, n_b	60
Number of rings / sectors	10 / 6
Form-finding	
Inner-cable force density [N/m]	50
Link force density [N/m]	175
Local boundary node stiffness (x,y,z) [N/m]	[9.2, 5.3, 5]×10^5
Mesh thickness, t_o [mm]	0.822
Mesh deposition angle, θ [°]	0
Mesh preload (longitudinal), N_L [N/m]	10
Mesh preload (transverse), N_T [N/m]	5
Finite element method	
Cables Young's modulus, E [GPa]	20
Mesh longitudinal modulus, E_L [kPa]	50
Mesh transverse modulus, E_T [kPa]	104
Mesh shear modulus, G_{LT} [kPa]	350
Shear Poisson ratio, ν_{TL}	0.588
Number of unloading steps, n_{steps}	100
Maximum residual force, max(|$\boldsymbol{g}$|) [N]	0.001

Table 2: Node and cable ID intervals identifying the portions of the cable net.

Node type	**ID range**
Front net inner (free) nodes	1–331
Rear net inner (free) nodes	332–662
Front net boundary nodes	663–692
Rear net boundary nodes	693–722
Cable type	**ID range**
Front net inner cables	1–930
Rear net inner cables	931–1860
Ties	1861–2191
Front net links	2192–2281
Rear net links	2282–2371

4.1. Zero-stress configurations

With the optimized form-finding completed, the tensioning forces are gradually released through the nonlinear FE procedure to obtain the undeformed geometries of net and mesh. Figs. 10 and 11 show the zero-stress states identified for the cable nets and the mesh, respectively, overlapped with the corresponding tensioned configurations.

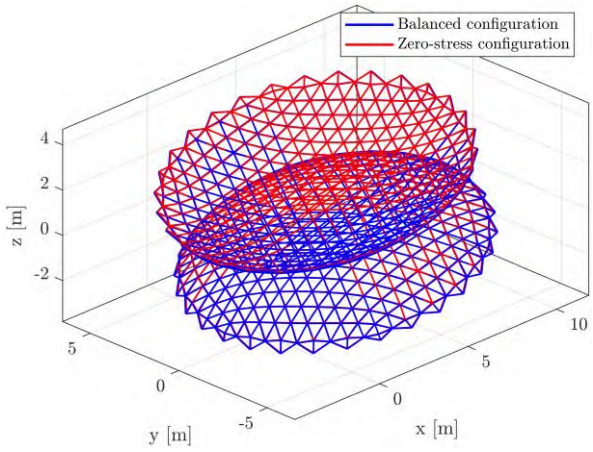

Figure 10: 3D view of the zero-stress configuration (red) overlapped with the tensioned configuration (blue) of the front and rear nets.

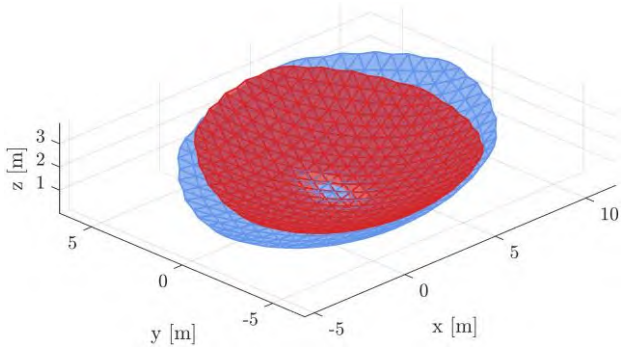

Figure 11: Undeformed mesh (red) superimposed on its tensioned configuration (light blue).

4.2. Validation against analytical predictions

As a first check, the unstressed cable lengths from the FE procedure are set against the Hooke's-law estimate. Fig. 12a and Fig. 12b show the absolute and relative difference between the two predictions, respectively, with an average relative difference below 0.01%, validating the method for the cable network.

The mesh strains obtained from the present Newton-Raphson procedure are shown in Fig. 13a. These values can also be compared with analytical predictions: each triangular facet is tensioned with the same values of N_L and N_T, assuming constant

thickness t_o and deposition angle $\theta = 0°$; in these conditions, Hooke's law $\bar{\boldsymbol{\varepsilon}} = \bar{\mathbf{Q}}^{-1}\,\bar{\boldsymbol{\sigma}}$ yields, substituting the input values of Tab. 1,

$$\bar{\boldsymbol{\varepsilon}} = \begin{bmatrix} 0.2089 \\ -0.0103 \\ 0 \end{bmatrix} \qquad (44)$$

These values match the numerical results of Fig. 13a. The values shown here can be compared with the local strain estimates obtained for $\theta \in [0, 90°]$ in Fig. 13b. The strain field can be better visualized in quasi-polar coordinates, as done in Fig. 14, where the radial, tangential and shear strain components over the mesh surface are reported for $\theta = 0°$.

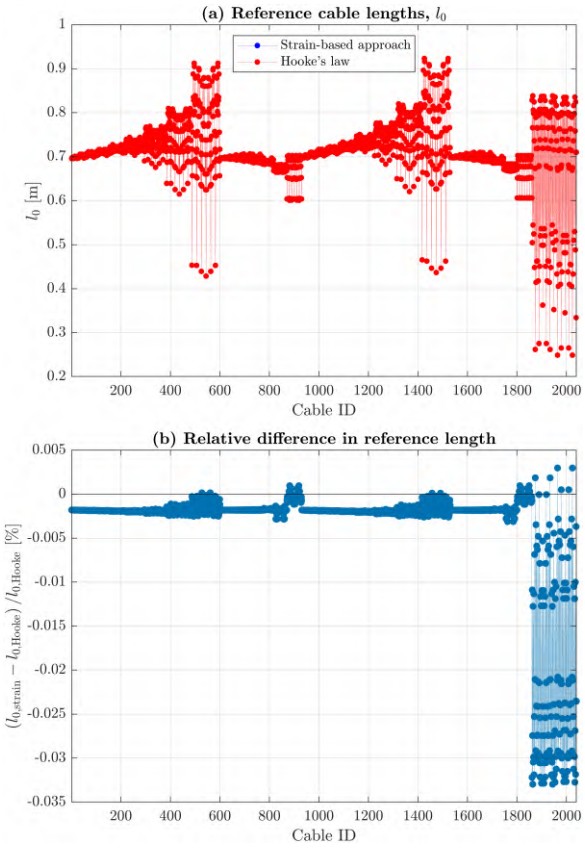

Figure 12: (a) Unstrained cable-length estimates from FE (blue) and the direct Hooke's law (red) predictions, (b) relative difference between the two predictions.

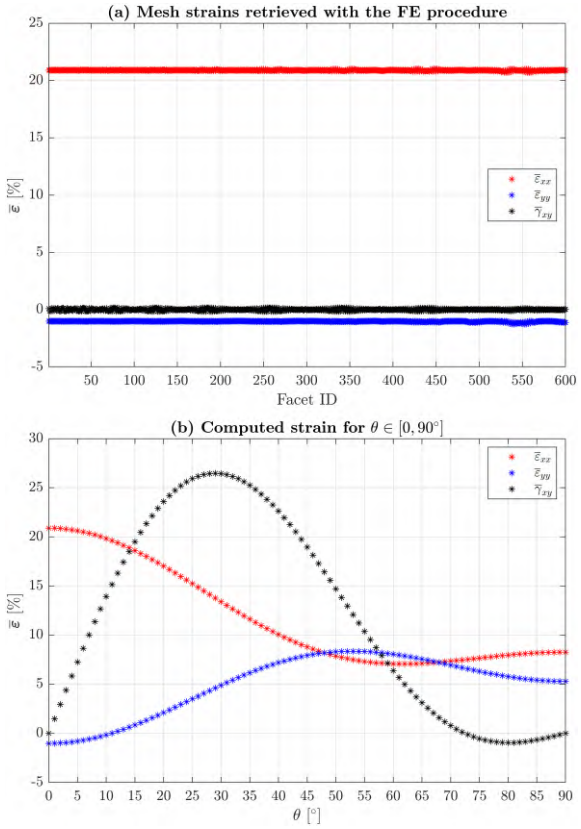

Figure 13: Mesh strain components evaluated with (a) null and (b) varying deposition angle θ.

4.3. Role of geometric nonlinearity

The role of geometric nonlinearity emerges clearly from the unloading path itself. In Fig. 15a and Fig. 15b the mean radius at the rim nodes is tracked against the mean tensioning force applied there, for both net and mesh, and compared with the linear estimate obtained by freezing the tangent stiffness at the reference configuration, $\mathbf{K}_\mathbf{t}^{(1)}$. Fig. 15c and Fig. 15d repeat the comparison for the depth, i.e. the maximum vertical distance from the boundary-node or rim-node plane, respectively. Both structures stiffen noticeably along the path: as unloading proceeds their geometric stiffness drops, and equal force reductions produce progressively larger displacements. Against this, the linear extrapolation accumulates substantial error, evidence that neglecting geometric nonlinearity would impact negatively on the computed zero-stress geometries and, through them, the deployed shape and the RF performance of the reflector.

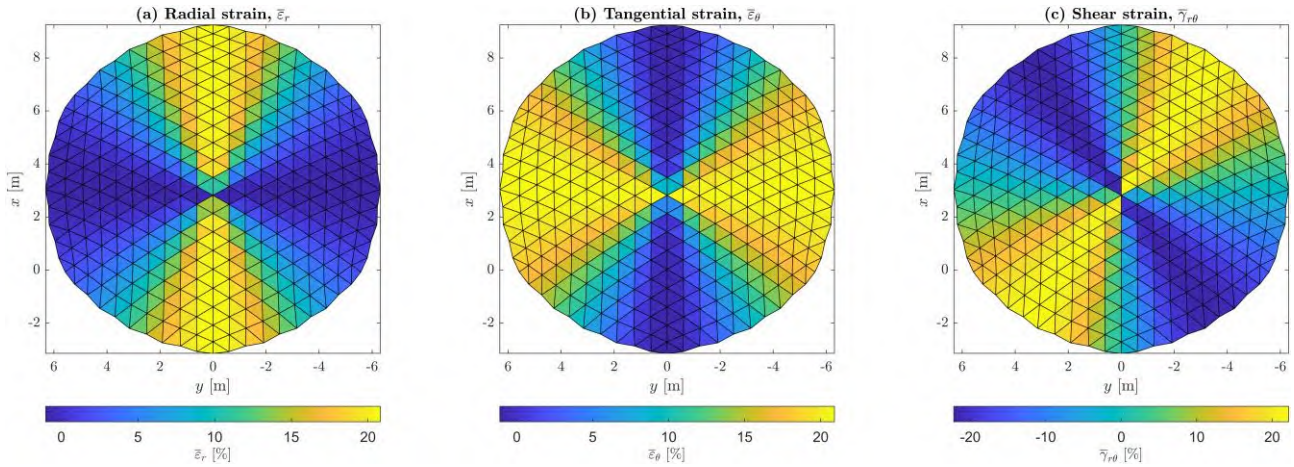

Figure 14: Facets' strain in quasi-polar coordinates for $\theta = 0°$: (a) radial component, (b) tangential component, (c) shear component.

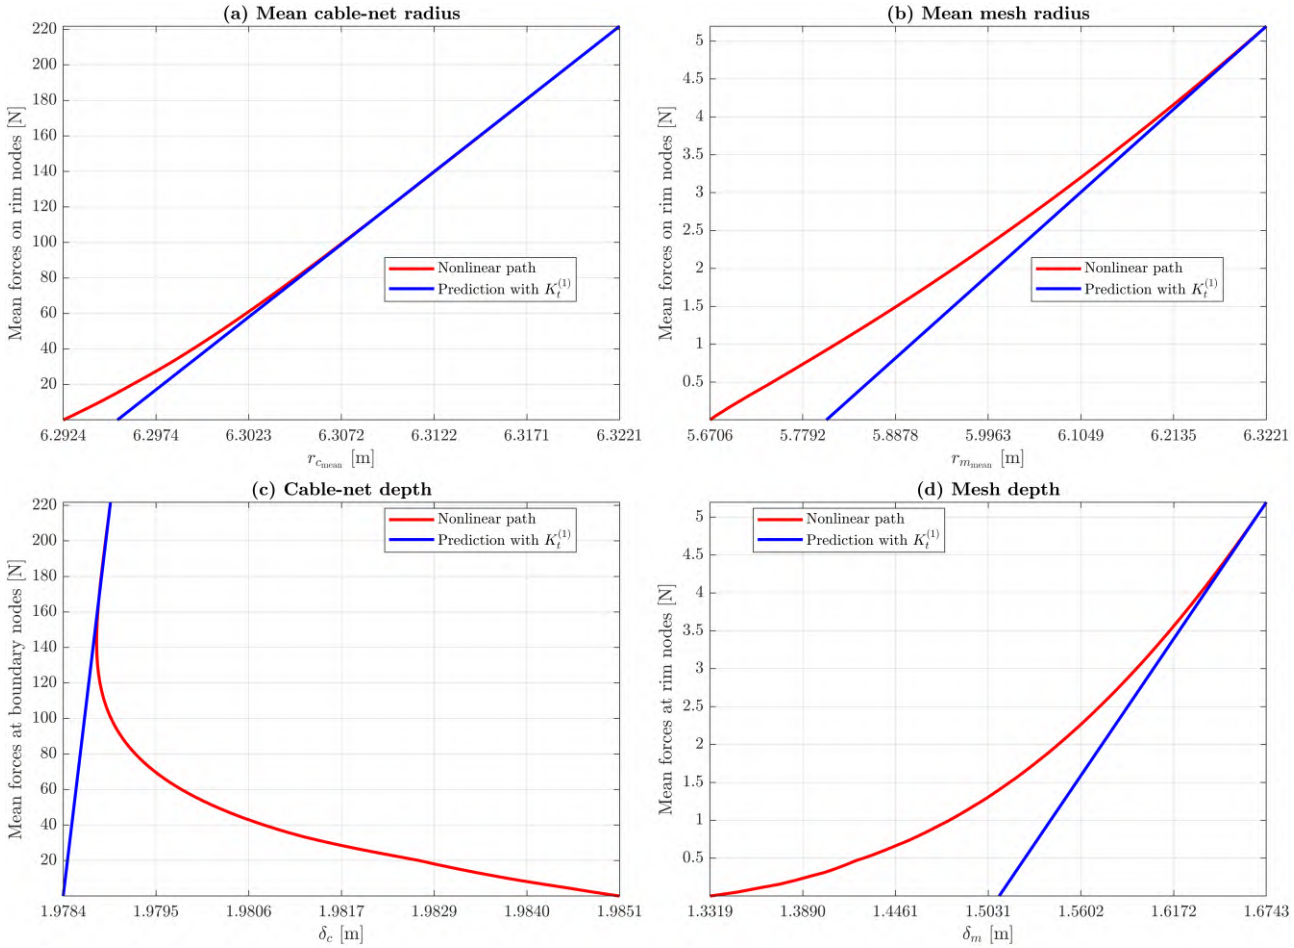

Figure 15: Front net and mesh unloading paths, compared with the linear predictions: mean rim radius for the (a) cable net and (b) mesh, and depth for the (c) cable net and (d) mesh.

5. CONCLUSIONS

A geometrically nonlinear, incremental-iterative finite element procedure has been presented to recover the zero-stress configurations of the cable nets and reflective mesh of a large deployable mesh reflector, starting from the deployed prestressed state provided by an extended Force Density Method [26]. The prestress is released by progressive load reduction within a total Lagrangian description, with consistent updating of the strain and stress states, treatment of cable slackening and reactivation, and orthotropic modelling of the mesh, including its deposition angle; numerical stability is ensured by filtering rigid-body modes through spectral decomposition of the singular tangent stiffness matrix.

For the 12.25 m case study considered, the

recovered cable rest lengths match the analytical Hooke's law prediction within 0.01%, and the mesh strain field reproduces the analytical orthotropic solution. The strongly nonlinear stiffening observed during unloading, in contrast with the linear prediction, demonstrates that geometric nonlinearity must be retained to obtain manufacturing-grade unstressed geometries: cutting patterns, cable rest lengths and assembly tolerances derived from a linearized model would introduce errors that directly propagate to the deployed shape and, ultimately, to the RF performance of the reflector.

Scalability guided the design of the proposed framework: rings, sectors, boundary nodes and aperture can each be varied on their own, so the design space can be swept systematically; and since the ring truss is decoupled from the net-mesh subsystems, one cable-mesh layout can serve supporting structures of different geometry.

Next steps include bringing the ring truss inside the nonlinear unloading model and enriching the cable and mesh constitutive laws with the material nonlinearities of lightweight space-grade components, towards realistic simulations of the complete deployment and tensioning sequence.

Abstract

Inflatable lunar habitats offer launch-volume efficiency but couple mechanism dynamics to a highly compliant restraint layer. This paper isolates deployability from subsequent pressurization and links three models: a FEMAP finite-element model of the complete habitat for static material screening; an MSC Adams multibody model of a three-ring, two-stage module for joint forces, work and power; and a geometrically and materially nonlinear LS-DYNA model of the dry Kevlar K300T2 restraint layer. Linear, half-cosine and quintic minimum-jerk laws are assessed for synchronized and staged motion under equal-global-time and equal-local-stroke-time criteria. At equal local time, staging reduces peak mean absolute force by $22.6 - 30.6\%$, cumulative mechanical work by $30.4 - 33.3\%$, and peak power by $59 - 63\%$. For the minimum-jerk case, the selected deployability-affected membrane area falls from 14.86% to 9.53% of nominal lateral area. Staging is therefore beneficial only when allowed a longer global maneuver, showing that motion smoothness, timing and membrane response must be co-designed.

1 INTRODUCTION

Expandable softgoods habitats can provide a larger habitable volume per launch volume than an equivalent rigid shell, but their structural function is distributed among a multilayer structure composed of a bladder, restraint, thermal and protective layers. TransHab and later NASA developments established the feasibility of large layered inflatables and the need for full-scale structural testing [1,2,3]. Certification studies further show that human-rated softgoods require a building-block approach, statistically supported knock-down factors and explicit treatment of material variability [4]. These issues become more severe for surface-based habitats because deployment must also interact with the ground, mechanisms and lunar gravity. Recent reviews classify lunar and Martian habitat concepts by architecture, material and construction strategy and identify deployable/inflatable solutions as mass-efficient but validation-intensive [1]. A related safety study emphasizes the risk of assigning packing, deployment and pressure retention to an insufficiently separated structural function [5]. The present work therefore treats deployment before inflation: only the structural restraint layer and the frame-guide mechanism are retained in the dynamic models. Pressure qualification, gas-barrier performance and the complete multilayer stack are outside the current study. The geometry originates from the authors' conceptual pressurized lunar habitat, for which a cylindrical configuration was selected after geometric, static, thermal and habitability trade-offs [6]. The contribution is a kinematics-driven, multi-model assessment that connects: (i) full-structure static screening, (ii) actuator demand from a multibody representation and (iii) nonlinear dry-fabric deformation under the same prescribed motions. Thin membranes may develop localized slack and wrinkles through geometric instability, making a large-deformation finite-element treatment essential [9,10]. Table 1 positions the analysis relative to the literature base.

2 HABITAT CONCEPT AND MODEL CHAIN

2.1 Static structural screening in FEMAP

The reference habitat consists of a cylindrical softgoods shell with a hemispherical endcap, eight internal rectangular rings, and a carbon-fibre floor with its support structure. The complete FEMAP model was subjected to a 1 atm pressure load. Five dry woven restraint candidates (see Tab. 2) from the project material catalogue have been compared using consistent geometry, boundary conditions and shell representation. The catalogue thickness, rather than a fitted laminate thickness, was used for this screening; the fibres are non-impregnated dry fabrics and are not treated as a resin-matrix composite.

$$\sigma_\theta = \frac{pR}{t},\ \sigma_x = \frac{pR}{2t} \tag{1}$$

For a cylindrical membrane, Eq. 1 provides the hoop and axial sizing references. Introducing safety factor SF and a restraint efficiency η = 0.80 gives the minimum thickness in Eq. 2. For Kevlar K300T2, $SF = 4$ gives $0.28\,mm$, below the $0.42\,mm$ catalogue thickness used in the finite-element comparison. This calculation is a screening check; discontinuities at rings and endcaps are resolved by the FEMAP model rather than by membrane theory.

$$t_{req} = SF \cdot \frac{pR}{\eta\,\sigma_u} \tag{2}$$

Table 2: Dry-fabric catalogue data used in the static screen.

Material	Mass/area (g/m²)	σ_u (MPa)	E (GPa)	t (mm)
Kevlar K300T2	300	2930	102.0	0.42
Vectran V200T2	200	3200	100.0	0.21
Zylon Z300T2	300	5800	270.0	0.42
CF50/Vectran50	200	3716	151.8	0.21
CF61/Aramid39	210	3850	179.0	0.25

Table 3: FEMAP response under 1 atm pressure differential.

Material	ucyl (mm)	uend (mm)	σcyl (MPa)	σend (MPa)
Kevlar K300T2	2.164	0.864	180	101
Vectran V200T2	11.02	3.95	679	385
Zylon Z300T2	2.00	0.73	341	92
CF50/Vectran 50	7.09	2.60	682	385
CF61/Aramid 39	5.06	1.86	571	323

According to Tab.3, Zylon gives the smallest displacement but the project trade also weights stress distribution, durability, availability and technology maturity. Kevlar K300T2 was consequently retained as the engineering compromise: its full-structure cylinder displacement is $2.164\,mm$ and its average cylinder stress is $180\,MPa$.

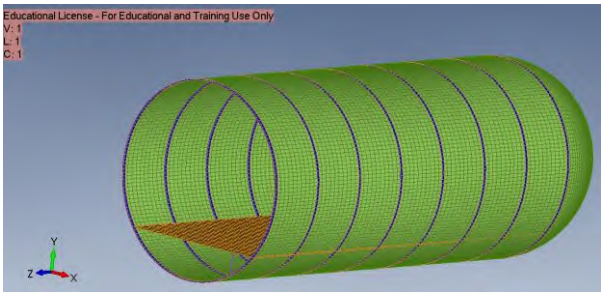

Figure 1: FEMAP finite-element model of the complete cylindrical habitat used for static screening.

2.2 Deployment module and information transfer

The modularity of the deployable structure has a radius of $R = 1600$ mm and total undeployed length of $L = 2000\,mm$. Three rigid frames are initially located at $0, 1000$ and $2000\,mm$, so each undeployed inter-ring span is $L_{span} = 1000\,mm$. The two telescopic deployable mechanism have a stroke of $\Delta = 500\,mm$. The modularity preserves the frame spacing and fabric span relevant to deployment while excluding the floor, secondary softgoods and pressure. Lunar gravity is included in the multibody model. Table 4 summarizes the analysis chain. FEMAP selects geometry and dry restraint material; MATLAB generates consistent kinematics; the same kinematic family is prescribed in MSC Adams and LS-DYNA. Adams's actuator forces are evaluated rather than imposed back into LS-DYNA.

Table 4: Purpose and information flow of the three numerical models.

Model	Representation	Inputs	Outputs
FEMAP FE	Complete habitat	1 atm; material candidates	Static stress, displacement, selection
MSC Adams MBD	3 rings; 2 prismatic stages	Lunar gravity; prescribed q(t)	Joint force, work, power
LS-DYNA FE	Dry Kevlar cylindrical span	Large motion; nonlinear table	u, strain, energy, affected area

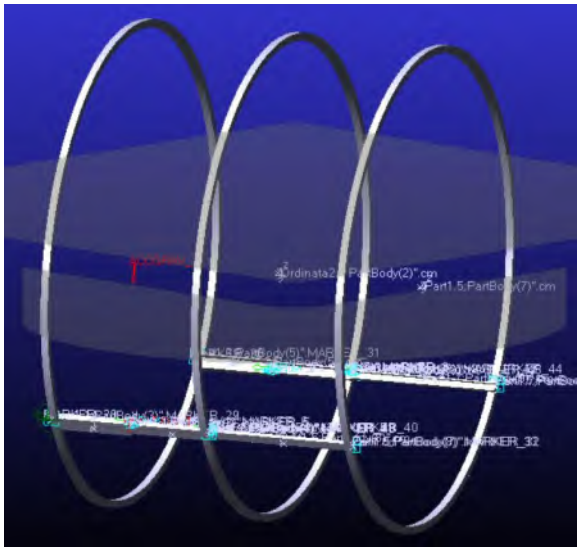

Figure 2: MSC Adams habitat's modularity with three frames and the telescopic guide system.

3 PRESCRIBED DEPLOYMENT KINEMATICS

3.1 Motion laws

For each stage, normalized time is $s = \tau/T_{loc}$ on $0 \le s \le 1$ and closure is $q = \Delta f(s)$. Three laws are screened: linear, half-cosine and quintic minimum jerk (QMJ). The QMJ polynomial is the standard zero-velocity, zero-acceleration endpoint trajectory [8].

$$f_{lin}(s) = s \tag{3}$$

$$f_{cos}(s) = \frac{[1-\cos(\pi s)]}{2} \tag{4}$$

$$f_{QMJ}(s) = 10s^3 - 15s^4 + 6s^5 \tag{5}$$

$$q = \Delta f, \quad \dot{q} = (\Delta/T_{loc})f', \quad \ddot{q} = (\Delta/T_{loc}{}^2)f'' \tag{6}$$

For the linear law, the in-stroke velocity is constant but jumps instantaneously between zero and Δ/T_{loc} at the stroke boundaries. In an ideal analytical description, this velocity discontinuity produces impulsive endpoint acceleration; therefore, the linear law is retained only as a baseline. The half-cosine law has zero endpoint velocity, providing a continuous transition in position and velocity. However, its acceleration is finite and non-zero at both endpoints, so the trajectory is not acceleration-continuous when connected to a stationary phase. The QMJ law has both zero velocity and zero acceleration at the stroke boundaries. It therefore provides a C^2-continuous transition between motion and hold phases, avoiding artificial velocity or acceleration discontinuities in the flexible-structure analysis.

Table 5: Kinematic-law properties for a single 500-mm stroke.

Law	Endpoint velocity	Endpoint acceleration	Implication
Linear	jump	impulsive	Baseline only
Half-cosine	zero	non-zero	Smooth velocity
QMJ	zero	zero	C² transition

3.2 Strategies and timing criteria

Synchronized motion commands both stages simultaneously. Staged motion commands stage 1 inserts a stabilization pause of $0.10T_{loc}$ and then commands stage 2; opening reverses the order. The monitored absolute positions are $x_2 = x_{2,0} - d_2$ and $x_3 = x_{3,0} - d_1 - d_2$, with $x_{2,0} = 1000\,mm$ and $x_{3,0} = 2000\,mm$. Hence the distal ring accumulates both closures. The equal-global-time criteria, named *criterion A* imposes equal global closure/opening time; staged local strokes must therefore be faster. The equal-local-stroke-time criteria, named *criterion B* imposes equal local stroke time; staged motion then takes longer globally. A reference velocity of $10\,mm/s$ has been chosen as the upper limit; a consequent reference time of $240\,s$ has been used. Table 6 gives the resulting cycle durations.

Table 6: Timing definition for the 200-s reference analysis.

Crit.	Strategy	T_{loc} (s)	Pause (s)	Closure (s)	Cycle (s)
A	Staged	114.29	11.429	240	600
A	Sync.	240	0	240	600
B	Staged	240	24	504	1128
B	Sync.	240	0	240	600

Table 7: Peak local velocities and finite accelerations.

Case	Linear v (mm/s)	Cosine v (mm/s)	QMJ v (mm/s)	QMJ a (mm/s²)
A-staged	4.375	6.872	8.203	0.2210
A-sync.	2.083	3.272	3.906	0.0501
B-staged	2.083	3.272	3.906	0.0501
B-sync.	2.083	3.272	3.906	0.0501

Table 7 reports actuator-level quantities. During synchronized deployment, the distal-frame velocity and finite acceleration are twice the corresponding local actuator values because the distal position depends simultaneously on $d_1$and d_2. During staged deployment, only one actuator moves at a time, and the distal-frame kinematic quantities therefore coincide with the active local actuator values. The highest prescribed local actuator velocity is $8.2031\ mm/s$ for the staged QMJ case under Criterion A, which remains below the selected reference limit of $10\ mm/s$.

4 MULTIBODY ACTUATOR-DEMAND ANALYSIS

4.1 MSC Adams model and metrics

The three frames are modelled as rigid bodies connected by two actuated translational joints, representing the two telescopic deployment stages. The first joint controls the motion of the intermediate frame, whereas the second joint contributes to the motion of the distal frame. Since the distal frame is affected by both telescopic stages, its absolute displacement includes the contributions of both joint motions. The axial forces calculated at the two translational joints are used to evaluate the actuator demand. At each time step, the absolute joint forces are averaged and the maximum value reached during the complete simulation is defined as the peak mean absolute force. The mechanical power associated with joint j is calculated as:

$$P_j(t) = \mid F_j(t) \cdot \dot{q}_j(t) \mid \qquad (7)$$

where $F_j(t)$ is the axial joint force and $\dot{q}_j(t)$ is the corresponding actuator velocity. The total mechanical power is obtained by summing the contributions of the two joints. Its maximum value defines the peak total power, whereas the cumulative mechanical work corresponds to the area under the total power-time curve. Stage 2 consistently requires a higher force because it moves a larger equivalent mass and carries the contribution associated with the distal frame.

4.2 Force, work and power results

Tables 8 to10 report the Criterion-B values at the precision available from the MSC Adams postprocessing. The reductions are calculated relative to the synchronized case of the same law. Criterion A is intentionally not mixed into these tables because its global time budget is different at the actuator level.

Table 8: Peak mean absolute force at equal local stroke time (Criterion B).

Law	Sync. (N)	Staged (N)	Reduction
Linear	≈ 31	≈ 24	22.6%
Half-cosine	≈ 44	≈ 31	29.5%
QMJ	≈ 49	≈ 34	30.6%

Table 9: Cumulative mechanical work at equal local stroke time (Criterion B).

Law	Sync. (J)	Staged (J)	Reduction
Linear	≈ 56	≈ 39	30.4%
Half-cosine	≈ 65	≈ 44	32.3%
QMJ	≈ 72	≈ 48	33.3%

Table 10: Peak total mechanical power at equal local stroke time (Criterion B).

Law	Sync. (W)	Staged (W)	Reduction
Linear	≈ 0.117	≈ 0.048	59.0%
Half-cosine	≈ 0.260	≈ 0.101	61.2%
QMJ	≈ 0.350	≈ 0.131	62.6%

At equal local time, staging reduces all the three actuation metrics. The power reduction is the largest $(59 - 63\%)$ because simultaneous motion superposes the power demand of both stages. Within either strategy, QMJ has the largest peak power for the selected duration. Thus, an endpoint-smooth trajectory protects the flexible model from kinematic discontinuities but is not automatically the lowest-power command.

5 NONLINEAR MEMBRANE ANALYSIS IN LS-DYNA

5.1 Dry-fabric model and convergence

The LS-DYNA model uses (i) dry Kevlar K300T2 for the cylindrical fabric segment and (ii) frame-driven boundary motion. Large deformation is enabled and the woven restraint response is introduced through a tabulated nonlinear orthotropic law. Independent tests on Kevlar 49 fabric show nonlinear, direction-dependent tension, strain-dependent transverse contraction and nonlinear in-plane shear [7], supporting a tabulated fabric representation rather than a single isotropic

modulus. The stress-strain curve for the fabric material has been added in the solve. Maximum transverse displacement $u_\perp$ is used as a global convergence indicator for the mesh sensitivity analysis. For time sample k and a small denominator regularization δ, the relative difference between two meshes i and j is $\frac{100|u_{\perp i}-u_{\perp j}|}{max(|u_{\perp j}|,\delta)}$. Table 11 shows the mean and maximum error of the mesh sensitivity analysis.

Table 11: Mesh-convergence statistics for maximum transverse displacement.

Mesh pair	Elems. i	Elems. j	Mean error	Max. error
1 → 2	127500	255000	6.4%	15.9%
2 → 3	255000	582500	0.8%	5.5%

5.2 Closure ratio and membrane-response metric

The imposed closure is normalized by the undeployed inter-ring span, $r = \Delta/L_{span}$. Here $\Delta = 500\,mm$ and $L_{span} = 1000\,mm$ at the beginning of the maneuver. Across the screened configurations, maximum transverse deflection rises rapidly at low r and then approaches a lower-sensitivity regime. This trend is represented phenomenologically by Eq. 8; in order to interpret the response.

$$w(r) = w_\infty[1 - exp(-kr)] \quad (8)$$

The final configurations are additionally compared through an affected-area indicator. In LS-PrePost, elements satisfying the same transverse-displacement selection operation are activated and their current surface area A_{aff} is measured. With the nominal cylinder lateral area $A_0 = 2\pi RL = 20.106\,m^2$, the percentage is

$$\eta_{aff} = 100\,A_{aff}/A_0 \quad (9)$$

This definition quantifies the selected affected surface, not wrinkle wavelength or amplitude, and remains dependent on the displacement threshold. It is therefore reported as a comparative indicator using an identical selection for the synchronized and staged cases.

Table 12: Final affected area for QMJ deployment under Criterion B.

Strategy	A_{aff} (m²)	η_{aff}	Change vs sync.
Sync.	2.98724	14.857%	Baseline
Staged	1.91557	9.527%	−35.87%

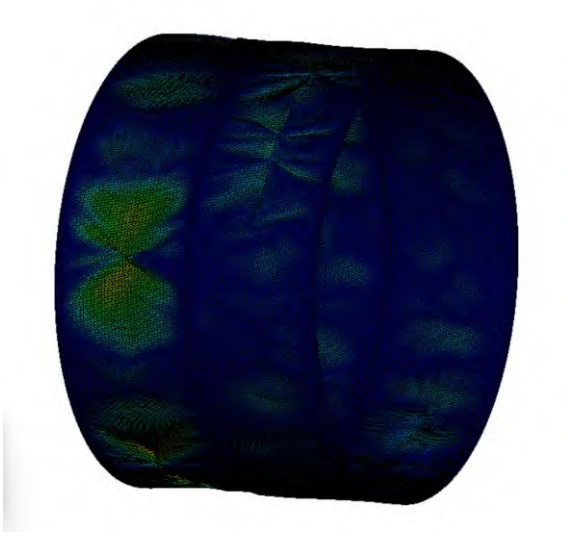

Figure 3: Final QMJ synchronized configuration under Criterion B; contours display transverse YZ displacement ($u_\perp$).

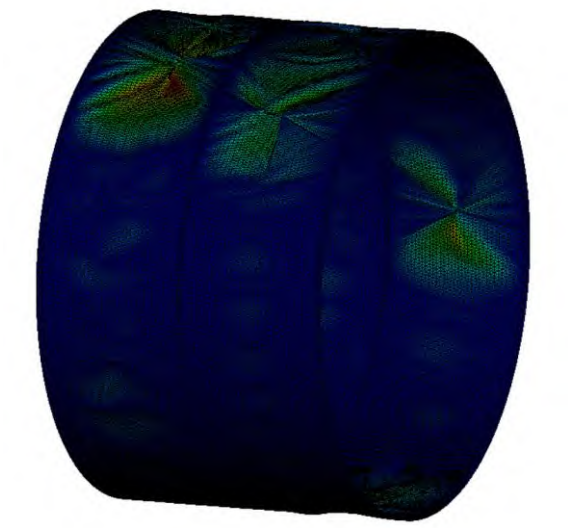

Figure 4: Final QMJ staged configuration under Criterion B; contours display transverse YZ displacement ($u_\perp$).

Sequential QMJ motion reduces the selected affected area from $2.987\,m^2$ to $1.916\,m^2$, i.e. the 35.87% in relation to the synchronized deployment. The result is consistent with reduced simultaneous forcing and with the staged redistribution of slack; it does not by itself establish a reduction in local peak strain.

6 DISCUSSION AND CONCLUSION

The combined FEMAP/MSC Adams/LS-DYNA methodology separates three complementary aspects of the habitat design. FEMAP establishes the full-structure static baseline and supports the

selection of dry woven Kevlar K300T2. MSC Adams evaluates the forces, work and power required by the telescopic deployable mechanism while LS-DYNA captures the geometric and material nonlinearities of the unpressurized fabric during deployment. The results show that the advantage of staged deployment depends on the adopted timing criterion. Under Criterion B, where both strategies have the same local stroke time, staging reduces peak mean absolute force from 22.6% to 30.6%, cumulative mechanical work from 30.4% to 33.3% and peak power from 59% to 63%. For the QMJ law, the affected membrane area also decreases from 14.857% to 9.527% of the nominal lateral area. However, the staged close-hold-open cycle increases from $600\,s$ to $1128\,s$. Under Criterion A, the same global duration requires the staged local stroke to be completed in $114.29\,s$, increasing its kinematic severity. QMJ remains the preferred law for nonlinear membrane analysis because its velocity and acceleration vanish at the motion boundaries, although it does not provide the lowest peak power at fixed duration. Future work will focus on manufacturing a scaled prototype of the aforementioned habitat's modularity. The prototype will be used to reproduce the staged and synchronized deployment sequences and experimentally measure joint forces, ring motion and fabric deformation. These tests will validate the interaction between prescribed kinematics and nonlinear structural dynamics before extending the analysis to the complete pressurized habitat.

Solar Array, Deployable Structure, Deployable Boom, CTM, Flexible Blanket Solar Array

ABSTRACT

A design trade study on a deployable solar array is presented. The array consists of a rollable boom and a flexible, rollable blanket, allowing even large arrays to be stowed in a compact volume. Based on a functional demonstrator that has been tested during a parabolic flight campaign, the flight model is currently being designed. However, major design decisions regarding configuration and architecture still need to be finalized. Therefore, a design tool is developed that allows detailed trade studies to assess the performance impact of specific design decisions in terms of power per mass and power per volume.

The tool employs an analytical approximation of the stiffness and stability of the boom based on non-linear FEA results. To assess volume, mass, and mass distribution, appropriate scaling laws are formulated for each component. The trade study is performed over a power range of 0.5 kW to 20 kW per wing and investigates, among other aspects, the deployment configuration, number of booms, and type of photovoltaic technology.

Analysis of the trade study results shows that, in the low-power region, the lower limits in the component scaling laws have a strong impact on array performance. In the high-power region, mass-related performance remains at a high level. However, maintaining high volume-related performance at high power levels is found to be challenging. Increasing the number of booms and carefully defining stability requirements are found to be effective means of improving this performance metric.

1. INTRODUCTION & PREVIOUS WORK

DLR has developed a deployable solar array [1] based on its rollable boom technology (see Figure 1) which originates from previous solar sail developments. The array is a so called flexible blanket solar array (see Figure 2) which uses a flexible sheet as the carrier of the photovoltaic (PV) cells. As boom and blanket are both rollable, even large arrays can be stowed within a compact form for space transport thus enabling high-power applications even with strong payload volume limitations.

Figure 1: DLR's rollable boom technology.

The main components of the solar array are the boom, the boom deployment mechanism, a spreader bar at the tip, the flexible blanket and a roller core. The roller-core allows stowage of the blanket. The deployment mechanism of the boom also drives the entire array deployment. A special feature is that it is also retractable to its stowed form wherefore frequent deployment-retraction-cycles are enabled.

Figure 2: Single and double wing array configuration with one central boom.

The solar array is a modular design that allows several variants that differ in configuration and architecture. From the same deployment mechanism and roller-core either one or two wings can be unfolded. Also, the number of booms can be altered and deployment can be conducted from the root and the tip.

A functional demonstrator of the solar array has been built and tested on ground as well as in zero-g during a parabolic flight campaign [2] (see Figure 3). During the test, repeated extension and retraction cycles of a double-wing configuration were demonstrated and no functional or behavioural anomalies were observed.

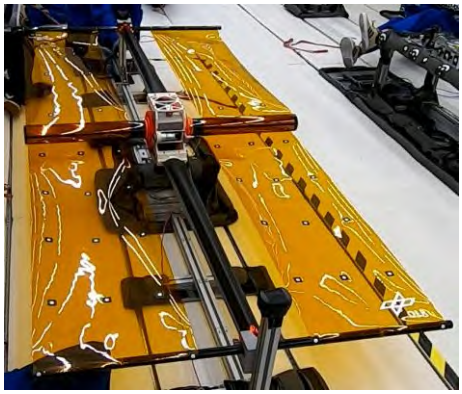

Figure 3: Double wing solar array demonstrator during a parabolic flight campaign.

2. MOTIVATION & AIM

The next step in the development of the solar array is the design of the flight hardware (see Figure 4). Its baseline design features a single mast with two blankets to its sides that are deployed from the root. Thereby, heavy parts such as the roller-core remain close to the spacecraft interface and the single boom and deployment mechanism reduces complexity.

Figure 4: CAD-images of the current baseline solar array design.

Although a baseline design is selected, major design decisions like the array configuration and architecture are not yet finalized as their impact on the array performance are not well understood. For this purpose, a design tool is established that allows quantification of specific design decisions in terms of the two main performance metrics of a solar array which are power per mass (in W/kg) and power per stowed volume (in W/m³).

3. SOLAR ARRAY DESIGN TOOL

The design tool was developed for use in the preliminary design phase. Consequently, the level of detail is limited to a practical level, in which only those components are considered in the underlying model that are significant in terms of volume, mass, and mass distribution. These components are the boom as the main load carrying structure, the blanket, spreader bar, roller-core, deployment mechanism and the spacecraft interface.

3.1. Solar Array Model

The underlying solar array model of the design tool consist of a structural model of the boom as well as mass and volume models of the main components. The array is sized to comply with two design constraints which are the deployed fundamental frequency f_{req} of the array and the resistance against a lateral acceleration load a_{req} given by equations (1) and (2):

$$f_0 > f_{req} \quad (1)$$

$$a_{crit} > a_{req} \quad (2)$$

The constraint functions impose certain loads on the boom. To comply with the fundamental frequency requirement the flexible blanket needs to be set under tension which induces a compression load P in the boom. The lateral acceleration induces lateral loads in the boom. If the boom mass is small in comparison to the other components, the lateral acceleration results mainly in a lateral tip load Q.

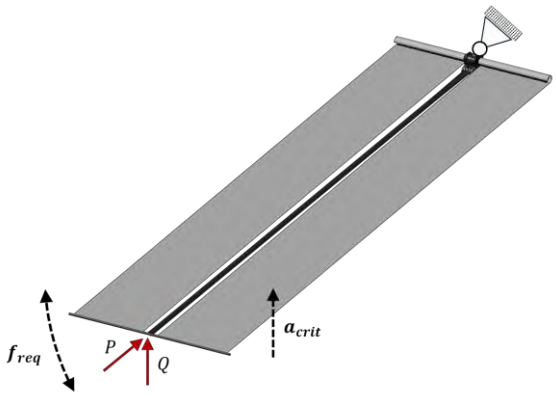

Figure 5: Solar array design requirements and corresponding boom laoding for a root deployment configuration.

The loads P and Q resulting from the dynamic requirements f_{req} and a_{req} depend on the component masses and the mass distribution throughout the array. However, these in turn depend on the boom sizing results, wherefore sizing of the array is done numerically.

3.2. Boom Stability Approximation

The boom is the main load carrying component in the deployed state and is sized according to the applied load set (P,Q). To simplify the sizing process the boom is approximated as a thin-walled tube of radius R and wall thickness t (see Figure 6).

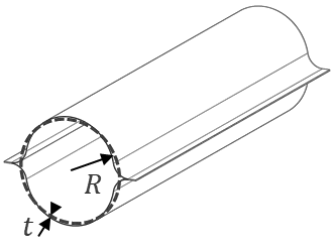

Figure 6: Approximation of the boom cross-section.

For a thin-walled ($t \ll R$), slender ($R \ll L$) tube subjected to compression and lateral force bending the failure mechanisms to be considered are global column and local shell buckling as well as cross-sectional collapse. An approximation of the boom stability behaviour is required for the design tool. The approximation is done on the basis of finite element analysis (FEA) results. It is found that within the considered slenderness and wall-thickness ratios the main failure mechanisms to be considered are global column buckling and cross-sectional collapse. Hence, the approximation needs to consider the interaction of both depending on the applied load set (P,Q).

3.2.1. Cross-Sectional Collapse

Cross-sectional collapse of a slender cylinder under pure bending is described by Brazier [3]. The longitudinal stresses from the bending load result in a lateral component due to the curvature of the beam. This lateral component causes the cross-section to ovalize. Brazier gives an expression for the critical moment of an isotropic cylinder:

$$M_{Brazier} = \frac{2\sqrt{2}}{9} \frac{ERt^2}{\sqrt{1-\nu^2}} \qquad (3)$$

Although the type of loading and the boundary conditions differ, the failure mechanism also occurs for the cantilever beam under combined axial and lateral tip load (see Figure 7).

Figure 7: Deformed boom in a cantilever cofiguration wih axial and lateral tip lad and deformed cross-section.

The maximum ovalization occurs in some distance to the clamped root where deformation of the cross-section is restricted. The location remains constant with increasing load and bending deformation (see Figure 8 and Figure 9) but is sensitive towards the beam slenderness ratio L/R.

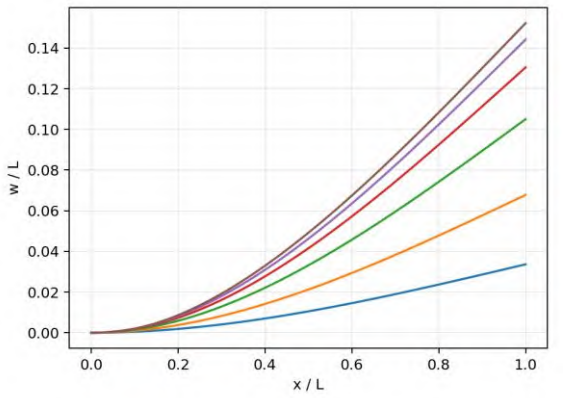

Figure 8: Displacement curves of the boom with increasing load.

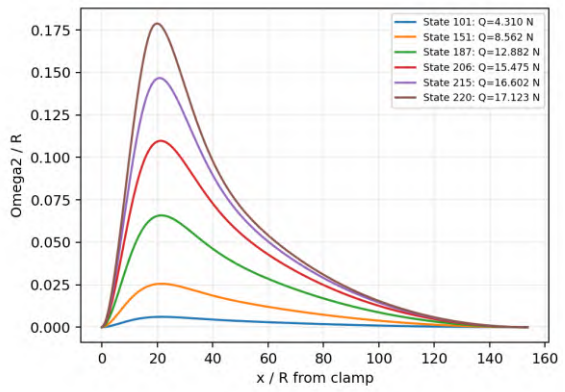

Figure 9: Ovalization profile over the boom length with increasing load.

However, in how far cross-sectional collapse or column buckling is the main failure mechanism depends on the ratio of compression P and lateral force bending Q.

3.2.2. P-Q-Interaction

A non-dimensional expression for the interaction of P and Q is established through approximation of FEA results. The non-dimensional form is achieved through formulation using the load ratios p and q:

$$p = \frac{P}{P_0} \qquad (4)$$

$$q = \frac{Q}{Q_0} \qquad (5)$$

Thereby, P_0 and Q_0 are the critical compression and lateral forces. The resulting interaction curve (see Figure 10) is derived for a slenderness ratio L/R of 154 and is approximated through the following bi-power-law:

$$p^{\alpha} + q^{\beta} = 1 \qquad (6)$$

The exponents are determined to $\alpha = 1.224$ and $\beta = 0.675$.

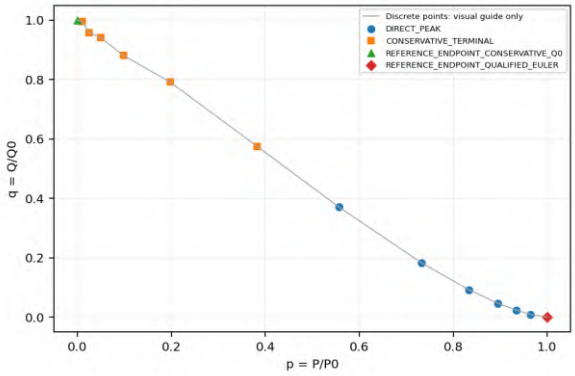

Figure 10: p-q-interaction curve based on FEA results.

The critical compression force P_0 is well described through Euler's expression for global column buckling:

$$P_0 = \frac{\pi^2 EI}{(2L)^2} \tag{7}$$

For calculation of the critical lateral force Q_0, it is found that the corresponding moment acting in the region with maximum ovalization is well described by Brazier's expression. However, as this maximum occurs in some distance to the clamping and this distance is sensitive towards the beam slenderness ratio L/R, a correction factor is introduced to enable the calculation of Q_0 based on Brazier's formula:

$$Q_0 = \frac{M_{Brazier}}{L}\left(1 + \frac{A_Q}{\frac{L}{R} + B_Q}\right) \tag{8}$$

The constants are determined to $A_Q = 25.495$ and $B_Q = 9.222$. Sensitivities are checked regarding influence of the slenderness ratio L/R and the wall thickness ratio t/R within certain intervals:

$$0.005 \leq \frac{t}{R} \leq 0.010 \tag{9}$$

$$51 \leq \frac{L}{R} \leq 307 \tag{10}$$

It is found that within these limits the interaction curve scales well with the boundaries P_0 and Q_0.

3.3. Component Scaling Laws

Scaling laws are formulated for the mass and volume of the array components. While the dimensions necessary to calculate the volume can mostly be derived based on the array size and the boom scaling result, this is not the case for the component masses. The latter is also relevant for accurate calculation of the boom loading as the component masses and the mass distribution throughout the array is required. The mass of a component m_j is derived using a power law based on a measured or calculated reference design:

$$m_j = \max\left(m_0, m_{ref}\prod_{i=1}^{n}\left(\left(\frac{X_i}{X_{i,ref}}\right)^{\alpha_i}\right)\right) \tag{11}$$

Thereby, m_0 is the lower scaling limit of the component, m_{ref} is the measured or calculated reference mass, the term $X_i/X_{i,ref}$ is the scaling term and the exponent α_i gives the scaling behaviour of X_i.
For the boom scaling is done through sizing regarding the applied loading. However, there are certain constraints which limit the design space. As the mast is stowed through elastic deformation the strain shall not exceed the region of elasticity during flattening and reeling. This is considered through a strain limit ε_{max}:

$$\varepsilon \leq \varepsilon_{max} \tag{12}$$

A lower scaling limit t_{min} is also set for the wall-thickness of the boom as availability and handling of very thin materials is limited:

$$t \geq t_{min} \tag{13}$$

A constraint similar to the strain limit is set to the wall-thickness ratio t/R of the boom. For small ratios local shell buckling becomes dominant which is not covered by the chosen boom stability approximation. For high ratios the strain during flattening becomes dominant, which would severely limit the available strain for reeling:

$$\left(\frac{t}{R}\right)_{min} \leq \frac{t}{R} \leq \left(\frac{t}{R}\right)_{max} \tag{14}$$

3.4. Design Tool Work Flow

The work flow of the design tool (see Figure 11) starts with reading the list of requirements and the study definition. This information is used to generate the initial mass and load values for the numerical sizing process. The results are the boom dimensions and a set of component mass and volume properties which in turn are used for the performance calculation of the overall array. Output is a list with all case results of the study definition.

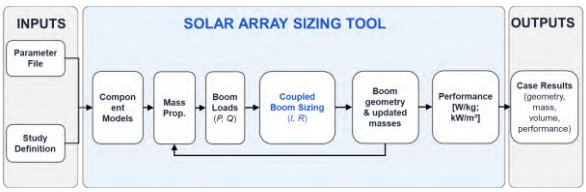

Figure 11: Design tool flow chart.

4. DESIGN TRADE STUDY

For the trade study several case studies have been defined. Within this paper the major design decisions in the early design process are addressed

as well as some sensitivities towards the design requirements. Addressed are the selection of the solar cell technology, the number of booms, the deployment configuration and the impact of the lateral acceleration requirement. For the discussion the solar array performance values in terms of power per mass in W/kg and power per volume in W/m³ is used. For calculation of the array mass the sum of all component masses is used. For calculation of the stowed array volume an envelope is defined. The width of the envelope corresponds to the array width, while the depth and height are determined by the largest dimensions of the components along those specific axes. In most cases, these dimensions correspond to those of the boom deployment mechanism. This approach of using an enclosing envelope for volume calculation ensures that the volume specifications are meaningful to engineers and mission planners.

4.1. Baseline Solar Array Performance

The results of the trade study are presented in reference to a baseline design. This baseline design is characterized as follows:

- PV-technology: Low cost, flexible Si-cells with 20% efficiency,
- Array architecture: Single, centrally aligned boom with two adjacent blankets,
- Deployment configuration: Root deployment,
- Design requirements:
    - Fundamental frequency $f_{req} = 0.1\text{Hz}$,
    - Lateral acceleration $a_{req} = 0.05\text{g}$.

The study is conducted over a power range per wing of 0.5kW to 20kW. The resulting mass specific performance of the baseline design (see Figure 12) shows a steep increase in the low power region with a pronounced peak of 285W/kg at 1.6kW. Hereafter the performance decreases but remains well above 200W/kg. The initial steep increase is a result of the lower scaling limits defined in the scaling laws. In this power region the minimum dimensions and mass properties are reached. The decline in the higher power region is a result of the increasing structural effort to support the large blanket.

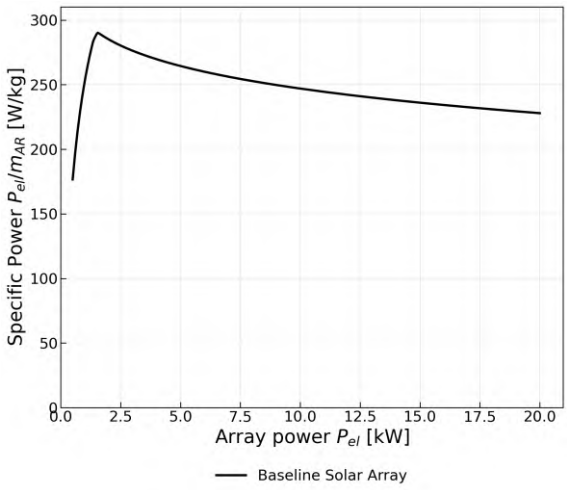

Figure 12: Mass specific performance of the baseline solar array plotted over array power.

The volume specific performance (see Figure 13) shows the same trend but even more pronounced. Initially a steep increase is observed with a peak at 44kW/m³ at 2.1kW. Afterwards the performance drops significantly with power to 13kW/m³ at 20kW. The initial increase is again a result of the lower, dimensional scaling limits. The decline in performance in the higher power region is primarily a result of the stowed boom dimensions and subsequently those of the boom deployment mechanism. The stowed array volume is driven by the largest component and regarding depth and height this component is the deployment mechanism. When the outer coiling diameter of the stowed boom increases, this also drives the deployment mechanism dimensions and thus stowed array volume.

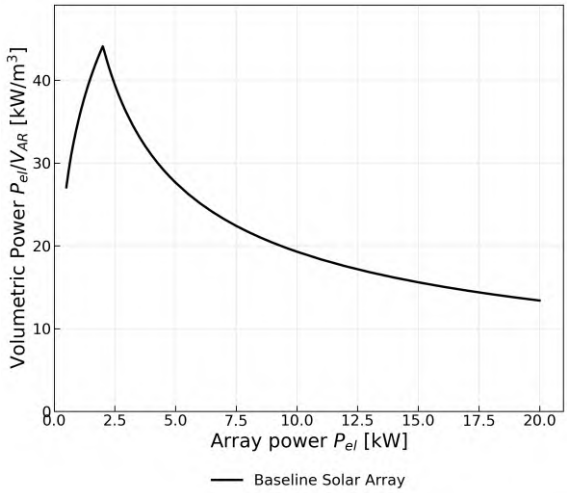

Figure 13: Volume specific performance of the baseline solar array plotted over array power.

In the following all trade study results are normalized by the according performance values of the baseline design and thereby given in non-dimensional form.

4.2. Solar Cell Technology

The solar cell technology is the driver for the blanket mass, minimum blanket reeling diameter and required array surface. In the trade study three types of solar cell technologies are compared:

- Flexible Si-cells with 20% efficiency, 150mm reeling diameter and 0.5kg/m² areal blanket mass,
- Rigid 3J-cells with 30% efficiency, 200mm reeling diameter and 1kg/m² areal blanket mass,
- Flexible Perowskit cells with 20% efficiency, 80mm reeling diameter and 0.2kg/m² areal blanket mass.

For Perowskit cells an optimistic assumption on performances available in the near future based on current data generated under laboratory conditions are considered.

The mass specific performance (see Figure 14) shows for state-of-the-art triple junction cells a decrease by 20% to 25% in comparison to the baseline design over the main part of the power interval. The higher performance reduces the required blanket surface area but the higher blanket mass is not sufficiently compensated.
The mass specific performance of the lightweight Perowskit blanket shows a strong increase in the small power region with a peak at almost 75% near 3kW. Hereafter, the gain in performance decreases slightly but still possesses a value of 59% at 20kW wing power. This strong increase in performance is the result of the lightweight blanket which in turn allows for a smaller boom and thereby less structural mass despite the larger surface area of the array. Hence, in terms of mass specific power a lightweight blanket promises significant gains in performance even when this comes with lower cell efficiency.

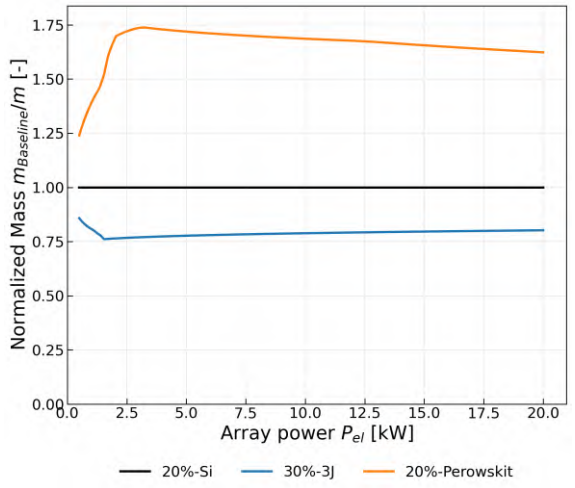

Figure 14: Mass specific performance for various cell technologies plotted over array power.

Looking at the volume specific performance (see Figure 15) the 3J-cells lead to a drop in performance by around 30% in the lower power region but to an increase of nearly 10% in the higher power region above 3kW. The initial decrease is caused by the in terms of stowage volume more severe lower scaling limits, particularly the higher initial reeling radius. However, above 3kW this restriction no longer applies and the increase in cell efficiency and thus reduced blanket surface area pays off.
The curve for the Perwoskit cell technology shows below 3kW a steep negative slope in the low power region with performances well above the baseline. This is again an interaction effect of the lower dimensional scaling limits, mainly the minimum reeling diameter. In the high-power region Perwoskit offers an increase in performance by 22% which is almost constant over the entire power range. This increase is a result of the low reeling diameter and also the low blanket thickness which adds less volume than the other two technologies.

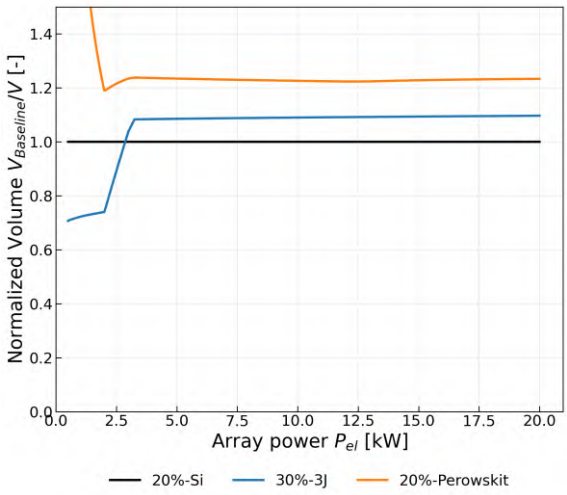

Figure 15: Volume specific performance for various cell technologies plotted over array power.

4.3. Number of Booms

The modular design of the array allows variation of the number of booms. However, adding one or more booms also adds complexity, increase in costs and differences in blanket segmentation. In the following the impacts of using 1, 2 and 3 booms on the array performance are studied.

The influence on the mass performance (see Figure 16) shows the same characteristic for 2 and 3 booms in comparison to the baseline with just a single boom. In the low power region below 3kW the added mass from the second and third boom and boom deployment mechanism significantly reduce performance. This results particularly from the lower mass scaling limits. However, above 3kW a moderate loss of 6 % to 8% for the 2-boom-architecture and of 8% to 12% for the 3-boom-architecture is visible.

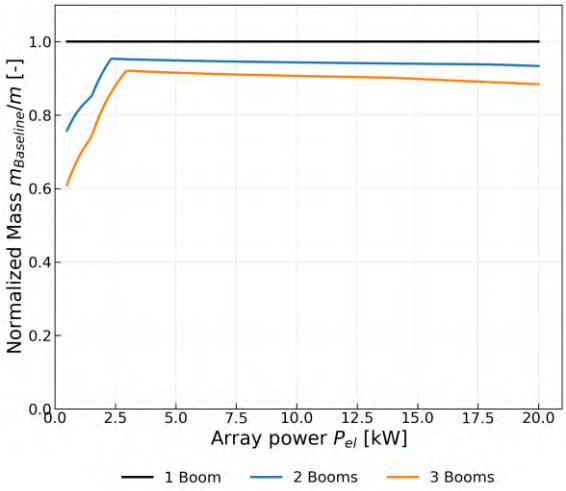

Figure 16: Mass specific performance for various numbers of booms plotted over array power.

The decrease in mass specific performance may be overcompensated through the gains in volume specific performance (see Figure 17). Below 2kW of array power slightly lower values are reached. Above a strong increase is observed culminating in an increase of 45% in case of the 2-boom-architecture and even 78% in case of the 3-boom-architecture. While again the smaller power region is dominated by the lower scaling limits of the boom and boom deployment mechanism, the reduction in individual boom loading pays off for higher power demands. As the load per boom is halved or even reduced to a third, smaller masts with lower wall-thickness can be used. These booms can be reeled more compactly which in turn reduces the depth and height of the array's stowage envelope and thus the overall stowed volume.

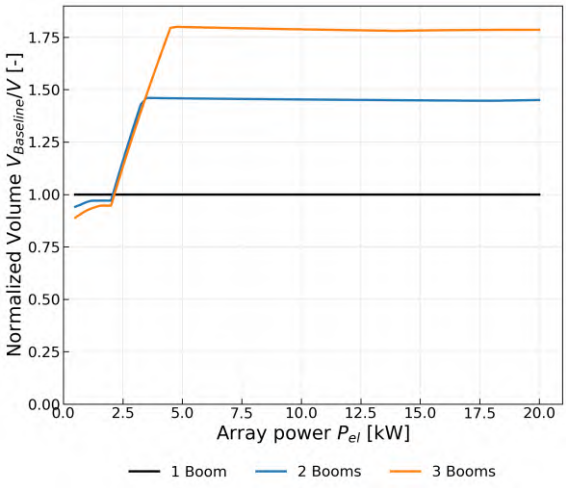

Figure 17: Volume specific performance for various numbers of booms plotted over array power.

Hence, increasing the number of booms adds mass, complexity and costs but is a very efficient measure to increase volume specific performance.

4.4. Deployment Configuration

Another major design decision is the deployment configuration whether a root or tip deployment shall be used. In the first case heavy components such as blanket roller core and deployment mechanism remain close to the spacecraft interface and do not contribute to the boom loading. On the other hand, in case of a tip deployment harnessing becomes less complex as getting power off the blanket is simplified as a continuous harness with rigid interface can be used.

The influence on the mass specific performance (see Figure 18) is significant. While the baseline design uses a root deployment the added mass at the boom tip when using a tip deployment becomes increasingly significant with higher power. While in the small power region a loss in performance of 15% to 20% is observed, this increases to more than 30% at 20kW of wing power.

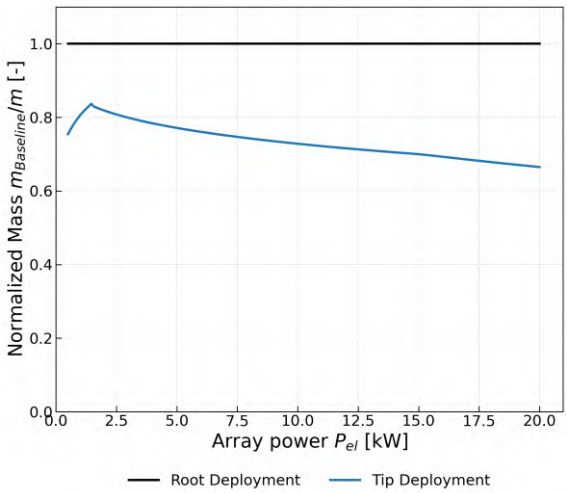

Figure 18: Mass specific performance for root and tip deployment plotted over array power.

The same behaviour is visible for the volume specific performance (see Figure 19). While in the small power region the losses are with 5% to 10% less pronounced, the loss at 20kW of wing power reaches again more than 30%.

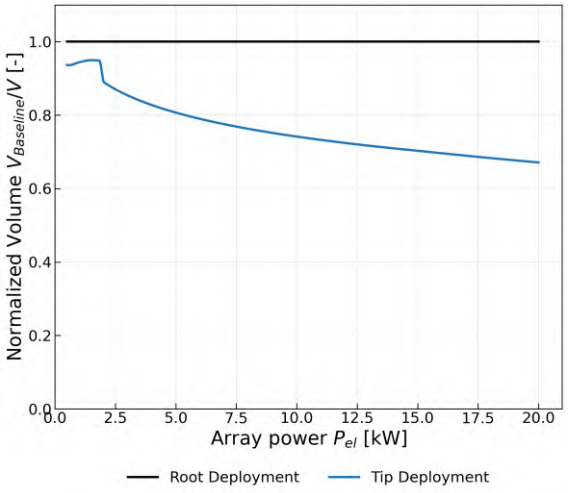

Figure 19: Volume specific performance for root and tip deployment plotted over array power.

Hence, the deployment configuration is a fundamental design decision. While for smaller arrays a tip deployment may be reasonable as the harness design and thereby array complexity and costs are reduced, for larger arrays a root deployment is advised.

4.5. Lateral Acceleration

Requirements are in general resulting from mission constraints. However, in some cases there is some influence on the requirement definition itself by tuning the mission design accordingly or introducing less demanding safety margins. In this case the sensitivity regarding lateral loads resulting from accelerations such as orbit correction or attitude control manoeuvres is studied. This is of particular interest for the presented solar array design as it features the ability to fully retract the array. Thereby, high load events can be avoided thus significantly reducing the constraints in the structural performance.

The baseline design considers a lateral acceleration of 0.05g. This is compared with acceleration requirements of 0.1g and 0.025g. In terms of array mass increasing the lateral acceleration requirement the array structure has to comply with leads to a loss in mass specific performance by 11% to 15% (see Figure 20). Lowering this requirement to 0.025g leads to a moderate increase in performance by 9% at around 3kW dropping to 7% at 20kW per wing.

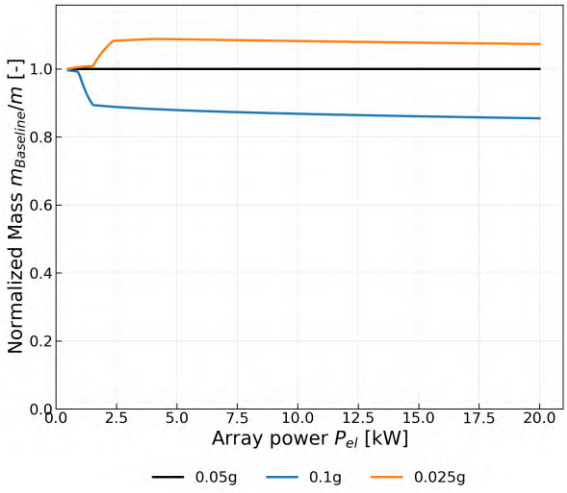

Figure 20: Mass specific performance for various lateral acceleration requirements plotted over array power.

Looking at the volume specific performance (see Figure 21) a significantly larger impact is observed. Increasing the acceleration loading to 0.1g, this causes a drop in performance by 36% to 38%. Lowering the same to 0.025g boosts volume specific performance by 55% at 3kW to 62% at 20kW of power per wing.

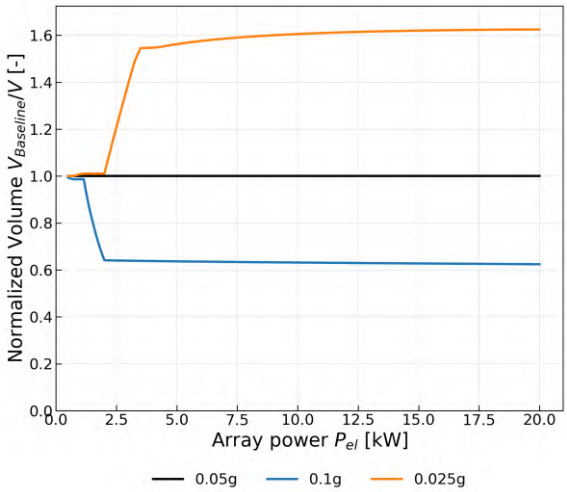

Figure 21: Volume specific performance for various lateral acceleration requirements plotted over array power.

Hence, carefully choosing the lateral acceleration requirement pays off especially in terms of volume specific power. Selecting an according mission design and less demanding margin policy are key factors to reduce array volume. In this regard, making use of the retraction capability of the presented array can generate significant volume savings.

5. CONCLUSION & OUTLOOK

A design tool to quantify the impact of the major design decision in the early design process of a

rollable solar array is developed. Based on this tool, a trade study regarding some of these decisions is conducted.
A major finding is that achieving high volume specific performance at power levels above 5kW per wing is a challenging design task that requires careful selection of array architecture, deployment configuration and mission driven design requirements. Especially, reducing the individual lateral boom load is an effective measure. This can be done either through increasing the number of booms, selecting a more favourable mass distribution through choosing a root deployment configuration or reducing the requirement regarding the lateral acceleration. The latter can effectively be addressed by making use of the retraction capability of the presented array design.
Major design drivers for the mass specific power are the photovoltaic technology and the deployment configuration. Selecting a PV-blanket with low areal mass is advantageous even when lower cell efficiency needs to be compensated through an increase in blanket surface area. Furthermore, it is found that the concentration of heavy components close to the spacecraft interface is beneficial. Therefore, a root deployment configuration is advised to minimize overall array mass particularly when aiming for high power levels per wing.

The presented results are based on the very first iteration of the solar array design tool. The trade study shows significant sensitivities in the small power region towards the component scaling limits. The same is true for the exponents in the scaling terms for the higher power region. Hence, further refinement of the scaling laws based on actual measurements on hardware or CAD-models is necessary to tune their accuracy.
Another update is necessary for the boom stability approximation. In this first design tool iteration, the p-q-interaction curve does not consider a follower force for the boom compression load. In a flexible blanket solar array, the compression load is always pointing in the direction of the boom root. This has a strong impact on the booms load carrying capability in compression which is not yet reflected in the tool and the results.

ABSTRACT

NanoMagSat is an ESA mission of the Scout program implemented with a constellation of three 16U nanosatellite, leveraging on the heritage of the ESA Swarm mission, aimed at monitoring the Earth's magnetic field and ionospheric environment on low Earth orbit.

A 3meter deployable nonmagnetic boom is used to keep the magnetometers away from any magnetic interference coming from the satellite platform, once in orbit.

The boom has recently reached TRL6 and this paper presents the results of the Qualification Test Campaign recently completed, which included vibration, shock and functional tests.

The qualification of the Speed Control Device (SCD), a critical component which allows controlling the deployment speed of the boom, is also described within this paper.

1. MISSION

The NanoMagSat (NMS) mission consists of a constellation of three geomagnetic observation satellites, aimed at monitoring the Earth's magnetic field and ionospheric environment on low Earth orbit in an innovative way to guarantee a coverage of all local times within an unprecedented timeframe.

One of the satellites is in a polar orbit and the rest have the same inclination with a Right Ascension of the Ascending Node (RAAN) of 90 degrees.

Each satellite contains the following instruments to monitor Earth's magnetic field and ionosphere:

- Miniaturised Absolut Magnetometer (MAM) with two startrackers (STR) at the tip of the boom.
- High Frequency Magnetometer (HFM) located at the middle of the boom.
- A Langmuir mNLP probe to measure electron density.
- Dual frequency GNNSS receiver.

Figure 1: NanoMagSat inorbit simulated view

Currently the project is undergoing an implementation phase to qualify a first model in 2026 and manufacture a total of 3 flight models to be launched from 2027 onwards.

The project is led by Open Cosmos Ltd. and CEA-Leti, with the scientific contribution of IPGP.

2. BOOM DESIGN

The complete boom assembly (Figure 2 & Figure 3) consists of the boom itself and the optical bench at the top, which includes the STR support. Payloads include the MAM, the HFM and two STR.

Metallic harness containers are also necessary to stow the different harness in stowed configuration.

A Speed Control Device (SCD) is located at the bottom of the boom assembly to control de boom deployment speed.

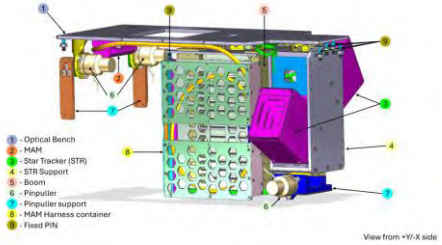

Figure 2: Boom assy. in stowed config. (view A)

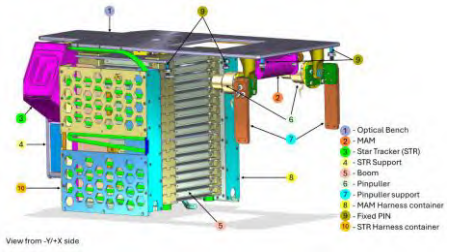

Figure 3: Boom assy. in stowed config. (view B)

In stowed configuration (Figure 4), the complete boom assembly fits within the 16U platform. A set of pinpullers are used to maintain the stowed position before deployment. The total height of the assembly in stowed configuration including the optical bench is 255 mm.

Figure 4: Stowed configuration

When deployed (Figure 5), the total height including the optical bench is 3017 mm, with the MAM located 2904 mm away from the platform reference system, which is the main objective of the boom, to separate as much as possible the MAM from any magnetic source coming from the satellite platform. Thus, a compaction ratio of 12 is accomplished.

The margin of motorization achieved is 2.2, obtained following ECSS standards and based on the measurements obtained during several deployment tests performed.

The following table includes the mass of the main boom assembly components:

Table 1: Mass breakdown

Component	Mass (kg)
Boom	3.26
Optical Bench	1.33
SCD (including HFM harness container)	0.68
MAM and STR harness containers	0.78
Interfaces	0.69
Harnesses	0.77

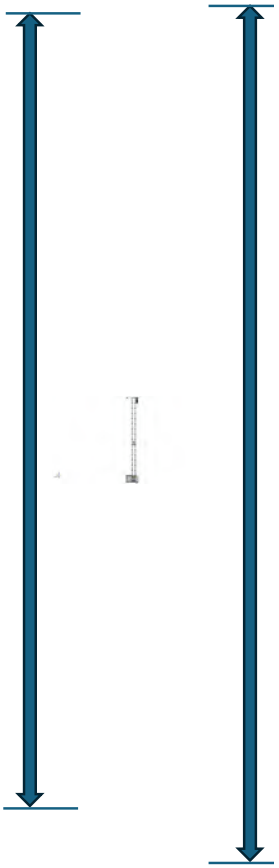

Figure 5: Deployed configuration

The boom consists of different modules joined through mechanical joints including torsion springs, which produce the boom deployment in a passive way. The final height of the deployed boom might then be easily adaptable to other mission requirements and applications.

The main parts of the boom: longerons and platforms are made of CFRP and the brackets and axis connecting the different elements are made of aluminium and titanium.

One of the most challenging mission requirements to accomplish is the thermoelastic stability of the optical bench. The relative position between MAM and STR accommodated at the optical bench has to be totally controlled and stable along the different orbit phases. To accomplish with this critical requirement, thermal stable materials are used as much as possible and the connection between the boom, optical bench and STR support has been

defined by means of elastic connections, to decouple as much as possible the thermoelastic deformations of the connected parts. Thermal and thermoelastic analyses have been performed to simulate the inorbit real behaviour and guarantee the fulfilment of the requirement.

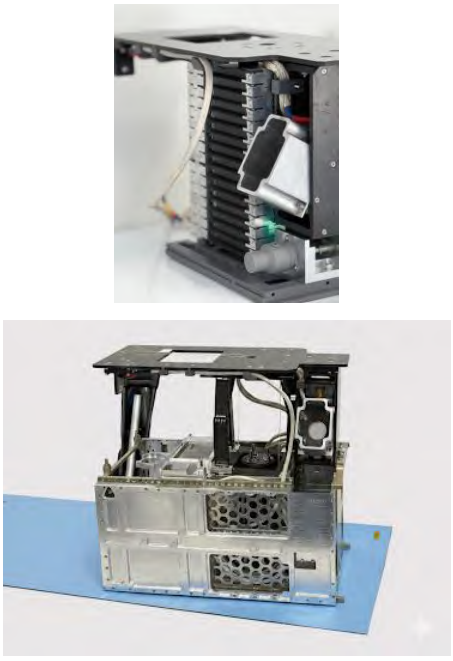

Figure 6: Boom assembly images

3. BOOM TEST CAMPAIGNS

Different test campaigns have been already performed through the different project phases since 2023.

- October 2023: when some resistance tests from loads envelope for quasistatic, sine, random vibration and shock were performed at room temperature. No damage was observedand all subsequent deployments were successful.
- March 2024: deployment tests after implementing some improvements on harness stowage, with successful results.
- October 2024: successful deployment tests including flight interfaces through pinpullers and the SCD.

3.1. Modal Test

As part of a previous consolidation phase, a modal test was performed on the boom Engineering Model in deployed configuration.

The boom was clamped at its base and the test was performed using the impact hammer method, with an accelerometer located at the upper module.

A first frequency of 1.03 Hz was obtained.

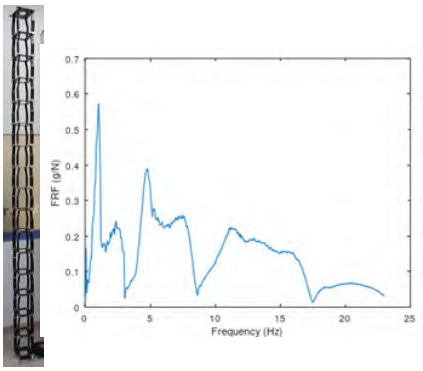

Figure 7: Boom modal test results

3.2. Qualification Test Campaign

As part of the qualification test campaign performed during 2026, a set of vibration and shock tests was performed. The boom assembly was tested within a NanoMagSat satellite platform, together with other satellite components.

3.2.1. Vibration Test

The satellite was housed inside an Exolaunch Exopod Nova test pod, fixed to an electromechanical shaker table and vibrated according to test specification.

A set of triaxial accelerometers were installed at different positions on the platform and boom assembly (see Figure 8).

Random vibration tests were performed in the three axis X, Y and Z independently in the range 52000 Hz.

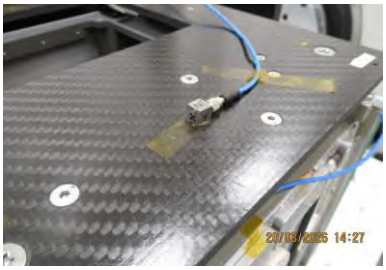

Figure 8: Accelerometers installation

Sine resonance search at 0.25 g were performed before and after each axis test and between each test level.

Random vibration test levels and durations were defined taking into account the envelope of the preselected launchers (potential candidates for NMS mission).

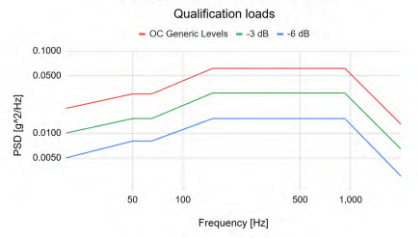

Figure 9: Random vibration levels

The test success criteria defined for the boom assembly was to achieve a complete boom deployment after vibration tests in all directions. This was successfully accomplished in March 2026, so the boom assembly was considered qualified and the TRL6 achieved.

Figure 10: Successful deployment after vibration test

3.2.2.Shock Test

Shock tests were performed at Surrey Space Centre facilities in Guildford, UK.

Figure 11: Shock test

Shock test levels applied are shown below, defined from the envelope of the preselected launchers (potential candidates for NMS mission).

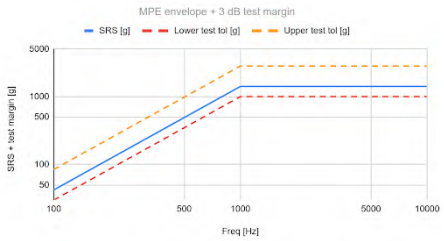

Figure 12: Shock levels

The test success criteria defined for the boom assembly was to achieve a complete boom deployment after shock tests. This was successfully accomplished in May 2026, so the boom assembly was considered qualified.

4. SCD QUALIFICATION TEST CAMPAIGN

The deployment of the boom depends on the elastic energy stored by the torsion springs installed along the boom articulations (passive deployment). Therefore, to prevent a sudden deployment a device to control and reduce the speed to the allowable value is necessary. This function is performed by the Speed Control Device (SCD), designed and developed specifically for this mission.

Figure 13: SCD and deployment test jig

The SCD operation is based on a control cable wound inside the SCD and connected to the boom, that is released with a constant and controlled speed.

A dedicated Qualification Test Campaign was recently performed on the SCD alone, in July 2026.

The test campaign consisted of a set of functional tests at room and cold temperature, vibration tests at qualification load levels, thermal cycling, bakeout and functional tests in TVAC conditions.

- Room temperature: 24ºC
- Cold temperature: 5ºC
- Thermal cycling from 6 ºC to 47.5ºC
- Bakeout at 60ºC and 10^4 torr.
- TVAC: 0°C, 24°C, 47.5°C and 10^4 torr.

The deployment speed can be adapted to the mission requirements. For this mission, the following values were obtained: 42 mm/s at ambient conditions.

30 mm/s at 0ºC and vacuum conditions.

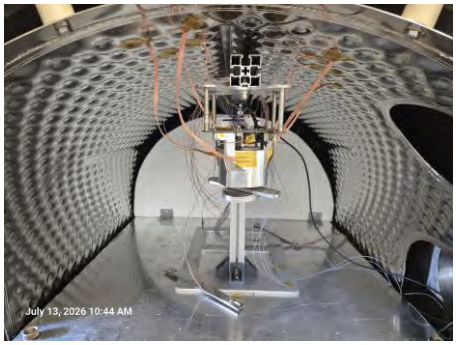

Figure 14: Installation of the SCD in TVAC

The functional test and the test success criteria is based on the control cable unwinding successfully, with constant and controlled speed.

All tests were completed successfully.

The SCD demonstrated good performance under lowtemperature and vacuum conditions, even up to 0ºC, despite the device was originally designed for a lower limit of 5ºC. No significant impact on performance was observed due to the vacuum environment, with results remaining comparable to those obtained under ambient conditions.

5. CONCLUSIONS

The design of the ultracompact deployable boom has been presented. The modular design allows to adapt the height of the boom to different missions and requirements with a very high compaction ratio of 12. The boom is nonmagnetic and the optical bench highly stable to thermoelastic deformations, as required for this specific mission.

Currently the boom assembly has successfully passed a Qualification Test Campaign, achieving a TRL6 and therefore, ready for integration into flight models, to be launched from 2027 onwards.

The critical device SCD to control the deployment speed has been also qualified for the mission.

6. ACKNOWLEDMENTS

The authors acknowledge the support of the European Space Agency (ESA) under the SCOUT program and members of the Consortium working on the NanoMagSat mission.

DEVELOPMENT OF THE BISTABLE ASYMMETRIC COLLAPSIBLE MASTS FOR ROLL-OUT MECHANISM

Roll-out Mechanism, Bistability, Asymmetric cross-section

ABSTRACT

Passive roll-out deployment requires collapsible tubular masts (CTMs) that remain stable in both deployed and coiled configurations. This study develops an asymmetric collapsible tubular mast (ACTM) to improve bistability and stowage compactness. The effects of the inner-shell radius on the bistability parameter and predicted coiled diameter are evaluated analytically. Relative to a symmetric CTM, the selected asymmetric configuration is predicted to exhibit a higher bistability parameter and a smaller coiled diameter. A fabricated ACTM maintains both stable configurations without an additional locking device. Its free-deployment behavior is investigated through numerical simulations and experiments and compared with that of the symmetric CTM. Finally, a guided roll-out mechanism incorporating a spindle guide and an outlet roller is developed to regulate boom release and prevent premature unwinding. These results demonstrate the feasibility of the ACTM and guided mechanism for compact, passive roll-out deployment.

1. INTRODUCTION

Collapsible Tubular Masts (CTMs) are attractive for deployable space structures because they provide high stiffness in the deployed configuration while allowing compact coiled stowage. For passive roll-out applications, bistable CTMs are particularly advantageous because both the deployed and coiled configurations correspond to stable equilibrium states. If bistability is not achieved, additional components are required to maintain the stowed configuration and to enable deployment, which results in an increase in the overall system mass. Bistable behavior can be achieved by tailoring the laminate stacking sequence, constituent materials, and cross-sectional geometry. Bistable CTMs require less energy to maintain the stowed state and show more predictable self-deployment compared to monostable designs [1].

Guest and Pellegrino [2] proposed a two-parameter strain-energy formulation for predicting bistability in composite cylindrical shells. Lee and Fernandez [3] extended this framework to two-shelled deployable booms and demonstrated that variations in laminate stiffness and shell geometry, including asymmetric configurations, can induce bistability and alter the stable coiled diameter [1]. In practical systems such as the NEA Scout solar-sail deployer, long booms are stored in multiple wraps [4]. To account for the resulting variation in coiled radius along the boom length, Liu et al. [5] incorporated Archimedean spiral geometry into the analytical formulation. Other studies have investigated the mechanical characteristics, flattening, buckling, folding, and deployment-related instability of composite CTMs [6–12]. Collectively, these studies establish the analytical basis for predicting bistability and identify cross-sectional geometry as an important design variable.

This study develops a bistable Asymmetric Collapsible Tubular Mast (ACTM) for passive roll-out deployment. The effects of the inner shell radius on the bistability parameter and predicted coiled diameter are evaluated analytically. The free-deployment behavior of the developed ACTM is then investigated through numerical simulations and experiments and compared with that of a symmetric CTM to determine the effect of ACTM on blossoming behavior. Finally, a guided roll-out mechanism incorporating a spindle guide and an outlet roller is developed to control the release of the coiled boom.

2. BISTABLE ASSESSMENT OF CTM

2.1. Geometry design

In the coiled configuration, the shell closer to the spindle is designated as the inner shell, whereas the shell farther from the spindle is designated as the outer shell. The subscripts (i) and (o) therefore refer to the inner and outer shells, respectively. Each shell consists of a central arc segment, denoted by subscript 1, and an edge arc segment, denoted by subscript 2. Accordingly, (r_{o1}) and (α_{o1}) represent the radius and subtended angle of the outer-shell central segment, while (r_{o2}) and (α_{o2}) represent those of the outer-shell edge segment. The corresponding geometric parameters of the inner shell are denoted by (r_{i1}), (α_{i1}), (r_{i2}), and (α_{i2}), as shown in Fig. 1. The outer-shell geometry of the ACTM and the web width (w) are defined as summarized in Tab. 1.

When the ACTM is fully flattened, each shell

forms a planar strip. The flattened lengths of the inner and outer shells are given by Eq. 1.

$$h_{i,o} = 2\left(L_{i,o1} + L_{i,o2} + w\right) \tag{1}$$

The arc lengths of the central and edge segments are defined by Eq. 2 and Eq. 3, respectively.

$$L_{i,o1} = r_{i,o1}\alpha_{i,o1} \tag{2}$$

$$L_{i,o2} = r_{i,o2}\alpha_{i,o2} \tag{3}$$

Geometric compatibility between the inner and outer shells must be maintained in both the deployed and flattened configurations. First, the flattened lengths of the two shells must be equal to prevent in-plane incompatibility during flattening and coiling. This requirement gives the compatibility condition in Eq. 4.

$$2\left(r_{o1}\alpha_o + r_{o2}\alpha_o + w\right) = 2\left(r_{i1}\alpha_i + r_{i2}\alpha_i + w\right) \tag{4}$$

Second, the edges of the inner and outer shells forming the longitudinal webs must coincide in the deployed configuration to preserve continuity of the closed cross-section. This condition is expressed by Eq. 5.

$$r_{o1}\sin\left(\alpha_o\right) + r_{o2}\sin\left(\alpha_o\right) = r_{i1}\sin\left(\alpha_i\right) + r_{i2}\sin\left(\alpha_i\right) \tag{5}$$

From Eq. 4, the relationship between the subtended angles of the inner and outer shells is expressed by Eq. 6.

$$\alpha_o = \frac{r_{o1} + r_{o2}}{r_{i1} + r_{i2}}\alpha_i \tag{6}$$

Substituting Eq. 6 into Eq. 5 gives Eq. 7.

$$\left(r_{o1} + r_{o2}\right)\sin\left(\frac{r_{i1} + r_{i2}}{r_{o1} + r_{o2}}\alpha_i\right) = \left(r_{i1} + r_{i2}\right)\sin\left(\alpha_i\right) \tag{7}$$

Eq. 7 is satisfied when the sums of the curvature radii of the inner and outer shells are equal, resulting in the geometric compatibility condition given by Eq. 8.

$$r_{i1} + r_{i2} = r_{o1} + r_{o2} \tag{8}$$

Based on the geometric compatibility condition in Eq. 8, the inner-shell edge radius (r_{i2}) is varied while satisfying ($r_{i1} + r_{i2} = 20mm$ to introduce cross-sectional asymmetry. The bistability criterion (S) is used to determine whether the coiled configuration constitutes a stable second equilibrium state, with a positive value indicating bistability. The predicted coiled diameter ($\emptyset$) represents the diameter of the second stable configuration. As summarized in Tab. 2, the symmetric CTM has a bistability criterion (S) of 0.68 and a predicted coiled diameter of $40.43\ mm$. The corresponding ACTM results are summarized in Tab. 3. Case 1, Cases 2 and 3 satisfy the condition. Case 3 is selected because it has the largest bistability criterion while maintaining a smaller predicted coiled diameter than the symmetric CTM. The radii of the inner segments are selected such that their sum is $20\ mm$. The outer-segment parameters are set to the values listed in Tab. 1, and the width of the web connecting the upper and lower shells is fixed at $3\ mm$.

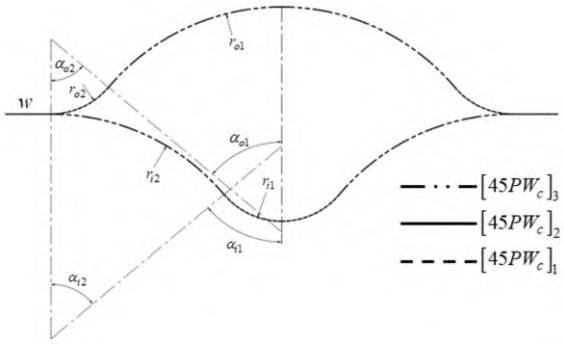

Figure 1: Coordinate geometry of the ACTM

w: Width of the web

To introduce geometric asymmetry, the radii of the outer and inner shells are intentionally defined to be different. Various geometric cases are investigated, as summarized in Tab. 3, to evaluate whether the bistable condition of the collapsible boom structure can be satisfied. When the inner-shell edge radius, fabrication becomes impractical because of the insufficient space available for web bonding. Therefore, larger values are not considered in this study.

2.2. Laminate design

The ACTM is fabricated from T300/E7 plain-weave prepreg. The corresponding mechanical properties, adopted from [13], are summarized in Tab. 4. After determining the cross-sectional geometry of the ACTM, the laminate stacking sequences are designed to achieve the required bistable behavior.

Table 4: Mechanical properties of T300/E7

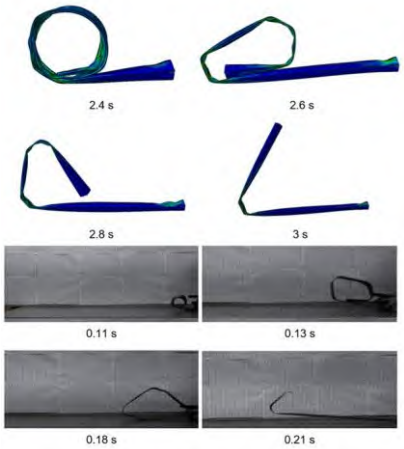
Properties	Value
Density $[kg/m^3]$	1760
Longitudinal Young's Modulus $[GPa]$	69
Transverse Young's Modulus $[GPa]$	69
Poisson's ratio	0.15
In-plane Shear Modulus $[GPa]$	3.3
Thickness $[mm]$	0.12

Different laminate stacking sequences are assigned to individual segments of the ACTM to tailor the bending-stiffness distribution and induce bistable behavior. Specifically, the laminate configuration $[45PW_c]_3$ is applied to segments that bend in the equal-sense bending relative to the initial transverse curvature. In contrast, segments experiencing bending in the opposite-sense bending are designed with reduced bending stiffness through ply drop implementation, resulting in the laminate configuration $[45PW_c]$ in those regions. This segment-wise stiffness tailoring enables controlled redistribution of bending rigidity between the shell segments, which plays a critical role in achieving bistable behavior in the collapsible boom with asymmetric cross-section. The web region connecting the two composite shells is formed by co-bonding the shells along the longitudinal web interface using the epoxy resin pre-impregnated in the prepreg, resulting in an effective laminate configuration of $[45PW_c]_2$. This co-bonded interface provides structural continuity between the inner and outer shells while maintaining sufficient compliance in the web region.

Based on the material properties of each ply and the corresponding stacking sequences, the equivalent laminate properties are evaluated using the Classical Lamination Theory (CLT). Furthermore, due to the symmetric laminate arrangement between the inner and outer shells, corresponding segments share identical stiffness characteristics. Based on these assumptions, the equivalent ABD matrices for the arc segments (segments 1 and 2) of the inner shell and the web region are computed.

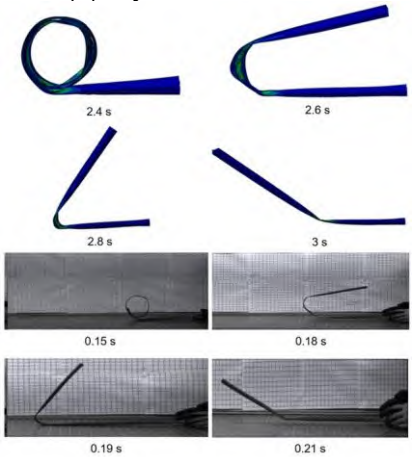
2.3 Experimental validation of bistability

The bistable behavior of the ACTM is confirmed. Both the deployed and coiled configurations remain stable without external force. The diameter of the coiled configuration is measured using a vernier caliper and found to be $50.49\ mm$, which is larger than the predicted value of $36.61\ mm$. The experimentally measured coiled diameter is therefore approximately $37.9\ \%$ greater than the analytical prediction. This difference is mainly attributed to manufacturing effects such as thickness variation of the laminate, increased local stiffness in the web region, geometric deviation during the molding process, residual stress generated during curing, and spring-back after demolding. Because the analytical model assumes an ideal geometry, a uniform laminate thickness, and perfect bonding, these fabrication-induced effects can result in a larger stable coiled diameter than predicted.



Although bistability provides two stable equilibrium states, it does not necessarily ensure stable deployment behavior. In practical deployment processes, dynamic instabilities such as blossoming may occur due to the rapid release of strain energy. Consequently, evaluation of deployment performance requires consideration of both static and dynamic stability. To investigate the effect of cross-sectional asymmetry on deployment behavior, a symmetric CTM is designed as a baseline configuration. The symmetric boom is constructed using identical upper and lower shell geometries, while the proposed boom employs an asymmetric cross-section obtained by introducing different radii in the inner and outer shell segments. Comparative free deployment analyses and experiments are conducted for asymmetric and symmetric configurations.

2.4 Free deployment experiments



To evaluate and validate the dynamic free-deployment behavior of the proposed structure, both experimental tests and numerical simulations using ABAQUS/Explicit are conducted, and the

resulting deployment sequences are compared (Fig. 2). The boom length used in the simulation is 600 mm, consisting of 5,474 nodes and 5,120 S4R shell elements. The simulation is carried out in four sequential stages: flattening, coiling, holding, and deployment.

A comparative analysis of the deployment sequences reveals a clear distinction in structural stability between the two configurations. For the symmetric configuration, both experimental observations and numerical results demonstrate that the coiled region rapidly expands after deployment initiation, leading to significant blossoming and loss of the initial coiled geometry. In contrast, the asymmetric configuration maintains its stable coiled geometry and releases the stored strain energy in a more controlled manner. These consistent qualitative trends indicate that the proposed asymmetric configuration reduces dynamic blossoming and provides a more controlled deployment response under the tested conditions.

(a) Symmetric cross-section

(b) Asymmetric cross-section

Figure 2: Free deployment analysis and experiments

2.5 Controlled deployment of asymmetric boom

To evaluate the controlled deployment behavior of the asymmetric boom, a deployment mechanism is fabricated, as shown in Fig. 3. The mechanism is configured to reproduce the boundary conditions employed in the numerical simulations and to enable controlled release of the boom from the coiled configuration.

Figure 3: Deployment device for the collapsible boom

An actuator briefly rotates the spindle to initiate the release of the coiled boom. After the initial release, no additional motor input is applied, and the boom deploys passively using the elastic strain energy stored during coiling. A guide installed around the spindle constrains the coiled boom and suppresses premature unwinding of the inner wraps. In addition, a roller positioned at the outlet flattens and guides the boom as it leaves the spindle. The guide and roller therefore control the release path during deployment without maintaining the static coiled equilibrium.

3 CONCLUSIONS

A bistable ACTM and a guided roll-out mechanism are developed for small-satellite deployment applications. Bistability is achieved by adjusting the inner-shell geometry and locally tailoring the laminate stacking sequences. The fabricated T300/E7 plain-weave prepreg ACTM maintains stable deployed and coiled configurations without an external locking device. Free-deployment simulations and experiments show that the ACTM maintains a more stable coiled shape and exhibits less pronounced blossoming than the symmetric CTM under the tested conditions. The guided roll-out mechanism incorporates a spindle guide and an outlet roller. The guide restricts premature unwinding of the inner wraps, whereas the roller controls the boom exit path. The results demonstrate the feasibility of integrating the

developed bistable ACTM with the guided roll-out mechanism for small-satellite applications.

ABSTRACT

The Twin ANthropogenic Greenhouse Gas Observers (TANGO) mission is a small satellite mission under the ESA Scout Programme tapping into NewSpace to quickly deliver affordable and innovative science, as part of ESA's FutureEO Programme, within a budget of 35M€ and a schedule of three years from mission kick-off to launch. It was kicked off in June 2025 and is planned to be launched in the middle of 2028, ready for operational service to start in Q4 2028.
TANGO aims to measure CO_2, CH_4 and NO_2 emissions at the level of individual facilities using two agile CubeSat platforms flying in close formation. Each 16U satellite carries a compact imaging spectrometer, with TANGO Carbon operating in the SWIR1 band for CO_2 and CH_4, and TANGO Nitro targeting NO_2 in the visible spectral range. To achieve the required optical performance within an 8U instrument envelope, both payloads employ freeform mirror optics, resulting in stringent mechanical and thermo-elastic stability requirements.

This paper discusses the mechanical and thermal design of the TANGO Nitro and Carbon instruments. Results of vibration testing on a Structural Thermal Mechanical (STM) representative model are discussed as well as stability measurements that were executed to assess the robustness of the instruments against severe vibration and shock loads.

1. INTRODUCTION

Accurate identification and quantification of anthropogenic greenhouse-gas emissions are important for understanding emission sources and supporting effective mitigation measures. The Twin ANthropogenic Greenhouse Gas Observers (TANGO) mission addresses this need by targeting carbon dioxide (CO_2), methane (CH_4), and nitrogen dioxide (NO_2) emissions at the scale of individual industrial facilities. The mission uses two agile CubeSats flying in close formation. One satellite carries the TANGO Carbon imaging spectrometer, operating in the short-wave infrared spectral range to measure CO_2 and CH_4, while the second carries the TANGO Nitro instrument, operating in the visible spectral range to measure NO_2. The combined observations provide complementary information for detecting emission plumes and attributing them to individual sources.
Both instruments build on the Spectrolite instrument family and on technologies developed for earlier Earth-observation instruments, including freeform mirrors, monolithic aluminium housings, opto-mechanical mounts, and damped struts. The instruments comprise a telescope and a spectrometer integrated into a stiff, box-shaped aluminium housing.

The mechanical coupling between the compact instrument, the CubeSat platform, and the launch deployer is complex design challenge. The instrument is suspended from the platform by six titanium struts incorporating passive damping. These struts must simultaneously provide sufficient launch stiffness, reduce the dynamic response transmitted to sensitive optical components, and provide conductive thermal isolation. Because the instrument represents a relatively large and stiff part of the satellite, its dynamic behaviour cannot be assessed reliably as an isolated, rigidly constrained subsystem. Verification therefore requires coupled structural modelling of the deployer, satellite platform, and instrument, complemented by testing at representative integration levels.

The thermal-mechanical development of the TANGO instruments follows an iterative Structural-

Thermal-Optical Performance (STOP) approach. Mechanical and thermal load cases are applied to finite-element and thermal models to calculate rigid-body motions and surface deformations of the optical components. These deformations are transferred to the optical model to determine their effect on instrument performance.

A dedicated Structural Thermal Model, subsequently upgraded to the STM configuration, supports the verification of the analysis and the representativeness of the instrument design. The STM includes a mechanically and thermally representative instrument housing, struts, optical-component dummies, mounts, interfaces, heaters, temperature sensors, and accelerometers. It has been integrated with the satellite structural model including satellite deployer and subjected to sine-burst (QSL), sine-vibration, random-vibration, shock, and thermal tests. The measurements are used to correlate the structural and thermal models, assess the damping behaviour of the struts, and derive local loads for critical equipment interfaces. Coordinate Measuring Machine (CMM) measurements performed before and after environmental testing provide an independent assessment of the positional stability of the installed optical elements relative to the instrument mechanical reference frame.

This paper describes the thermal-mechanical design and verification of the TANGO instruments. It first presents the principal mechanical and thermal design choices, including the aluminium housing, opto-mechanical mounts, damped struts, and active thermal-control concept. It then discusses the coupled structural analyses and the STOP methodology used to evaluate optical performance under mechanical and thermal loading. Finally, results from STM vibration, shock, thermal, and dimensional-stability measurements are presented and compared with the numerical predictions. Together, these activities demonstrate the followed combined analysis-and-test approach to verify the maturity of the TANGO instruments designs and their compliance to mechanical, thermal and stability requirements.

2. MECHANICAL DESIGN TANGO INSTRUMENT

Most of the design choices are based on TNO's heritage from the TANGO predecessor Spectrolite and other optical instruments like TROPOMI, Sentinel 5 (UV1 spectrometer and TSBOA telescopes).

The TANGO Nitro and Carbon instruments share an identical telescope design. Their spectrometers, however, differ slightly in layout and are equipped with different cameras. The tested STM model is a representative combination of both instruments: Carbon housing lay-out with a dummy Nitro camera attached to an adapter (see Figure 2-1 and Figure 2-2).

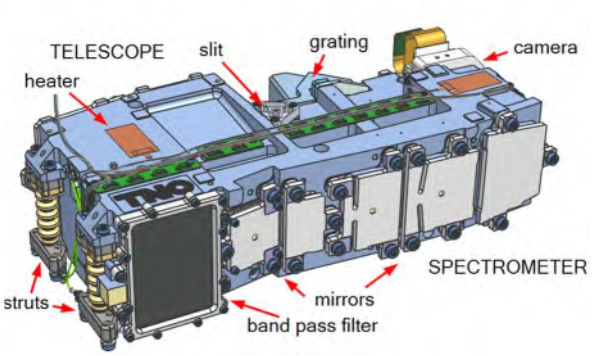

Figure 2-1 TANGO Carbon Instrument PDR design

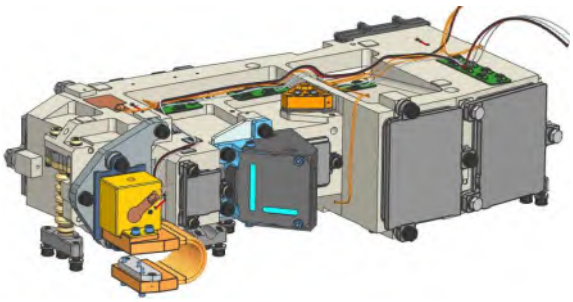

Figure 2-2 TANGO STM model (seen from the spectrometer side)

The housing is a box-shaped hollow structure with high stiffness and dimensional stability made from standard Aluminium (6082 T651). The Instrument contains two compartments: the Telescope and the Spectrometer. The milled internal chambers follow the optical light path with margin through the instrument. A stress-relief heat treatment is applied to minimize residual stresses.

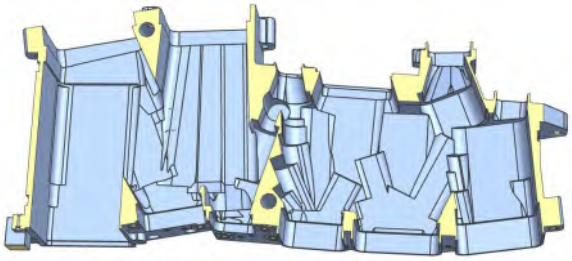

Figure 2-3 milled-out Instrument Housing (cross section)

The instrument is isostatically suspended by 6 orthogonal oriented damper struts. The damper struts, developed by TNO for the CubeCAT satellite 3], support the instrument and dampen the external vibration to the instrument.
The TNO Damper Strut contains an outer structure (the flexure) and an inner structure (the damper), both made by additive manufacturing from Laserform Ti Gr23 (A). The damper structure contains a dedicated rubber layer (SCVBR60)

which bears the shear loads. The rubber material is provided by the Dutch company ERIKS and is designed for applications where high precision and extreme cleanliness are demanded. The damper strut is 3D-printed, injection moulded, post milled and assembled with precise fittings and screws.
The axial stiffness of the flexure is carefully tuned by design and analyses to balance the stiffness ratio between the damper and the flexure. From numerical simulations the damping ratios of the rigid body modes of the TANGO instrument are predicted to be at least 7%.

The struts also provide a good thermal isolation: Analysis shows that the conduction of an individual strut is 1W/128K = 0.0078W/K. A cross-section CAD render of one of the damper struts is provided in Figure 2-4. The orange-coloured component represents the rubber material.

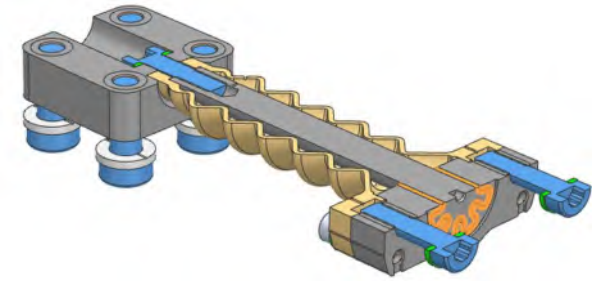

Figure 2-4 Damper struts

The instrument optical elements are bolted onto the housing on accurate pads with shims in between. The lateral position can be tuned +/- 0,5 mm by means of gauge blocks and reference features on the housing. Its position is fixated by the pre-loaded bolts.

The mirror consists of three segments: a body with the mirror surface at the front, a plate with mounting and aligning features at the back and a pedestal in between. It is able to handle structural and integration loads with little effect on the mirror surface shape. The enlarged plate at the back reduces the opening between the mirror and the housing, blocking external light. The mirror material is the same as for the housing.
The mirrors for this STM are coated with Surtec 650 and have no optical quality.

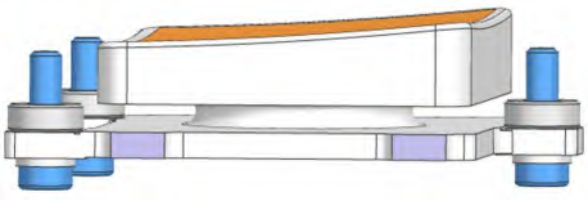

Figure 2-5 mushroom shaped telescope mirror

The grating is isostatically fixed via three flexures and glue spots to overcome the thermal expansion difference between the Fused Silica grating and the aluminium bracket.

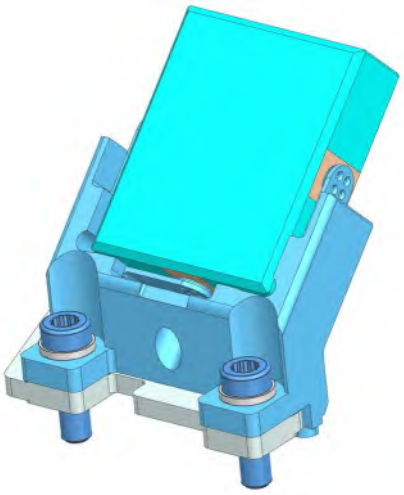

Figure 2-6 grating mount assembly of the TANGO Carbon Instrument

A coated Silica Bandpass / optical Filter is attached at the entrance of the Instrument. The filter is clamped within two frames with rubber in between. An accurate compression is set with use of shim rings.

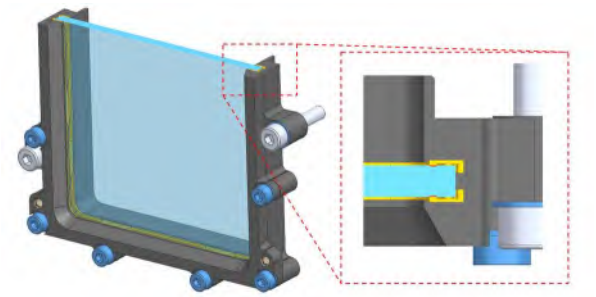

Figure 2-7 Band Pass Filter assembly (cross section)

A slit assembly is placed in between the Telescope and the Spectrometer compartment and functions as a field stop. The preliminary design consists of an etched silicon wafer containing the slit, mounted on an Invar carrier. The detailed design and manufacturing of the slit assembly are subcontracted to Fraunhofer IOF. For the STM vibration campaign, a representative dummy slit assembly was used. The measured responses were subsequently used to derive the vibration design loads for the slit assembly analyses.

A dummy camera assembly is attached to the housing that is structurally and thermally representative of the Nitro camera. An adapter was used to match the mechanical interfaces. A Camera back-end electronic box is attached behind the camera to the satellite frame.

3. THERMAL DESIGN

The both TANGO instruments operate in a thermally unstable environment. The effects of the orbit and the operation of surrounding platform electronics cause fluctuating thermal loads to the instrument. To mitigate these fluctuations, the instrument is thermally isolated from its environment. Conductive isolation is realized through the damped struts, Radiative isolation is achieved through a Surtec-650 coating, providing an effective emissivity of 0.12.
The heaters are distributed symmetrically along the instrument housing as shown in Figure 2-1.
The temperature of the instrument is controlled at the Thermal Reference Point, located at the geometrical center of the instrument housing.
Both TANGO instrument are equipped with a nominal and redundant heater circuit to maintain the instrument housing at a controlled temperature between 21 °C and 24 °C. The heating system consists of a series-connected heater chain comprising four Kapton heater pads manufactured by Zoppas Industries. Each heater pad has a nominal electrical resistance of 7.0 Ω and a surface area of 50 × 25 mm. To ensure redundancy, each heater pad incorporates two electrically independent heater elements within a single pad, see Figure 3-1.
the minimal and maximum power dissipation are respectively 4.8W and 5.5W. The heaters of the circuit are positioned such that the thermal gradient along the instrument housing is minimized. The heaters will be covered with aluminium adhesive foil to ensure a low emissivity of the instrument housing.

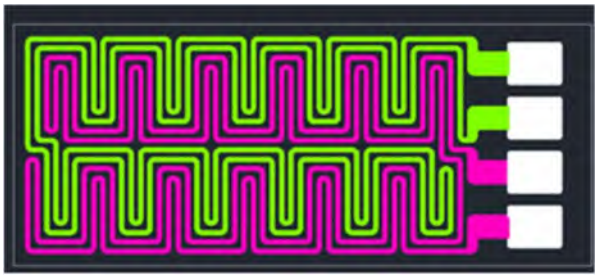

Figure 3-1 Schematic overview of the single layer heater with double circuit.

The Thermal Reference Point is the location at which the temperature of the instrument housing is monitored and controlled using a thermistor of type 15K4D489. The instrument housing is equipped with a main and redundant thermistor at the TRP location. Both heater strings and the thermistors are wired to a single connector on the housing of the instrument, for interfacing with the control electronics of the platform.

4. MECHANICAL ANALYSIS

The instrument was modelled and analysed in NASTRAN, in a combined FEM with the deployer and CubeSat platform. A deployer-platform-instrument combined analysis was favoured over an instrument analysis in isolation because of the strong coupling between all three elements. This strong coupling is due to the high relative stiffness and size of the instrument relative to the platform, and to the extended contact interface between deployer and platform over the entire length of the platform. Because of these reasons, standalone instrument and platform analyses with hard mounted conditions, even with impedance correction using interface forces (notching), proved to yield unrealistic results both for load derivation and strength margins. The coupled load analysis would achieve to capture more realistically the dynamic amplification, modal coupling, and local interface load redistribution.

After the model checks, the combined model was analysed for QSL, Sine and Random for Qualification Loads levels, which were derived as an envelope of VEGA, F9, and ISAR.

Since the mission's launcher has not yet been decided, the loads used consist of an envelope of the loads featured in the launcher manuals of all candidate launchers. Additionally, since the orientation of the deployer mounting on the launcher main interface is different for some of the candidate launchers, two configurations were analysed for the deployer boundary conditions: side-mounted and back-mounted.

Primary notching using the Peak RMS method was performed only for the random vibration load case, using the SPCF data extracted from the analysis.

In Figure 4-1 the combined model and instrument FEMs are shown.

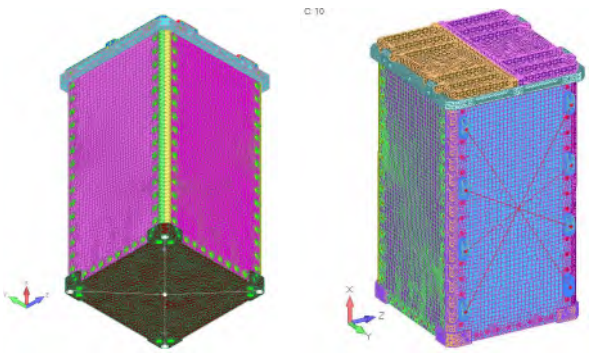

Figure 4-1 Boundary conditions for a) side mounted and b) back-mounted configuration.

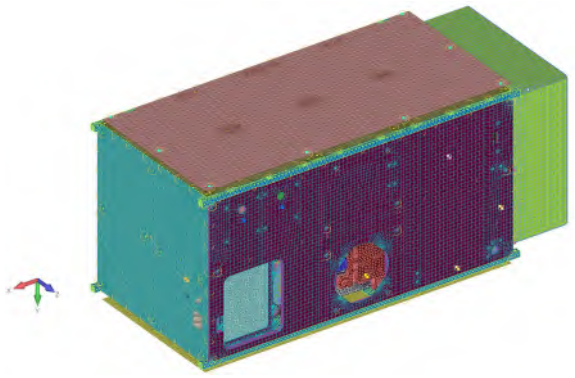

Figure 4-2 FE Mesh of the S/C Platform

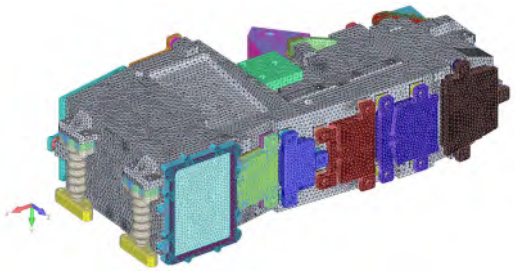

Figure 4-3 FE Mesh of the STM optical instrument

The instrument was modelled using primarily quadratic solid elements. For the damper struts the rubber material was modelled explicitly, while all fastener joints were modelled using RBE2+spring elements.

The modal analysis results show the first eigenfrequency to be at 146 Hz and 149 Hz, for the side-mounted & back-mounted configurations respectively, satisfying the first eigenfrequency requirement of 115 Hz. The eigenmode is shown in Figure 4-4. As shown, the instrument is rocking within the S/C, while being attached to a structural frame.

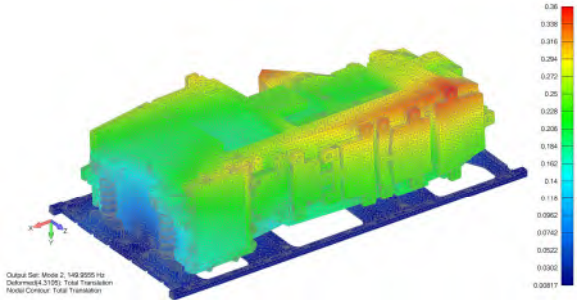

Figure 4-4 1st Global Eigenmode of the STM instrument side-mounted (146 Hz)

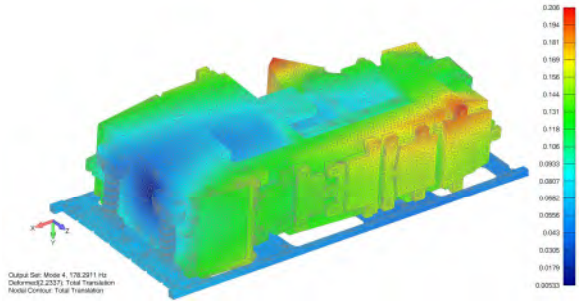

Figure 4-5 2nd Global Eigenmode of the STM instrument side-mounted (178 Hz)

All analyses (QSL, Sine & Random) were performed, and all margins of safety (MoS) for part stresses in the instrument were shown to be positive.
Moreover, bolt analysis was performed following ECSS standards, also showed positive MoS for most joints. In some fastener group cases where negative MoS were present, they were accepted as they had negative MoS for flange bearing in the range of -0.06 to 0, as they should be covered by the additional margin taken from the Kp, Km, and other fastener safety factors.

5. VIBRATION TESTING

The vibration test was performed on the TANGO STM which included the platform STM, the deployer STM and the STM instrument at ETS (Noordwijk, The Netherlands).

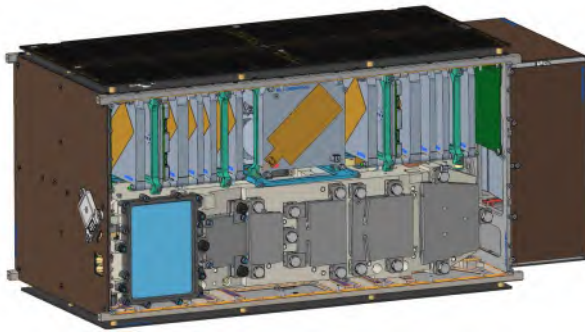

Figure 5-1 CAD render of the TANGO STM platform.

The TANGO STM was mounted in the deployer in both side-mounted (see Figure 5-2) and back-mounted configurations to cover all possible launch configurations. The loads associated with these launch configurations were a combination of VEGA, F9, and ISAR launchers. In this way, the instrument was subjected to all relevant flight conditions, with particular attention paid to the vibration levels experienced by the camera, slit assembly, and grating mount. The results show a clear damping effect provided by the struts, indicating that they performed as intended and thus the instrument passed all vibration tests.

Figure 5-2 The STM TANGO satellite including the deployer mounted on the vibration table (side mounted configuration)

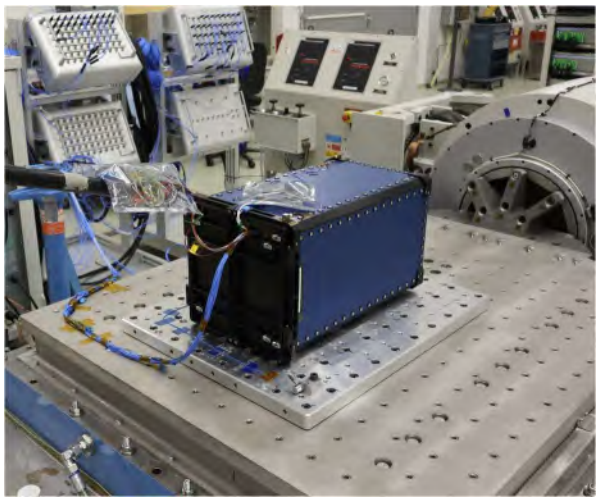

Figure 5-3 The STM TANGO satellite including the deployer mounted on the vibration slip table (side mounted configuration)

5.1. Sine-burst (QSL), Sine and Random vibration test

The sine-burst (QSL), sine and random vibration tests were carried out in the 80kN shaker. For all tests, acceptance level loads were used and are shown in Table 5-1 for side-mounted, and for back-mounted in
Table 5-2. No notching was performed.

Table 5-1 QSL, Sine & Random Acceptance loads side-mounted configuration

QSL - All directions			RND - All directions	
Accel [g]	15		f [Hz]	PSD [g^2/Hz]
			20	0.0071
Sine - All directions			50	0.0071
f [Hz]	Accel [g]		100	0.0142
5	2		200	0.0355
110	2		500	0.0355

			925	0.03
			1000	0.0284
			2000	0.0071
			GRMS	**6.63**

Both test campaigns were successfully completed without any major anomalies. Post-processing of the test data after the test showed that there was a good match between the predicted and measured accelerometer responses, even before any changes were performed as part of the model correlation. The comparison between the predicted and measured transfer functions is shown in Figure 5-4 for the sensors that see the highest amplification for the main modes in each direction. This comparison is only shown for the side mounted configuration, but very similar plots were obtained for the back-mounted configuration.

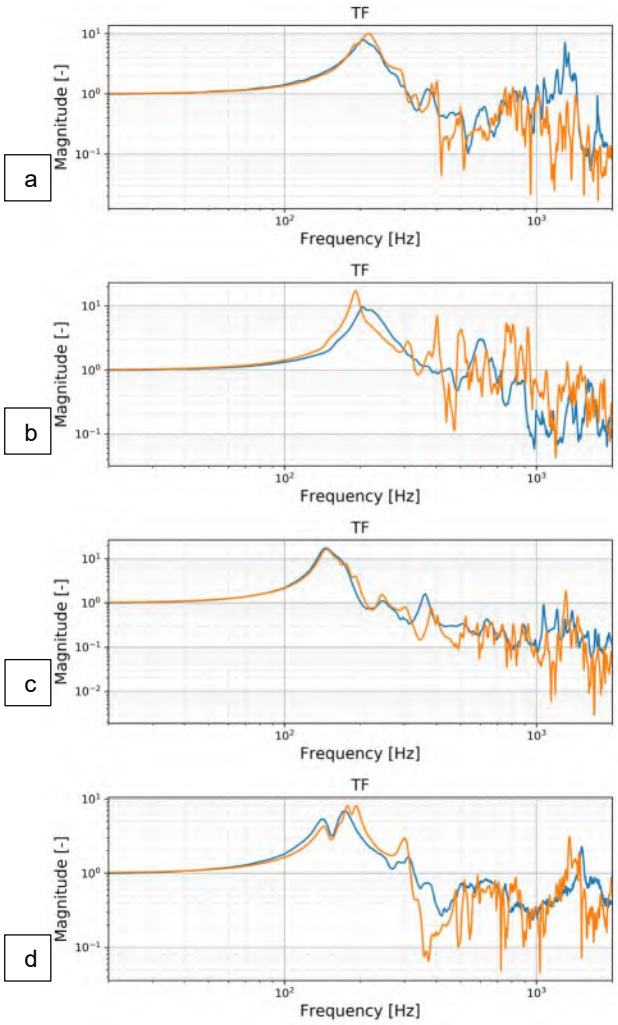

Figure 5-4 Derived transfer functions, comparing uncorrelated FEM (orange) and test data (blue), for the highest amplification sensor location. a) X-axis, b) Y-axis, and c), d) Z-axis

5.2. Shock testing

The shock analysis indicated negative margins of safety with respect to structural integrity and stability for a significant number of optical components mounted on the instrument housing of both TANGO instruments. It is however possible that the SRS shock analysis method overestimates the reaction forces and stresses as pointed by some researchers [5]. Therefore, shock testing is needed to qualify the TANGO satellite and the instrument for shock loads. An STM of the satellite, deployer and instrument is used for shock testing. The STM instrument is provided with shock sensors to monitor the shock response of the interface of a number of components mounted on the instrument. Figure 5-5 provides the location of the shock sensors on the instrument housing. Note that the sensors are mounted on the instrument housing close the optical components of interest. The sensor labelling is provided in Table 5-3. Note that tri-axial shock monitor sensors are used.

10000	2538		10000	2115

Table 5-5 Shock loads back mounted configuration

X-direction			Y- and Z-direction	
f [Hz]	SRS [g]		f [Hz]	SRS [g]
100	42.3		100	42.3
800	1551		800	1106.1
1000	1797		1000	1410
1600	2538		1600	2115
10000	2538		10000	2115

Tuning of the shock setup was done with a dummy deployer construction.

Visual inspection of the of the STM before and after shock tests did not show any signs of damage of the mechanical construction.
The responses at the shock sensors were used to derive qualification shock loads for the camera DCU and DPU, the nitro grating mount and the slit mount. Shock spectra are derived by enveloping the responses of the shocks applied in the different directions. As an example, the derived shock loads for the slit mount (based on shock sensor 6) are provided in Table 5-6. Note that the derived shock loads are lower than the applied shock loads, most likely due to the attenuation effect of the damped struts on which the instrument STM is mounted. Similar levels were also derived for the camera DPU and the grating mount.

Table 5-6 Derived qualification shock loads for the slit mount.

6. CMM MEASUREMENTS

CMM measurements are performed before and after the vibration test of the STM. Comparing these two measurements enables the stability of the installed optical elements to be assessed. The Zeiss Prismo Ultra CMM is used which is a high-accuracy, bridge-type Coordinate Measuring Machine (CMM), designed for extreme precision metrology. The CMM is provided with advanced air bearings, high resolution Zerodur scales, and high scanning speeds for demanding industrial and scientific use. The length measurement error E0 = 0.5+L/500 µm, the repeatability is 0.4 µm. The CMM is installed in a temperature-controlled cleanroom at TNO to ensure measurement stability and accuracy.
The positions of several components are determined with respect to a global reference frame defined on the instrument housing. This global reference frame is established using six reference surfaces located on the housing. These six surfaces define three reference planes, whose intersections determine the origin of the Mechanical Reference Frame (MRF). Figure 6-2 shows the MRF and the six reference surfaces, highlighted in red.

The locations and orientations of the following components are assessed with the CMM: The Camera mount, Dummy Camera, Grating, Grating Mount, Slit mount, TM2 mirror, TM2 Stop aperture, TM3 mirror. The positions of the components are defined with respect to the mechanical reference frame on the STM instrument housing.

Figure 6-1 Zeiss CMM measurement setup to measure the stability of the STM instrument.

The translational and angular movements of the dummy optical components mounted on the STM instrument housing after vibration and thermal testing are presented in Table 6-1 and
Table 6-2. All the movements are calculated with respect to the mechanical coordinate frame which is shown in Figure 6-2.

Table 6-1 Derived translational movements of the STM components after Random Vibration and Shock testing.

Component:	ux [µm]	uy [µm]	uz [µm]
Camera Mount	0.5	-0.4	2.3
Dummy Camera	12.2	-3.3	-1.2
Grating Mount	-0.4	0.2	1.2

7. STOP ANALYSIS

Structural Thermal Optical Performance (STOP) analysis is done to assess the impact of mechanical and thermal loads to the optical performance of the TANGO instruments.
The following load cases are considered:

- Gravity release
- Fluctuations in ambient temperature
- Manufacturing and integration loads
- I/F loads
- Thermal mechanical loads

The thermal-mechanical deformed state of all optical components is assessed for all load cases. Next, the Zemax STAR module is used to import the point clouds of the deformed optical surfaces. Finally, these deformed surfaces are used to analyse the performance degradation of the instrument, see Figure 7-1 with the nominal and (exaggerated) deformed state of the TM1 mirror during thermal load.

The STOP process was used iteratively in the instrument design process to improve the thermal mechanical design and control. Instrument requirements that were most sensitive to the STOP load cases were (amongst others): the stability of the spectral response function and energy distribution function, the co-registration and the pointing stability. The largest change that had to be made was to add an active thermal control of the instrument housing. With the current design, the impact of the thermal-mechanical loads on the performance budgets is acceptable and in most cases no longer driving.

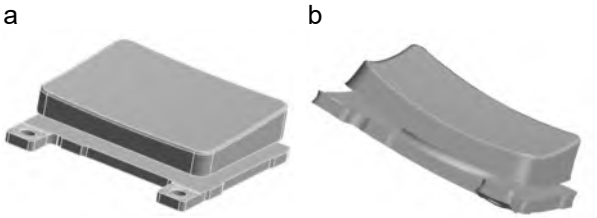

Figure 7-1 TM1 mirror in nominal (a) and deformed configuration due to a thermal load (b)

8. CONCLUSIONS AND FUTURE WORK

The thermal-mechanical design of the TANGO Carbon and Nitro instruments has been verified through a combination of numerical analyses and representative environmental testing. The instrument architecture combines a stiff aluminium housing, thermally isolating damped struts, active thermal control, and compact freeform optics to meet the challenging stability requirements imposed by the ESA Scout mission concept.

A coupled deployer-platform-instrument finite element model was developed to accurately capture the dynamic interactions between the spacecraft and payload. The analyses demonstrated compliance with the stiffness and structural integrity requirements, with the first eigenfrequency above 145 Hz and positive margins of safety for all critical instrument components. Environmental vibration testing of the STM confirmed the predicted dynamic behaviour and demonstrated the effectiveness of the damped struts in reducing the transmission of launch loads to sensitive optical hardware.

Shock testing was performed to derive realistic qualification loads for critical instrument subsystems, including the camera, grating mount, and slit assembly. The measured responses showed substantial attenuation relative to the applied shock environment, validating the use of the damped suspension concept. In addition, high-precision CMM measurements before and after vibration and shock testing showed that the mounted optical components remained stable within a few micrometres and tens of microradians, demonstrating the robustness of the mechanical design.

The developed STOP methodology links thermal and mechanical loads directly to optical performance and has been used throughout the design process as both an optimisation and verification tool. Combined with the successful environmental test campaign, the results provide confidence that the TANGO instruments can maintain the required optical stability during launch and in orbit.

Future work will focus on completing the correlation of the thermal and structural models, extending the STOP analyses with flight-model configurations, and verifying optical performance at instrument and satellite level during the upcoming qualification and flight campaigns.

9. ACKNOWLEDGEMENT

This work was performed in the scope of the Scout Programme of European Space Agency (ESA). The authors gratefully acknowledge ESA's support for this activity.

Qualification, Protoflight Model (PFM), Calibration, Mechanism, Vibration, Stepper motor, INVAP, Torsion.

ABSTRACT

Ocean Colour Mission Satellite developed and manufactured by INVAP, performs In-Flight calibrations of the main optical instruments by using a Stepper motor - harmonic drive actuator that rotates a disc into different positions to expose specific surfaces in front of the electro-optical modules. These mechanisms are called Calibrators and the main distinctive feature is the lack of any type of Hold Down and Release Mechanism (HDRM) to keep both disc and motor in position during launch phase.
This paper describes the qualification campaign of Calibrators, including:

- Breadboard model to evaluate and validate the position sensing system, torque Ratio and Back Electromotive Force (EMF) measurements, and to conduct a lifetest of the entire mechanism and its associated control electronics.
- An innovative vibration test developed to assess the torsional behavior of the mechanism under dynamic angular accelerations induced to actuator flange.
- Final PFM qualification environmental campaign where several functional and performance test were conducted.

1. MISSION OVERVIEW

Ocean colour Satellite low and medium resolution data are used to study the ocean´s biosphere.
The main instruments on-board are:

- Visible – Near Infrared (VIS-NIR) Camera, multispectral 11 bands camera.
- Near Infrared – Short Wave Infrared (NIR-SWIR) Camera, multispectral 6 bands.

2. CALIBRATOR KEY REQUIREMENTS

There are two calibrators mounted on the Satellite, each one in front of each main instrument.

Both Calibrators share the same requirements, and they were therefore developed following the same design philosophy.

2.1. High level requirements

The key requirements that guided the calibrator conceptual and basic design are:

- They shall allow the following 4 functions:
  - Allow free instruments field of view (FOV).
  - Allow to shut the instruments exposition to the light.
  - Allow the exposure of two quasi-lambertian surfaces to sunlight and instruments.
- Design shall allow lambertian surfaces to be replaced at any time during Assembly. Integration and Test (AIT) process.
- Design has to be based in a rotary disc that expose all the required surfaces in front of the instrument´s optics, as seen in Figure 1.

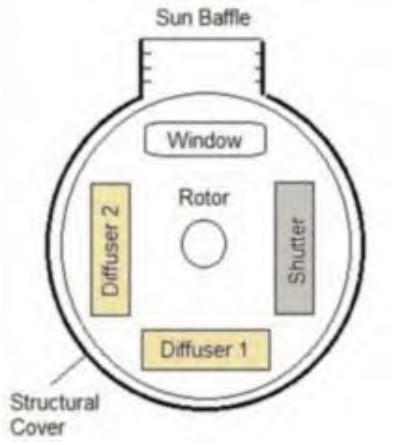

Figure 1: Calibrator Conceptual Design Scheme.

2.2. Performance requirements

Based on the high level requirements, there are key performance requirements that shall be accomplished:

- The disc positioning shall have an accuracy of +/- 0.25°.
- The actuator torque ratio shall be greater than 3 for both calibrators.
- The Calibrator actuator shall be capable to operate a number of cycles that doubles the

ones expected for AIT and in flight operations.

2.3. Environmental requirements

Considering the expected in-flight environments, the following requirements are derived:

- The calibrator´s operating temperature range shall be -20°C to 50°C. For non-operating conditions, this range shall be extended by ±10°C.
- Calibrators shall withstand sine loads of 12g peak in the out-of-plane (OP) condition and 10g peak in the in-plane (IP) condition. Random loads requirements shall be 14.1 gRMS OP and 10.3 gRMS IP.

3. CALIBRATOR DESIGN DESCRIPTION

3.1. Design overview

Calibrator design is presented in Figure 2. The disc contemplates four positions to achieve the main functions, Free FOV, Shutter and two diffusers (quasi-lambertian surfaces). Disc rotation is made by a stepper motor - harmonic drive mechanism that allows calibrators to have zero backlash and to reach each position with the required accuracy.
There are three structural components called front, ring and rear cover. The covers are attached to a main support that interfaces with the spacecraft. Disc is located inside the covers. Ring cover is where position sensing system is located.
There are two apertures in calibrators, each one followed by baffles that limit light entrance to the optical system while improving stray light performance, one points at nadir for science image acquiring (noted as Science Baffle in Figure 2), and the other, called solar baffle, is intended to capture sunlight to perform in-flight solar calibration.

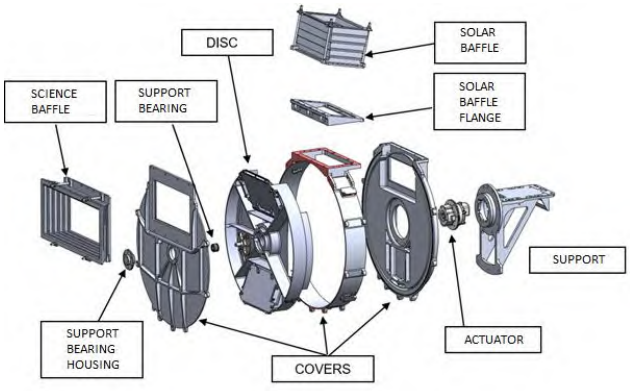

Figure 2: Calibrator Design.

3.2. Subassemblies: Drive Mechanism

In order to accomplish mission requirements regarding performance on accuracy of the disc positioning, torque ratio and the necessity to use a heritage proven component, a commercial off-the-shelf rotary actuator was selected. The main features of the actuator are:

- Actuator type: Stepper motor – Harmonic Drive mechanism set.
- Zero backlash.
- Output step angle: 0.0375°.
- Output torque: 3.6 Nm.
- Unpowered Holding Torque (UHT): 3.51 Nm.

Corresponding to its reduced disc dimensions and mass, the NS Calibrator has a cantilevered configuration with the disc attached only to the actuator. Opposed to that, the VN disc incorporates a spherical bushing on its front side, allowing to withstand bending and radial loads during launch, see Figure 3.

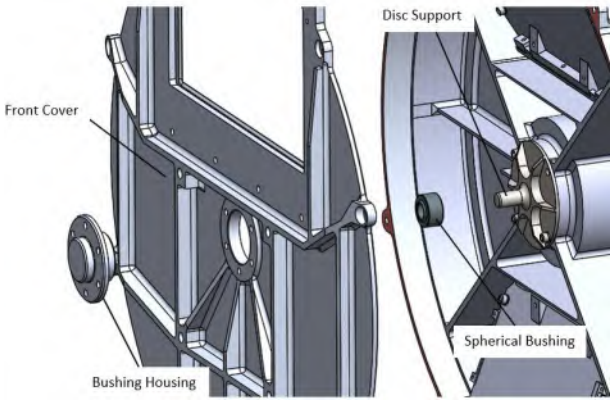

Figure 3: VN Disc support configuration.

In order to minimize the friction added in VN configuration by the spherical bearing, a self-lubricated polytetrafluoroethylene (PTFE) liner bearing was selected.
Given the lack of any Hold Down and Release Mechanism (HDRM), and that there is no extra mechanism implemented for managing the launch loads, the torsional induced loads and their transfer to the disc must be supported by the actuator itself.

3.3. Subassemblies: Position Sensing System

The position sensing system is composed by eight position sensors or switches placed on the ring cover, two for each disc position (nominal and redundant). On the perimeter of the disc, there is a tab that obtrudes the sensors when it reach a certain position.
There are two types of position sensor, optic and Hall Effect. Hall Effect sensors were selected given their heritage in previous projects, however, when it comes to calibration positions (exposure of the diffusers to the instrument´s optics), optical sensors were preferred given their better accuracy and the criticality of the position accuracy for diffuser mode. Hall Effect sensors were selected for the FOV and shutter positions, and Optic Sensors for the two diffuser positions. The tab development regarding its material, surface finishing and final dimensions is explained in section 5.1.1 and 5.1.2.

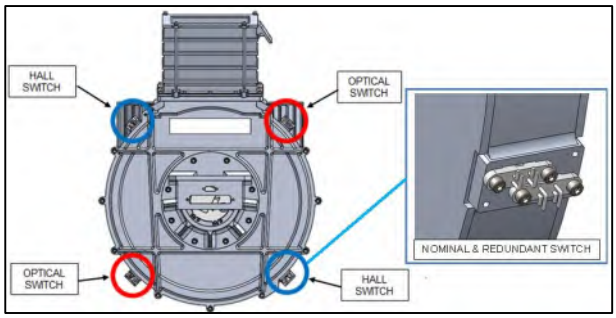

Figure 4: Disc Position Sensor Arrangement.

3.4. Subassemblies: Structure

Calibrator's structure is composed by three covers on the front, back and perimeter of the disc, and the rear cover is attached to a main support that interfaces with the Spacecraft structure.
As mentioned before, there are also two baffled apertures that allows the light entrance coming from earth surface for image acquisition and from the sun for solar calibration. The baffles also limit the stray light that enters the optical systems, improving their performance. In line with that, calibrator structure is completely black painted on its interior for optical proposes and on its exterior for improved thermal performance as there is no active thermal control on this equipment.
One major feature regarding calibrator structure is the fixing mechanism for the diffusers (quasi-lambertian surfaces) on the disc. Those are made of a material, similar to PTFE that has a greater thermal expansion coefficient than the aluminium used on the support. The fixing shall not induce high mounting pressures on the diffusers to keep their optimal optical properties and their physical integrity. To overcome this and allow the Diffuser to expand and contract within the entire required thermal range, flexure brackets were designed, allowing Diffusers to expand and contract within its resistance limits while keeping it in place during launch phase.

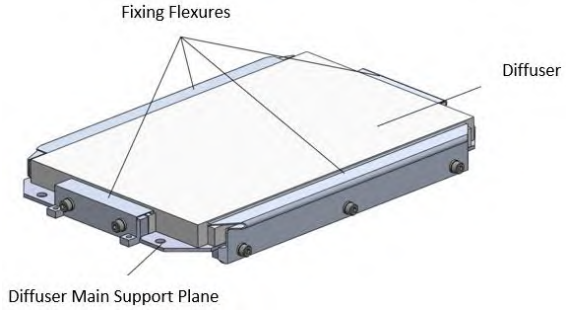

Figure 5: Diffuser Support.

4. TEST SEQUENCE

The test sequence was designed for the evaluation and validation of each subsystem critical aspects before their implementation in proto-flight model (PFM). In order to achieve that, a breadboard model was developed for the earlier stages of the design.
Test sequence is presented in the figure below:

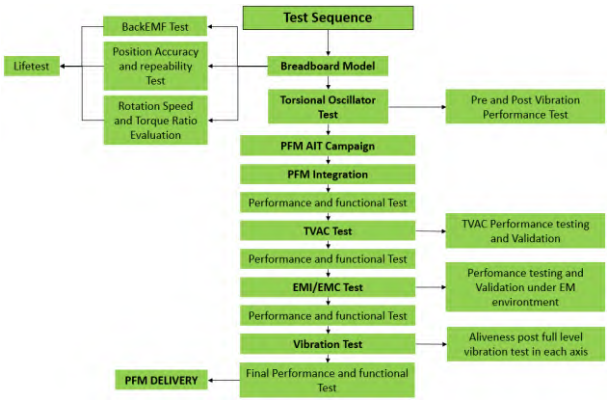

Figure 6: Test Sequence.

4.1. Contamination Control Plan

Because the calibrators are placed right in front of the optics of the main instruments of the mission, strict contamination control had to be taken into account during all PFM AIT stages, including the use of covers on both baffles, only dismounted for thermal-vacuum (TVAC) and electromagnetic interference / compatibility (EMI/EMC) campaigns. For vibration testing, lummaloy covers were used in order to keep the contamination budget as lower as possible and not to add considerable mass to the device under test (DUT). Furthermore, diffuser is made of a highly hydrophobic material which easily absorbs contaminants and is almost impossible to clean back to its previous state, therefore diffuser dummies were integrated into PFM for all the AIT campaign, flight diffusers will be integrated on calibrators for the spacecraft delivery to launch site.

5. TEST DESCRIPTION AND RESULTS

5.1. Breadboard Model

5.1.1. Development model for Position Sensing System

The first test aimed to define tab minimum thickness in order to accomplish the 0.25° accuracy requirement coming from clock-wise and counter clock-wise direction.
The setup indicated in Figure 7 was implemented.
Several engineering tabs from calibrated gauges were manufactured, then, each one was placed on a linear translation table actuated by a micrometre, over that, an optical switch was placed.

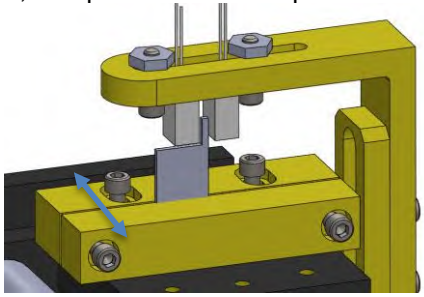

Figure 7: Setup for determining optimal tab thickness.

The tab was then slowly moved inside the sensor gap, and the switch response was measured. Several switch activation cycles were executed, from left to right and vice versa, starting from a 0.3 mm thickness tab and increasing it by 0.1 mm increments. The minimum tab thickness required to activate the switch in all cases was 0.5mm.

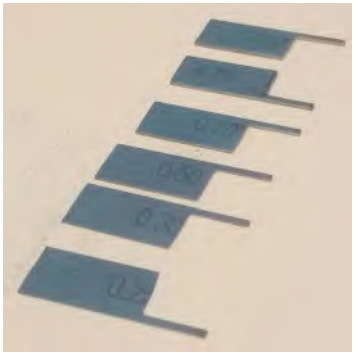

Figure 8: Engineering tabs.

This test concluded with the determination of minimum tab penetration into the optical switch gap. The same testing procedure was executed, moving manually the tab up and down, measuring and registering tab penetration. The minimum tab penetration required to activate the switch in all cases was 2.8 mm.

5.1.2. Breadboard model for evaluation and validation of the Sensing System

Once the main dimensions of calibrators were determined by design, a new breadboard model was developed. This included an engineering model (EM) actuator with the same features and performance of Flight Models (FM) also incorporating Hall Effect and optical sensors.

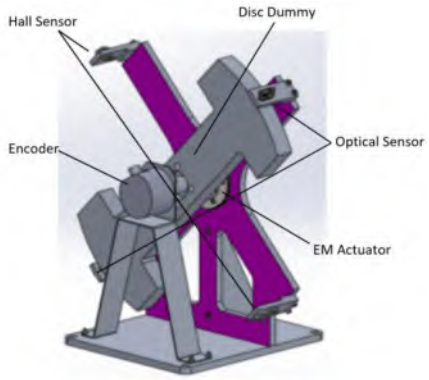

Figure 9: Final Breadboard model.

The electronic drive of the mechanism sends a signal to the stepper motor after checking if any sensor is activated in order to achieve that the tab detection is completely independent from the rotational speed.
For the first test, the penetration of the tab was determined to be 3 mm for ease of manufacturing and the material used was AISI 304 Stainless Steel.

At the very beginning of the test, it was noticed that the tab only activated the optical switch, and was not detected by the Hall Effect Switch. For further tests, SAE 1008 steel was selected due to its higher magnetic permeability. In order to avoid oxidation during on-ground storage and manipulation, a low phosphorus niquel plated surface finish had to be developed at INVAP´s surface treatment facility, keeping also in mind that this surface treatment does not affect the magnetic behaviour of the tab. Furthermore, it was noticed that for Hall Effect switches, besides section and penetration of the tab, the mass of the tab teeth had also influence in the detection.
With this first test, the optimal tab dimension that activated all types of switches was defined, being substantially different that the one determined for the optical switches in the previous test. This implied that the position accuracy requirement for reaching the sensor in clockwise (CW) and Counter-Clockwise (CCW) positions could not be met. In order to accomplish the requirement, it was required to add a certain quantity of steps after the tab was detected by the switch.
Depending on the direction of the rotation, the tab reaches the switch for the left or the right, giving two positions for the same sensor.

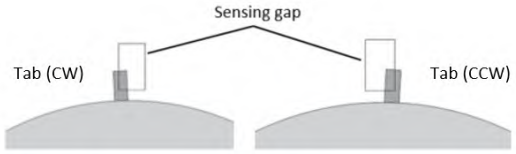

Figure 10: Differences in sensing position CW and CCW.

However this steps quantity will be then defined in PFM during integration, the strategy was tested on breadboard model in order to verify that the same number of steps are required when approximating the tab CW or CCW. This is, commanding a “Go To” CW the desired switch, then commanding a fixed number of steps (200) in CW direction and finally, command a “Go To” command to the same sensor but in CCW direction relieving in real time by the actuator telemetry the number of steps that it takes to reach the sensor in this last command (calling it B), then, the quantity of steps to be added to reach the theoretical central position in the sensor gap is:

$$Steps\ to\ be\ added = \frac{200 - B}{2} \qquad (1)$$

During the test it was verified that the steps to be added did not depend on the direction of the tab approximation to the switch (CW or CCW).
With all the data acquired during testing, the position accuracy requirement was considered fulfilled, and allowed the manufacturing of the PFM tab.

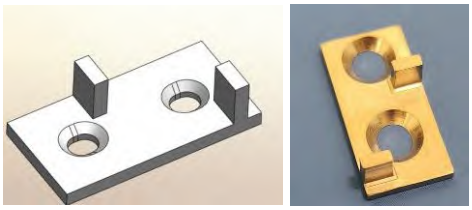

Figure 11: Final Tab design and PFM Tab.

5.1.3. Rotation Speed and Preliminary Torque Ratio Evaluation

The following step in breadboard model testing was to define the optimal rotation speed and a torque ratio evaluation.

The electronic drive of the actuator gave the possibility to tune the output rotational speed of the mechanism from 0.5 to 2.5 revolutions per minute (RPM). It also allowed to adjust the power current for the actuator (with a fixed voltage, given by the Spacecraft power bus). The nominal current was 360 mA.

The dummy disc integrated in breadboard model has the same rotational inertia that PFM VN calibrator disc, so it is representative of the worst condition for the actuator, given NS has lower inertia because of its smaller size.

Torque ratio evaluation was carried out at room temperature. The motor current power was decreased from the nominal until the disc did not indicate any movement when a command was sent, in this case, step loosing was not a problem because the disc only had to travel between two positions, no matter how many steps it took to do it in that condition. The current shall be one third of the nominal power current, taking into account that the actuator was tested in the current range where torque is directly proportional to power current. The result of this test finally indicated that the minimum actuation current was from 100 mA to 105 mA which accomplish the requirement. Torque ratio will also be measured during PFM TVAC test in order to verify the requirement in vacuum environment.

In parallel to that test, different rotation speeds were tested, founding that 1 RPM was the optimal speed. Above that value, the minimum actuation current starts to get higher, particularly at the beginning of the rotation (the electronic ground support equipment –EGSE- electronic drive is not able to control acceleration ramp), speed below that value presented vibrations on the entire mechanism and were therefore discarded.

5.1.4. Back EMF and Unpowered Holding Torque measurements

It was required by the Power team to measure the Back EMF that produces the actuator when the disc is turning by hand while actuator is connected to its EGSE turned off. Given that the mechanism is clearly reversible and there is no HDRM for the launch phase, verification was required to ensure that the voltage generated by the motor remained within the allowable limits of the electronics upstream the Motor Actuation Module. Figure 12 shows the back EMF measurement on the oscilloscope.

Finally, a static unpowered holding torque measurement was done. The measurement consisted in attaching a torque-meter wrench to the disc to measure the minimum toque value that initiates the rotation. Minimum measured values were between 3.2 and 3.3 Nm. Those holding torque values are important for considering the torsional load management as explained in section 5.2. For the measurements, the motor was connected to the EGSE (turned off) replicating the flight configuration. The motor behaviour changes depending if it is connected or not to its EGSE, when connected, every step of the motor induces a resistance torque to the wrench and when disconnected, once the UHT is reached, the rotor turns much easily, without the same resistance between motor steps.

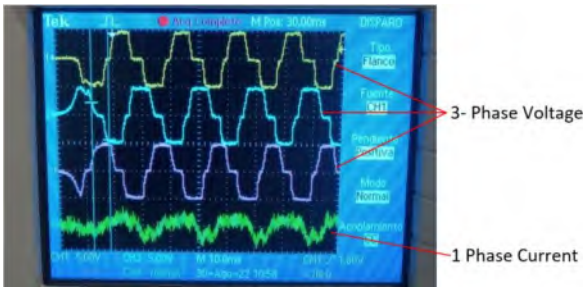

Figure 12: Back EMF measurement.

5.1.5. Lifetest

Finally, breadboard model was used to carry out a lifetest of the entire mechanism and its associated electronic drive EGSE.

This lifetest was executed in clean room ISO 8, it could not be done in thermal vacuum environment because of programmatic conflicts with other spacecraft (SC) subsystems that required the INVAP´s Thermal Vacuum facility at the same time that the test was being executed.

The breadboard cycling quantity was calculated based in the standard GEVS gsfc-std-7000B [1], considering the number of operating cycles expected for the mechanism in orbit and during functional testing.

For this test, breadboard included the spherical bushing of the VN configuration, to make the test the most representative possible for that stage of the project.

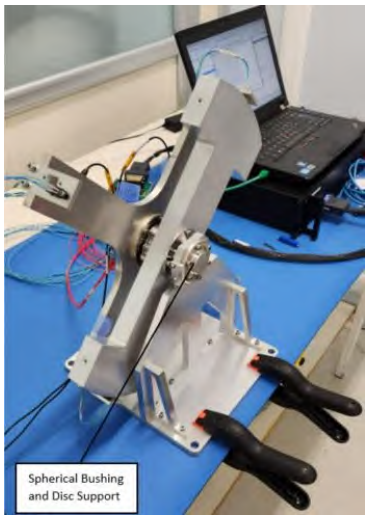

Figure 13: Breadboard lifetest configuration.

Control software was modified for autonomous operation of the breadboard requiring only personal supervision during the test. The cycles applied were divided with five stops in between, being programed stops for measuring a series of variables that allowed to evaluate the evolution of the mechanism during the test. In the Table 1 the test schedule is shown, each actuator drive indicate that the disc goes from one point to another in one movement sequence following a flight representative behaviour:

Table 1: Lifetest sequence.

Applicable Test	**Actuator drives**				
	Start	1600	3200	4800	6360
A1	R	R	R	R	R
A2	R	MIEM			R
B	R	R	R	R	R
C	R	MIEM			R
D1	R	MIEM			R
D2	R		R		R
E	R		R		R
G	R	R	R	R	R
I	R	MIEM			R

Being:

A1: Root Mean Square (RMS) current in each phase and RMS voltage between every phase.

A2: RMS current in one selected phase and RMS voltage between two selected phases.

B: Electrical resistance between every phase.

C: Step signal sent to the actuator by the electronic in every movement, automated acquire.

D1: Steps between fixed physical positions, for step loss evaluation.

D2: Accuracy and repeatability on positioning, evaluated with graphic scale.

E: Actuator vibration measurement with accelerometer.

G: Minimum actuation current, plus oscilloscope capture of current per phase and voltage between phases characteristic curves.

I: Actuator temperature acquisition.

And:

R: Required.

MIEM: Measure In Every Movement.

The Success criteria was:

- To complete all the proposed cycles.
- The variation of the minimum current shall remain below 30% of the value measured at the beginning of the test.
- The variation of the RMS current shall remain below 20% of the value measured at the beginning of the test.
- The variation of the resistance between phases shall remain below 20% of the values measured at the beginning of the test.
- The variation of steps executed between same positions shall no change more than 10%.
- Position accuracy shall be within limits (±0.25°) by the end of the test.

During the test, the software that controlled the automated actuation of the mechanism presented two failures, mainly due to the delay in the transfer rate of the data from the oscilloscope to the PC that stores it, however, the personal supervision implemented during lifetest execution allowed to take actions over the software almost immediately, reducing test delays and also preventing test data loses.

Post processing the data obtained from test, it was found that all the success criteria were accomplished, proving that the mechanism could execute al the cycles without failures.

Some of the data acquired and post processed is presented hereby, note that one calibration cycle indicated in the graphics is equivalent to 4 movements:

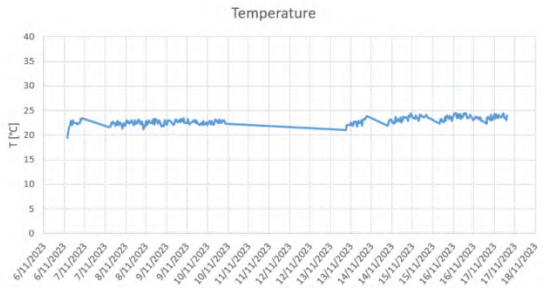

Figure 14: Temperature Acquisition (note that the test stopped in the middle because of non-availability of personal supervision).

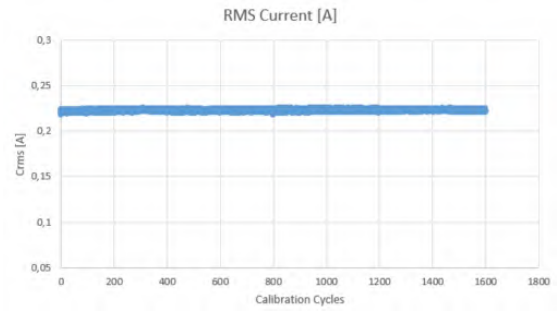

Figure 15: one phase RMS Current Acquisition.

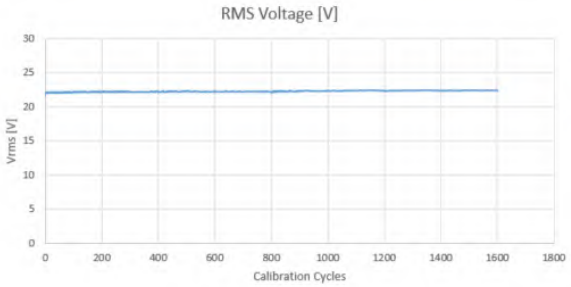

Figure 16: RMS Voltage between two phases Acquisition.

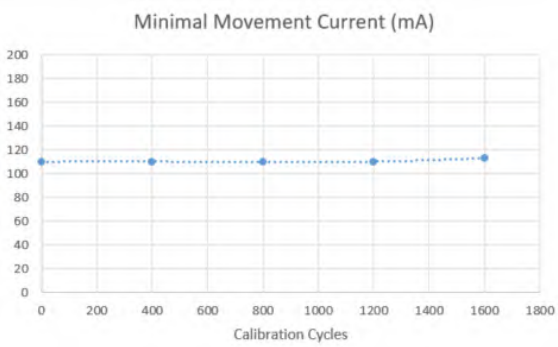

Figure 17: Minimum actuation current measurment.

- No changes in the step number were registered in any movement between same two positions.
- The main vibration modes invariable by the end of the test, verifying that no damage to the internal actuator mechanism was registered.

After visual inspection of the components that were subjected to friction (disc support and spherical bushing) no appreciable changes were noted respect to the pre-test visual inspection, together with the almost invariant minimum actuation current, verifying that the friction wear did not produce appreciable effects in the mechanism.

5.2. Dynamic Angular Oscillator Vibration Test

Because of the lack of HDRM keep the disc in position during launch phase, a test was developed to assess the behaviour of the actuator mechanisms when subjected to torsional loads.

Because of a natural mode of the spacecraft structure where both calibrators are mounted, an angular acceleration is induced on the actuator flange. This natural SC mode could couple with the natural frequency of the actuator-disc torsional mode given that the frequencies are similar (around 69 Hz), particularly for NS calibrator.

At early stages of the design, it was supposed that once the torsional loads reached the UHT, the mechanism would slip between actuator steps, without compromising either the motor or the harmonic reducer. To verify this hypothesis, a novel angular oscillator test was developed. This oscillator consist in a pedestal where the EM actuator is mounted. Dummy disc is attached to the actuator. This dummy disc had the same inertia and mass than PFM NS calibrator disc. This pedestal was designed to replicate the behaviour of the SC structure regarding de angular acceleration induced on the actuator flange.

Figure 18: FEM Model and test Setup for Dynamic Oscillator.

Instrumentation for the test was developed considering the variables that determine the theoretical torque calculation for the actuator. Instrumentation consisted of one control accelerometer on the test adapter for shaker control, one accelerometer in the front face of the disc, two accelerometers on the actuator flange and four accelerometers placed tangentially on the back of the disc.

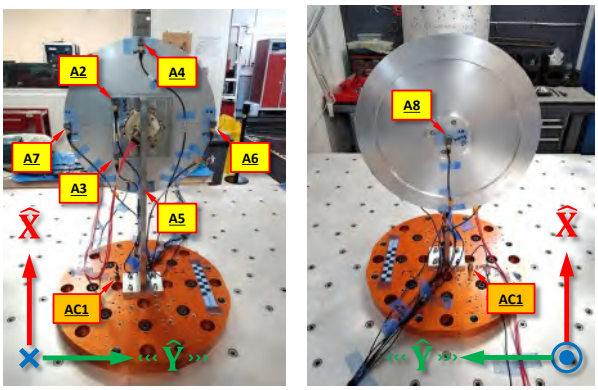

Figure 19: DUT instrumentation and test axis.

The methodology for the torque calculation [2] assumed that the disc behave as a rigid body and it is perfectly balanced. Given that, the equation that represents the torque estimation for the rotor axis is

given by:

$$M_P = I_P \ddot{\theta}_P \qquad (2)$$

$$\ddot{\theta}_P = \frac{\ddot{X}_B - \ddot{X}_A}{2s} \qquad (3)$$

Considering:

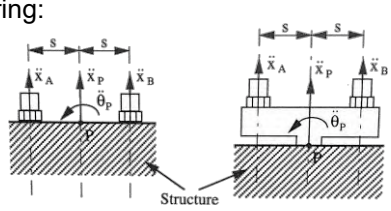

Figure 20: Torque calculation hypotesis.

Inertia of the disc was obtained from the finite elements model (FEM), and the accelerations were extracted from the data acquired during the test, decoupling acceleration in the flange zone versus those acquired from tangential disc accelerometers.

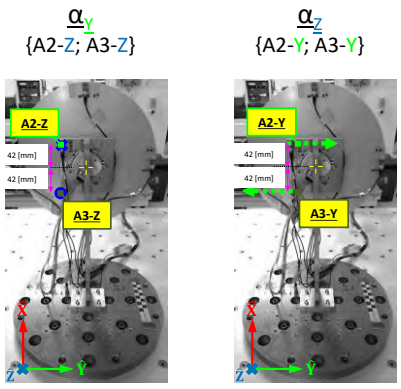

Figure 21: Angular acceleration on motor flange estimation.

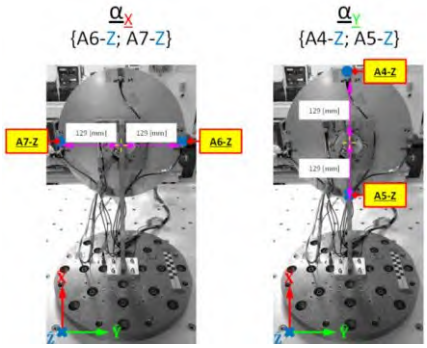

Figure 22: Angular acceleration on disc estimation (X,Y).

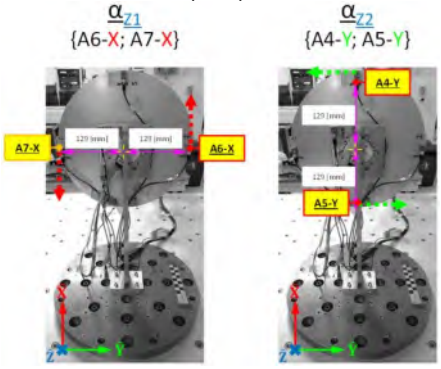

Figure 23: Angular acceleration on disc estimation (Z).

This metodology was useful for determining the test level based on the UHT previoulsy measured.

An oscilloscope was also used for monitoring the tension between phases during the vibration test, in case that the motor behaves as a generator, as predicted.

The first low level vibration test was aimed to give feedback to adjust the FEM model, however, as the test levels were increased, many non-linearities were detected, difficulting test vibration level estimation, so test levels were increased in small steps.

Due to this non-linearities, the UHT of the actuator was not reached for the imposed levels during the test as it was expected, as seen in Figure 24:

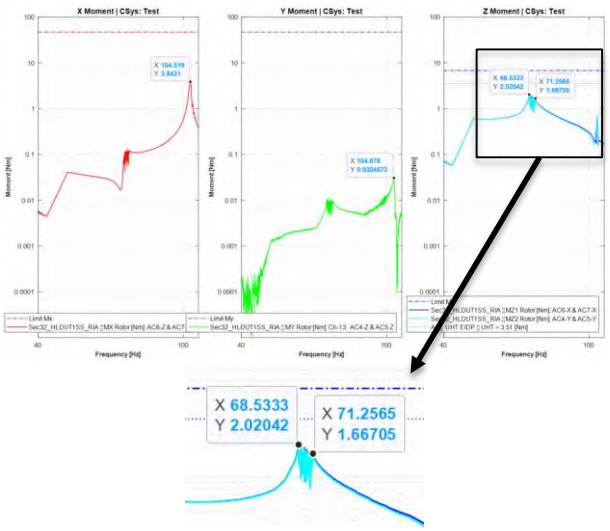

Figure 24: Torque for UHT level test, note that the torque is below UHT (3.2 Nm).

Until this test, the hypothesis considered that the torque would not increase up more than the UHT value seemed to be valid as the vibration amplification stopped at resonance frequency, but in the following tests at higher levels, something different was observed, furthermore, the acceleration and the moments registered in the disc did not increase linearly with the test level. Also, the frequency range in where the resonance of the mechanism is observable started to get wider as test level went up. After several tests, the final one is shown in Figure 25.

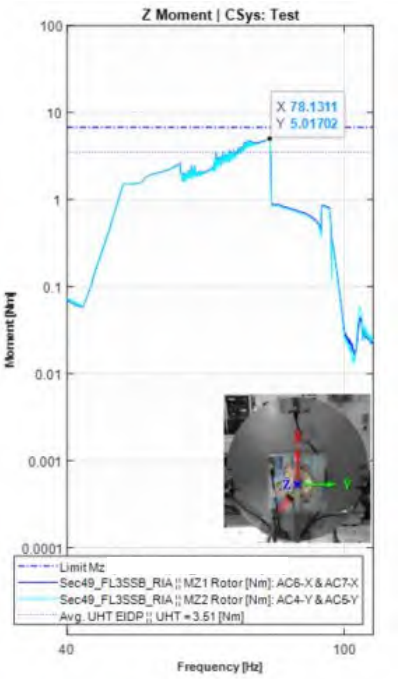

Figure 25: Torque, final dynamic oscillator test.

In the previous figure, is shown that the resonance continued amplifing even once the UHT was reached, which was opposed to the intial hyposthesis.
It was resolved to abort the test in order to protect the EM actutator and use the data already obtained to drive PFM dynamic test control. Figure 26 shown a maximum amplitude for tension between phases while the actuator behaves as a generator, which may constraint the PFM testing.
After each vibration test, an aliveness of the actuator was executed, checking that the minimum actuation current remains the same. Visual, audible and resistance between motor phases inspections were also carried out.

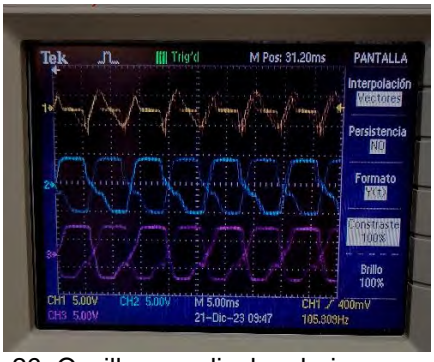

Figure 26: Oscillosope display during resonance. Tension between phases. Last test.

5.3. PFM Environmental Qualification Campaign

With all the data acquired during previous tests, PFM calibrators were manufactured, integrated and prepared for their environmental qualification campaign.

5.3.1. EMI / EMC

It was not expected to have any issues during electromagnetic interference/compatibility test. Data acquired during breadboard tests guided the pass / no pass criteria for the calibrator´s performance expected during EMI/EMC test.
RF Emissions generated by the actuator and position sensors power supply and operation were measured. All emissions were within the requirements.
No susceptibility to EM environment was shown during the test. Optical and Hall Effect switches kept performing as expected for Tab detection, there was not any fake telemetry status detected when disc reached any position. Actuator did not lose steps between two same positions.
Setup for EMI/EMC test is shown in Figure 27.

Figure 27: PFM VN Calibrator during EMI/EMC test.

5.3.2. TVAC

For thermal vacuum test, special functional and performance tests were developed, as for EM life test, taking special care in controlling the actuator temperature in order to avoid overheating during consecutive testing.
The functional test consisted in:

- Tab detection: Prove that all the position sensors detect the tab for the whole operation temperature range, given that there are tight manufacturing and assembly tolerances and the thermal distortions of materials could influence the sensors performance.
- Step loss and position repeatability: Check that the steps sent by the electronic drive between all fixed sensor position remained the same during two complete turns of the disc for every temperature tested and the summation after the complete turn is 9600 steps. Given the 0.25° requirement, the allowable difference between turns is 6 actuator steps.
- Minimum actuation current, torque ratio shall continue to be 3 or more, so, for each temperature, when limiting power motor current, this could not fall below 120mA.

This had two implications, on one hand, motor windings resistance goes up with temperature, while friction goes down. When temperature goes down, resistance also does and friction goes up.

- Then, electric variables characterization were carried out. Those variables were tension/voltage and resistance between phases, and phase current. However there is no requirement for this variable, they allow us to monitor the operational integrity of the actuator along the test and to detect any potential problem.

Test temperature profile is shown in Table 2.

Table 2: TVAC test temperatures.

	Tmin Qual [°C]	Tmax Qual [°C]	Cold Start up [°C]
Operative	-30	60	-30
Non Operative	-40	70	

There were 4 operative hot plateaus (HP), 4 operative cold plateaus (CP), 1 Non operative hot plateaus (Nop HP) where no test were executed and 1 non operative cold plateaus (Nop CP) where tab detection was tested and verified.

Before TVAC closing, all the test were executed at room temperature, after TVAC opening, the same test were executed in order to verify that calibrator performance remained invariable after thermal cycling.

Test were satisfactory, some remarks are:

- The steps executed between positions vary with temperature as expected, because of thermal expansion/contraction of materials, but for the same plateau, it was verified that no difference was perceived after two complete turns of the disc. Only in one single test Hall Effect sensor varied 1 step between turns which is, however, within requirement.
- The electronic drive GSE showed that in cold plateaus with nominal current (360mA), given the decrease in motor windings resistance, the voltage powered to the actuator had to be controlled in order to maintain the imposed current limit, as seen in oscilloscope display in Figure 28. The electronic drive is the same that the one that will be used in flight and it's expected to happen also in orbit.

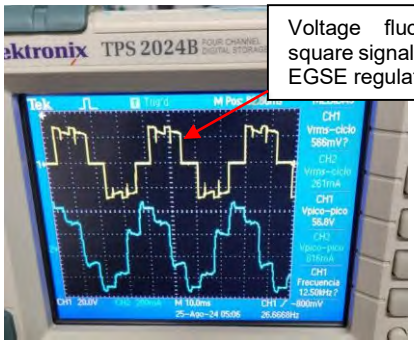

Figure 28: Oscilloscope display during CP.

- During one HP, temperature in the actuator varied significally enough to stop the test for a few minutes in order to allow the heat to escape from the motor. It was not considered as an issue because the actuator´s contact area is enough to dissipate heat trough calibrator´s structure and in-flight operations consist in a reduced number of sequences per orbit that the ones executed during TVAC testing and characterization.
- In CP, minimum actuation current reached 140 mA, which overpass the torque ratio requirement.
  This non-compliance was analyzed together with the thermal control team, who indicated that thermal analysis for in-orbit temperature profiles showed that neither NS nor VN calibrators temperatures fall below 0°C. Given that information, the test result was accepted.
- Elastic brackets that hold diffusers in place were visually inspected with satisfactory results. Optical tests were carried out at system level, showing that no performance degradation on diffusers was detected.

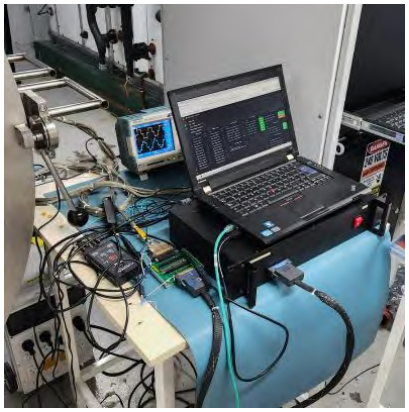

Figure 29: Test setup at INVAP´s TVAC facility.

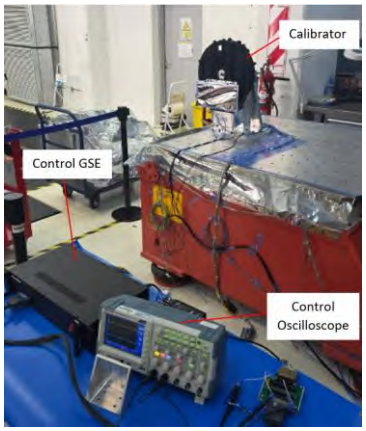
5.3.3. Vibration Test

Dynamic test target was to manage the torsional loads on the actuator. Because of the configuration of the test, in where calibrators were hard mounted to a rigid test adapter, it was not foreseen that the adapter modes induce torsional loads in motor flange. The only expected torsional excitation of the

motor was because of minimal misbalances on the discs.
Torsional loads on actuator were controlled in real time while the test was executed by the use of an oscilloscope. The actuator was connected to its EGSE and the EGSE was turned off, same as for the UHT measurement. As explained before, the actuator behaviour under torsional loads changed when the UHT test was carried out with actuator connected or disconnected.
One of the test no-abort criteria was not to exceed the back EMF signal amplitude measured during Angular Oscillator testing. If that happened during PFM vibration test, it would be immediately aborted and vibration levels recalculated prior to continue shaker campaign. Oscilloscope display was however recorded during all the PFM testing.
Test setup and configuration is hereby presented.



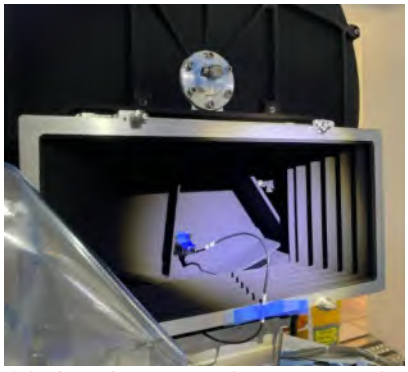


Figure 30: Test setup at INVAP´s Shaker facility.

During sine sweep test, when actuator first frequency mode was reached, the oscilloscope showed signals of the motor actuating as a generator. However, the levels remained sufficiently low to ensure that the dynamic Oscillator test levels would not be exceeded during any test. During random test, this behaviour was less noticeable.
Furthermore, for VN configuration, calibrator dimensions allowed to instrument a unique accelerometer on calibrator disc, the information acquired with this accelerometer will be especially important for system level dynamic test.

Figure 31: Accelerometer instrumented on disc.
As mentioned before, aliveness test was carried out between each axis testing. This test allowed to verify the functional integrity of calibrator at every step of dynamic testing and included:

-Actuator driving and tab detection in every position.

-Vibration Acquisition by an accelerometer instrument on motor flange during motor actuation, similar to the life test.

- Minimum actuation current test
- Resistance between phases.

The extensive characterization made on Breadboard model of all variables that indicated calibrator performance, as well as the functional and performance testing made during the rest of AIT campaign, allowed to evaluate and assure that the performance of calibrators remained the same during each step of vibration testing, giving confidence along the test and providing more variables to evaluate than only low level sine sweep signatures.
As an example of the previously explained, when testing VN calibrator, low level sine sweep signatures showed a sway in one natural calibrator frequency mode greater then the internal pass / no pass criteria. This sway was not a systematical frquency mode drop, instead of that, it fluctuated around within a frequency range around the mode frequency.
All functional test were executed for calibrator performance evaluation with no diference with previous environmental testing stages. Given that the frequency sway gone up and below one value, this did not necessary represent a structural damage as one might have thought with a systematical mode frequency drop.
After further analyses, it was noticed that the axial play between the spherical bushing and its housing, caused the bushing to move and re-allocate its position after each vibration test. This was the cause of the frequency mode oscillation, and was determined as a non-critical phenomenon.
Dynamic test concluded satifactory, as all the variables evaluated during functional and aliveness tests remained invariable, if compared to the test executed in the rest of environmental campaign and no structural damage was registered. Furthermore, observing the flexures that fixes diffusers to calibrators disc, allowed to confirm that the adopted solution was correct since no visually appreciable diffuser movements were observed. Adittionaly, an optical test was carried out together with the electro-optical components after mating, showing that the position of the diffuser remained without changes as designed.

6. CONCLUSIONS AND LESSONS LEARNED

Calibrators for the main instruments of ocean colour mission were successfully designed, manufactured, tested and qualified, getting its PFM delivered for integration on spacecraft.
All the data acquired and registered during the test campaign will now be available for performance evaluation during system level testing as well as in-

orbit performance, since the obtained telemetry will be compared with the obtained ground test data.
Design was optically validated in post environmental testing together with the electro-optics components in flight configuration at optic laboratory at INVAP facility.
The lessons learned from the qualification campaign are:

- Testing and validation of the data obtained at every stage of components development, is a key factor for the success of the subsequent testing, allowing to evaluate the performance at any stage of the qualification campaign. Letting to predict what to expect and even to drive PFM or system level testing control and functionality monitoring.
- Testing as early as possible every subsystem involved allowed several design feedbacks that improved and optimized system performance.
- Consider that many of the testing can be done in parallel to the different equipment subsystems development in order to avoid programmatic issues. On the other hand, this testing philosophy allowed to detect deficiencies in the design or its implementation that can be discovered as early as the test is carried out, if it is not done this way, programmatic issues will come from rework of pieces, re-manufacturing or even re-testing.
- The variables to be controlled or measured during testing have to be always carefully selected. Incorrect selection of these variables can lead to re-testing, under-testing or wrong interpretation of test results
- Data given by providers of COTS or customized equipment should be always tested in house when the concerns comes about some critical aspect of the component, as seen for the value of UHT of calibrator actuators.

Thermal Protection System (TPS), Reusability, Launcher, Material Testing, Database

ABSTRACT

To reduce launch costs for space projects, research and development efforts are increasingly focusing on reusable rocket first stages. For applications subjected to moderate thermal loads (<1000 °C), ceramic solutions as Thermal Protection Systems (TPS) are often complex, expensive, and oversized; Ablators as alternative are not fully reusable.
The goal of the hereafter presented work is to bridge this technological gap by developing concepts for a passive, reusable, thin-layered thermal protection system designed for use on reusable first-stage rockets and intended to offer economic benefits through reusability.
To achieve this, a database was created that contains relevant material properties and enables the comparison of material candidates that are potentially suitable for the application.
Then, supported by thermal-transient numerical optimization analyses, concepts for future, passive and thin-layered TPS are developed and compared. The investigated materials and concepts are finally tested within a burner-testbench setup to prove their feasibility.

1. INTRODUCTION

Since the German Federal Ministry for Economic Affairs and Energy identified "New Space" ten years ago as a major economic opportunity for the German economy [1], projects aiming at the development of Vertical Take-off Vertical Landing (VTVL) launch vehicles were commenced:
With Themis, ESA aims to develop a flagship European demonstrator for low-cost rocket recovery and reuse [2].
And with CALLISTO (Cooperative Action Leading to Launcher Innovation in Stage Toss-back Operations) the German Aerospace Center (Deutsches Zentrum für Luft- und Raumfahrt e.V., DLR) is partner of a project that aims to develop and operate a technology demonstrator for a reusable rocket first stage capable of VTVL [3].
As many structures of these spacecrafts are exposed to moderate thermal loads, a state-of-the-art solution is to use thin layers of ablative materials as TPS.
Phenolic cork ablators, for example, are an often-used solution. While they offer certain advantages, these ablative material systems are generally not reusable.
Ablators pyrolyze during heating, absorbing energy, with the decomposition gases additionally cooling the boundary layer. While this works for very high heat fluxes, due to the caused recession of the

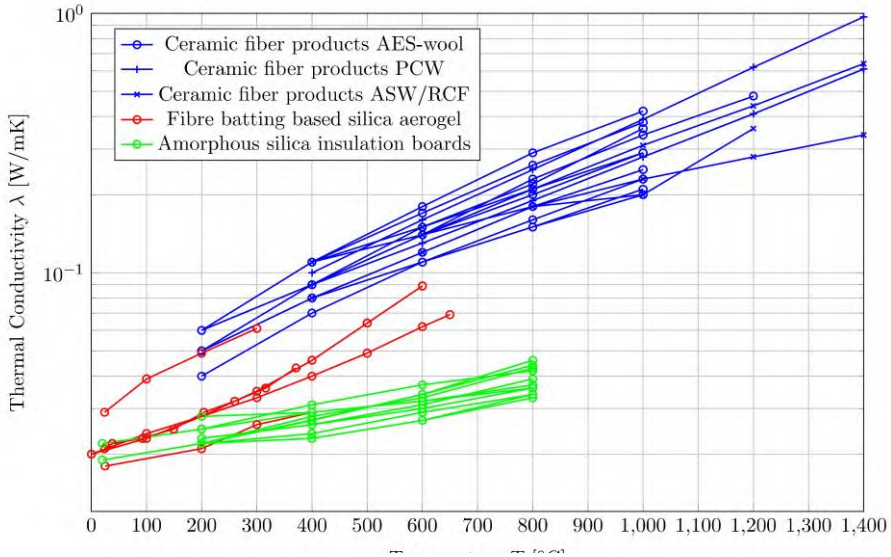

Figure 1: Collection of potentially interesting, commercially available, high temperature resistant insulation materials.

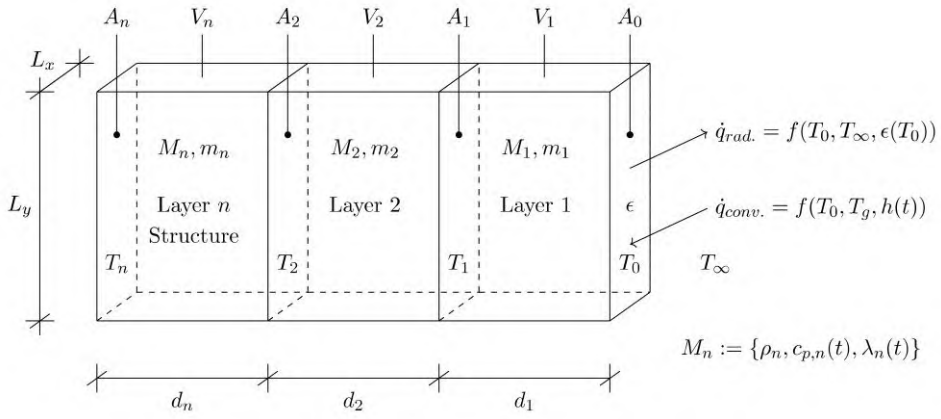

Figure 2: Nomenclature used for simulation and optimization of multi-layer TPS-solution.

materials surface, ablators are mostly single use materials and can only be refurbished to a limited extent [4].

Therefore, alternatives for a passive TPS were explored. First, material research and collection of material candidates for the application were performed. This was then followed by a thermal transient calculation and optimization of different materials and material layers to test their thermal performance regarding different use-case specific load cases. Subsequently, concepts for designing a TPS out of the thermally suitable material combinations are developed. This was concluded by experimental tests in the burner testbench to test the insulation materials for their thermal performance and the concepts for their feasibility.

2. MATERIAL CANDIDATE COLLECTION

To investigate the possibilities of designing a passive TPS solution, material research was conducted. Therefore, the relevant requirements regarding material characteristics, such as e.g thermal conductivity, were identified. Then, a database was created that contains relevant material properties and enables the comparison of material candidates that are potentially suitable for the application. Here, particular focus was placed on commercially available high temperature resistant insulation materials. The results of this research are shown in Fig. 1 for thermal conductivities of said materials. An emphasis was placed on ceramic fibre products, aerogel composite materials and microporous insulations.

Regarding ceramic fibre products, Alkaline Earth Silicate (AES) products were chosen for investigation. This is because of their possible application within the desired temperature range and fewer health concerns compared to the alternatives (Poly-crystalline-wool (PCW) or Aluminium Silicate Wool (ASW) / Refractory Ceramic Fibers (RCF)) [5].

Silica Aerogel Composite Materials and Microporous insulations were investigated alternatives due to even lower thermal conductivities of the materials, while being in a comparable weight range. The type of Silica Aerogel investigated has a temperature limit of 650°C for long term exposure. Aerogels of higher temperature capabilities are currently in research [6].

In addition to the collected data regarding high temperature resistant insulation materials, possible material candidates for coatings, adhesives and structural connections were collected.

3. NUMERICAL SIMULATION AND OPTIMIZATION

A parametric study was conducted to compare the previously identified material candidates for the intended application and to identify optimal combinations and layer arrangements for the thermal loading regarding the use case on a VTVL Reusable Launch Vehicle (RLV). Thermal transient FE-simulations were performed using ANSYS simulation software and OptiSLang optimization extensions.

3.1. Methodology

The Methodology for the numerical calculations is explained in the following.

3.1.1.Load Cases

Two load cases were used in the simulations.

These two specified load cases were defined as generic loads applicable for typical VTVL RLV TPS in the scope of this work and were defined as requirement. They are derived from internal data and various sources and do not represent a specific, real-world mission. Both load cases represent the dimensioning load case of the mission scenario for a VTVL rocket stage. The retro-boost maneuver is leading to the highest thermal loads during the mission. As these loads are additionally strongly dependent on the parameters of the flown trajectory and especially the angle of attack in which the rocket stage descents through its exhaust plume, the two different load cases are used for comparison reasons, addressing diverse scenarios. Both load

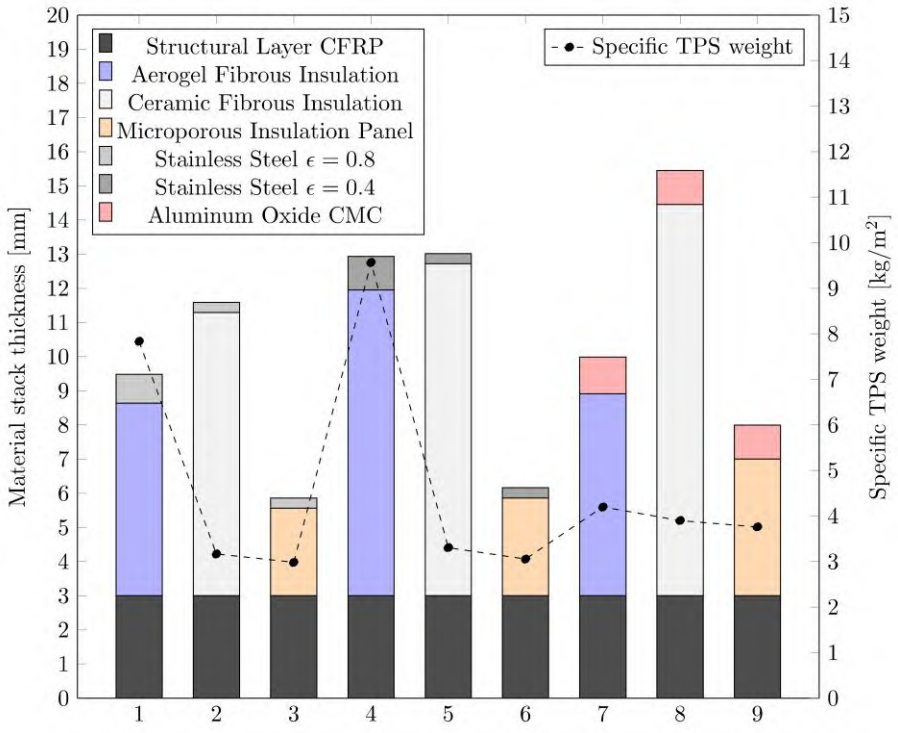

Figure 3: Results of three-layer simulations and optimizations regarding the needed TPS insulation to protect a 3 mm thick CFRP structure in a VTVL scenario.

cases shall represent the thermal loads on the aft bay of the rocket stage, with calculations beginning at the moment of engine ignition for the retro-boost maneuver. The rocket then is not only subjected to thermal loads for approx. 30s - 60s, depending on the load case, due to the surrounding rocket engine exhaust flow, but also to additional heating after touchdown. This is due to remaining on the landing platform, which has been significantly heated by the exhaust plume.

To reconstruct these load cases, the time-dependent heat flux is given dependent on the temperature of the outer structure wall for both load cases.

For practical implementation reasons, those values are converted into a convective boundary condition for the simulations.

3.1.2. Simulation Model

Those load cases are then used in a parameterized, extendable simulation model. It uses adaptive optimization algorithms to adjust the layer thicknesses of the individual materials within specified limits, based on the generic load cases. This allows to determine the optimal solution in terms of the thermal protection systems weight per unit area for various materials and their combinations. Simultaneously, the employed optimization method ensures that the thermal load on the substructure component remains within specified limits.

The nomenclature used for this model is shown in Fig. 2.

3.1.3. Optimization

Optimizations were performed to adapt the layer thicknesses of the investigated materials to optimize them towards minimal weight for the subjected loads. These optimizations were performed for multiple material combinations, and for up to four material layers.

The optimizations were performed using ANSYS Version 2025 R2, and OptiSLang extensions. ANSYS One Click Optimization (OCO) was used, generally using at least 100 Design Point (DP) iterations as limitation for the number of individual optimization simulations. Convergence of the optimization was considered reached, when the maximum temperature of the substructure is not exceeding the defined limit of 100°C with a maximally allowable deviation of 1%.

ANSYS OCO uses adaptive Algorithms to avoid local minima, arbitrary changes, and the overhead that comes with a manual selection of the optimization procedure [7].

4. OPTIMIZATION RESULTS

The results of the optimizations show, that the aforementioned insulation materials are well suitable for light-weight and thin TPS solutions.

For two-layer simulations and both load cases examined, necessary material thicknesses for insulation of CFRP or Aluminium substructures would stay below 10 mm and insulation weights below 1 kg/m^2. The results for some of the performed two-layer calculations are shown in Fig.5

The main disadvantage, later confirmed by experimental testing, is seen in the poor mechanical

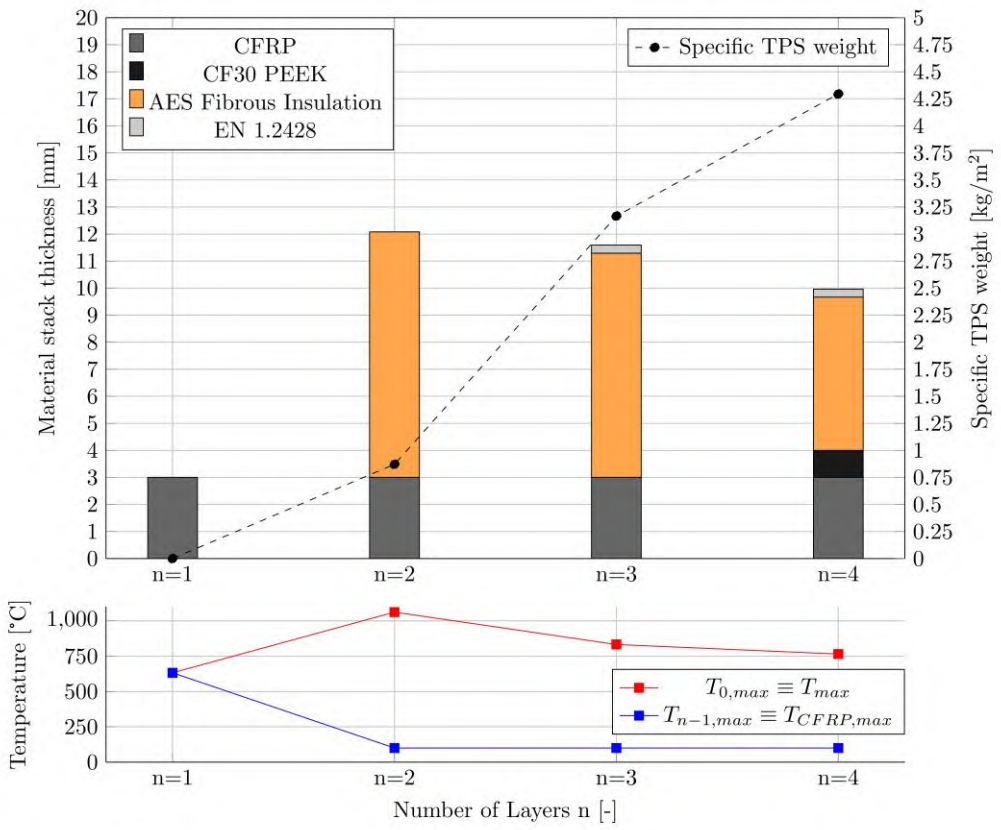

Figure 4: Results of one-layer to four-layer simulations and optimizations regarding the needed TPS insulation to protect a 3mm thick CFRP structure in a VTVL scenario.

characteristics of all the insulation options. To investigate possible mitigation strategies, the effects of additional material layers were implemented into the simulations, leading to three- and four-layered simulations. They are particularly covering the underlying insulations with top-layers of different materials, enhancing the mechanical strength of the TPS.

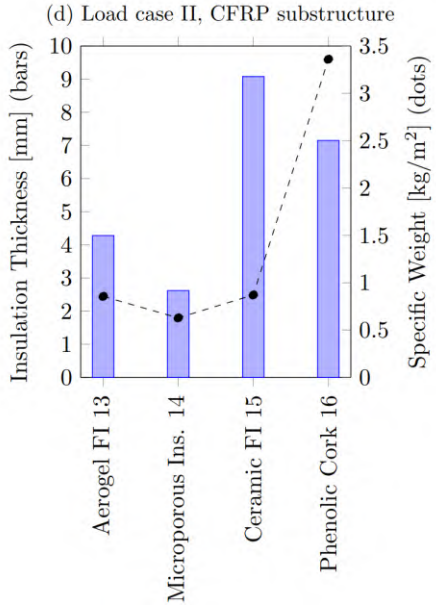

Figure 5: Results of two-layer simulations and optimizations regarding the needed TPS insulation to protect a 3mm thick CFRP structure in a VTVL scenario.

The three-layer simulation results show, that covering the insulations with thin layers of austenitic high temperature resistant steel would provide weight benefits compared to expensive CMC covering, especially considering the constraints regarding possible material thicknesses.

The results of these calculations are summarized in Fig. 3. A three-layer solution would result in a TPS of 3 - 4 kg/m² weight. A high temperature resistant stainless-steel alloy in combination with a microporous material is the theoretically calculated best combination in terms of thickness and weight.
The four-layer simulation results showed that adding a connection layer between structure and material could make the needed material stack for thermal protection even thinner, but would result in an additional weight disadvantage. The results of these calculations are shown in Fig. 4.

5. CONCEPT CREATION

Based on the results of the conducted material research, the results of the simulations and considering also historic and state-of-the-art TPS designs, different concepts for passive & reusable TPS were developed.
As a result of chapter 4, high temperature resistant insulation materials with low mechanical stability were identified as promising materials to build a lightweight, thin-layered TPS, using the described FE-calculations and optimizations. The developed

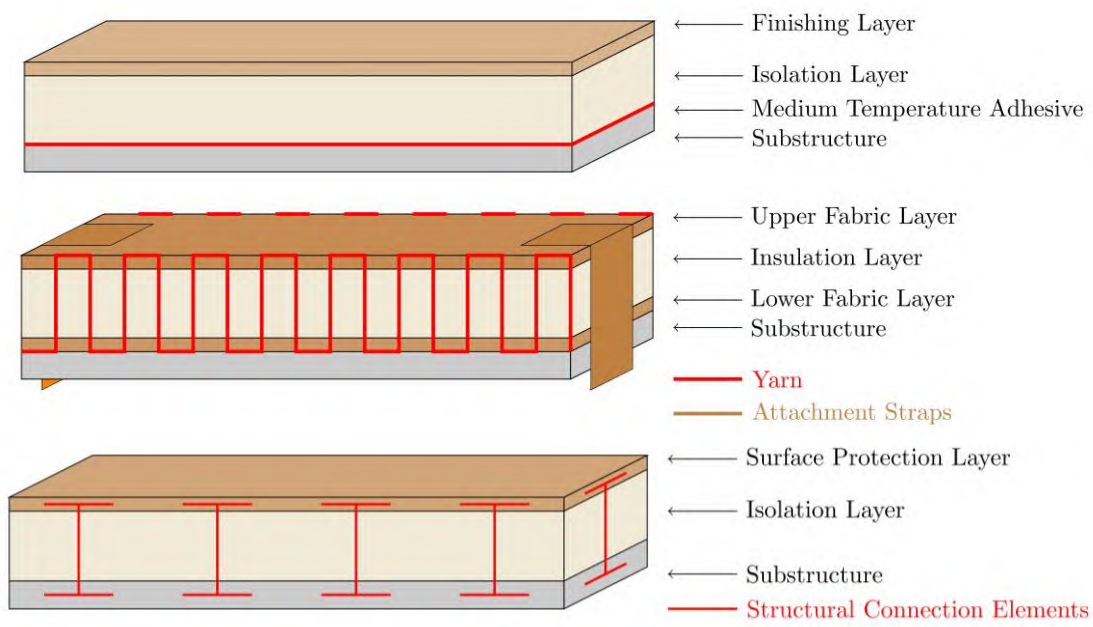

Figure 6: Schematics of concepts for thin-layered passive TPS solutions.

concepts address how these materials could be attached to the substructure, resulting in a TPS with the lowest weight, while providing the necessary thermal protection, as well as providing the required structural rigidity to withstand the environment of high-velocity atmospheric flight. For each concept, matching materials out of the material database compiled were assigned for each needed component. A schematic overview of the three developed concepts can be seen in Fig. 6. and are briefly described in the following.

Concept I is based on the idea of gluing an insulative material directly to the structure and improving the surface quality with an additional coating to rigidize it and enhance thermal properties, forming a very lightweight TPS solution.

Concept II uses methods of packaging and attaching insulative materials to the structure using textile technology, namely high temperature resistant ceramic fabrics and yarns.

Concept III can be understood as a tiled TPS solution. Here, the functions of heat absorption and re-radiation are separated from the insulative function of the intermediate material, and the surface-exposed tile is mechanically attached to the substructure.

Those three concepts were systematically compared using a procedure based on a VDI guideline on design engineering methodics: Engineering design at optimum cost [8], in which evaluation criteria are defined, weighted using a decision matrix and then used to evaluate the developed concepts using a Weighted Sum Model (WSM) calculation. This evaluation showed best results for Concept I (63%) and Concept III (67%), compared to Concept II (42%), which is why they were selected for further investigation and experimental testing regarding feasibility.

6. EXPERIMENTAL TESTING

Based on the calculated material thicknesses in chapter 4 and the concepts evaluated in chapter 5, a simplified test series was conducted. Samples of the promising material combinations were built, glueing the insulation materials to GFRP and CFRP plates with high temperature resistant epoxy-based glue. Temperature measurements were conducted using thermocouples and LabVIEW software to allow for the analysis of temperature profiles in between insulation and substructure (sublayer thermocouple) and on the outer surface (surface thermocouple).

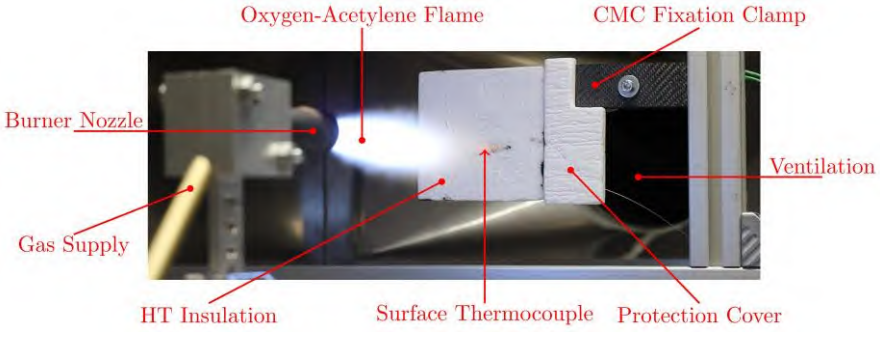

Figure 7: Torch testbench experimental setup with calibration sample.

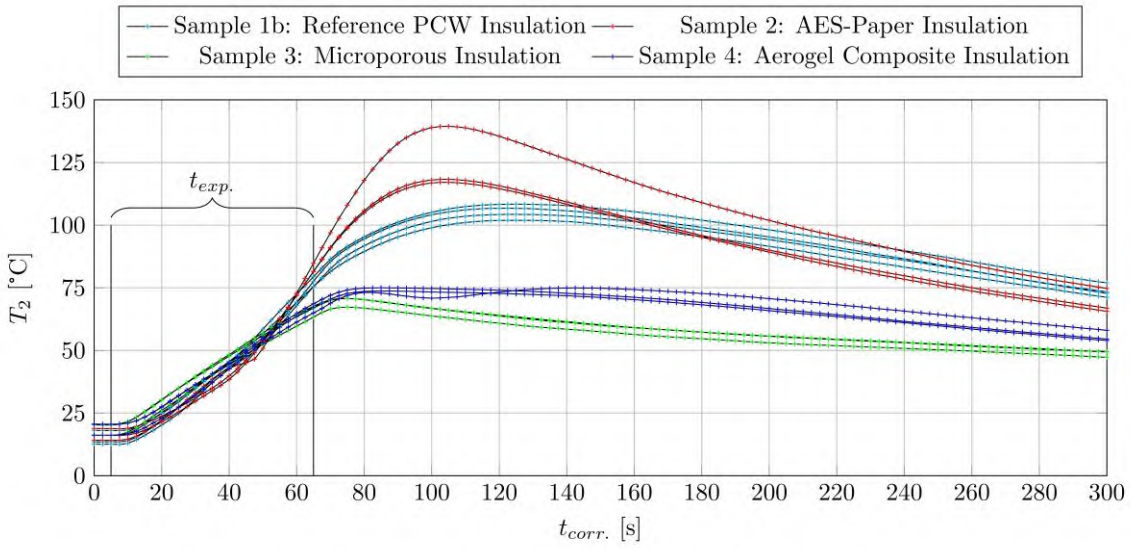

Figure 8: Temperature measurements on the sublayer thermocouple at the structure for an equal exposure time and distance to the torch flame for the different insulation materials.

These samples were then exposed to thermal loads in the torch-testbench of the DLR Institute of Structures and Design in Stuttgart. To allow for a qualitative comparison of the thermal insulation performance, the thermal load and insulation thickness used for testing were kept constant for all samples and test runs. All insulations were therefore tested with a thickness of 10mm.

6.1. Tested Samples and Materials

A picture of the experimental setup can be seen in Fig. 7, showing the calibration sample during test. Tab. 1 lists all the tested samples and which insulation and top-layer materials they are made of.

Table 1: Material Combination of Samples tested.

	Insulation	Top-Layer

8	AES Wool Paper	EN 1.4841 0.3mm
9	Microporous Insulation	EN 1.4841 0.3mm
10	Aerogel Composite	EN 1.4841 0.3mm

6.2. Test Results

The results for the different tested insulation materials and used concepts are described in the following. The temperature measurements of the sublayer thermocouple for Samples 1b to 4 are shown in Fig. 8.

6.2.1. Insulation Materials

The results show that aerogel composite materials and microporous insulations outperform the commonly used ceramic fibrous insulation materials, regarding their thermal insulative performance, comparing material samples of the same thickness of 10 mm. Especially the aerogel composite material, weighing 1,92 kg/m^2, additionally showed good material handling, while being lightweight and comparatively cheap. The microporous material had best insulative properties of the materials tested, but serious disadvantages regarding handling and the weight of 3,68 kg/m^2. An AES-Wool material tested, weighing 2.11 kg/m^2, insulated far less effective than expected. It was intended to be a cheaper, less health hazardous, ceramic fibre insulative option, compared to commonly used PCW ceramic fibre products. This result was likely caused in part by the material's higher gas permeability, but can also be seen with the covered material. The adhesive connection resisted the thermal loads for the insulative materials tested. For microporous insulation, some problems with glue adhesion occurred.

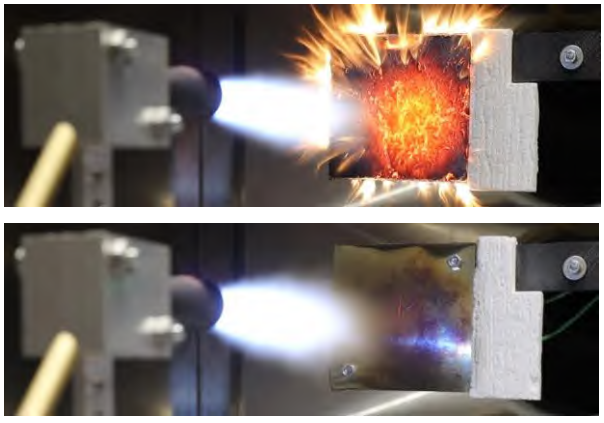

Figure 9: Reaction of two tested surface cover options for insulation materials: High temperature resistant ceramic paint coating (Top) proved to be unsuitable due to ignition under load and high temperature resistant austenitic steel.

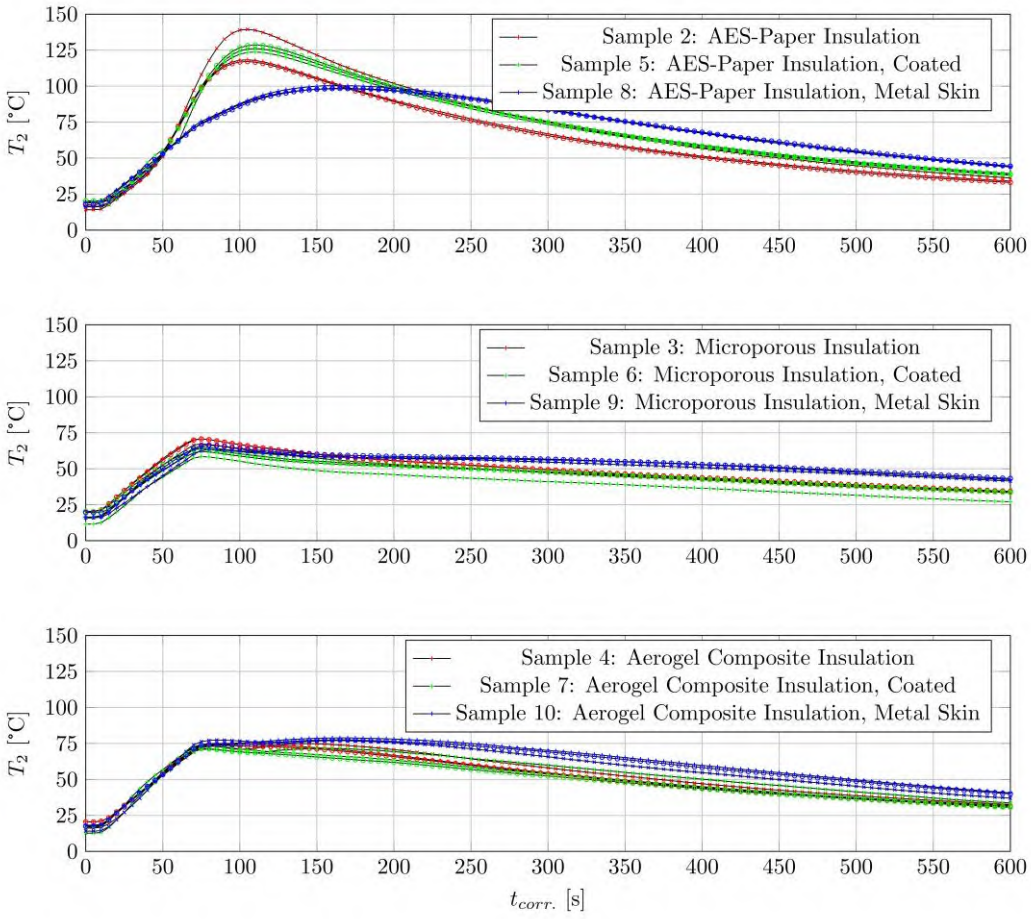

Figure 8: Comparison of the effect of adding two different surface protections to the insulation materials: high temperature resistant ceramic paint coating and a cover out of high temperature resistant austenitic steel alloy.

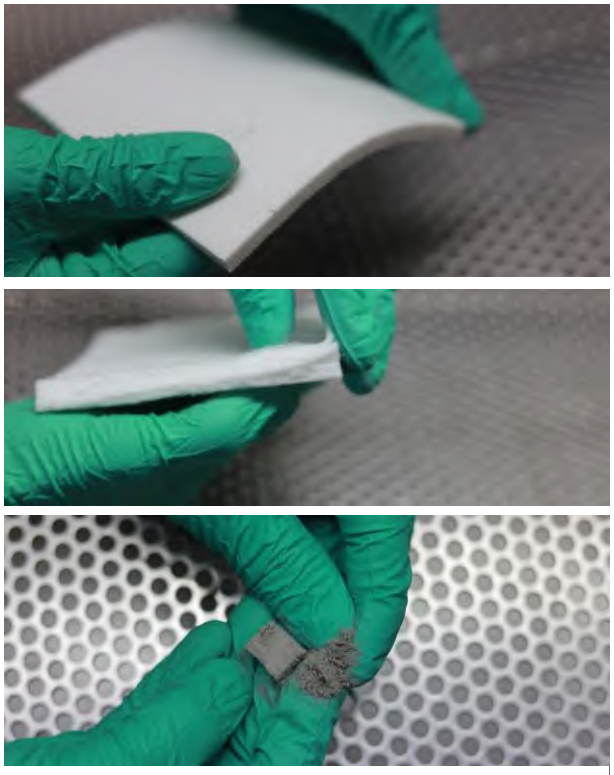

Figure 9: AES-wool paper, aerogel composite material and microporous insulation

6.2.2. Top-Layer Materials

The experiments were not only designed to test for the insulative components suitability, but also to comparatively test the developed concepts.
Therefore, the three insulation materials were also tested covered with (i) a high temperature resistant ceramic black paint coating and (ii) a high temperature resistant austenitic steel (EN 1.4841 / X15CrNiSi25-21). The resulting measurements of the sublayer thermocouple are shown in Fig. 10. The reactions of the tested surface cover materials to the torch flame exposure are shown in Fig. 9.

As expected, the test results show, that the impact from covering the insulation surface with the ceramic coating is negligible. One of the coating options tested ignited under torch flame exposure, despite the coating being rated for higher temperatures than exposed to. The selected coating therefore proved to be unsuitable. A surface rigidizing effect was achieved, but surface quality was less smooth than expected. As this solution was shown to be far lighter than the steel covered option it is nonetheless considered a favourable option in principle. Other surface reinforcing coatings are proposed for further investigation, e.g.

borosilicate glass coating, special ceramic fibre rigidizers or thermal sputtering. Benefits are then expected to be mainly the mechanical reinforcement and a negligible effect on thermal performance for the intended use case.
The steel covered version showed very good resistance to the thermal loads, while increasing cooldown times of the samples after torch flame exposure. For realization of a comparable TPS, the design of a thin mechanical connection to the substructure is seen as the main challenge for further development. The design needs to accommodate the thermal expansion cycles of the top-layer material, while being of low thermal conductivity.

6.2.3.Material Handling

In addition to the results regarding the thermal insulation of the different insulations and cover materials tested, valuable experience regarding handling and assembly of the investigated materials was gained. Fig. 11 illustrates specific behaviour of the tested AES wool product, aerogel composite and microporous insulation.
Especially microporous insulation materials could only be used in an enclosed fabric wrap or under a metal covered protection, as they are very brittle and dusty with low mechanical stability. They are nonetheless the best insulative material available and tested for higher temperature applications.

6.3. Outlook

A general focus as basis for further development needs to be laid on acquiring reliable properties for selected materials, which can then be better used for simulations regarding specific projects. Values provided by manufacturers' Technical Data Sheets (TDS) were partially unreliable for the application. Further, systematic material testing would have to be done to qualify the used materials for use on spacecraft structures. For insulative materials, this particularly includes their behavior under vacuum conditions and their resistance to a larger number of thermal cycles. In addition, determination of thermal conductivity and heat capacity across the operating temperature range is required.
A specific focus for further research is set on (i) finding better suitable protective surface rigidizers for the application, based on concept I, and (ii) constructing a suitable structural connection for a stainless steel-covered metallic TPS, based on concept III. Furthermore, using the tested aerogel composite material as insulative layer in combination with the tested austenitic steel is suggested. With the proposal of these two TPS concepts, a basis is placed to develop a more detailed design for a specific mission of future RLVs.

7. SUMMARY

The work presented in this paper investigated lightweight, thin layered TPS for spacecraft structures exposed to moderate heat loads.
Initial ideas to protect temperature sensitive spacecraft structures have been gathered, based on available materials and their limitations. They were formulated into concepts based on FE simulations performed and were subsequently tested for feasibility. As a result, promising approaches for future TPS exposed to moderate heat loads evolved.
Especially a tested Silica Aerogel composite proved to be a promising insulation choice for future use in an application as insulator in a TPS exposed to moderate heat loads. Despite the nominal degradation of the material above 650°C no degradation of insulative performance was measured in multiple test runs. As a surface protective measure, a tested high temperature resistant ceramic paint coating did not resist the exposed loads. Covering the surface with high temperature resistant austenitic steel resulted in very good results.

Spacecraft, mechanical test, correlation

ABSTRACT

This paper presents the dynamic test correlation strategy developed for the European Union's and European Space Agency - ESA's Copernicus Radar Observing System for Europe at L-band (ROSE-L) spacecraft during sine and acoustic qualification. The campaign addressed prediction and interpretation of structural responses during sine vibration testing of CFRP–aluminium spacecraft structures intended for refurbishment after qualification.

The ROSE-L platform consists of two cylindrical sections connected to a base cone, interfacing with a 1194 mm Launch Vehicle Adapter and optimized for the Vega-C fairing envelope, while remaining compatible with Ariane 6 launch environments. Testing was performed on the Structural Model, representative of flight mass properties, materials, and geometry, and planned for refurbishment into Flight Model 2.

During sine testing, the first longitudinal mode was measured at a higher frequency than predicted by the initial finite element model, requiring dedicated model correlation. Frequency correlation was achieved through refinement of interface stiffness modelling, while amplitude correlation relied on calibration of amplification factors using accelerometers employed for notch control.

The novelty lies in a correlation strategy for CFRP–aluminium spacecraft structures qualified with refurbishable models, balancing correlation accuracy with conservative load prediction. The correlated model reproduced measured responses and enabled interface load verification.

Acoustic qualification was performed using the DFAN system, with exceedances evaluated through Extreme Response Spectrum severity assessment. The proposed methodology provides practical guidance for dynamic test correlation and interface load assessment in spacecraft qualification campaigns.

1. INTRODUCTION

The mechanical test campaign conducted on the spacecraft (S/C) structural model was aimed at qualifying the structure against launcher-induced mechanical environments. In this context, it is standard practice to subject the structure to limit loads, which may result in localized structural damage or failure.

Within the framework of the Rose-L program, the structural model is planned to be refurbished following qualification activities and subsequently converted into Flight Model 2 (FM2). Accordingly, the structural model hardware is fully representative of the flight configuration. In particular, the primary, secondary, and tertiary structures accurately replicate the mass and stiffness properties of the flight hardware, together with the main dummy appendages and representative dummy units (Fig. 1,.2).

Under these conditions, the loads induced by the sine vibration environment on the structural components—specifically the tertiary structures supporting the payload—must be evaluated through a correlated spacecraft finite element (FE) model.

This paper presents the model correlation methodologies adopted to achieve the target correlation criteria, including the matching of the principal lateral and longitudinal natural frequencies, accelerometer response amplitudes employed for notching control, damping characteristics, and overall mass properties. Furthermore, the procedures implemented for the assessment of the primary internal mechanical interface loads and their verification against structural requirements are described.

In addition, the random vibration environment generated by acoustic excitation was assessed with respect to the qualification levels of all onboard equipment.

The paper also addresses the severity assessment of the random vibration transmitted by the platform to the onboard units. In this context, the already consolidated Extreme Response Spectrum (ERS) methodology is introduced and discussed. Nevertheless, the ERS application for random vibration severity is a novelty for the Rose-L programme.

2. REFERENCE FRAME AND HARDWARE DESCRIPTION

The Rose-L S/C has an innovative configuration, born with the aim to fit inside the Vega-C launcher's fairing and to be compatible with the mechanical environment of both Vega-C and Ariane-6 launchers.
The platform is embraced by the SAR Antenna in L-Band and is composed by the primary, secondary and tertiary structure. The primary structure is composed by two internal cylinders supported by the base cone, all made by CFRP.
The secondary structure, is composed by several sandwich panels made of aluminium honeycomb core and both aluminium and CFRP skins. The panels are identified as shear, horizontal, top, bottom, lateral and radiator panels, and have the purpose to sustain all the units and all the mechanical supports (brackets), as well as to transmit the loads to the primary structure.
The tertiary structure is composed by all the brackets. The several brackets have the purpose to connect the panels of secondary structure with the primary structure, as well as to sustain the external units and appendages (figure 1).

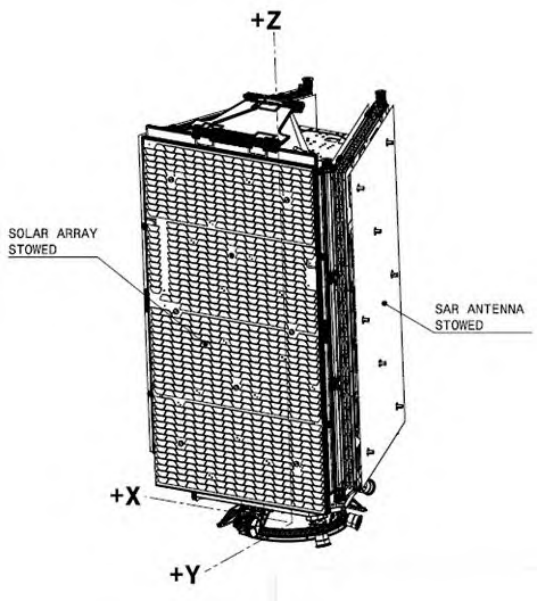

Figure 1: Rose-L Spacecraft stowed configuration and satellite mechanical reference frame description

This paper proposes highlights the load evaluation of the brackets of both SAR antenna and Solar array (Payload Brackets), which loads evaluation has a crucial role in the verification of the structural wellness of the S/C mechanical design.
The S/C reference frame is a Cartesian reference frame, positioned at the geometrical centre of the LVA ring, with the Z axis parallel with the S/C longitudinal direction, the X axis is parallel to the velocity direction and the Y axis defined as the consequence of the two other axis (Fig. 1).

The payload bracket local reference frame is a Cartesian reference frame with the Z axis parallel with the S/C longitudinal direction, the X axis oriented in the out of plane direction of the mechanical interface towards the payload and the Y axis is defined as a consequence of the other axis. (Fig. 2)

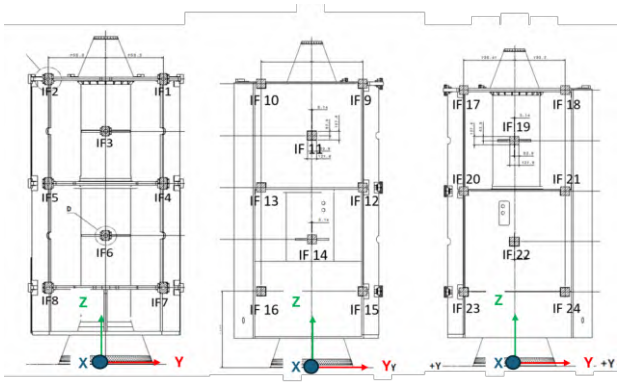

Figure 2: Payload interfaces local reference frame

3. SINE TEST FINDINGS AND FINITE ELEMENT MODEL CORRELATION

3.1. Findings and finite element model correlation

The correlation acceptance criteria applied for the correlation of the model Structural Model (SM) are resumed in the following table.

Table 1: Finite Element Model correlation acceptance criteria.

Parameter	Acceptance criteria (delta between test and model)
Main mode frequency	<5%
Amplitude	<10%

During the Structural Model (SM) sine vibration test campaign [1], a discrepancy was observed between the predicted and measured main longitudinal natural frequencies, exceeding the acceptance criterion of 5% (Table 2)

Table 2: Comparison between predicted and observed S/C main longitudinal frequency

Sine Z	Predicted	Observed	Frequency %Delta
Long. Freq.	47.1Hz	51.86Hz	-9.17

The comparison between model prediction and real main frequency is reported as a percentage delta, computed as follows:

$$Frequency\ \%Delta = \frac{f_{model} - f_{Observed}}{f_{Observed}} \quad (1)$$

Where:
$f_{Observed}$ is the main frequency in a specific direction.
f_{model} is the main frequency predicted in the same specific direction.

In this context, the primary objective of the model correlation activity was to improve the agreement with the experimentally observed S/C main longitudinal frequency without modifying the material properties of the model.
The correlation issue was addressed through a more realistic modelling of the primary mechanical junctions connecting the shear panels to the internal cylinders, top and bottom decks, and external panels. In the actual hardware configuration, these junctions exhibit distributed contact interfaces (Fig. 3)

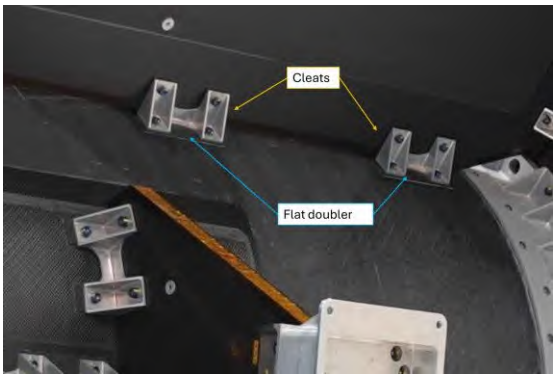

Figure 3: Detail from real hardware of Cleats-Cylinder mechanical junction.

Whereas the original FE model represented the connection through a single-node linkage between adjacent elements (Fig. 4)

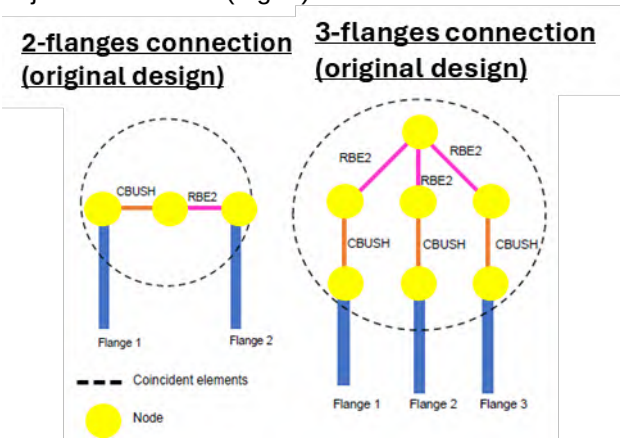

Figure 4: Original model of Flanges connections

Although such an approach could have some inner conservatism from a structural strength verification standpoint, as it tends to simulate localized load concentrations, it does not accurately reproduce the actual stiffness characteristics of the junctions.

Consequently, the rigid elements (RBE2) connecting the mechanical junctions to the primary structure were updated as reported in (Fig. 5).

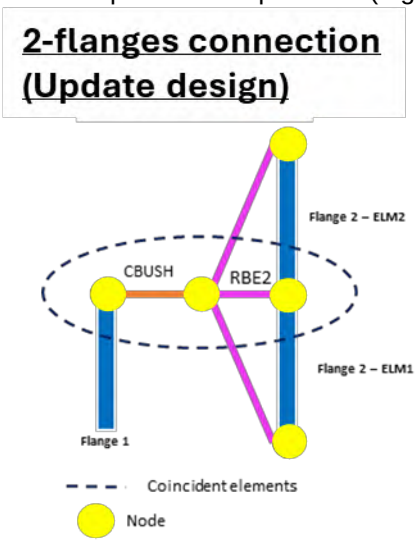

Figure 5: Modified model of flanges connection

in order to provide a more representative distribution of the interface stiffness and increase the local structural rigidity.
Following the implementation of these modifications, the predicted main longitudinal natural frequency achieved compliance with the acceptance criterion (Table 2).

Table 2: Comparison on main longitudinal frequency between S/C correlated model and SM test results.

Sine Z	Predicted	Observed	Frequency %Delta
Long. Freq.	49.36Hz	51.86Hz	-4.8

Additional correlation activities were performed on the response amplitudes measured by the primary accelerometers. In particular, the structural model exhibited damping characteristics different from those initially predicted by the analytical model.
Therefore, the correlation of the acceleration response amplitudes was achieved through the tuning of the damping matrices along all three axes and across the entire frequency range considered in the analysis. In the following is reported the three-step strategy applied, on each axis, for the amplitude correlation:

Step 1) For each axis, the frequency spectrum is divided into three sub-ranges, defining the corresponding frequency bands: Low, Medium, and High.

Step 2) Within each frequency band, the accelerometer that was active in the notching control is selected as the reference for the amplitude correlation.

Step 3) For each frequency band, the damping parameter is adjusted to match the amplitude response of the selected reference accelerometer.

The amplitude correlation is quantified by using the following equation:

$$Amplitude\ \%Delta = \frac{A_{model} - A_{Observed}}{A_{Observed}} \quad (2)$$

Where:
$A_{Observed}$: is the peak amplitude of the transfer function of the selected accelerometer, in the selected frequency range.
A_{model}: is the predicted peak amplitude of the transfer function of the node correspondent to the selected accelerometer, in the selected frequency range.

3.2. Rose-L structural model correlation results

The verification by test of the launcher main frequency requirement is fundamental for the success of a S/C design [9,10]. Therefore, the correlated model must be representative of the main modes.

This paragraph aims to show the results of the FE model correlation performed in the frame of Rose-L mission, providing the evidence of the representativeness of the real main S/C modes.

The accelerometer (A1302XYZ) used for the main modes of the satellite is placed on the top panel of the structure. The tables 3 and 4 show the results of model correlation on the three axes, highlighting both frequency and amplitude correlation.

Table 3: Model correlation results - Main frequency comparison

Frequency	Target	Correlation result	Frequency %Delta
Sine X	14.67Hz	15.07HZ	+2.7
Sine Y	15.04Hz	15.71Hz	+4.5
Sine Z	51.86Hz	49.36Hz	-4.8

Table 4: Model correlation results - Amplitude comparison

	Frequency range (Hz)	Sensor ID	Test Max Amplitude	Model Max Amplitude	Amplitude %Delta
SINE X	1 – 35	A1302X	28.3	28.6	1.0%
	35 – 90	A1004X	6.59	6.64	0.8%
	90 – 140	A7033Y	75.7	74.1	-2.1%
SINE Y	1 – 35	A1302Y	26.1	26.1	0.0%
	35 – 60	A1002Y	4.54	4.73	4.2%
	60 – 90	A7012Z	29.96	30.82	3.2%
	90 – 140	A7033Y	11.6	11.8	1.7%
SINE Z	1 - 60	A1302Z	20.8	20.3	-2.4%
	60 - 90	A7012Z	20.5	19.68	-4.0%
	90 - 140	A1203Y	3.12	3.07	-1.6%

In the following (Fig. 6, 7, 8) is shown the comparison between the transfer function of the response of the accelerometer A1302XYZ and the transfer function of the correspondent node on the correlated model, in both in-plane (X,Y) and out of plane (Z) directions.

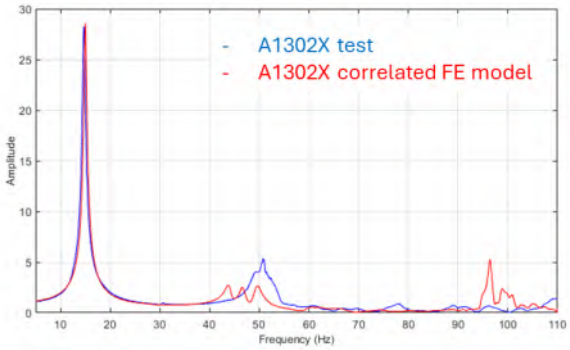

Figure 6: Sine X - test vs correlated FEM - transfer function comparison

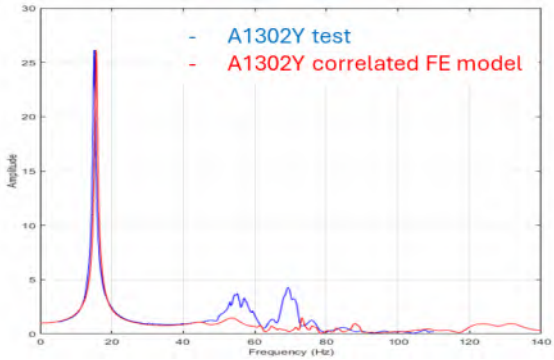

Figure 7: Sine Y - test vs correlated FEM - transfer function comparison

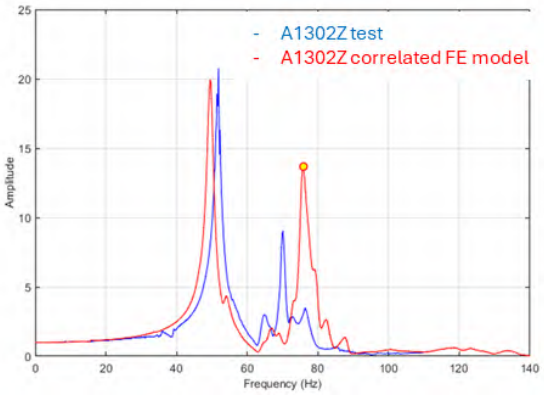

Figure 8: Sine Z - test vs correlated FEM - transfer function comparison

The model correlation results show in the in-plane directions almost a perfect agreement between the first mode of FE model and the test both in frequency and amplitude.
Instead, as already mentioned in the paragraph 3, shows a minor discrepancy between the first mode of FE model and the test both in frequency and amplitude. Nevertheless, both the differences are inside the acceptance criteria. In addition, the main longitudinal mode of the FE model is lower than the once of shown by the test. Therefore, since the main

frequency predicted from the correlated model is well above the launcher main longitudinal frequency requirement, the result is considered acceptable.

4. PAYLOAD BRACKETS LOADS EVALUATION

4.1. Correction Factor

The payload bracket loads evaluation is based on the following strategy.
The acceleration results acquired on the payload brackets during the SM sine test have been compared with the acceleration predicted on the correspondent node of S/C correlated model
From the acceleration comparison, the corrective factor (CF) between test data and model results has been defined as in equation (3)

$$CFi = A_m i / A_t i \qquad (3)$$

$A_m i$ = maximum acceleration level in the whole frequency range computed with the correlated FE model, in the node coincident with the accelerometer i.
$A_t i$ = maximum acceleration level in the whole frequency range observed during sine test in the accelerometer i.

The Corrective factors computed on all Payload brackets accelerometers have been computed for every direction of local reference frame, for all the positions (described in paragraph 2) on all the three-excitation axis.
The Payload brackets load computed from the correlated FE model are then corrected by using the following rationale:

Force Evaluation→

If the CF is >1 → No correction is applied since the model results are on the conservative side.
If the CF is <1 → The correction is applied with the following formula:

$$Fnew_i = Fmodel_i / CF_i \qquad (4)$$

$Fnew_i$ → Corrected force value in the direction i.
$Fmodel_i$ → Force value predicted by the correlated FE model in the direction I, without any correction applied. The formula is applied on each force direction. [2]

Moment Evaluation→

Since no rotation measurement are available, the moment correction was done with the following criteria:

$$Mnew_i = Mmodel_i / MinCF \qquad (5)$$

Where:

$Mnew_i$ → Corrected moment value.
$Mmodel_i$ → Predicted moment value, without any correction applied.
$MinCF$ → The minimum CF computed on the three directions of each sensor. [2]

Even if, in principle, the CF is not derived from the interface rotation responses, the proposed approach is deemed to be the best compromise. Indeed, it adds some conservativism on the interface moment evaluation on the payload bracket. It is important to mention that CF application for the moment evaluation is an engineering choice, driven by the instrumentation availability and facility limitation in channels acquirement. It is not intended to be a generic physical relation.

In addition, the above load correlation strategy is enforced by the good linear behaviour observed on the S/C. Indeed, from the low level to the qualification run the response of the accelerometers increased accordingly with the excitation levels. Therefore, the load computation by means of accelerometer responses is deemed reliable.

5. VIBRO ACOUSTIC TEST

The vibro-acoustic test was performed with the DFAN technology (Fig. 9), with the aim to predict the random environment transferred to the platform unit on the proto flight model (PFM), in order to evaluate the compatibility with the item's random qualification levels.

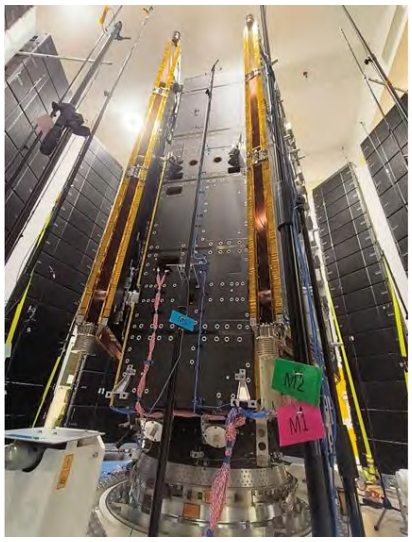

Figure 9: SM Vibro-acoustic test configuration

The post processing of vibro-acoustic test data concerns in comparing the measured acceleration PSDs with the PSDs of the random qualification profiles of the units.
It may happen that some spikes on the tests surpass the unit qualification. The evaluation of the spikes is done through the ERS (Extreme Response Spectrum).

5.1. Extreme response spectrum (ERS)

The Extreme Response Spectrum (or Maximum Response Spectrum, MRS) of a random acceleration $\ddot{x}(t)$ is defined as a curve that gives the value of the largest peak Z_{sup} of the response of a single-degree-of-freedom linear Mass-Spring-Damper system to the given vibration for a given damping factor ξ, accordingly to its natural frequency f_0.
The ERS can be computed both from time random signal and PSD signal.
This paper highlights the methodology of ERS computation directly from the PSD [4].

Under the assumption that the random vibration $\ddot{x}(t)$ is Gaussian and of zero mean, it is possible to compute the mean number per second n_a^+ of crossing a given level 'a' with positive slope:

$$n_a^+ = n_0^+ e^{-\frac{a^2}{2z_{rms}^2}} \qquad (6)$$

Where:

a: target level
n_a^+: mean number per second of positive crossing of the target value a.
n_0^+: number of positive crossings of the 0 value.
z_{rms}: root mean square of relative displacement of the Mass Spring Damper system.

The (5) can be written, over a time duration T, as follows:

$$N_a^+ = n_0^+ T e^{-\frac{a^2}{2z_{rms}^2}} \qquad (7)$$

Where:

N_a^+: is the mean number per second of positive crossing of the target value a, over duration T.

The largest level a during the time T is the one which is exceeded only one time. That lead to the following equation:

$$N_a^+ = 1 = n_0^+ T e^{-\frac{a^2}{2z_{rms}^2}} \qquad (8)$$

That allows to compute the maximum level a:

$$a = z_{rms}\sqrt{2\ln(n_0^+ T)} \qquad (9)$$

The ERS amplitude can be than computed by multiplying the maximum level a by ω^2, in order to covert displacement to acceleration.
In addition, under the engineering assumption of a one degree of freedom (DoF) system, responding at its main frequency f_0, the value n_0^+ can be substituted by f_0. Therefore, the ERS final equation can be plotted as (10), for a selected value of the amplification factor Q.

$$ERS = (2\pi f_0)^2 z_{rms}\sqrt{2\ln(f_0 T)} \qquad (10)$$

5.2. ERS Approximate expressions

This paragraph aims to share some simplified approaches to determine the ERS of the random vibration [4]. Nevertheless, those are not applied for Rose-L mission.
Considering a Single DoF linear system submitted to white noise with main frequency f_0 and amplification factor Q, the ERS can be approximated by means of the Miles equation, under the assumption of low damping a:
The simplified ERS expression at each point of the PSD (G_i) becomes:

$$R_i = k\sqrt{\frac{2}{\pi} f_{0_i} Q G_i} \qquad (11)$$

Where:
R_i = Simplified ERS expression of point i.
k = a constant value imposed to the computation.

Sometimes the k is considered = 3, in relation with the 3σ Gaussian probability approach.
K. Foster chooses k = 2.2 for the study of fatigue failure [5]. Sometimes, the value of k is even considered = 1

Even if the simplified approach is valid for a white noise excitation, it remains usable under the following conditions:
-The PSD experiences little variations between half-power points
-The natural frequency of the one DoF. system is inside the frequency boundaries of the PSD.

The error of this formulation is significant at PSD edges and in the frequency ranges where it presents great variations

5.2.1. Validity of the approximation

This paragraph reports an example that shows the precision of the ERS calculation methods.
Indeed, as reported in reference [4], the computation of the ERS of a PSD with the simplified expression (11), considering K=1 and K=3, leads to a not excellent approximation in the PSD frequency range and to a poor approximation at frequencies above the frequency domain of the PSD.
Instead, the computation of the ERS with the expression (10) leads to a spectrum larger than three times the rms value, even for small values of duration T.

This example highlights that the ERS computation

by using the rms values (Miles relation) could lead to a not sufficient approximation in the severity evaluation of a PSD.

5.3. Rose-L vibro-acoustic test post processing

This paragraph aims to show some examples on the random environment severity evaluation by means of ERS.

Indeed, in the frame of the post-processing activity of ROSE-L SM vibro-acoustic test, some dummy equipment shown higher amplification with respect to the qualification level. That means that the probability to see a seminal behavior in the frame of PFM/FM2 testing activities is not negligible.

In figure, is reported the random vibration (APSD/ERS) measured at the base of the dummy unit (A1402Z), compared with the random qualification profile (APSD and ERS).

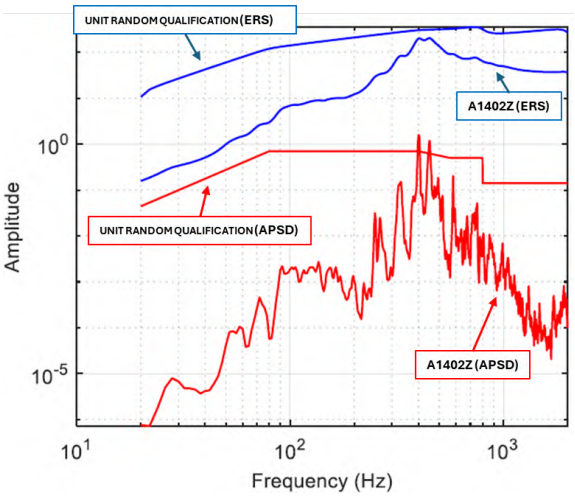

Figure 10: A1402Z - APSD and ERS - test responses vs unit random qualification

The red curves represent the comparison in terms of APSD. Instead, the blue curves represent the same comparison in terms of ERS.
Conventionally, the ERS is computed considering Q=10. Instead, the T parameter used for the qualification profile is dependent on the test duration.
Since the qualification test duration is 120 seconds [8], the duration considered for the ERS calculation is 120 seconds.
The ERS computation of both random profiles, shown that, even if the A1402Z response (APSD) surpass the qualification profile (two spikes are above the qualification profiles), the severity of the random environment induced at the base of the unit is below with respect to the environment seen by the unit during the qualification campaign.

The example shows how, the ERS is a helpful methodology to verify the compatibility of the random vibration induced by the S/C to the units against the unit qualification status.

6. CONCLUSIONS

This paper is an overview of the S/C testing, model correlation and post-processing activities.

It reports a description of the ROSE-L mission platform and design. Also, it emphasizes the methodologies applied for FE model correlation, sine test load (force and moment) computation and random environment severity evaluation, providing some detailed examples related to the mission.

In particular, the paper highlights some lesson learned, which are hereto summarized:

- Model main frequency correlation: It shows a fast methodology to improve the connection element model.
- Model amplitude correlation: It shows how the damping matrix can be modified for tuning the model responses with the real ones.
- Payload interface loads evaluation: Is shows the methodology of interface load evaluation by means of correlated model, developed in the frame Rose-L program.
- The evaluation of the severity of random vibration environment by means of ERS (Extreme Response Spectrum)

7. ACKNOWLEDGEMENTS

This work has been developed within the framework of the European Union and the European Space Agency (ESA) Copernicus programme, in the context of the ROSE-L (Radar Observing System for Europe at L-band) mission.

KEYWORDS

Deployable Reflector Antenna, SAR (Synthetic Aperture Radar), mechanical qualification, deployable mechanisms, redundancy verification, surface accuracy

ABSTRACT

Oxford Space Systems has qualified a large deployable offset reflector antenna accommodated on a 300 kg-class spacecraft platform for a C-Band SAR application. Building on prior Engineering Model design and correlation activities, this paper presents the qualification-level mechanical verification campaign of critical subassemblies and the full stowed antenna. The campaign covers functional and environmental qualification of the Hold Down and Release Mechanism (HDRM) arms, strap band release mechanism, hinge and deployable arm, and the Reflector Deployment Structure (RDS), including a single-failed-actuator case to demonstrate deployment redundancy. A motorisation margin of 3 was demonstrated across all required thermal conditions for all mechanisms, and deployed surface accuracy remained within the RF loss budget throughout the campaign, with RMS deviation from the ideal paraboloid of 1.91 mm pre-test, degrading to 2.42 mm after twelve cumulative stow/deploy cycles, vibration, thermal cycling, and five months of stowage. Manufacturing and design lessons captured during the campaign including preload control methods and bond-preparation verification are discussed. The results demonstrate qualification of the mechanisms and structural architecture for flight, with the qualification methodology and lessons learnt directly applicable to future small-sat class deployable antennas for SAR and other applications.

1. INTRODUCTION

Spaceborne SAR deployments have grown exponentially over the past two decades, from 16 satellites launched between 1978 and 2006 to 109 satellites from 2022 alone, bringing the total to 200 SAR satellites in orbit by mid-2025 [1]. This growth has been driven primarily by the proliferation of small and micro-satellite platforms on rideshare launches [1]. Average spacecraft mass across the commercial sector has fallen sharply, from 3281 kg in 2003 to 248 kg in 2022, as launch costs declined and smallsat share of commercial launches rose to over 95% [2]. Within SAR specifically, average satellite mass has followed the same trajectory, contracting significantly over the past twenty years as microsatellite buses replace traditional large legacy platforms [1]. This trend is forecast to continue, with approximately 16,900 small satellites under 500 kg projected for launch between 2026 and 2035, representing roughly a third of all satellites launched globally in that period [3]. A key technology enabler for small-sat SAR is a large deployable reflector. For the deployable reflector design stowed volume, deployment reliability, deployed surface accuracy, and structural mass efficiency must be reconciled without compromising RF performance.

In line with these trends, Oxford Space Systems has qualified a large deployable offset reflector antenna for the Space Norway MicroSAR mission, accommodated on a 300 kg-class SSTL satellite platform. The antenna's design was first presented at the Engineering Model level, covering the Reflector Deployment Structure, hinge, HDRM, and cable-network architecture, along with early static and modal FEA results [4]. Subsequent work reported further Engineering Model structural testing in stowed and deployed configurations, test-analysis correlation, and lessons learnt [5]. The present paper builds on this development history, presenting the qualification-level verification of mechanical performance in both stowed and deployed configurations.

2. ANTENNA ARCHITECTURE

The architecture of the OSS offset reflector antenna is briefly described here. The reflective surface consists of a foldable Carbon Fibre Reinforced Surface (CFRS) which is held in place through a pretensioned cable network. This cable network is supported by a deployable Carbon Fibre Reinforced Polymer (CFRP) ring truss structure called the

Reflector Deployment Structure (RDS). The RDS is attached to a deployable arm and a hinge which is used to actuate the RDS to the right location and orientation once deployed in orbit. In the stowed configuration the RDS is supported by two retractable arms which constitute a Hold Down and Release Mechanism (HDRM). The two arms are connected through a CFRP shield, also referred to as “beetle wings”. A further strap band restrains the RDS in stowed configuration to avoid blooming of the RDS structure when partially deployed from the HDRM. Once the strap band is released through a pin puller mechanism, motors drive the RDS into the fully deployed offset reflector configuration. Deployed and stowed configurations are shown in Fig. 1 and Fig. 2 respectively.

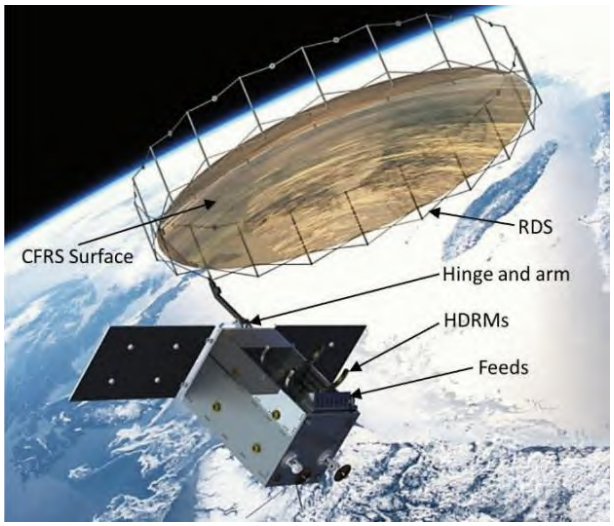

Figure 1 Offset Reflector Antenna in full deployed configuration. Credit: SSTL/Space Norway [4]

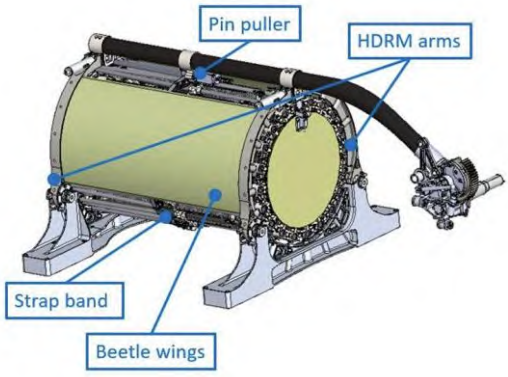

Figure 2 Offset reflector antenna in stowed configuration for launch.

Due to the large size and flexibility of the complete antenna, the qualification approach was to break down the antenna into its constituent subassemblies for functional and environmental testing, then combine them together for stowed vibration, shock and thermal cycling of the complete antenna while integrated into a Structural Qualification Model (SQM) spacecraft. After stowed testing the antenna was removed from the S/C SQM then broken down again for functional testing of the subassemblies post vibration and thermal cycling. This paper therefore discusses qualification testing of the different subassemblies that constitute the antenna: the RDS, the HDRM arms, the strap band deployment mechanism, and the deployable arm and hinge mechanism. The paper then goes on to describe the stowed antenna qualification vibration testing at S/C level. This paper discusses key mechanical qualification tests performed and is not exhaustive of the full qualification campaign of the antenna. Fig. 3 shows the overview of the testing sequence described in this paper. Note that, for brevity, results from all test instances of a given subsystem have been combined within each section, for example hinge testing performed pre-vibration, post-vibration, and post-thermal-cycling has been reported together rather than as separate sub-sections.

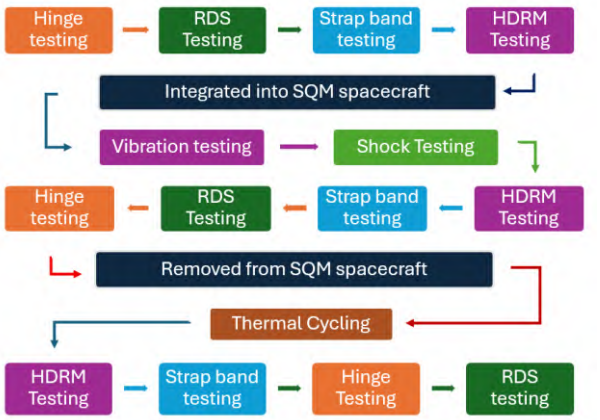

Figure 3 Qualification test campaign procedure as discussed in the paper.

3. HINGE TESTING

The objectives of this subassembly test campaign were to verify the motor performance during ambient, Worst Hot (WH) and Worst Cold (WC) temperatures pre and post Environmental Verification Testing (EVT). To demonstrate a motorisation margin of 3, hinge deployment tests were performed at 1/3 of the nominal current limit including WH and WC conditions.

The hinge test setup inside the climatic chamber is shown in Fig. 4. The assembly was orientated so that the hinge could fully rotate about the RDS support arm without obstruction. The hinge motor was connected to a power supply with set voltage and current limits of maximum current and 1/3rd of the max current. The power supply was set to record the current and voltage of actuation. A camera was setup to record the actuation of the hinge and thermocouples were attached to the hinge to monitor the temperature of the different elements of the hinge.

Figure 4 The hinge test setup inside climatic chamber

The graph in Fig. 5 shows the voltage and current variation at 1/3rd of the current limit at WH temperatures. The current initially peaks at the beginning and then reduces for the rest of the actuation, before reaching the current limit as it latches at the end of travel. The current in the middle of actuation was slightly lower than in the ambient test. Similarly tests at ambient and WC conditions showed nominal deployment and current withdrawal. The hinge motor successfully actuated to the latching point in all of the test conditions, with both the full and 1/3 current limits. The desired temperature was reached in all tests within a margin of +4°C/-0°C in the hot tests and +0°C/-4°C in cold tests. In the WC condition test at -20°C, the hinge actuated slowly with the reduced current limit, but it still latched within 540s, which is the requirement of maximum time allowable for hinge deployment. The hinge had no issues actuating in the other tests. This demonstrates that the hinge has a Margin of Safety (MoS) of at least 3 as torque margin. No degradation to the hinge assembly was observed during the testing.

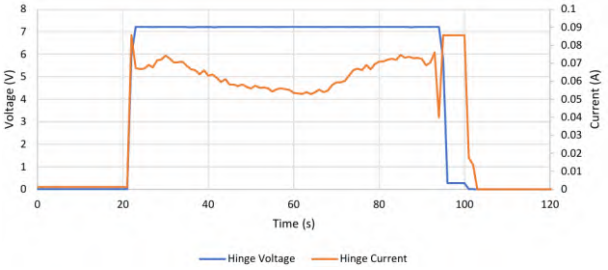

Figure 5 Functionality Test at WH temperature with 1/3 Current Limit

Hinge sub-assembly tests were repeated after the system-level vibration, shock and thermal cycling by detaching it from the RDS, and no degradation in the performance was observed. An additional initial motion functional check was carried out post vibration and thermal testing whilst the full stowed Qualified Model (QM) antenna was still integrated to the S/C. This also rehearsed planned flight model testing. The weight of the RDS and deployment arm was offloaded to minimise gravity effects. The antenna and Ground Support Equipment (GSE) were then mounted on horizontal test GSE, and the HDRM arms were manually opened. The overhead crane was positioned directly above the far end of the deployment arm. One end of the bungee cords was hooked into the overhead crane, and the other end was connected to the load cell using the lifting eye bolts. Proper offload was applied to the other end of the bungee cord after removing the slack in the bungee cord. The load cell was zeroed before applying the offload, then an offload of 9kg was applied to the end of the arm. The offload reduced as the arm deployed. Due to these limitations in the offloading setup, the motor was run only for a few seconds rather than through a full deployment; this was considered acceptable because the initial motion was identified as the most critical phase. Voltage limit of 7.21V with a current limit of 260mA was set up for the hinge motor. The resulting current profile was compared with the hinge-only run and remained within the defined limits and the current limit was not reached during the test. Fig. 6 shows the test setup used for the initial-motion hinge test along with RDS with the gravity-offset setup.

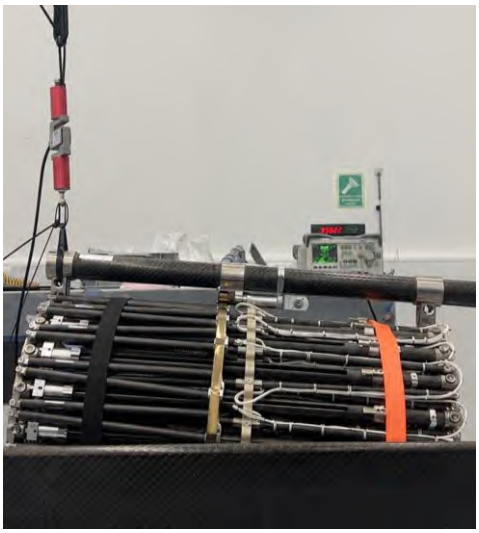

Figure 6 Test setup of hinge deployment with RDS under gravity offloading whilst integrated to the SQM S/C

4. STRAP BAND AND HDRM TESTING

This section describes the testing that was performed to qualify the functional and environmental aspects of the HDRM arms and strap band, critical for the release of the antenna prior to deployment in orbit. Reliable and repeatable pretensioning of the HDRM is key to achieve the required hold down forces and stiffness to survive the launch environment. To perform the pretensioning of the HDRM, the RDS is mounted into the HDRM assembly. Special care is needed to ensure that the cup and cones of the RDS and hinged arms are seated correctly. Two ratchet straps are used to assist in compressing the hinged arms around the RDS. Once the two hinged arms were lined up, the release bolt (release nut mechanism) was inserted into the HDRM. To

achieve the desired control and accuracy on the preload, bolt stretch measurements are used. The bolt stretch target was calculated from the structural FE model to be 0.2mm. The bolt stretch target was found to be hard to achieve in practice, however in the end the desired bolt stretch was achieved with a total tolerance of 0.02mm. The bolt stretch method for measuring preload was selected because of the perceived higher preload control accuracy, however during assembly the difficulties in measuring stretch ended up negating any benefits anticipated. Lesson learnt: Alternative preload measurement methods should be traded considering downstream implementation and trialled & reported on during earlier engineering development model phases to conclude on the most suitable preload measurement approach prior to qualification models.

After the hinged arms were preloaded, the strap band was attached to the RDS. Equivalent strain required to obtain desired preload was 530 με which was derived from previous EM phase testing. A strain gauge was attached to each of the strap bands while they were loosely attached to the RDS. The strain gauge was zeroed while the band was loose so that the change in strain when tightening the band can be measured during the test.

During the test, desired preload in the strap band could not be achieved. Only approximately 300με was achieved instead of 530με, equating to a tension of 113N. The difference was due to the test setup. In EM test campaign the preloading was done without the HDRM arms, while in QM testing the HDRM arms were assisting to compress the blooming force and hence resulted in lesser strains achieved. The preload was accepted as full stowage of the antenna was achieved and later no issues during the vibration test or deployment were observed. Lesson learnt: Consistent measuring method should be used during different stages of testing. The test plans for the Flight Model (FM) were updated for preload measurement after placing the RDS in the HDRM arms and preload applied to them.

After preloading the hinged arms and strap band, their functionality was tested. The test assembly was mounted in vertical position to eliminate any gravity related effects on the HDRM arms as shown in Fig. 7.

A high-speed camera was used to capture the retraction of the release bolt. HDRM arms were successfully deployed. Following successful HDRM arm deployment, the hinge motor was powered briefly to confirm the RDS was fully clear of the HDRM assembly. Full RDS deployment was not performed at this stage, as the antenna cannot be fully deployed under gravity in this configuration. Full RDS deployment was carried out later, following separation from the HDRMs, and is discussed in the subsequent RDS testing section. Fig. 8 shows the voltage and current drawn by the hinge motor. In this vertical test setup, the motor initially does not require much torque to move the RDS, however as it actuates further, more torque is required, increasing the required current. After a few seconds the motor was turned off as the RDS was free of the HDRM assembly

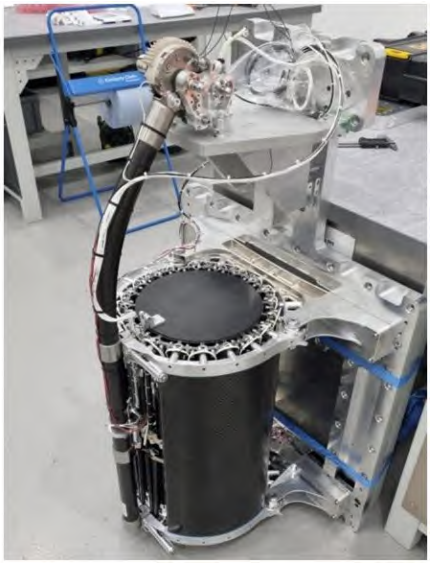

Figure 7 Vertical Test Setup for HDRM Arms Deployment

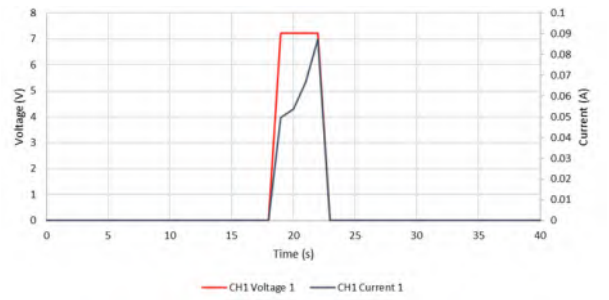

Figure 8 Hinge Motor Current and Voltage

After HDRM Arm and hinge tests, the antenna was set up for the strap band HDRM deployment test. Two pull straps were loosely wrapped around the RDS to prevent it from deploying fully, while not affecting the deployment of the Strap Band HDRM. Bubble wrap was attached to the inside of the HDRM Arms to protect them from the deploying strap band. This is not an issue in flight as the strap band is not normally fired until the RDS Support Arm is fully actuated. Again, high speed camera was used to capture movement of the pin-puller. The strap band deployed successfully when the actuator was supplied with the required voltage and current. Deployment occurred too quickly for the power supplies to record instantaneous current. Lesson learnt: Use data acquisition with sufficient sampling rate to capture current during rapid deployments in future testing.

Strap band deployment was also carried out at WC. Measured strap tension was 334 με above the nominal 530 με, attributed to strap-band shrinkage at low temperature. Deployment was successful, confirming release capability at strains well above nominal. Deployment in WH condition was not performed. In WH the strap band expands and results in reducing tension below nominal. Since deployment at the higher WC tension was already demonstrated, and release becomes easier as tension decreases, WH is inherently bounded by the WC case and does not require separate verification.

After firing the HDRM actuators, the test article is inspected to check the successful deployment, i.e. there are no loose or missing parts, no damage to test article, no marks on actuator rods etc. The inspection showed that even with the bubble wrap, the strap band HDRM deployment caused minor damage to the inside of the beetle wings, again not an issue for flight due to deployed configuration of the arm. This resulted in action to cover shields with higher energy absorbing material for any future deployment testing.

5. VIBRATION AND SHOCK TESTING

The objective of this test is to qualify the full antenna assembly under vibration at the levels as per the specifications defined by spacecraft provider for the SQM sine, random vibration and shock loading. The success criteria for the test is that there is less than 10% in frequency shift, and less than 20% amplitude shift for modes with an effective mass greater than 10% during the vibration testing and the antenna maintains its structural integrity after the test and deploys successfully. High-level sine, quasi-static and random level testing were performed, and low-level resonance search was performed before and after each test to check the antenna's integrity. Six accelerometers were attached to the antenna as shown in Fig. 9. Three accelerometers were attached to the active members, one was on the hinge housing, one on the deployment arm and one on the HDRM arm. The accelerometer on the antenna interface was positioned between the two HDRM base brackets. Fig. 10 shows the complete antenna mounted into spacecraft for vibration testing.

Fig. 11 and Fig. 12 shows the Low-Level Resonance Search (LLRS) response, at the key sensor locations pre and post the entire vibration test campaigns. The response is along the X-axis which is the worst axis in terms of loading at the antenna. From the comparison it can be observed that there has been no major shift in peak and amplitude throughout the high-level sine, quasi-static and random vibration levels. Responses in the other axes similarly remained within the defined success criteria. No further correlation was done at QM level as the FE model had been correlated at the EM stage.

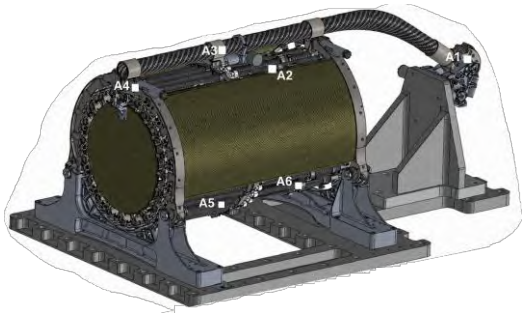

Figure 9 Accelerometer locations in stowed configuration during vibration testing

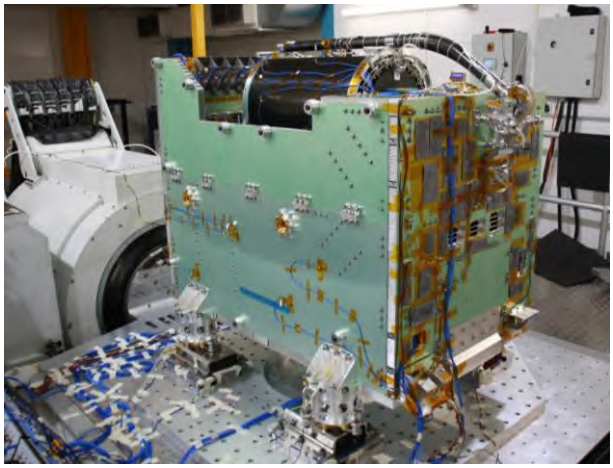

Figure 10 complete antenna mounted into spacecraft for vibration testing.

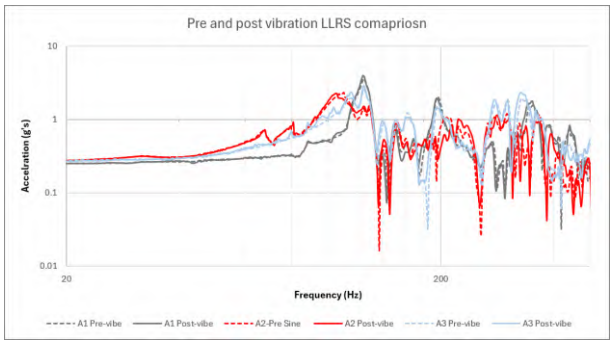

Figure 11 Pre and post LLRS comparison on accelerometers # 1, 2 and 3

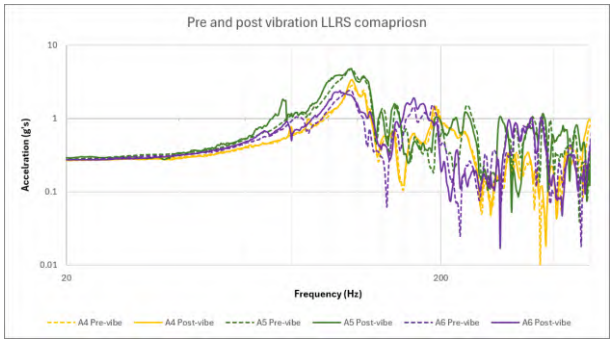

Figure 12 Pre and post LLRS comparison on accelerometers # 4, 5 and 6

After the vibration testing, antenna was subjected to deployment shock loading coming from the spacecraft solar panels and separation system. The antenna survived the shock loading with no degrading effects on the subsequent deployments.

The HDRM release of the arms and the strap band test was also performed after the vibration and shock testing, Energy absorbing foam was used on the inside of the HDRM shields, to prevent possible damage from the Strap Band HDRM firing as per the lesson learnt from the previous deployment in similar configuration. All the post-test releases and deployments were successful.

6. THERMAL CYCLING

Thermal cycling was carried out in stowed configuration in climatic chamber after attaching to a fixture. At this point, the HDRM actuators had already been fired. Therefore, dummy actuators were used to simulate the HDRMs. Prior to the closing of the HDRM arms, the release bolt stretch was measured. The HDRMs were preloaded by stretching the release bolts by 0.2mm. Five thermocouples were be placed on the antenna to monitor the temperature during the test. One on the hinge, one on the active members, one on the deployment arm, one on the top of the far HDRM arm and one at the base of the far HDRM arm. Fig. 13 shows the antenna when placed inside the climatic chamber and Fig. 14 shows the temperatures limits achieved by all the sensors during hot and cold cycles.

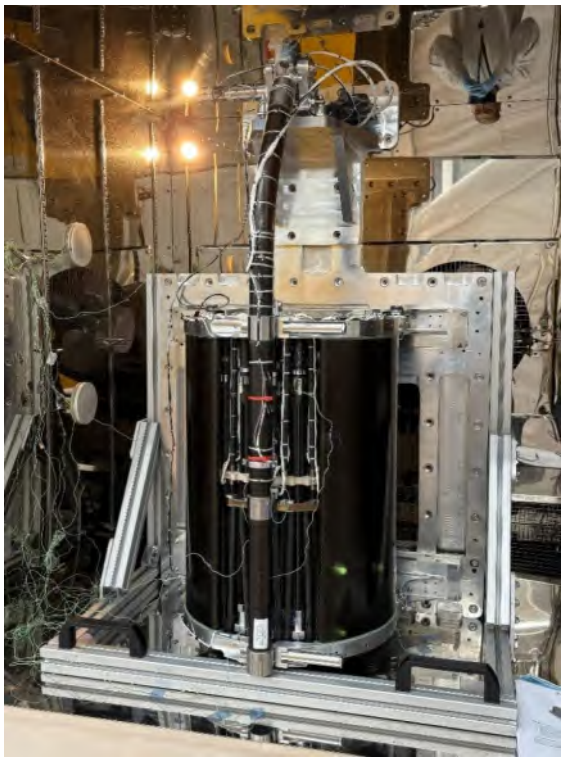

Figure 13 QM Antenna inside of Climatic Chamber

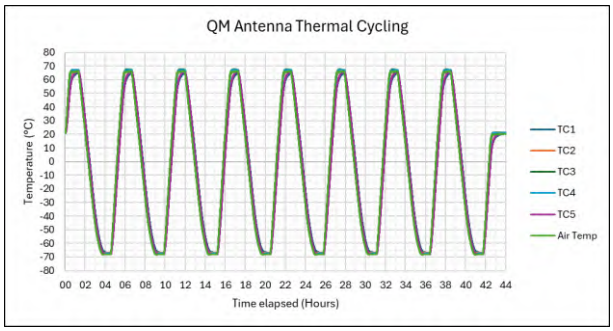

Figure 14 Thermocouple Data for QM Thermal Cycling

7. REFLECTOR DEPLOYMENT STRUCTURE (RDS) TESTING

The objectives of this subsystem test campaign were to verify that

- The RDS can be deployed in ambient, hot and cold conditions.
- Verify that the RDS can be deployed with one failing actuator.
- The manufacturing accuracy respects the surface accuracy budget.
- Verify that after subjecting to mechanical and thermal environmental loading and consecutive deployments in temperature the deformation of the reflector surface is still within specification.

This test campaign was performed with the QM Reflector Dish Test Article as shown in Fig. 15. The subsystem is intended to be representative in fit, form and function of the FM build, including the harness which will be routed and dressed as for flight.

Ambient deployment was carried out to characterise the subassembly before testing it at the extreme operating conditions and to check the motorisation margin. Test Success Criteria was that each active member needs to travel until it latches without interruptions or failure and with all the v-folds latching. Also to demonstrate the MoS of 3 as motorisation margin, the same condition needs to be verified when the current limit is set 1/3rd of full current limit.

Figure 15 QM Reflector Dish Ambient Deployment Setup

This test was conducted twice in each of ambient, hot and cold conditions, once with the full current limit and once at 1/3rd of the current limit. Hot and cold deployment tests were carried out in a large climatic chamber to achieve the full deployed configuration. The first active member was fixed to the GSE and rest were allowed to move freely on the floor by use ball bearing attachments. Four thermocouples were installed at different locations to ensure that desired temperature is achieved consistently across the antenna. The required temperature was achieved on all thermocouples in WC and WH cases as shown in Fig. 16 and Fig. 17 respectively. Fig. 18 shows the test setup for RDS deployment inside the climatic chamber prior to and post deployment.

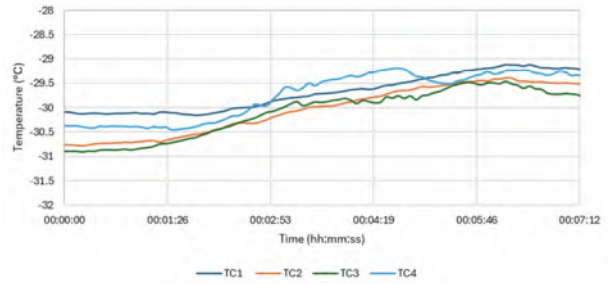

Figure 16 Thermocouple temperatures for cold deployment

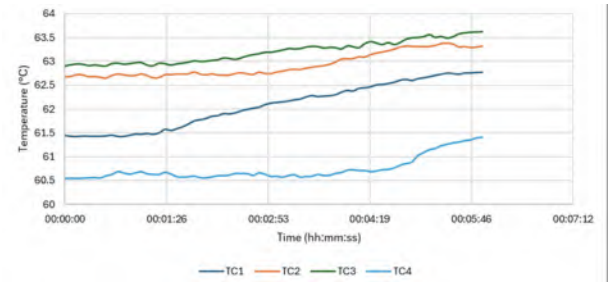

Figure 17 Thermocouple temperatures in hot deployment

All these tests were successful, and all the motors latched into place at the end of deployment and all V-folds deployed, tensioning the cable network and membrane surface. The deployment at WC conditions at 1/3rd of the current limit was slower as compared to other temperatures as the maximum current limit was hit, however still all the test objectives were met.

An RDS Deployment test with one non-operating actuator was carried out to ensure the built-in redundancy of the Reflector Dish subsystem, by having one of the 20 motors non-operating. The reflector dish assembly is designed to continue in deployment in the event of one failed motor. Test success criteria was that each powered active member needs to latch correctly at the end of travel and the “failed” active member stops within 10mm of the latching point. To replicate the failure mechanism, one of the actuators was not powered.

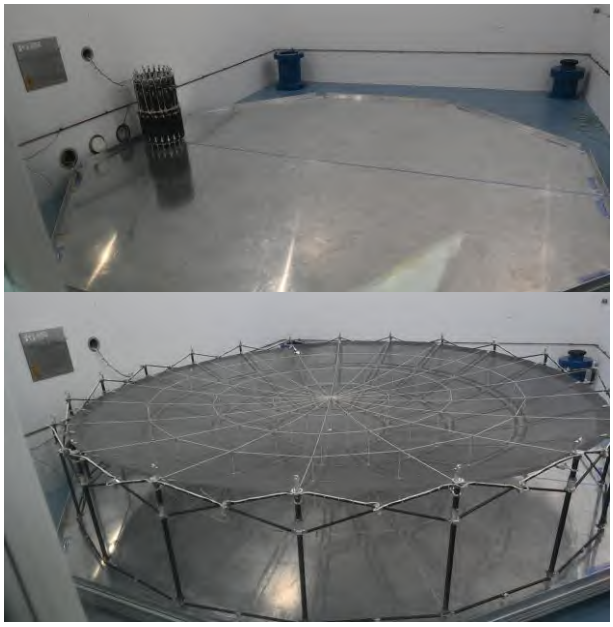

Figure 18 Test setup of RDS deployment inside climatic chamber pre and post deployment

The test was successful and the ‘failed actuator’ was found to be within 9mm of its latched position. One observation was that the motors close to the ‘failed’ actuator drew more than nominal current at ambient conditions as more torque was required to deploy the reflector, however this current was still within the 1/3rd of the maximum current limit, hence demonstrating sufficient margin and redundancy in the design.

To measure the manufacturing accuracy of the as-built reflector, laser scanning was done to characterise the reflective surface accuracy and provide justification for the surface accuracy assessment and loss budget. The reflector dish was deployed inside of the Gravity Offset jig and hung on springs. The setup is shown in Fig. 19.

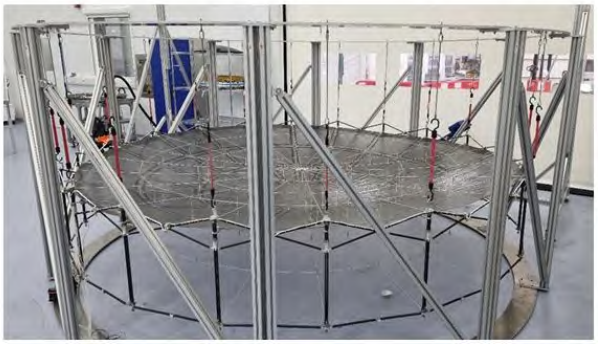

Figure 19 Reflective Dish Surface in deployed configuration in gravity offset jig.

A laser tracker (AT960) was used for measuring the surface accuracy of the reflective membrane, with either a medium range or a long-range scanner head. The long-range scanner can quickly measure the surface of the reflective membrane, which was

useful when making tension adjustments in the cable network, however it has some losses in accuracy and detail. The medium-range scanner is much more accurate and has an accuracy of 0.001mm, however scanning takes much longer, and the scanner needs to be much closer to the surface which makes it tedious due to the presence of the cable network. This was used to get the final scan of the reflective membrane surface. Great care was taken not to touch the GSE or the reflector dish during the scans as this would create a shift in the scan clouds. Fig. 20 shows the reflective surface of the antenna using the medium-range scanner after no further adjustments. The overall Root Mean Square (RMS) deviation of the measured surface as compared to ideal paraboloid surface was found to be 1.91mm.

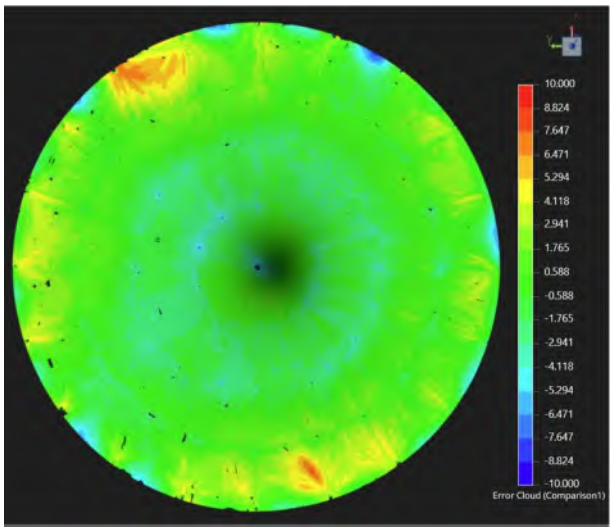

Figure 20 Pre-Test Medium Range Scan (RMS = 1.91 mm)

During one stowage cycle of the antenna, it was discovered that one of V-fold bonds had failed and one CFRP tube was cracked. Upon investigation, it was found that the CFRP tubes were not being abraded properly prior to bonding with end attachments. Then in one of the V-fold deployments, the bond failed and the tube was damaged. To prevent this issue from occurring again, the manufacturing and assembly procedures were updated to include proper abrasion and surface roughness checks of a sample of the tubes to ensure the abrading step is done properly.

During the thermal deployment testing, it was discovered that the staking had failed on the membrane connector shaft, allowing it to rotate, distorting the shape of the reflector. The staking was on a single M2 bolt on the connector shaft, which did not have enough preload to resist the forces of the manual stow of the antenna. The connector shaft was redesigned to have a key in the design to prevent rotation, rather than relying just on the bolt preload. Future recommendation: do not solely rely on bolt preload to prevent rotation when using only a single bolt.

The post EVT test campaign scan showed some degradation and the RMS increased from 1.91 to 2.42mm. This degradation captured the effect from 12 stowed and deployed cycles, including 4 deployments in each of ambient, hot and cold conditions. The antenna had also been subjected to vibration and thermal cycling in stowed configuration, and a total stowed storage time of 5 months. This value was consistent with the allowable surface accuracy error requirements as per the RF loss budget for C-Band SAR operation.

8. CONCLUSION

The successful qualification campaign for the OSS offset reflector has been presented covering the approach and highlights of critical subsystem level tests and full stowed antenna level testing, including lessons learned.

Hinge and deployable arm motorisation margin was demonstrated across all thermal conditions, with successful latching in all cases. HDRM and strap band testing was successful with preload control issues accepted based on successful stowage and no downstream issues.

Full stowed antenna Vibration and thermal cycling testing showed no significant frequency or amplitude shift pre- to post-test, confirming structural integrity, with successful releases and deployments post EVT.

Full RDS deployment succeeded across all thermal conditions, and single-failed-actuator testing confirmed built-in redundancy. Surface accuracy remained within the RF loss budget throughout the campaign, despite some degradation following repeated stow/deploy cycling, thermal cycling and extended stowage.

The campaign demonstrates qualification of the mechanisms and structural architecture for flight, with methodology and lessons learnt applicable to future small-sat class deployable SAR antennas.

Small Satellite; Platform Standardization; Design for manufacturing; High-cadence production; Modularity; Industrialization

ABSTRACT

The increasing demand for small satellite constellations is driving a shift from mission-specific structural designs toward standardized, production-oriented platforms. This paper presents the mechanical architecture of HAWK PLUS, a multi-mission microsatellite platform developed by Argotec to combine modularity, structural efficiency, and industrial scalability.
The platform adopts a bay-level modular architecture in which the primary structure is subdivided into self-contained functional modules connected through standardized mechanical interfaces. Particular focus is placed on the design of the inter-bay interfaces, developed to preserve load path continuity and alignment accuracy while enabling assembly-based production. The paper discusses the structural trade-off between monolithic and modular concepts, highlighting the application of Design for Manufacturing and Assembly (DFMA) principles to reduce part count and simplify production.
The manufacturing and verification strategy of the Structural Thermal Model (STM) is also presented, including impact and environmental testing used to validate the structural concept at both platform and payload-interface level. Finally, the paper discusses the management of mission-specific structural deltas within a standardized platform core.

1. INTRODUCTION

1.1. Background and Motivation

The classical spacecraft development lifecycle, as defined by the NASA Systems Engineering Handbook [1] and ECSS standards [2], follows a sequential process of requirements definition, design, manufacturing, integration, verification, and operation. While this approach ensures high reliability and mission-specific adaptability, it is poorly suited to the emerging New Space paradigm, where commercial constellations require shorter development cycles, recurring production, and reduced Non-Recurring Engineering (NRE).

These constraints are driving a shift toward standardized and production-oriented platform architectures. In this context, modularity has emerged as a key enabler for scalability and recurring manufacturing, while introducing challenges related to structural efficiency, load path continuity, and interface complexity.
Within this framework, HAWK PLUS platform builds on Argotec's heritage in small satellite missions [3,4,5] progressively evolving from mission-specific spacecraft designs toward a standardized modular platform architecture. Applications range from optical and Synthetic Aperture Radar (SAR) Earth Observation (EO) to 5G satcom, space-based Intelligence, Surveillance, and Reconnaissance (ISR), distributed edge computing, and CubeSat dispenser missions. The platform, with a launch wet mass in the 100–200 kg range (including payload), is designed for series production at Argotec's SpacePark facility, where streamlined manufacturing and assembly processes embody the industrialization model required to meet the demands of next-generation satellite production [6].

1.2. Structural Modularity Challenges

The adoption of a bay-level modular architecture requires the primary structure to satisfy two contrasting objectives. On one hand, the structure must provide the stiffness, strength, and dimensional stability required to withstand launch environments. On the other, it must allow independent manufacturing, integration, and replacement of functional modules without compromising the structural integrity of the spacecraft.

Achieving this balance presents major engineering challenges, particularly in mitigating structural mass penalties and preventing a proliferation of Part Numbers (PNs). Standardized modular joints naturally introduce local mass overhead compared to tailored, monolithic structures; furthermore, maintaining platform flexibility without over-complicating the supply chain requires an aggressive strategy of component commonality.

These objectives are reconciled through the definition of standardized mechanical interfaces that ensure repeatable assembly, controlled load transfer, and accurate positioning of adjacent

modules. The interface design thus becomes the cornerstone of the structural architecture—directly influencing global dynamic behavior, manufacturing repeatability, and the ability to accommodate mission-specific configurations while preserving an optimized, low-complexity platform core.

1.3. Scope of the Paper

This paper presents the structural architecture and mechanical design approach adopted for HAWK PLUS platform, with particular focus on the trade-off between structural performance, modularity, and manufacturability.
The paper first describes the deck-and-bay structural architecture and the mechanical interface philosophy adopted to enable standardized and repeatable configurations. The manufacturing and verification approach is then presented through the Structural Thermal Model (STM) test campaign, including modal, vibration, and thermal testing.
The paper also discusses how manufacturing and verification feedback was incorporated into the structural design, leading to targeted design optimizations. Finally, the approach adopted to manage mission-specific structural modifications is presented, highlighting how configuration-specific requirements are progressively incorporated into a common and evolving platform baseline.

2. MECHANICAL ARCHITECTURE OF HAWK PLUS

2.1. Design Drivers and Structural Requirements

The mechanical design of HAWK PLUS has been developed to support high-cadence, cost-effective microsatellite production while preserving structural performances, mission adaptability and minimizing non-recurring engineering. Key structural drivers include:

- **Standardization** end-to-end: establish common mechanical, electrical, and data interfaces, with selected components and controlled Bill of Materials (BOM), to reduce variants, simplify integration, and accelerate configuration qualification.
- **Modularity** and **functional segregation**: implement function-specific modules that are pre-integrable and testable in isolation, enabling a plug-and-play architecture and parallel Assembly, Integration and Verification (AIV) workflows to increase throughput and compress the integration critical path, while maintaining deterministic structural interfaces between functional modules.
- **Scalability** and **Multi-Mission Compatibility**: Define a flexible baseline architecture designed to easily adapt to diverse operational scenarios, accommodating a wide spectrum of payload configurations and ensuring broad compatibility across multiple launch vehicles.
- **In-House Manufacturing Optimization:** Design and optimize structural components specifically tailored for Argotec's internal manufacturing capabilities and equipment, ensuring direct control over fabrication quality, reducing lead times, and maximizing production efficiency.
- **DFMA** and PNs reduction: minimize part diversity and geometry complexity to support repeatable assembly processes, lower production risk, and stabilize cycle times across series builds.
- Design for **testability**: architect modules and interfaces that are observable and verifiable during the platform AIV process.
- **Model-driven verification**: maintain a coherent set of physical and software models to validate the platform early, reduce the risk of interfaces and environments, and validate the flow AIV.

These requirements define the basis for a modular structural concept in which performance and industrialization constraints are treated as coupled design drivers.

2.2. Deck-and-Bay Structural Architecture

The HAWK PLUS platform adopts a deck-and-bay structural architecture in which the spacecraft primary structure is functionally partitioned into three decks: payload, avionics, and propulsion. Each deck represents a distinct structural partition with dedicated load paths and interfaces, enabling independent integration and testing prior to system-level assembly. This architecture is a direct consequence of the platform's DFM-oriented design. Each deck can be manufactured, assembled, and verified independently before final spacecraft integration, enabling parallel production and AIV activities.

- **Payload Deck**: The platform provides standardized mechanical, electrical, and data interfaces for a wide range of payloads. The top payload envelope supports dimensions up to 540 × 540 × 300 mm, referenced to the baseline Falcon 9 launch vehicle with a RPUG half-plate configuration. Payloads up to 340 × 340 × 360 mm can be accommodated within the internal Core envelope, depending on the Propulsion System (PS) tank configuration. For instruments mounted on the top plate, the baseline payload mass is up to 30 kg; however, both higher masses and expanded envelope dimensions for top-plate payloads can be evaluated on a case-by-case basis.
- **Avionic Deck**: Accommodates the core satellite bus functions. This architecture

enables scalability in both functionality and performance while preserving a common mechanical framework.

- **Propulsion Deck**: Accommodates the propulsion subsystem and the primary attitude actuators while providing the mechanical interface with the LV through the standard 15-inch separation ring. Different propulsion configurations can be integrated without modifying the structural architecture of the upper decks.

The HAWK PLUS architecture therefore combines two levels of modularity: **deck-level functional partitioning** and **bay-level subsystem modularity**. The former enables independent integration of major spacecraft functions, while the latter provides configuration flexibility within a common structural framework.
From a structural perspective, the deck architecture ensures that the primary launch loads are transferred through well-defined and repeatable load paths while preserving the modularity required for independent manufacturing and integration.

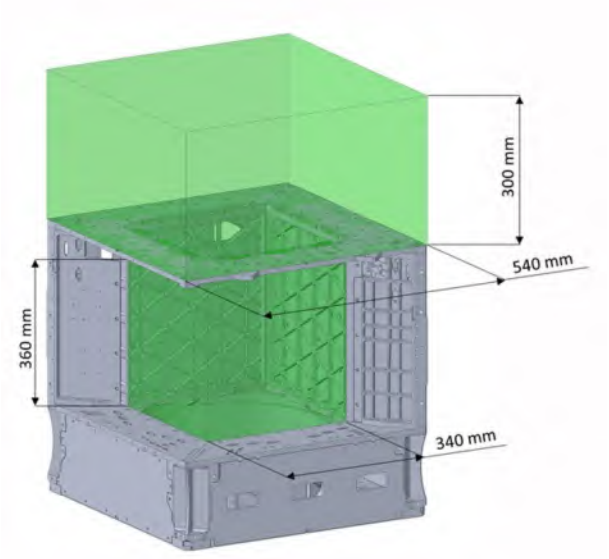

Figure 2-1 Mission-specific available envelope

Mission diversity in terms of payload characteristics, pointing requirements, communication capability, and available power is accommodated through a modular bay architecture within the Avionic Deck. Each bay constitutes a self-contained structural module with standardized mechanical, electrical, and data interfaces, allowing independent manufacturing, assembly, inspection, and acceptance testing prior to deck integration. The common interface philosophy enables different subsystem configurations to be accommodated without modifications to the surrounding structure.

- **Avionics Bay**: Accommodates the OBC and telecom suite.
- **AOCS Bay**: Accommodates the ADCS electronics, GNSS receiver and star trackers.
- **EPS Bay**: Accommodates the electrical power subsystem through three standardized configurations based on mission power requirements. Scalability is achieved using Argotec ZEUS PCDUs and ELEKTRA battery modules while preserving identical external mechanical interfaces.

Across all bays, standardized bracketry, connector layouts, and predefined routing paths ensure repeatable assembly, simplified visual inspection, and consistent integration procedures. The connector arrangement maintains accessibility throughout the assembly process, enabling bay-level acceptance testing prior to deck integration while preserving access for subsequent system-level verification.

2.3. Structural Load Paths and Interface Philosophy

The HAWK PLUS structural architecture is based on a decentralized primary load path strategy that eliminates the need for a traditional load-bearing central thrust tube. Instead, each bay operates as an autonomous, self-supporting structural module, with the spacecraft's primary structural loop and global stiffness closed directly through standardized deck-to-deck and inter-bay interfaces.

This approach provides a clear, predictable load distribution from the launch vehicle adapter straight to the payload interface. By maintaining a modular primary load path without a central core, the mechanical loads transmitted to the payload can be uniquely characterized and evaluated. This enables rapid structural and mission assessments to efficiently verify compatibility across a wide range of payload configurations and mission profiles, while preserving full manufacturing and integration independence for each individual bay.

3. STM MANUFACTURING AND VERIFICATION

3.1. Verification Approach

To support recurring production across multiple missions, the verification strategy is designed to be applicable at platform level rather than mission-specific. Structural load paths, thermal behaviour, electrical/data interfaces, and flight software are validated early using representative models that replicate flight ICDs and environmental envelopes. This approach enables reuse of analyses, test procedures, and acceptance criteria across builds, limiting mission-specific effort to well-defined configuration deltas.
To operationalize this methodology, the verification plan is based on three complementary models:

- a STM, correlated with the finite element model, used to anchor mechanical and

thermal predictions and to define representative environmental test conditions;
- a 3D-printed harness mock-up used to validate routing paths, cable lengths, bend radii, connector accessibility, and geometric fit against the CAD definition prior to hardware integration;
- a system RackSat reproducing the platform electrical and data architecture and integrating the relevant avionics and flight software, providing a representative environment for end-to-end functional and interface validation, early system bring-up, and regression testing prior to spacecraft integration.

3.2. STM Configuration

The STM reproduces the flight-representative primary and secondary structure of the HAWK PLUS platform. The avionic units are replaced by dedicated mass dummies designed to replicate the mass properties, center of gravity, envelope, and mechanical interfaces of the corresponding flight hardware.

In detail:

- Mass dummies represent all platform subsystems, including a modular propulsion dummy to cover different configuration scenarios and a modular payload dummy designed to reproduce representative payload mass properties and mechanical interfaces. The payload dummy enables the assessment of the structural dynamic response under different payload mass configurations while covering the relevant payload envelopes.
- The primary and secondary structural assemblies are identical to those of the Flight Model, including materials, manufacturing processes, fastening philosophy, and secondary retention methods.
- All load-carrying interfaces between decks, bays, payload, and the launcher adapter are fully representative of the flight configuration, ensuring representative load transfer and boundary conditions during the test campaign.
- The STM configuration was defined to support representative combinations of platform subsystems and payloads. Dedicated modular dummies can be adapted to reproduce the relevant mass properties and mechanical interfaces of different PS and PL configuration.

The resulting STM, as assembled prior to the test campaign, is shown in Figure 3-1.

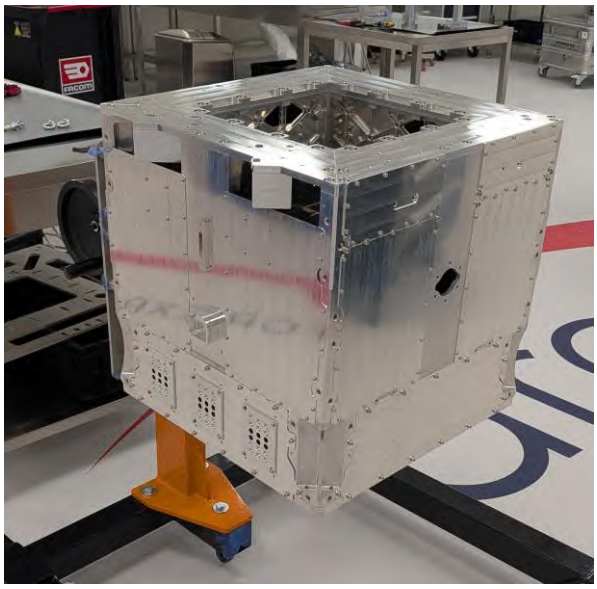

Figure 3-1: STM assembled in the cleanroom at Argotec's SpacePark facility.

3.3. STM Testing

The STM test campaign was structured to characterize and verify the mechanical and thermal behavior of the platform while simultaneously supporting model correlation activities. The comprehensive test flow encompassed physical property measurements, impact testing for Experimental Modal Analysis (EMA), vibration testing, and Thermal VACuum (TVAC) testing. The whole test campaign was performed at the Argotec facility.

The impact testing was performed to identify the structural modal parameters and provide experimental data for correlation of the Finite Element (FE) model. The test campaign also provided transfer functions and Shock Response Spectra (SRS) between the separation system interface and selected locations on the Item Under Test (IUT), considering both free-free and fixed boundary conditions.

Vibration testing was performed an IMV 65 kN electrodynamic shaker. The campaign included Random Vibration, Sine Load, and Static Load tests performed at the qualification levels specified by the Falcon 9 RPUG [7], which serves as the baseline for the platform requirements.

Resonance surveys were performed before and after each test to monitor changes in the dynamic behaviour and verify the predefined acceptance criteria. The experimental setup comprised 19 triaxial accelerometers for structural response measurements and 2 monoaxial accelerometers for vibration control (Figure 3-2).

Figure 3-2: HAWK PLUS STM mounted for vibration testing in the SpacePark cleanroom facility at Argotec.

The STM subsequently underwent a TVAC test campaign to support correlation of the Thermal Mathematical Model (TMM). Aluminum dummy masses coupled with resistors were used to reproduce representative subsystem dissipations, while 51 type T thermocouples were placed in key locations of the platform to monitor temperature variations, as shown in Figure 3-3. Both cold- and hot- case conditions were tested by varying the power dissipated by the dummy resistors.

The resulting test data provide a reference for structural and thermal model correlation and support the assessment of the platform across the defined configuration space. This approach reflects the broader industrialization strategy adopted for HAWK PLUS, in which both the product and its verification process are conceived to support recurring missions while limiting configuration-specific activities.

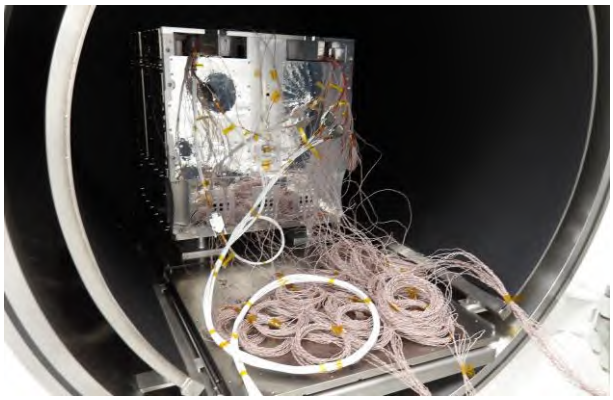

Figure 3-3: HAWK PLUS STM equipped for TVAC testing in the SpacePark cleanroom facility at Argotec.

3.4. Structural Design Optimization

The manufacturing and verification campaign performed on the STM generated valuable feedback extending beyond the structural verification. The practical experience gained during machining, assembly, and testing enabled the identification of design improvements aimed at increasing manufacturability, simplifying integration, and improving the structural performance of the platform. These modifications were implemented in the flight configuration, demonstrating the iterative design-to-manufacturing approach adopted during the industrialization of HAWK PLUS.

Optimization activities were carried out across several primary and secondary structural elements to streamline manufacturing processes while enhancing structural stiffness. Among these improvements, the most notable modification was applied to the Propulsion Deck central core. The initial cylindrical geometry was redesigned using the SOL 200 topology optimization of Simcenter Nastran, resulting in an octagonal cross-section that better distributes structural material along the principal load paths. Besides increasing the overall stiffness of the structure, the new geometry improves the accommodation of propulsion components and other internal equipment by creating additional usable volume and more regular installation surfaces. Furthermore, it significantly simplifies machining operations, shortening lead times and ensuring tighter manufacturing tolerances.

Another notable modification targeted the secondary structure supporting the solar array attachment interfaces. Measurements collected during the STM vibration campaign highlighted local dynamic amplification in this region. Consequently, the geometry was locally reinforced and redesigned, resulting in a 16% reduction in the measured grms level at the relevant interface.

Beyond component-level structural enhancements, the STM campaign proved essential for testing and refining the assembly procedures. Hands-on experience during the integration phase allowed the team to optimize AIV workflows, eliminate assembly

bottlenecks, and collect empirical timing and handling data. These preliminary operational insights provided the necessary foundation to size and structure an efficient, high-throughput industrial production line for series manufacturing.

These optimizations illustrate the iterative development process adopted for HAWK PLUS, where manufacturing experience and verification results are continuously fed back into the design. Rather than qualifying a single spacecraft configuration, the STM campaign was used to mature the baseline platform, improving both its structural robustness and its suitability for repeatable industrial production.

4. MANAGEMENT OF CONTROLLED STRUCTURAL DELTAS

4.1. Baseline Evolution

The industrialization of a multi-mission platform does not imply the complete elimination of mission-specific structural modifications. Rather, the objective is to progressively reduce their extent by distinguishing between recurring requirements that can be incorporated into the platform baseline and changes that are inherently driven by a specific mission configuration.

The first HAWK PLUS implementations provided practical feedback on this distinction. Requirements emerging from customer missions, manufacturing activities, and verification campaigns highlighted structural features and interfaces that could be improved or made more versatile. When a modification was identified as beneficial across multiple configurations, it was incorporated into the baseline design. Conversely, changes directly driven by a specific payload, propulsion configuration, or mission environment were retained as configuration-specific deltas.

To ensure long-term platform stability, the mechanical design is architected so that mission-driven variations remain strictly localized. Structural interfaces and load paths are decoupled in a way that prevents design changes from propagating to adjacent assemblies or core platform components. Modifications are thus confined exclusively to designated, adaptable structural elements without impacting the qualified core platform.

The objective is therefore not to freeze the platform design, but to progressively mature it while preserving the standardized interfaces, load paths, and manufacturing processes that define the common architecture.

4.2. Lessons Learned

The STM manufacturing and test campaign provided direct feedback on both structural performance and manufacturability. This feedback resulted:

1. **Modularity Must Be Interface-Centric:** True modularity extends beyond merely dividing a structure into discrete bays. The mechanical interfaces themselves become the primary drivers of structural performance, controlling overall dynamic behavior, load distribution, and platform stiffness.
2. **Verification Results Drive Baseline Maturation:** Empirical feedback gathered during environmental testing and AIV must be systematically fed back into the core design, ensuring that baseline qualifications continuously evolve to reflect real-world testing insights.
3. **Structural Optimization Must Account for Production:** An analytically optimal structure is not necessarily the best solution for series production. Optimization must strike a trade-off between structural performance and Design for Manufacture and Assembly (DFMA) to safeguard throughput, lead times, and repeatability.
4. **Standardization Should Enable Controlled Variation:** The goal of platform industrialization is not to eliminate mission-specific adaptations entirely, but to confine and control them. By localizing variations to dedicated structural elements, custom mission requirements can be accommodated without invalidating the qualified core architecture.

5. CONCLUSIONS

This paper presented the structural architecture and mechanical design approach adopted for the HAWK PLUS modular platform, focusing on the integration of structural performance, modularity, manufacturability, and recurring production requirements. The deck-and-bay architecture provides standardized interfaces and continuous load paths while enabling independent manufacturing and integration of structural modules.

The STM manufacturing and verification campaign provided experimental data for structural and thermal model correlation and generated practical feedback on both manufacturability and structural dynamic behaviour. This feedback was incorporated into the platform design through targeted structural optimizations, demonstrating the iterative interaction between design, manufacturing, and verification.

The HAWK PLUS development demonstrates that platform standardization does not require the complete elimination of mission-specific modifications, but rather their controlled management within an evolving common baseline. This approach supports a more scalable and repeatable development and production model for multi-mission small satellites.

ABSTRACT

This paper presents the design and verification of an optimised pyrotechnic Gas Expansion Tube (GET) for integration into a Frangible Joint (FJ) system used for horizontal separation of Payload Fairings (PLF). An advanced simulation framework was developed to model the detonative loads, the consequent expansion of the explosive tube assembly and the controlled severance of the associated structural profile assembly.
A coupled Euler-Lagrange finite element approach was used to simulate the detonation-driven gas expansion and the structural deformation of the GET together with the coupled FJ profile assembly. Explosive loading was represented using the Jones-Wilkins-Lee (JWL) equation of state to simulate the detonation-driven gas expansion. A hierarchy of finite element models was developed to investigate the coupled physical mechanisms at different levels of geometric detail and computational effort.
The numerical models were iteratively refined using experimental data from development and qualification test campaigns, including sub-length, intermediate-length, and full-length separation tests. The resulting GET design provides the required separation performance while maintaining structural integrity over the qualification envelope and enabling improved control of the transmitted shock level.

1. INTRODUCTION

The horizontal separation of large PLF is a mission-critical event requiring a highly reliable separation system with predictable fracture behaviour and a controlled shock environment. In the FJ system considered in this study, separation is initiated by a pyrotechnic GET, which converts the energy released by the explosive charge into a controlled mechanical load acting on the structural profile. The design of the GET is therefore a key factor governing the functional performance of the separation system.
A major challenge in the development of such pyrotechnic separation systems is the simultaneous fulfilment of functional and structural integrity requirements over the complete thermo-mechanical qualification envelope. The GET must withstand the high transient pressure generated by the detonative event while expanding sufficiently to provide the energy required for reliable severance of the FJ assembly.
At the same time, the expansion process must be carefully controlled to prevent tube rupture and unwanted secondary fractures in the surrounding structural components. These requirements must be fulfilled over a wide range of operating conditions while accounting for temperature variations, manufacturing tolerances, and the inherent statistical scatter associated with energetic materials. For the FJ system investigated in this programme, the qualification temperature range extends from −43 °C to +125 °C.
In practice, this means that the same design must reliably sever the FJ under the least favorable explosive underload condition (80 % of the nominal charge) while simultaneously preventing rupture of the GET under the most severe overload condition (120 % of the nominal charge). Such margin conditions give rise to conflicting design requirements. At low temperatures and reduced explosive loading, the FJ must still sever completely and reliably. Conversely, at elevated temperatures and increased explosive loading, the GET must maintain its structural integrity and hermetic tightness while ensuring the absence of secondary fractures within the profile assembly.
An overview of the overall development, verification, and qualification programme of the final frangible joint separation system solution is presented in the companion paper by F. Marques Novo et al. [1]. The present work focuses specifically on the physical mechanisms governing the initial GET design, its expansion and the resulting severance process, together with the characterisation of the shock generated by the separation event.
Experimental investigations were performed throughout the programme to characterise the behaviour of the separation system and to measure the shock transmitted to representative adjacent structures. In parallel, advanced finite-element models based on an Euler-Lagrange coupling approach

were developed to simulate the detonation process, the expansion of the GET, the severance of the FJ, and the resulting structural response. The explosive loading is represented using the JWL equation of state, enabling the transient interaction between the detonation products and the deforming structural components to be captured.
Emphasis is placed on the correlation and validation of the numerical models against the initial set of experimental data, the influence of test-specific boundary conditions, and the use of model scaling to enable efficient parametric investigations. While experimental testing is essential for demonstrating functionality and validating the simulation methodology, the inherent scatter of shock measurements can make it difficult to isolate the influence of individual design parameters. Numerical simulation therefore provides an important complementary tool for understanding the governing physical mechanisms and systematically assessing design modifications.
The objective of this work is to demonstrate how the combination of early development testing and advanced Euler-Lagrange simulation can be used to characterise, optimise and verify the performance of a pyrotechnic GET-based separation system, with particular emphasis on the expansion and severance mechanisms and the transmitted shock environment.

2. DEVELOPMENT APPROACH

2.1. Development Tests

Initial development tests were performed to investigate the structural response of the GET under extreme detonative loading conditions and to identify the associated failure modes and structural limits.

Figure 1: Failure of a GET specimen under extreme overload conditions in an unconstrained region

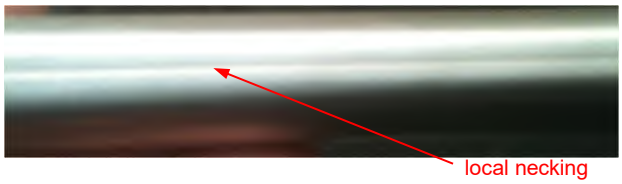

Figure 2: Local necking observed along GET length after expansion under overload conditions

The centre of Figure 1 shows a section of a ruptured tube specimen observed during an early detonative test performed under deliberately extreme explosive overload conditions. The test combined an increased explosive charge with a large unsupported region of the tube. To the left of the specimen, part of an L-shaped angle profile is visible. The profile incorporates a closely fitting passage that provides support to the tube and locally constrains its expansion. The explosive initiation point was located on the left-hand side, and the detonation wave propagated towards the right. Under these extreme conditions, the tube specimen ruptured in the unsupported region following the passage of the detonation wave. As illustrated in Figure 1, the failure occurred along the direction of detonation propagation.
Prior to detonation, the GET has an oblong cross-section. During the detonation event, the gaseous reaction products generated by the explosive cause the tube to expand, resulting in an approximately circular cross-section. As shown in Figure 2, the expanded tube exhibits pronounced local necking along its length, creating a preferential failure path. In tests performed with such deliberately excessive explosive loading, the resulting internal pressure exceeded the structural capacity of the unconstrained tube section. Consequently, the GET ruptured along the preferential failure path formed by the local necking. This failure mode was consistently observed in tests, in which the explosive loading exceeded the allowable range.

2.2. Design Optimisation

Representative sub-length specimens were conditioned to the required functional temperature extremes prior to separation testing, either by heating them in an oven or by cooling them in a refrigerator. In selected tests, the acceleration of the clevis profile was measured and in most tests the separation process was recorded using a high-speed video camera.
The following design parameters were investigated:

- Explosive loading of the detonation cord, expressed as the amount of High-Explosive (HE) contained within the GET;
- Design and material of the inserts used to position the detonation cord within the GET;
- Thickness of the separation plane in the FJ structural assembly;
- Distance between consecutive pins and collars.

Based on these parametric studies, the combination of detonation-cord loading and frangible-joint notch thickness was optimised to achieve consistently the required explosive loading margins under both underload and overload charge conditions across the complete temperature range. The selected design provides adequate design margins against both insufficient severance capability and loss of tube structural integrity along the complete temperature and explosive loading envelope. Its influence on the transmitted shock environment was subsequently investigated through dedicated output shock testing and numerical simulation.

2.3. Output Shock Characterisation

Following the initial design activities, a dedicated output shock characterisation test campaign was conducted to establish the shock environment generated by the initial GET and FJ configurations. This campaign provided the initial experimental data used

for correlation of the numerical models and for subsequent investigation of design modifications.
Figure 3 shows the test setup used for the initial characterisation and measurement of the structural shock generated during actuation of the initial FJ system configuration. The setup is representative of the flight configuration but installed in an inverted orientation. The aluminium plate with dimensions of 1 m × 2 m, represents a surrogate for the Launch Vehicle (LV) structure. Shock sensors A_0, A_1, A_2, A_3, and A_7 measure the transverse (out-of-plane) acceleration, while sensor A_{10} records the accelerations in all three spatial directions.

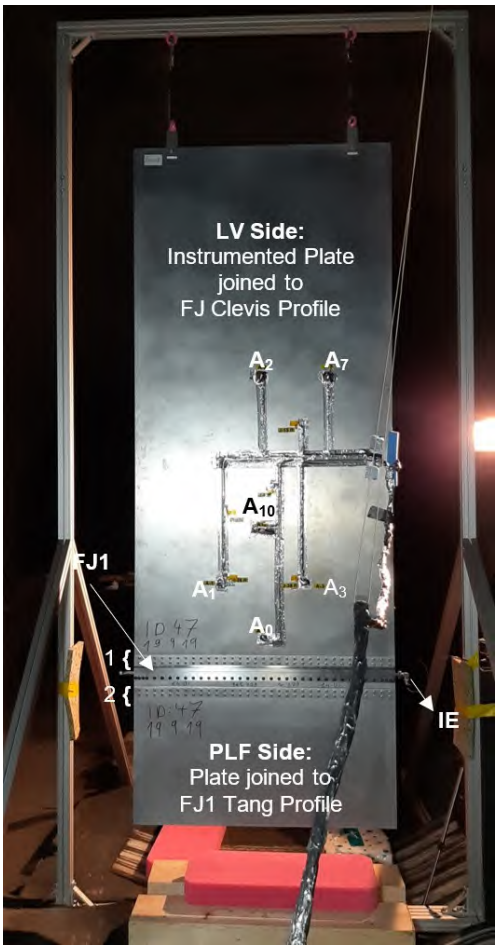

Figure 3: Output shock panel test setup of initial FJ design

The FJ is integrated into the clevis profile (CP), with the GET clamped inside the profile. The detonation cord is initiated at the Ignition End (IE), causing the FJ assembly to sever progressively from right to left. The plate representing the LV shell is attached to the CP using a splice plate and a series of screws, as shown in Figure 3 (item 1). A second plate, representing the PLF, is attached to the FJ tang profile (TP) using a similar connection. Details of this interface are shown in Figure 4 (item 2). A small gap is maintained between the TP and the PLF-representative plate. This feature ensures that the shock wave reflected from the bottom edge of the plate does not return to the FJ before completion of the severance process.

Figure 4 shows the deformation of the CP of the initial FJ design following the separation process. The TP is connected to the CP by means of a press fit pin-and-collar assembly (item 4). On the right-hand side, the plate representing the PLF side is visible. It is attached to the CP using a splice plate, screws, and nuts (item 2).

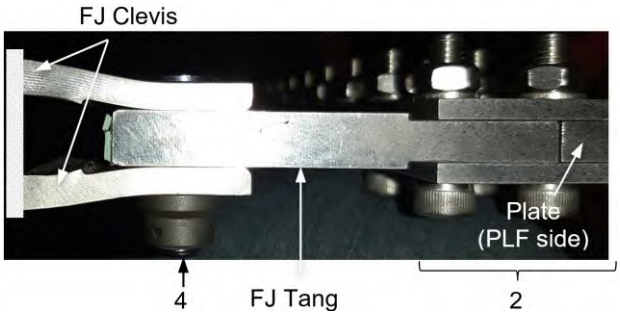

Figure 4: Deformation of FJ Clevis (initial design)

The corresponding Shock Response Spectra (SRS) measured during the initial development campaign are shown in Figure 5. The SRS curves were calculated from the measured acceleration time histories using the methodology described by Irvine [2].

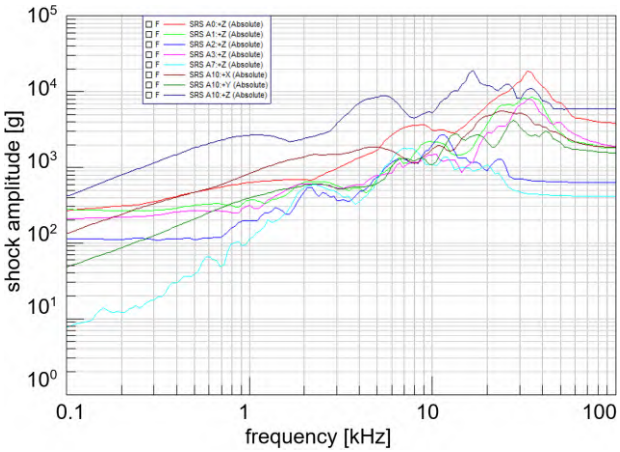

Figure 5: Measured SRS for initial FJ design

3. NUMERICAL MODELLING APPROACH

3.1. Numerical Models

Three finite-element models with different levels of geometric detail and computational size were developed to investigate both the structural response and the shock transmission of the initial FJ design, while enabling efficient evaluation of GET structural integrity and FJ severance behaviour.
The GET system following to Figure *6* was modelled using a coupled Eulerian-Lagrangian finite element formulation. The tube (item T) was discretised using Lagrangian hexahedral elements, whereas the detonation cord and the centring holders (item H) were represented as material volumes within a structured Eulerian mesh. This formulation enables the interaction between the rapidly expanding detonation products and the deforming tube to be captured without explicitly prescribing the tube expansion. The high-

explosive (item HE) charge is located at the centre of the model and is surrounded by the cable sheath (item C), together forming the detonation cord. The influence of the holder configuration on the dynamic expansion of the GET and the subsequent severance behaviour was investigated as part of the numerical study.

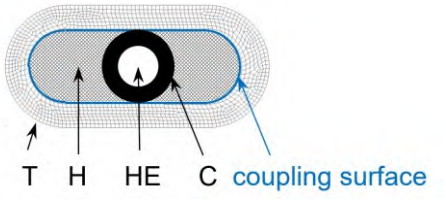

Figure 6: Eulerian-Lagrangian coupling used for the GET model

The full-scale model, corresponding to the experimental configuration shown in Figure 3, is presented in Figure 7. The dark-grey regions represent the attached plates and are modelled using shell elements, while the light-grey regions correspond to the FJ separation system. Details of the separation system are shown in Figure 8 and Figure 9.

Acceleration time histories were extracted at nodal locations corresponding to the positions of shock sensors A_0, A_1, A_3, and A_{10}, as well as at additional locations in the vicinity of the frangible joint. In addition, stress time histories were extracted from selected solid elements located within the FJ notch to assess the local structural response during severance.

The full-scale model was computationally demanding because of the large structural dimensions and the fine spatial and temporal resolution required to capture the relevant high-frequency shock response. The full-scale model contained 3'225'235 Eulerian multi-material elements, 807'796 first-order Lagrangian solid elements and 31'920 quadrilateral shell elements. The total simulated time was 20 ms, with output data recorded at intervals of 1 µs. This temporal resolution was required to evaluate the SRS over the specified frequency range, from 0.1 kHz to 100 kHz. A complete simulation required approximately three months of computational time. To reduce the computational effort, an intermediate-scale model exploiting geometric symmetry was developed. The model retained the relevant structural details of the full-scale configuration while reducing its length from 1.0 m to 0.5 m. For configurations with initiation from both ends of the detonation cord, as in the nominal flight configuration, the two detonation fronts meet at the symmetry plane. This allows the reduced model to reproduce the relevant structural response while substantially reducing the computational cost.

For the extensive parametric studies, a further sub-length model was developed. This model represents the narrow strip between the two red dash-dotted lines indicated in the full-scale model of Figure 8. Its length was reduced to half the distance between two adjacent pin-and-collar connections. Owing to its significantly lower computational effort, this model was used for most of the design investigations, with a typical computation time of approximately 30 hours per simulation.

Table 1: Three-scale FE modelling approach

Model	Length	Computational Effort
full-scale	1.0 m	~3 months
intermediate-scale	0.5 m	~6 weeks
sub-length	half pin/collar pitch	~30 h

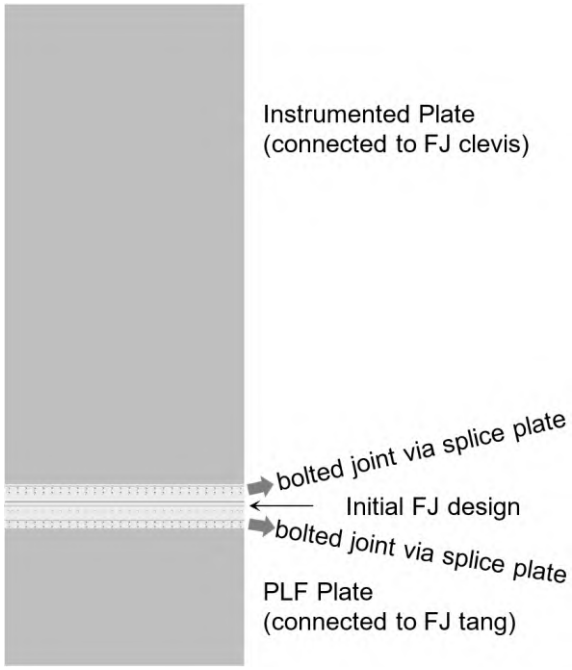

Figure 7: Complete Finite Element model of the test setup

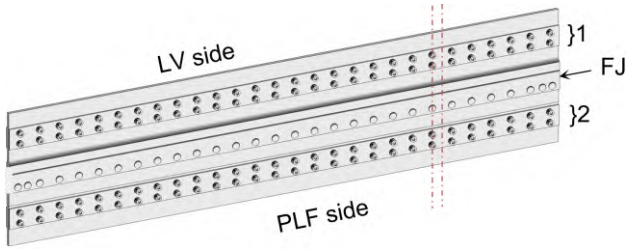

Figure 8: Full-scale model of the profiles with initial FJ and splice plate connections; 1 m length

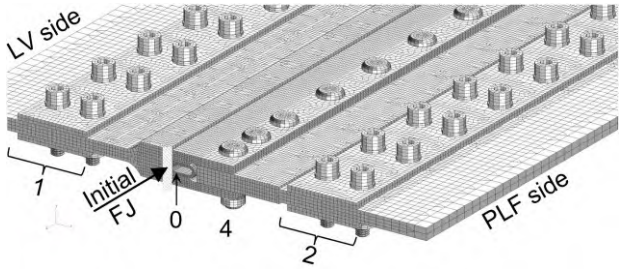

Figure 9: Detail of the Full-Scale FE-Model

The different design configurations and parameter variations introduced in section 2.2 were analysed using the sub-length model, as illustrated through Figure 10 to Figure 13.

Figure 10 shows the connection between the representative LV shell and the initial CP definition using a splice plate, screws, and nuts (item 1). A gap is present between the LV shell and the CP, as shown in greater detail in Figure 11. This configuration corresponds to the experimental setup shown in Figure 3. In selected simulations, this gap was intentionally closed, as illustrated in Figure 12. Furthermore, the splice, screws, and nuts were either included or omitted in the model to investigate the influence of their additional mass on the dynamic response. The initial GET (item 0) is clamped within the CP, which is connected to the TP by a pin-and-collar assembly (item 4). Due to limitations of the finite-element software, the preload introduced by the pin-and-collar connections, as well as that generated by the screws and nuts could not be explicitly represented. Consequently, all such connections were modelled without initial pre-stress.

The initial FJ configuration incorporates the original separation-plane design. The notch shape and thickness were varied as part of the parametric study to investigate their influence on the severance behaviour and the resulting structural response. The results were subsequently used to support the transition towards the final optimised design.

The most significant difference between the investigated configurations is illustrated by the two separation-system concepts shown in Figure 10. The upper configuration represents the reference design, whereas the lower configuration incorporates a shock-attenuation feature in the CP. The slits reduce the axial stiffness of the CP and consequently modify the propagation of stress waves through the structure, with a portion of the shock energy shifted towards lower frequencies. The slits introduced into the clevis profile reduce its axial stiffness. As a result, a reduction of the high-frequency shock response is expected. This attenuation concept was patented by John A. Graham [3] and has been used in here for investigation purposes only. Such shock-attenuation features can also be implemented in the TP.

The complete set of design parameters and combinations is summarised in Figure 13. Items 1 and 2 represent the interfaces between the separation system and the representative LV and PLF shell structures, respectively. The corresponding gaps G_1 and G_2 were modelled either in their nominal open configuration or as closed interfaces. For the closed-interface configurations, the corresponding splice plates, screws, and nuts were either included or omitted to assess the influence of their additional mass on the structural response. The shock-attenuation features (items 10 and 20) were compared with equivalent solid profiles without slits.

3.2. Material Models

In this study, special emphasis was placed on the characterisation of the GET tube and structural profiles, as their material behaviour directly influences both the structural integrity of the GET and the severance response of the FJ. Material properties inevitably exhibit manufacturing and batch-to-batch

variations and therefore cannot be represented by a single unique set of parameters. For metallic materials, quantities such as yield strength, ultimate strength, and elongation at break are usually provided as ranges with specified tolerances. Nevertheless, numerical simulations require a well-defined reference material model. Such a reference model enables a consistent assessment of the influence of individual design parameters and facilitates the identification of comparatively small design effects. The material characterisation presented in this section begins with the metal used for the GET tube. The constitutive models adopted for the tang and clevis profiles were developed in an analogous manner. All remaining metallic components, such as screws, nuts, pins, and collars, were represented as purely elastic materials. The final part of this section addresses the modelling of the energetic material and its detonation products.

The Johnson-Cook constitutive model Eq. (1) was used to describe the behaviour of the metallic components.

$$\sigma_y = \left(A + B \cdot \varepsilon_p^n\right) \cdot \left(1 + C \cdot ln\left(\frac{\dot{\varepsilon}}{\dot{\varepsilon}_0}\right)\right) \qquad (1)$$

A, B, C are material parameters

Yield stress σ_y is a function of plastic strain ε_p, strain rate $\dot{\varepsilon}$ with respect to reference strain rate $\dot{\varepsilon}_0$

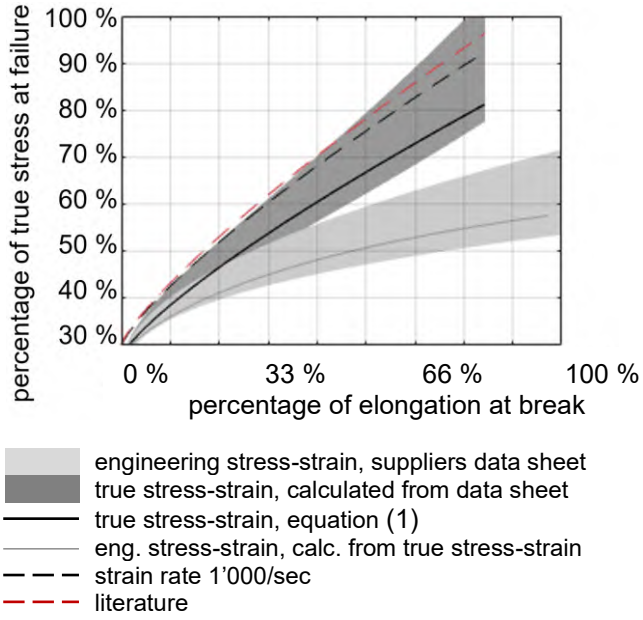

Figure 14: Yield stresses of GET tube

Material parameter ranges derived from the respective supplier specifications were considered to assess the sensitivity of the structural response to material variability. The resulting envelopes are shown as light-grey shaded areas in Figure 14. As the supplier data were provided in terms of engineering stress and engineering strain, the data were converted into true stress and true strain before implementation in the numerical model. The dark-grey shaded areas represent the scatter bands obtained from the corresponding uniaxial tensile tests. For the material parameters used in our simulations, the predicted elastic-plastic response remains within the ranges of the suppliers' specifications. The solid black curves show the true stress-strain response under quasi-static loading conditions. The black dashed curve illustrates the predicted behaviour at elevated strain rates according to the Johnson-Cook model. In addition, Figure 14 includes a red dashed curve taken from peer-reviewed scientific literature including studies of material behaviour at high strain rates and under severe deformation. These data were used to assess whether the selected reference model adequately represents the dynamic response of the material over the range of loading conditions relevant to the present study.

The JWL equation of state, given by Eq. (2), was used to describe the pressure-volume behaviour of the detonation products. The JWL formulation is widely used for numerical modelling of high-explosive detonation products, with material parameters available for a broad range of energetic materials [4-6].

$$p = A \cdot \left(1 - \frac{\omega \cdot \rho}{\rho_0 \cdot R_1}\right) \cdot e^{-R_1 \frac{\rho_0}{\rho}} + B \cdot \left(1 - \frac{\omega \cdot \rho}{\rho_0 \cdot R_2}\right) \cdot e^{-R_2 \frac{\rho_0}{\rho}} + \omega \cdot \rho \cdot e \qquad (2)$$

A, B, R_1, R_2, and ω are material parameters

Pressure p is a function of the volumetric expansion ρ_0/ρ and internal specific energy e.

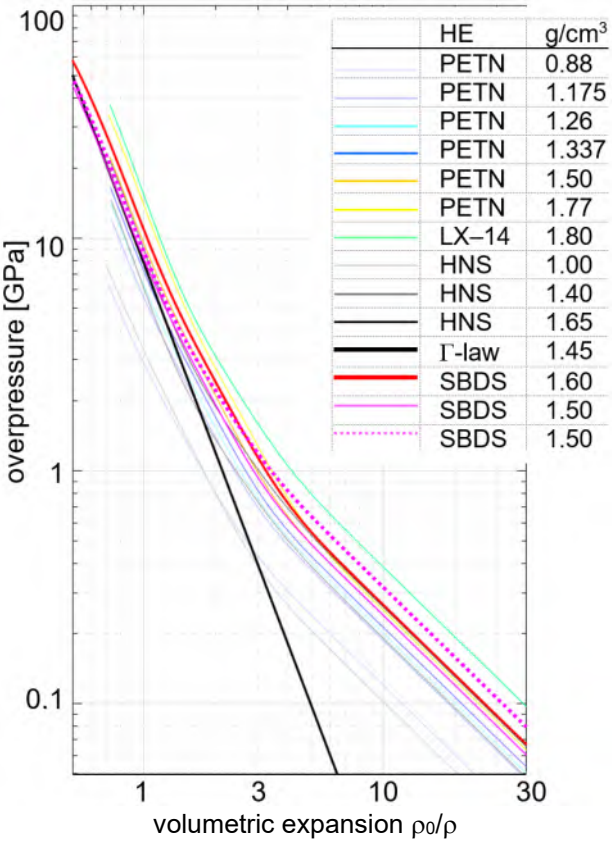

Figure 15: Overpressure versus volumetric expansion of different high explosives

Figure 15 shows the pressure-volume relationships of the detonation products for various explosives. Materials with different densities, such as PETN and HNS, were considered and compared with LX-14, a high-performance explosive commonly used in shaped-charge applications.
Based on these reference data, a set of JWL parameters was derived to represent the low-density HE charge, which are labelled as SBDS in Figure 15. For the simulations presented in this work, the material properties corresponding to the solid pink curve, representing HE with a density of 1.50 g/cm³, were adopted. The two SBDS curves with a density of 1.50 g/cm³ differ primarily at expansion ratios greater than approximately two. Beyond this point, the dotted pink curve predicts higher pressures than the solid pink curve. Consequently, higher pressures are sustained in the fully expanded GET, resulting in an increased deformation of the CP (see Figure 4).
It is interesting to note that an increase in the deformation of the frangible joint does not necessarily imply a corresponding increase in the shock transmitted through the clevis profile to the LV shell. Once the frangible joint has fractured and the separation process has been completed, the mechanical load path between the two structures is significantly reduced. Therefore, pressure differences occurring during the later stages of tube expansion may contribute to additional deformation of the joint while having only a limited influence on the shock transmitted to the LV shell.

4. NUMERICAL RESULTS

4.1. Tube Deformation

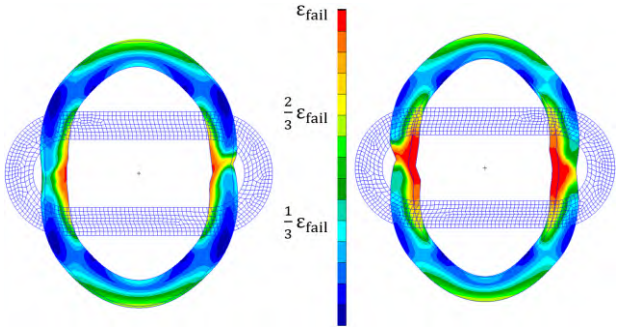

Figure 16: Initial GET: effective plastic strain (w.r.t. elongation at break ε_{fail}) at nominal (left) and overload (right)

Figure 16 shows the cross-section of the GET obtained from the numerical simulation. In this specific case, the tube was not confined by the surrounding structure. The results should therefore be compared with the experimental observations presented in Figure 2. For clarity, only the tube, modelled using Lagrangian hexahedral elements, is shown. The blue mesh represents the original geometry of the GET before the detonation front passed the cross-sectional plane. The coloured contour plot shows the effective plastic strain, normalised with respect to the material elongation at break, at the instant of maximum tube expansion. The simulation on the left corresponds to the nominal explosive loading, whereas the simulation on the right represents an overloaded condition.
The numerical results show good agreement with the experimental observations shown in Figure 2. In particular, the characteristic localised necking observed experimentally is reproduced by the simulation. Under the increased explosive loading, the strain concentration becomes significantly more pronounced along the necking region, reaching the material failure criterion and resulting in local rupture of the tube. These results demonstrate the capability of the Eulerian-Lagrangian model to reproduce the characteristic deformation and failure mechanism of the GET under unconstrained conditions. Moreover, they also illustrate the optimised structural margin of the unconfined tube under increased explosive loading, providing a useful reference for the subsequent analyses of the constrained GET configuration.

4.2. Profile Deformation

Figure 17 compares the profile deformation predicted by the simulation of the initial design configuration with the permanent plastic deformation observed in the initial development tests, as previously presented in Figure 4. The simulation result is shown in the foreground in the upper image, while the tested specimen is shown in the foreground in the lower image.

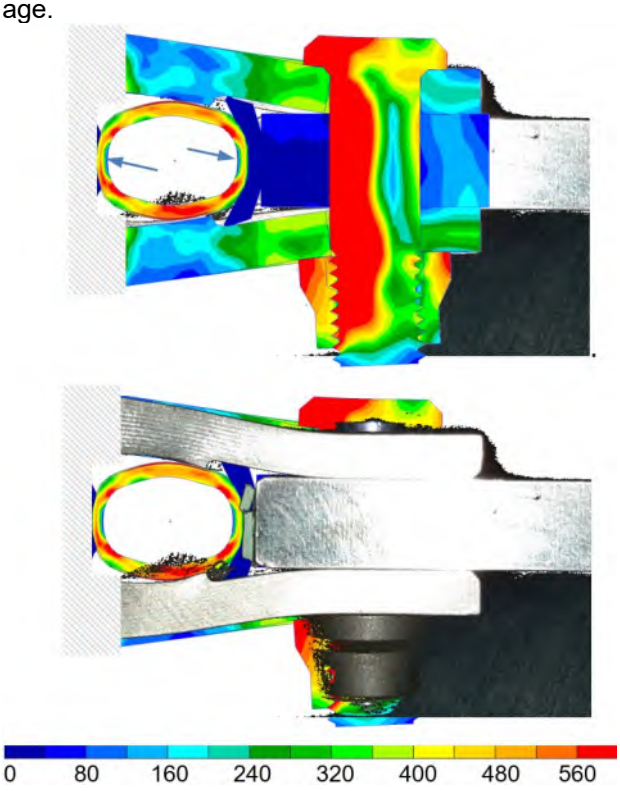

Figure 17: Equivalent stress in N/mm² and deformation of the simulation vs. test results (Figure 4)

Overall, the predicted deformation pattern is in good agreement with the experimental observations. However, the simulation results correspond to the instant of maximum displacement, and do not account for

the subsequent elastic recovery of the actual specimen.
High stresses are predicted in the pin-and-collar connections, which are subjected to a combination of tensile and bending loads. Comparable stress levels are also observed in the GET. However, the stresses on the inner side of the tube appear to vanish locally, as indicated by the arrows in the upper image of Figure 17. This behaviour is a consequence of the implemented material's failure criterion. Once the equivalent plastic strain exceeds the prescribed elongation at break, the material strength is locally reduced to zero, thereby representing the onset of material failure. Although local failure initiation is predicted at the inner surface of the tube, the damage does not propagate through the wall thickness. Consequently, the tube remains intact, which is consistent with the experimental observations. The simulation therefore reproduces both the observed deformation pattern and the absence of a complete tube rupture.

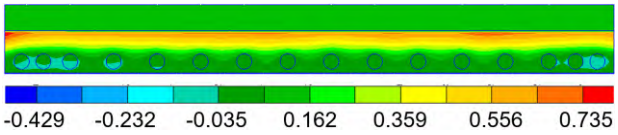

Figure 18: Intermediate-scale model, transverse displacement field in mm

Figure 18 shows the transverse displacement field of the FJ clevis profile. The model used for this analysis has a length of 0.5 m. In contrast to the intermediate-scale model described before, no symmetry boundary condition was applied. Instead, both side edges were modelled as free boundaries. Consequently, the model exhibits a dynamic behaviour similar to that of the full-scale model with a length of 1 m, while requiring only approximately half the computational effort.
The primary objective of this specific analysis was to compare the predicted transverse deformation with the permanent deformation observed in the test specimens. Between adjacent pins, the simulation predicts a slightly increased transverse displacement. Under favourable lighting conditions, a similar phenomenon can also be observed visually on the tested hardware, where the resulting deformation appears as subtle reflections on the slightly polished metallic surface. The presence of such wave-shaped deformation pattern suggests that the regions between neighbouring fasteners could be further adapted to improve the robustness of the separation system. In particular, the spacing and arrangement of the screws may offer opportunities for locally tailoring the structural compliance of the overall system assembly.
As in the simulations presented in Figure 21, the detonation front propagates from the right-hand side towards the left-hand side of the model. The transverse displacement at the left end is slightly larger than at the initiation end. This behaviour can be explained by the treatment of the free surfaces within the Eulerian domain. At the end of the GET, the approaching detonation products are reflected, resulting in a local increase in pressure. A similar effect was observed during the experimental tests. In the actual separation system, the GET must remain tight to prevent the release of hot gaseous detonation products that could potentially endanger the payload. Consequently, the detonation-induced pressure wave is reflected at the closed end of the tube, leading to locally elevated pressure levels and increased structural deformation in this region.

4.3. Shock Wave Propagation

The simulation results are first examined in terms of stress-wave propagation through the separation system and into the surrounding structure. Figure 19 to Figure 21 show selected stages of the wave propagation, with associated contour plots of the effective stress. The colour scales differ between the images because the stress levels within the separation-system components are approximately two orders of magnitude higher than those transmitted to the representative PLF and LV shell plates. Individual scales were therefore adopted to make the relevant stress patterns visible in each part of the structure.
The corresponding SRS curves are presented subsequently in section 4.4.

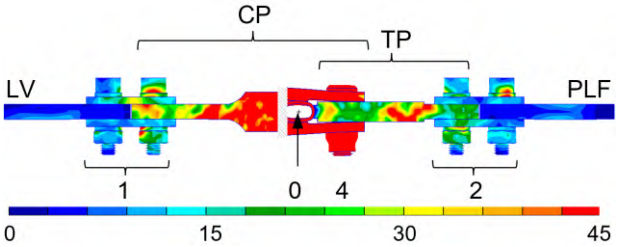

Figure 19: Effective stress in N/mm² after 135 µs

For orientation, the item numbers and nomenclature used in Figure 19 are identical to those introduced in Figure 4, Figure 9, and Figure 13.
As expected, the highest stress levels occur within the separation system at the centre of Figure 19, whereas significantly lower stresses are observed in the plates representing the LV shell and the PLF. The stress distribution clearly reveals the bending-dominated character of the transverse wave component. In particular, the highest stresses in the cross-section of the plate representing the PLF occur near the outer surfaces of the plate, while the stresses close to the mid-plane remain comparatively low.
The observed stress distribution is also governed by the way the plates are connected to the separation system. In particular, the gaps between the front edges of the plates and the profiles, which are connected by means of splices, screws, and nuts (items 1 and 2), interrupt the direct transmission of membrane waves across the interface. Consequently, the direct transmission of axial membrane forces is reduced. The resulting impedance discontinuity promotes a conversion of wave modes and attenuates the longitudinal shock component transmitted into

the adjacent shell structures.
The FJ opens progressively in a zipper-like manner, with the detonation front acting as a moving driver that advances progressively the severance along the joint. The highest local stress levels occur in the pin-and-collar connections, whose structural strength is considerably higher than that of the surrounding profiles, as also indicated by the results presented in Figure *20*. The detonation front requires approximately 135 µs to travel from one end of the FJ specimen to the other. The resulting severance process therefore occurs within a very short time interval compared to the overall simulation duration.

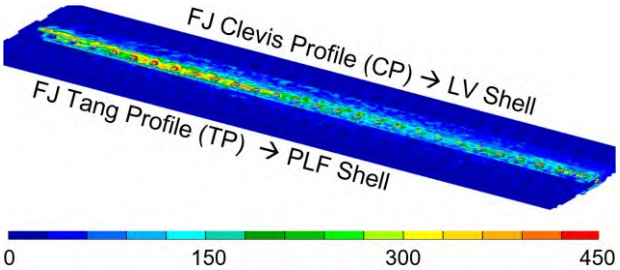

Figure 20: Effective stress in N/mm² after 135 µs

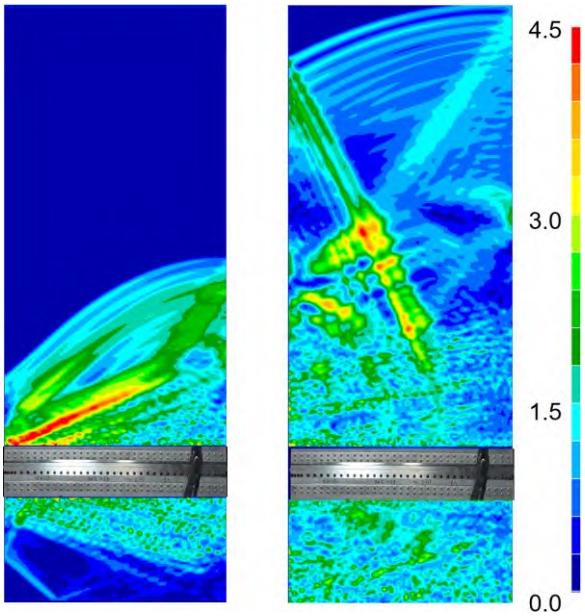

Figure 21: Effective stress in N/mm² after 260 µs (left) and 480 µs (right)

Figure 21 illustrates the subsequent propagation of stress waves within the plate representing the LV shell. For clarity, stress contours are not shown for the profiles. Instead, a detail of the profiles taken from Figure 3 is superimposed at the corresponding locations to facilitate the interpretation of the wave field.
Near the wave front, the stress pattern resembles water waves propagating and reflecting at structural boundaries. At larger distances behind the wave front, however, the wave field becomes increasingly complex owing to the superposition of incident and reflected waves. This behaviour can be observed in Figure 21 at 480 µs, where the stress distribution above and below the profiles already exhibits a highly irregular pattern. As the wave propagates further through the structure, repeated reflections and mode conversions lead to a progressive loss of coherence of the wave field. After approximately 20 ms, the deterministic wave propagation has largely evolved into a broadband structural vibration with an essentially stochastic character. Based on this observation, it is expected that the SRS obtained from the sub-length model will not differ significantly from that of the full-scale model, despite the substantially different boundary conditions at the side edges of the plates. Since the shock energy has undergone multiple reflections and redistributions before the SRS is evaluated, the local response is governed more by the overall statistical characteristics of the vibration field than by the exact geometry of the remote boundaries.

4.4. Shock Response Spectra

Owing to the large number of investigated design variants during the initial development phase, it is neither practical nor necessary to present the SRS results for every configuration in this paper. Before discussing individual design variants, it is necessary to assess the influence of model scaling and test-specific boundary conditions on the predicted shock response of the initial design definition of the FJ system. This comparison also provides insight into the extent, to which subtle design effects can be distinguished from the variability inherently present in experimental shock measurements.
The figures in the remaining part of this paper (Figure 22 to Figure 29) are organised as follows: The plots on the left-hand side show the transverse out-of-plane shock amplitudes, i.e. in the radial direction of the LV, whereas the plots on the right-hand side show the longitudinal shock amplitudes in the axial direction of the LV. The coloured curves correspond to the numerical simulations, while the grey curves represent the experimental results obtained from the test series described in Figure 5. The lowest grey band represents the range bounded by the minimum and maximum SRS values measured by sensors A_1 and A_3. Since these sensors are located at comparable distances from the separation system, this band provides an indication of the repeatability of the shock measurements. The shock levels measured by sensor A_0 are generally higher, which is expected because this sensor is located closer to the profile. Sensors A_0, A_1, and A_3 measure only the transverse acceleration. Their SRS results are nevertheless included in all plots to facilitate the comparison between transverse and longitudinal shock amplitudes. Sensor A_{10} is capable of measuring acceleration in all three spatial directions. Its transverse shock response is shown in the plots on the left-hand side. Surprisingly, these measurements exhibit the highest shock amplitudes, although sensor A_{10} is located furthest away from the separation system. This behaviour might be related to the mounting

configuration of this specific sensor, which was attached to the plate by means of an L-shaped adapter. Consequently, the measured amplitudes may be influenced by local structural dynamics of the sensor mounting arrangement rather than by the shock environment itself, as demonstrated in the final characterisation tests presented in [1]. For this reason, the corresponding transverse shock levels should be interpreted with caution. The longitudinal shock response measured by sensor A_{10} is shown as the dark-grey curve in the plots on the right-hand side.
In summary, the transverse shock measurements obtained from sensors A_0, A_1, and A_3 exhibit the expected behaviour. In particular, the comparison between sensors A_1 and A_3 provides a useful indication of the measurement variability and repeatability expected in pyroshock testing.

4.4.1. Influence of Model Scaling

Excellent agreement between experiment and simulation is observed for the transverse shock response of the full-scale model in the frequency range between approximately 2 kHz and 10 kHz (Figure 22, sensor A_0). Within this frequency range, the corresponding shock amplitudes predicted by the sub-length model are noticeably lower (Figure 23). One possible explanation is related to the boundary conditions. In the sub-length model, the edges of the narrow strip are constrained by symmetry conditions. In contrast, the corresponding location in the full-scale model is situated at a considerable distance from the free side edges of the plate. Consequently, the structural response is less affected by the artificial confinement introduced in the sub-length model, leading to lower transverse shock amplitudes. A similar discrepancy is not observed for the longitudinal shock response. Figure 25 and Figure 26 show a good agreement between the full-scale and sub-length models over a wide frequency range. Furthermore, the transverse shock amplitudes predicted by the full-scale and sub-length models show excellent agreement for frequencies below approximately 1 kHz. In contrast, and as already mentioned above, the longitudinal shock amplitudes of the sub-length model are slightly reduced in the frequency range between 1 kHz and 10 kHz.
Overall, the results indicate that the sub-length model tends to underestimate the shock response owing to the symmetry constraints applied at the lateral boundaries. These constraints increase the effective stiffness of the structure and therefore reduce the predicted shock amplitudes. Consequently, absolute shock levels obtained from the full-scale and sub-length models should not be compared directly. Instead, each model scale should be regarded as a separate analysis environment. The purpose of the sub-length model is not to reproduce the exact shock amplitudes of the full-scale configuration, but to efficiently evaluate the relative influence of design modifications under consistent boundary conditions.

4.4.2. Influence of Test-Specific Boundary Conditions

In the experimental setup, the plates are connected to the profiles by means of splices, screws, and nuts, as illustrated in Figure 11. A gap is usually present between the front edge of the plate and the corresponding edge of the profile. To assess the influence of this feature, additional simulations were performed with the gap closed. The corresponding SRS results are shown in Figure 24 and Figure 27. Additional simulations were carried out without the splices, screws, and nuts. In these configurations, the plates and profiles were merged into a single continuous part. By comparing both configurations, the effect of the additional mass can be isolated. In general, the resulting shock levels are higher than those obtained for the reference configuration with the gap present. For the transverse shock response, this increase is most pronounced at frequencies above approximately 10 kHz. However, a large part of this increase can be attributed to the omission of the additional mass represented by the splices, screws, and nuts. The direct influence of the gap itself becomes noticeable only at frequencies above approximately 20 kHz to 30 kHz. The effect of the gap is considerably more pronounced for the longitudinal shock response. At frequencies above approximately 10 kHz, closing the gap leads to shock amplitudes that are up to an order of magnitude higher than those predicted for the reference configuration. At lower frequencies, the differences are of the same order as those observed between the transverse shock measurements of sensors A_0 and A_1/A_3.
In summary, the test setup incorporating the gap provides representative measurements of the transverse shock response. The influence of the gap remains smaller than the scatter observed between repeated experiments and is therefore of limited practical significance for the evaluation of transverse shock levels. In contrast, the experimental data do not allow a reliable validation of the longitudinal shock predictions, despite the significant influence of the gap observed in the numerical simulations.

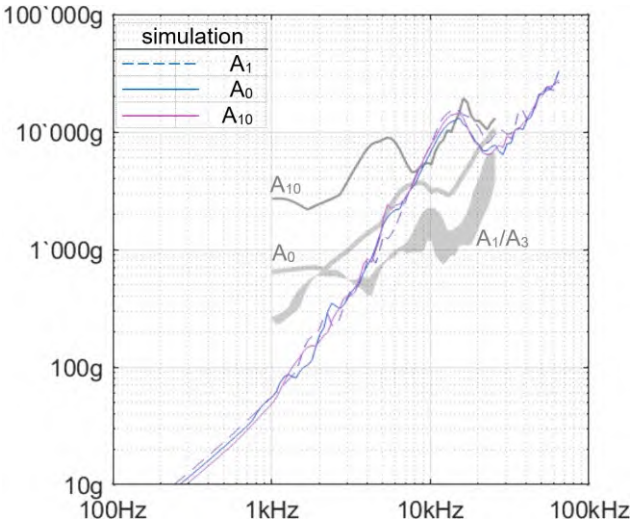

Figure 28: Full-scale model, transverse shock, clevis profile with shock-attenuation feature

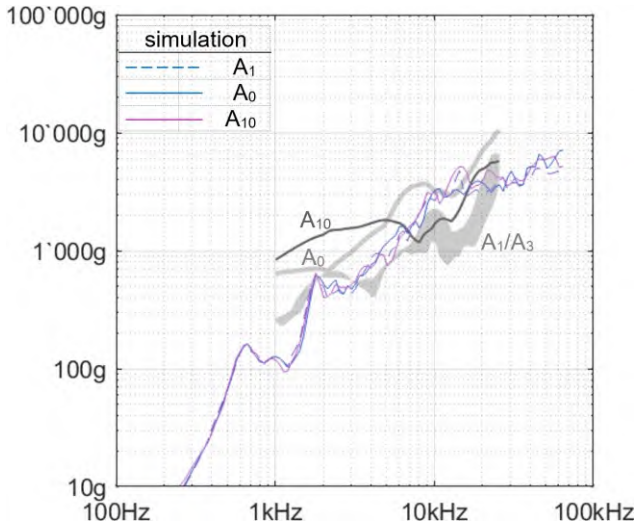

Figure 29: Full-scale model, longitudinal shock, clevis profile with shock-attenuation feature

4.4.3. Influence of Shock-Attenuation Feature

Finally, the influence of the shock-attenuation concept proposed by John A. Graham [3], introduced in Figure 10, was investigated. The results obtained with the full-scale model are shown in Figure 28 and Figure 29 and should be compared with the corresponding reference results presented in Figure 22 and Figure 25, respectively. The numerical model represents the actual experimental configuration, including the small gap between the edges of the profiles and the plates. As expected, no significant reduction of the longitudinal shock response is observed. The reason is that the gap itself already provides a very effective attenuation mechanism for longitudinal wave propagation. Fortunately, the connection by means of splices, screws, and nuts does not substantially interrupt the transmission of transverse shock waves. Consequently, the influence of the patented feature remains clearly visible in the transverse response. The results demonstrate that the shock-attenuation concept efficiently reduces the transverse shock levels at frequencies below approximately 4 kHz to 5 kHz. These findings confirm that the patented feature can also effectively mitigate low-frequency transverse shock loads.

5. CONCLUSION

The present study investigated the behaviour of a pyrotechnic separation system consisting of a GET and a FJ assembly by means of experimental testing and numerical simulation. The experimental campaign demonstrated reliable operation of the separation system over a wide range of operating conditions and provided the basis for validating the finite-element models. Good correlation was obtained for both the deformation behaviour of the separation system and the predicted shock response in the most relevant frequency ranges.

Moreover, dedicated simulations of the initial output shock test setup revealed that the gap between the FJ profile assembly and the attached test plates acts as an efficient attenuator of longitudinal shock waves, while having only a limited influence on the transverse response. The latter effect remains within the experimental scatter and therefore does not compromise the suitability of the test setup for the evaluation of transverse shock levels.

Although shock measurements proved essential for validating the numerical approach, the observed scatter between repeated experiments was found to be larger than the influence of various secondary design parameters. Consequently, subtle design effects can only be assessed reliably by means of validated numerical simulations. The combination of testing and simulation therefore represents the most effective approach for the development and optimisation of robust pyrotechnic separation systems operating under severe environmental and performance constraints.

Sandwich Panels, CFRP, Inserts, Testing, FEA

ABSTRACT

Sandwich panels are used extensively in spacecraft structures, with CFRP facesheets becoming ever more prevalent. Current design guidelines in the ECSS insert design handbook focus predominantly on metallic facesheets, with some gaps in the guidelines for CFRP facesheets or notes that CFRP skins require further investigation or extensive testing. This often leads to cost and schedule impacts, or limits designs to existing heritage.
With the aim of eventually reducing the cost and effort of extensive qualification testing, work was performed to advance the understanding of insert design and performance in CFRP facesheet sandwich panels, including finite element (FE) modelling, testing, and correlation activities. The resulting design and analysis guidelines are proposed for an update of the ECSS insert handbook.

1. INTRODUCTION

Design methods for CFRP panels and inserts are currently based on the ECSS insert design handbook (ECSS-E-HB-32-22A), design rules or heritage.
When using CFRP panels, extensive time and resources are spent in order to ascertain the validity of the design (extensive test and qualification activities); alternatively, design solutions may be constrained by existing (company) heritage in order to avoid long and costly qualification campaigns. Significant conservatism (safety factors) is also usually applied to alleviate any residual risks.
The current ECSS insert design handbook focuses primarily on inserts potted in sandwich panels with metallic facesheets, with some gaps in the guidelines for CFRP facesheets. Often the ECSS HB notes that failure modes associated with CFRP skins are too complex and require further investigation. Alternatively, the ECSS handbook recommends performing extensive insert specimen testing in order to quantify insert load capability. This inevitably leads to an extensive test campaign, which is costly and time-consuming.
The work performed focused on the in-plane load capability of inserts, since this is primarily driven by the facesheet properties. Out-of-plane load capability is also considered, but is secondary to the main objectives, which are to:

- Derive updated design and analysis methods for CFRP skin sandwich inserts to reduce the test effort currently required for all ESA missions
- Produce high fidelity finite element models of inserts for typical configurations in order to predict failure
- Test the modelled configurations to confirm the predictions
- Raise technology readiness level from TRL4 to TRL6

Both undisturbed inserts as well as inserts with edge and proximity effects have been considered.

2. BACKGROUND

CFRP sandwich panels are commonly composed of CFRP facesheets with a metallic honeycomb core and spool type inserts potted in a cold bonding process. Alternative materials, configurations and manufacturing methods are feasible, however are not considered common in the industry.
Facesheets are predominantly quasi-isotropic (QI) layups, with different numbers of plies to achieve the necessary skin thickness and mechanical properties.
The core is commonly a honeycomb core made of Al 5056 alloy with varying foil thickness and cell size. Typical core densities range from 50 kg/m^3 (3/16” cell size) to 130 kg/m^3 (1/8” cell size).
Inserts are usually Al 7075 alloy with SurTec 650 coating, potted in a cold-bonding process using an adhesive such as Stycast 1090.

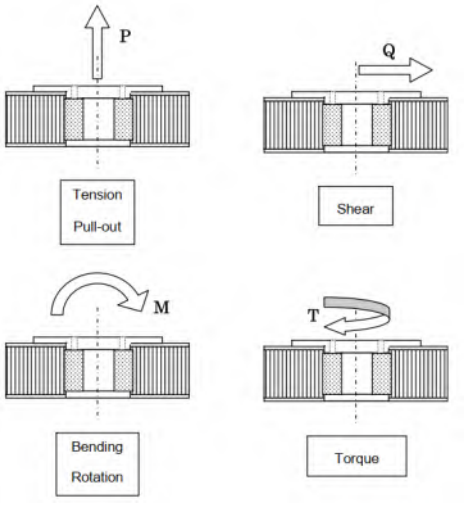

Figure 1: Typical Insert Loading Modes [1]

Reference [1] is the primary source for analytical

insert sizing methods, considering facesheet, core, and potting adhesive failure modes. Figure 1 shows the possible insert loading modes, however it is considered best practice to react torsion and bending loads via groups of inserts. Pull-out and shear loads are therefore the dominant loading modes.

There are however limitations and gaps in the analytical methods for CFRP facesheet sandwich panels. In order to explore these limitations, a test and analysis plan was derived based on typical sandwich panel and insert configurations with existing flight heritage. The plan consists of:

- Elementary material property testing of the panel laminates, to derive mechanical properties for analysis
- Pin-hole bearing tests and FE model correlation, in order to understand the bearing strength of the laminates
- Insert breadboard tests and FE model correlation, including insert design variations

3. TESTING

Testing was performed on the elementary CFRP material properties, on pinhole bearing test samples, and on insert samples with varying configurations.

For this activity a common sandwich panel configuration was selected for consistency, based on configurations from company heritage:

- EX-1515 AFC49 M55JB 6K 50B 80g 33% 0.6m CQP47 prepreg
- HexBond 312L, 150 g/m2 film adhesive
- Phosphoric Acid Anodized Al 5056 honeycomb core, perforated, with two cell sizes (3/16" – 50 kg/m^3, and 1/8" – 130 kg/m^3)

Two independent manufacturers (OPT and ADM) of sandwich panels were used to source the raw laminate and panel samples, with a single batch of M55J/EX-1515 prepreg procured to ensure consistency in raw materials. The manufacturer cure cycles deviated, mainly due to different heating ramp rates and use of their own consumables, resulting in some differences in mechanical properties. Three companies subsequently performed potting of inserts, all of the same design and supplier, with different insert types. Variations due to manufacturing differences are thus included in the study.

3.1. Elementary Material Properties

As a quality check of the cured laminates, the following tests are performed on uni-directional (UD) and QI (24 ply symmetric [45°/-45°]) laminates:

- Tg (ASTM D7028)
- Fibre Volume Content (FVC) and Void Content (VC) (EN 2564)

The following material tests were performed in order to characterize the CFRP material, to obtain properties which can be processed and used in the FE model (FEM) setup:

- Tensile modulus and strength (ASTM D3039) on 0° and 90° UD laminates
- Compressive modulus/strength (ASTM D3410) on 0° and 90° UD laminates
- ILSS (ASTM D2344) on UD laminates
- In-plane shear strength (ASTM D3518) on symmetric 24 ply [45°/-45°] laminate

Both panel manufacturers have performed these characterization tests independently, and the corresponding material properties are used for FE models representing the relevant test samples. It is important to note that this study is dedicated to the modelling and correlation of the insert test specimen results; average material property data is hence used for correlating against average insert test results. The material characterization test data are summarized in Table 1.

Table 1: CFRP Characterization Test Results

Property	OPT	ADM
0-deg Tens. Strength [MPa]	2243.5[1]	1356.3[2]
0-deg Tens. Modulus [GPa]	341.0[1]	306.9[2]
90-deg Tens. Strength [MPa]	20.5	20.7
90-deg Tens. Modulus [GPa]	5.7	5.4
0-deg Comp. Strength [MPa]	740.0	380.0
0-deg Comp. Modulus [GPa]	275.8	248.8
ILSS [MPa]	57.6	61.6
IPS Strength [MPa]	67.8	55.4
IPS Modulus [GPa]	4.1	4.1

[1] *No post-curing cycle*
[2] *With post-curing cycle*

The FVC for all insert and pin-hole plate test specimens was measured to be within the range 58-62%, hence 60% is a reasonable average value. The UD test laminates used to determine the 0-degree moduli and strength values have larger variation in FVC measurement, therefore these values have all been normalized to 60% FVC.

In addition, the 0- and 90-degree tensile and compressive moduli have been averaged to derive E_1 and E_2 moduli values for the purposes of the FE modelling. The resulting material properties used in the FE models is summarized in Table 2.

Table 2: Summary of FEM Material Data

Property	OPT	ADM
E_1 [GPa]	296[1]	281[2]
E_2 [GPa]	6.1	5.8
G_{12} [GPa]	4.1	4.1
Xt [MPa]	1994[1]	1284[2]
Xc [MPa]	774	380
Yt [MPa]	20	21
Yc [MPa]	125	142
S [MPa]	68	55

[1] *No post-curing cycle*
[2] *With post-curing cycle*

3.2. Pin-Hole Bearing Tests

Both double shear and single lap shear pin-hole bearing tests were performed, in order to determine the bearing failure stress of laminates with different thicknesses and pin-hole diameters. The laminate is representative of the insert breadboard definition, with M55J/EX-1515 prepreg in a QI layup with either

8-plies ([0°/45°/-45°/90°]s) or 16-plies (2x [0°/45°/-45°/90°]s). The configurations tested are summarized in Table 3. The test setups are shown in Figure 2.

Table 3: Pin-Hole Bearing Test Configurations

Config.	Hole Diam. [mm]	Edge Dist. [mm]	Laminate (No. of Plies)
1	14	14	8
2	14	21	8
3	14	28	8
4	14	21	16

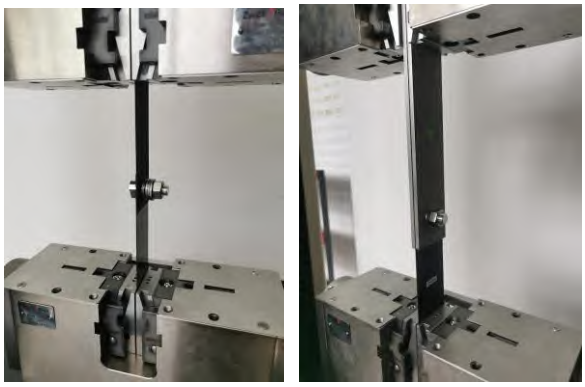

Figure 2: Pin-Hole Bearing Test Setups (Left Side Single Shear; Right Side Double Shear)

Results of the single shear tests are summarized in Table 4, while those of the double shear tests are summarized in Table 5. All samples failed in bearing failure. In single shear, five specimens per configuration and manufacturer were tested, while in double shear three specimens per configuration and manufacturer were tested. Bearing stress at failure was determined and averaged. The coefficient of variance (CoV) is in the range 5-15%.

Table 4: Single Lap Shear Test Results

Config.	Manuf.	Avg. Bearing Stress (Failure) [MPa]	CoV (%)
4	OPT	191	8
4	ADM	150	11

Table 5: Double Lap Shear Test Results

Config.	Manuf.	Avg. Bearing Stress (Failure) [MPa]	CoV (%)
4	OPT	284	7
4	ADM	248	4
3	OPT	190	15
3	ADM	177	5
2	OPT	217	8
2	ADM	179	7
1	OPT	200	8
1	ADM	194	5

The OPT average stress at failure is generally higher than that of the ADM samples, consistent with the findings from the material characterization tests, due to small differences in actual cure cycle.
The results from the double shear test with thicker laminate tests (config 4) show higher bearing strength than the thinner laminates. Also of note is that no significant edge effect observed.
Figure 3 shows an example of the ductile bearing failure mode observed in the pin-hole bearing test samples.

Figure 3: Double Shear Ductile Bearing Failure

3.3. Insert Breadboard Tests

Insert specimen tests were performed following the testing guidelines laid out in [1] (100mm x 100mm sample size, with test jigs as recommended in section 29 of [1]). Figure 4 shows the insert test setup used for shear and pull-out tests. A total of 254 breadboard specimens have been tested, broken down into study groups with varying parameters as summarized below. Typically, five samples per configuration were tested.

Laminates:
- M55J/EX1515, QI layup
- Variations:
  - Baseline: 8 plies [0°/45°/-45°/90°/90°/-45°/45°/0°]
  - Thin skin: 4 plies [0°/45°/-45°/90°] → very sensitive to imperfections!
  - Thick skin: 16 plies [0°/45°/-45°/90°/90°/-45°/45°/0°] + [0°/45°/-45°/90°/90°/-45°/45°/0°]

Core:
- Al alloy 5056, honeycomb core, perforated
- Preferred product: CR III – 5056 series
- Core height: 20mm
- Variations:
  - Baseline core: 3/16-5056-0.001P (50 kg/m^3)
  - Heavy core: 1/8-5056-0.002P (130 kg/m^3)

Potting:
- Loctite Stycast 1090 with Catalyst 9

Insert:
- Material: Al alloy 7075, SurTec 650
- Insert flange: 14mm
- Variations:
  - Baseline: blind with a collar
  - Through insert with a collar
  - Blind flush

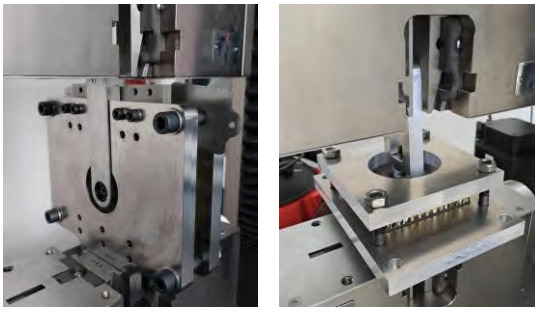

Figure 4: Insert Test Setup (Shear and Pull-Out)

A small number of 2-insert breadboards were tested

in shear using the setup shown in Figure 5. This approach avoids loading of the insert breadboard at the jig contact edge, which can result in crushing of the CFRP facesheet, which is visible in the load-displacement curve. The 2-insert specimen load-displacement plots show a clearer linear relationship up to a clear failure peak load. Figure 6 compares the load-displacement plot for a single insert specimen (right side) versus that of a two-insert specimen (left side); the insert configurations in the two plots were otherwise the same.

Figure 5: Two-Insert Shear Test Setup

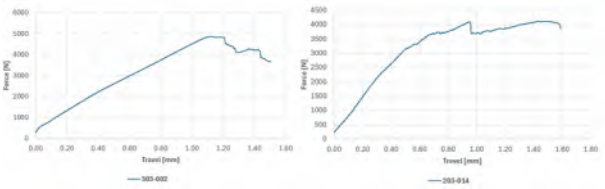

Figure 6: Load-Displacement Curve for 2-Insert Specimen (Left) vs. 1-Insert Specimen (Right)

The insert breadboards were tested to failure, with some tests stopped immediately after the first indication of failure was observed in the load-displacement plot. Figure 7 shows the typical pull-out failure mode (core shear), while Figure 8 shows the typical in-plane failure mode (ductile bearing failure).

Figure 7: Typical Core Shear Failure Mode

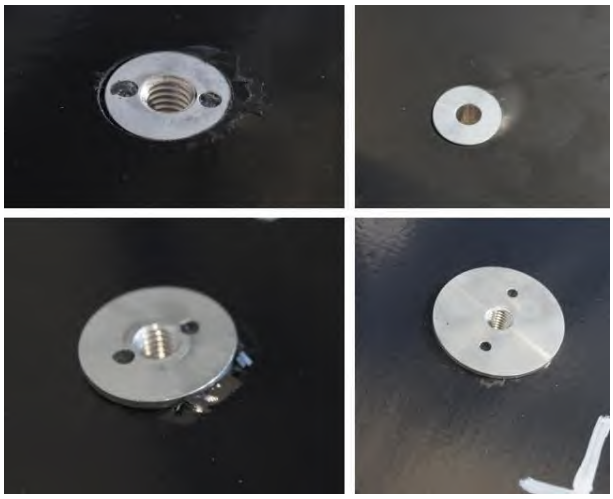

Figure 8: Typical Ductile Bearing Failure Mode

A number of samples were subsequently cut through the cross-section in order to observe the failure modes. Examples are shown in Figure 9 (core shear failure), Figure 10 (facesheet bearing failure) and Figure 11 (potting adhesive failure).

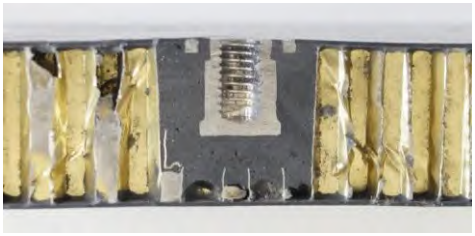

Figure 9: Core Shear Failure Mode

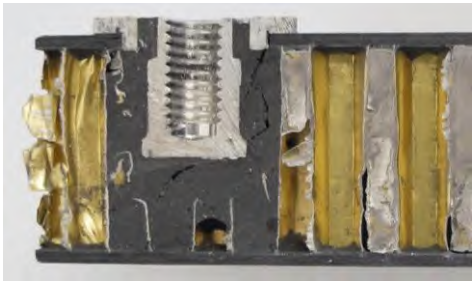

Figure 10: Facesheet Bearing Failure Mode

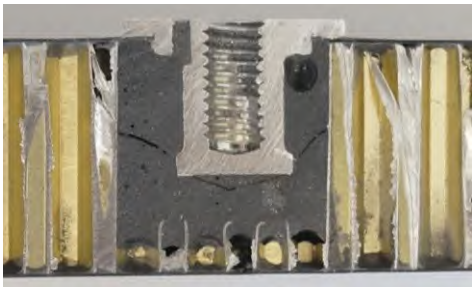

Figure 11: Potting Adhesive Failure Mode

The failure load of each insert has been identified, and the failure loads plotted per insert configuration. These are shown in Figure 12 (shear) and Figure 13 (pull-out). The CoV in both shear and pull-out tests was in the range of 1-7%.

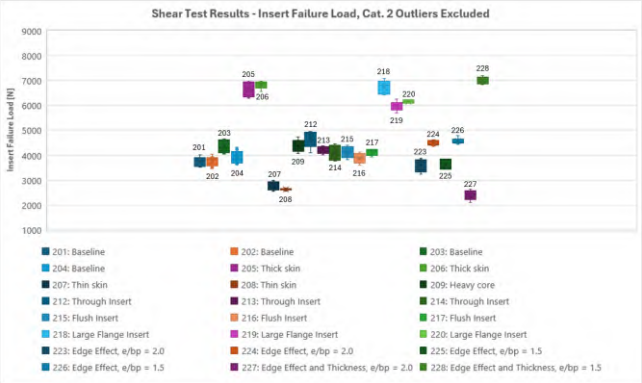

Figure 12: Insert Shear Test Failure Loads

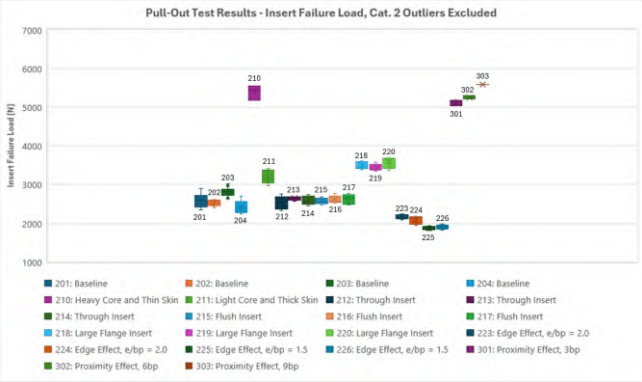

Figure 13: Insert Pull-Out Test Failure Loads

4. FE MODELLING

For the FE modelling phase of this activity, Nastran SOL101 has been used as the solver, i.e. a linear elastic modelling approach, with the use of existing laminate failure theories to predict laminate failure. This approach is pragmatic and available to most of the industry. While progressive failure modelling and advanced models such as LaRC05 are available, they are not commonly used in industry. The selected approach therefore explores the standard available methods before moving into more advanced modelling and post-processing techniques.

4.1. Pinhole Bearing FEM

The double shear tests have been modelled with laminates represented by solid elements using PCOMPS card property with MAT11 material card to define the CFRP material properties. The pin is also modelled with solid elements (PSOLID with MAT1 card), with sliding contact between the pin and laminate via a BCTSET card. This modelling is selected in order to capture the bearing contact between parts. The smallest element size (around the pin-hole location) is comparable to the laminate thickness. A 1kN unit load is applied to the pin in the shear direction, and the model is constrained at the opposite laminate edge via SPC. An additional out-of-plane SPC is applied to the pin, to ensure pure shear is applied.

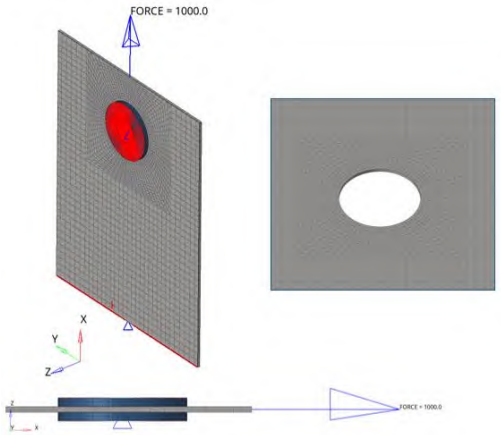

Figure 14: Double Shear Pin-Hole Bearing FEM

The single shear FEM is similar to the double shear FEM, but with additional contacts to represent the more complex interaction between components. Sliding contact is defined between the laminates, at the laminate to pin contacts, and between the pin flange and the laminates. One laminate is constrained via SPC, while the other has the 1kN unit load applied at the opposite end.

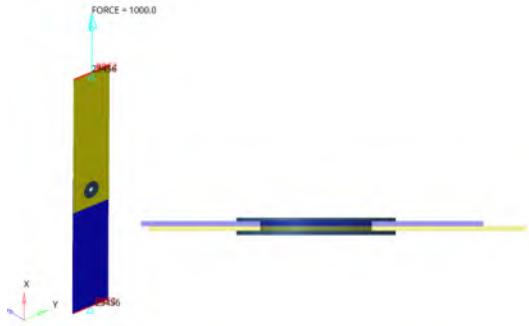

Figure 15: Single Shear Pin-Hole Bearing FEM

4.2. Insert Breadboard FEM

Baseline insert breadboard FEM are generated using solid elements for all components except the bolt, which is represented by an RBE2 element. Figure 16 shows a typical FEM from the study. A single FE model is used for both in-plane and out-of-plane loading scenarios. A unit load is applied to the bolt RBE2 central node. Sliding contact is defined via BCTSET card between the insert flange (where present) and the facesheet with a 0.2 friction coefficient; details are shown in Figure 17.

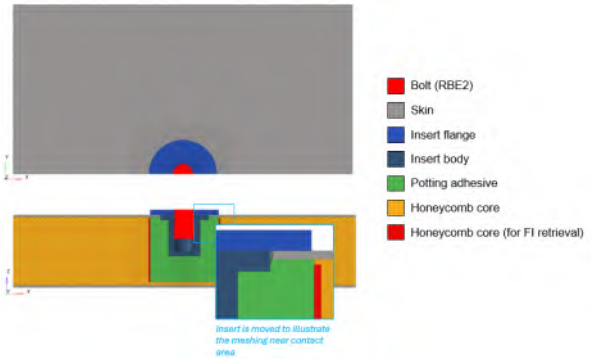

Figure 16: Insert Specimen FEM Overview

Solid elements representing the facesheets are defined via a MAT11 card using the elementary material characterization test data and a PCOMPS card to define the CFRP layup.
The honeycomb solid elements are defined via a MAT9 card (solid element anisotropic property). The MAT9 card parameters are computed based on the honeycomb datasheet homogenised properties with the following assumptions:

- Low stiffness in in-plane directions: $E_X = E_Y \approx 0$
- $E_Z = E_C$ – compression modulus of the core material (stabilized)
- $G_{XZ} = G_L$ – shear modulus in L-direction
- $G_{YZ} = G_W$ = shear modulus in W-direction
- $\mu_{XZ} = \mu_{YZ} \approx 0$

The potting adhesive is modelled via isotropic material (PSOLID with MAT1 cards). For simpler evaluation of the core strength during post-processing, one layer of elements representing the core, adjacent to the potting compound, is highlighted by a dedicated property.
Contact between the potting, insert body and flange, and the core is realized via merged nodes shared between different components. The adhesive layer between skin and core is ignored as it does not contribute to the failure mode (assuming proper bonding between skin and core).

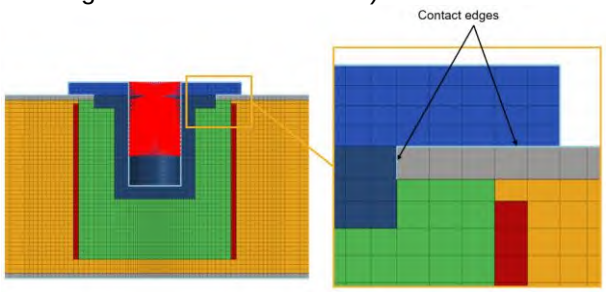

Figure 17: Insert FEM – Insert to Skin Contact

From this baseline FEM, the FEM of other tested configurations is quickly produced by minor modifications:

- Skin thickness:
  - Translation of upper/lower surfaces of skins and insert
  - Update of the PCOMPS card by adding or removing plies
- Potting radius: change in element assignment between core and potting, using concentric rows of elements
- Core density: change in MAT9 card values
- Insert type:
  - Change in insert geometry requires mesh update
  - Change in potting radius

Some of the FEM design variants are shown in Figure 18.

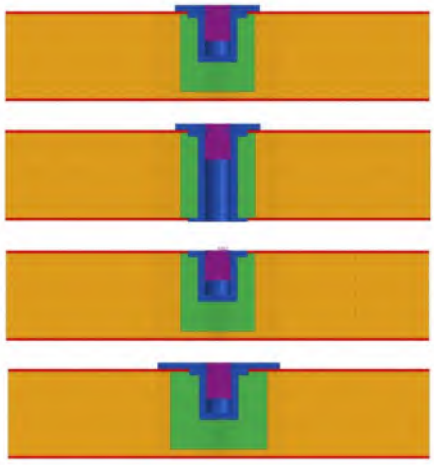

Figure 18: Insert FEM – Design Variants

The FEM are loaded and constrained as follows (Figure 19 shows the shear load FEM boundary conditions):

- DOF 345 on the outer surface nodes of the top skin, except for a 50mm diameter zone around the insert consistent with the test jig contact
- 500N load applied either in-plane or out-of-plane to the central independent node of the bolt RBE2 element
- DOF 246 on the XZ symmetry plane nodes
- In-plane loading:
  - DOF 23456 on the bolt RBE2 independent node
  - DOF 14 on the +X side of the specimen upper skin, over the distance of the contact with the test jig
- Out-of-plane loading:
  - DOF 12456 on the bolt RBE2 independent node

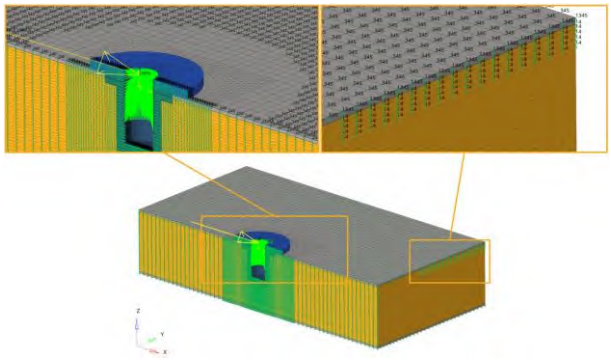

Figure 19: Insert In-Plane FEM Boundary Conditions

5. POST-PROCESSING & CORRELATION

5.1. Laminate Failure Models

The following failure models have been considered: Hill; Tsai-Hill; Hoffman; Hashin.
All of these failure models work via the calculation of a failure index (FI), where a FI > 1 indicates onset of failure. The FI is calculated for each ply in every laminate element of the FE models, based on the

elemental stress data. The FI for each element is thus the maximum FI among the plies in the element – this is the first-ply failure assumption.
Calculation of the failure indices has been performed externally to the FEM, using a python script with the following approach:

1. Apply a 1kN load in the FEM and obtain elemental stress data (output in HDF format)
2. Compute the maximum FI throughout each ply for each laminate element (first-ply failure assumption)
3. Determine the critical load leading to FI = 1.0

5.1.1.Generic Hill

The following formulation of Hill's failure criterion has been used and is implemented directly in NX Nastran and in Digimat:

$$FI = \frac{\sigma_1^2}{X^2} + \frac{\sigma_2^2}{Y^2} + \frac{\sigma_3^2}{Z^2} - \left(\frac{1}{X^2} + \frac{1}{Y^2} - \frac{1}{Z^2}\right)\sigma_1\sigma_2 - \left(-\frac{1}{X^2} + \frac{1}{Y^2} + \frac{1}{Z^2}\right)\sigma_2\sigma_3 - \left(\frac{1}{X^2} - \frac{1}{Y^2} + \frac{1}{Z^2}\right)\sigma_1\sigma_3 + \frac{\sigma_{12}^2}{S_{12}^2} + \frac{\sigma_{13}^2}{S_{13}^2} + \frac{\sigma_{23}^2}{S_{23}^2} \quad (1)$$

Where:

$\sigma_1, \sigma_2, \sigma_3$ are the element stresses in the 1-, 2- and 3-directions
X, Y, Z are the allowable stresses in the 1-, 2- and 3-directions
S_{12} is the allowable in-plane shear strength
S_{13} and S_{23} are the allowable shear strengths in the 13- and 23-directions

The sign of the directional stress components $\sigma_1, \sigma_2, \sigma_3$ is used to determine the appropriate allowable (tensile or compressive) in X, Y, Z. Strength properties in the 2- and 3-directions are assumed to be the same.
Although this is an anisotropic plasticity yield criterion that may not be applicable for CFRP, it is included in the study since it is implemented directly in commercial software.
The critical load F_{crit} leading to FI = 1.0 is then a simple quadratic function of the load applied in the FEM and the FI:

$$F_{crit} = {F_{app}}\Big/{\sqrt{FI}} \quad (2)$$

5.1.2.Tsai-Hill

The Tsai-Hill failure criterion is a failure specific adaptation of Hill's criterion for composite materials formulated for plane stress assumption. Since the FE models use 3D elements to represent the laminate (in order to achieve more accurate contact modelling between the insert and laminate), the following 3D formulation of the Tsai-Hill criterion has been used, as implemented in RADIOSS. Note that there are several different extension forms available in literature.

$$FI = \frac{\sigma_1^2}{X^2} - \frac{\sigma_1\sigma_2}{X^2} - \frac{\sigma_1\sigma_3}{X^2} + \frac{\sigma_2^2}{Y^2} + \frac{\sigma_3^2}{Z^2} + \frac{\sigma_{12}^2}{S_{12}^2} + \frac{\sigma_{31}^2}{S_{12}^2} \quad (3)$$

Similar to the Hill criterion, the sign of the directional stress components $\sigma_1, \sigma_2, \sigma_3$ is used to determine the appropriate allowable (tensile or compressive) in X, Y, Z. Strength properties in the 2- and 3-directions are assumed to be the same. The critical load leading to FI = 1.0 is determined using the quadratic function defined in Eq. (2).

5.1.3.Hoffman

The Hoffman criterion is originally expressed in 2D, however due to the use of 3D elements in the FEM for the laminates, the 3D formulation as implemented in RADIOSS has been used. Note that there are several different 3D extension forms available in literature.

$$FI = \left(\frac{1}{X_t} - \frac{1}{X_c}\right)\sigma_{11} + \left(\frac{1}{Y_t} - \frac{1}{Y_c}\right)\sigma_{22} + \left(\frac{1}{Z_t} - \frac{1}{Z_c}\right)\sigma_{33} + \frac{\sigma_{11}^2}{X_tX_c} + \frac{\sigma_{22}^2}{Y_tY_c} + \frac{\sigma_{33}^2}{Z_tZ_c} - \frac{\sigma_{11}\sigma_{22}}{X_tX_c} - \frac{\sigma_{11}\sigma_{33}}{X_tX_c} + \frac{\sigma_{12}^2}{S_{12}^2} + \frac{\sigma_{13}^2}{S_{12}^2} \quad (4)$$

The strength properties in the 2- and 3-directions are assumed to be the same. The FI is a complex function of the load (second order polynomial), hence the critical load is found via root-finding algorithms. A python post-processing script using Brent's method in the scalar root finding function of the SciPy library has been used.

5.1.4.Hashin

The Hashin criterion is a partial interaction model that distinguishes between different failure modes.
For the tensile/shear fibre mode ($\sigma_{11} > 0$):

$$FI = \frac{\sigma_{11}^2}{X_t^2} + \frac{\sigma_{12}^2 + \sigma_{13}^2}{S^2} \quad (5)$$

For the compressive fibre mode ($\sigma_{11} < 0$):

$$FI = \frac{\sigma_{11}^2}{X_c^2} \quad (6)$$

For the tensile matrix mode ($\sigma_{22} + \sigma_{33} > 0$):

$$FI = \frac{(\sigma_{22} + \sigma_{33})^2}{Y_t^2} + \frac{\sigma_{12}^2 + \sigma_{13}^2}{S^2} + \frac{\sigma_{23}^2 + \sigma_{22}\sigma_{33}}{S^2} \quad (7)$$

For the compressive matrix mode ($\sigma_{22} + \sigma_{33} < 0$):

$$FI = \frac{(\sigma_{22}+\sigma_{33})^2}{4S^2} + \frac{\sigma_{12}^2+\sigma_{13}^2}{S^2} + \frac{\sigma_{23}^2+\sigma_{22}\sigma_{33}}{S^2} + \left[\left(\frac{Y_c}{2S}\right)^2 - 1\right]\frac{\sigma_{22}+\sigma_{33}}{Y_c} \quad (8)$$

Due to the different formulations for each failure mode, comparison of the failure indices is not a reliable means of determining first failure mode. Instead, the critical load to reach FI = 1.0 is calculated for each failure mode, and the minimum critical load is taken for each element.

The critical failure loads for the tensile fiber failure, compressive fiber failure and tensile matrix failure are calculated following the quadratic function in Eq. (2). Since the compressive matrix failure is a second order polynomial, the critical load is found via root-finding algorithms. Consistent with Hoffman model implementation, a python post-processing script using Brent's method in the scalar root finding function of the SciPy library has been used.

5.2. FEM Checks & Mesh Sensitivity Study

Plausibility checks have been performed on the pin-hole bearing test FEMs. Deformation and contact force vector plots indicate realistic distributions. An example for the double shear test FEM is shown in Figure 20.

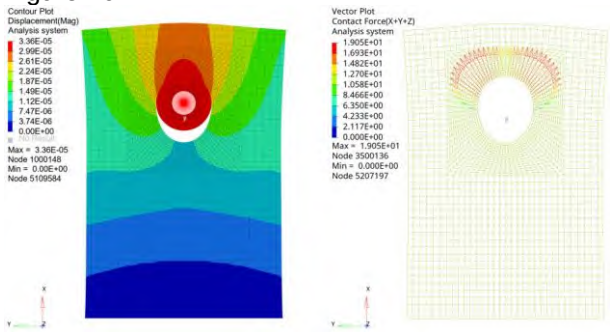

Figure 20: Double Shear FEM Plausibility Checks

A mesh sensitivity study was also performed. The convergence study used PSOLID and MAT1 cards for simplification. As the mesh is refined, the von Mises stress peak increases, whereas the overall stress distribution remains the same. This is primarily due to the nature of the contact problem, where stress levels are highly dependent on the discretization and contact model parameters.

Solid elements modelling was selected for this study to enable surface-to-surface contact definition at the bearing surface of the laminate. For PCOMPS modelling, a single element in the thickness is considered sufficient, and element size is recommended to be comparable with the plate thickness. For the results correlation, it is thus necessary to fix the mesh and contact parameters for consistency. Note that further mesh refinement than shown resulted in irregularities in the stress levels near the contact region, likely caused by the contact algorithm implementation.

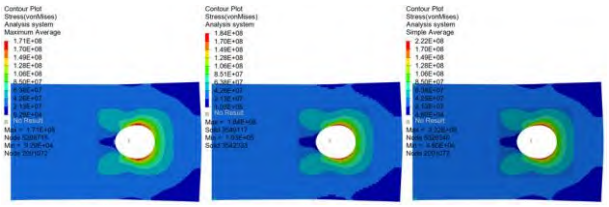

Figure 21: Double Shear FEM Mesh Study

5.3. Post-Processing Methods

The post-processing method is determined by the component and failure mechanisms. The insert and potting adhesive stresses are compared against the datasheet yield strength allowable values. For the skin and core components, a FI is calculated; a FI of 1 or greater indicates failure of that component.

5.3.1. Insert and Potting Adhesive

Failure of the insert is determined by comparison of the peak insert von Mises stress from the FEM versus the yield strength in Table 6. Similarly, failure of the potting adhesive – a brittle material – is determined by comparison of the maximum principal stress from the FEM versus the yield strength in Table 6. Failure is considered to occur when the stress exceeds the specified allowable yield strength. Potting strength is computed based on minimum and maximum principal stresses (P1 and P3) and corresponding compression and tensile allowables.

Table 6: Insert and Potting Adhesive Allowables

Component	Yield Strength [MPa]	Ref.
Insert	393	[2]
Potting Adhesive	20.7 (tension) -82.7 (compression)	[3]

5.3.2. Laminates

The laminates are post-processed using the described failure models, considering the maximum FI in each ply (first ply failure assumption).

5.3.3. Core

For the honeycomb core, a FI, FI_{core}, is calculated based on the shear stress components τ_{xz} and τ_{yz} from the FEM compared to the allowable shear stress (τ_L or τ_W) in the respective plane:

$$FI_{core} = \sqrt{\left(\frac{\tau_{XZ}}{\tau_L}\right)^2 + \left(\frac{\tau_{YZ}}{\tau_W}\right)^2} \quad (9)$$

Table 7: Honeycomb Core Shear Strength Allowables (MPa, Typical)

Core Designation	L-Dir.	W-Dir.
ECM 4.8-50 5056 PAA-CP	1.862	1.069
ECM 3.2-130 5056 PAA-CP	6.619	3.964

All of the honeycomb core failures observed in the test specimens were shear failures of the cell walls immediately adjacent to the potting adhesive. This

is consistent with the typical honeycomb core pull-out failure mode predicted by [1].

A common approach is to determine the insert pull-out load capability based on the maximum FI of the core elements near the potting. However, the ECSS equations are based on the total applied pull-out load, therefore it is more representative to assess the average core strength capability rather than using the peak element FI from the FEM. The core post-processing has therefore calculated the critical force based on minimum, maximum, and average FI in the first row of concentric elements adjacent to the potting adhesive component.

The honeycomb core component defined in the FEM is used to define the single row of concentric elements directly adjacent to the potting adhesive component; this allows for easier retrieval of the FI and automation of the post-processing. Note that the uppermost (and lowermost, in the case of a through insert) row of elements has been excluded from this component.

The critical load is calculated from the FI (minimum, maximum or average) obtained from the FEM according to Eq. (10).

$$P_{failure} = P_{app} * \frac{1}{FI_{core}} \qquad (10)$$

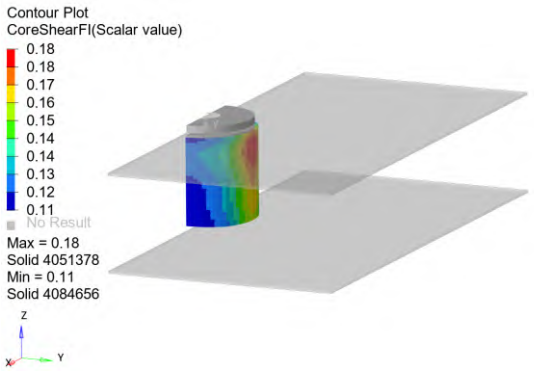

Figure 22: Core FI Example

5.4. Correlation

5.4.1. Pin-Hole Bearing Tests

The FEM of the baseline (configuration 2) pin-hole bearing tests were initially run and processed using the material characterization test allowables and the laminate failure models. Comparison of the FI plots (Figure 23) shows that the Hill failure model results in a significantly lower failure load prediction, together with an unusual stress distribution. The Tsai-Hill and Hashin models show consistent distributions with similar failure load predictions, with the Hoffman model marginally more conservative. Of these three models, the Hashin model is the simplest in terms of correlation, since the failure is driven by the fibre compressive failure, which is governed by a single parameter, X_c. Correlation of the FEM has therefore been performed by scaling X_c in order to achieve a FEM critical load prediction approximately equal to the average value from the tests. This was done for both double shear and single lap shear tests independently. The correlated double shear FI plots are shown in Figure 24. The resulting correlated X_c values are shown in Table 8 and correlated average bearing stresses for the double shear tests shown in Table 9.

Table 8: Correlated Xc [MPa] (Pin-Hole Bearing Tests)

Test Type	Manuf.	Mat. Test X_c	Scale Factor	Correlated X_c
Double Shear	OPT	774	0.90	697
	ADM	380	1.52	576
Single Shear	OPT	774	1.17	906
	ADM	380	1.90	722

1	Test	200	194
	Hoffman	140	130
	Tsai-Hill	164	148
	Hashin	185	162

5.4.2. Insert Breadboard Tests

Correlation of the insert breadboard FEM to the shear test results was performed using the same approach as for the pin-hole bearing test FEM correlation, using the Hashin failure model and scaling the X_c parameter only. The baseline configuration (8-ply laminate, 50 kg/m^3 core, blind insert) from each manufacturer was used. The scaled X_c values are shown in Table 10. Figure 25 shows an example of the FI plots (uncorrelated and correlated) for the Hashin, Tsai-Hill and Hoffman failure models.

Table 10: Correlated Xc [MPa] (Insert Tests)

Manuf.	Mat. Test X_c	Scale Factor	Correlated X_c
OPT	774	1.27	983
ADM	380	2.15	817

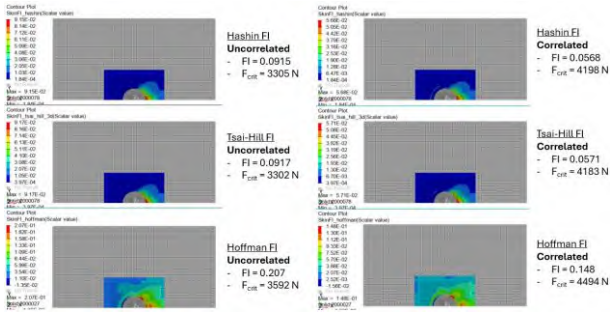

Figure 25: Insert FEM Correlation (OPT)

6. ANALYSIS RESULTS AND COMPARISON TO TEST AND ECSS GUIDELINES

The correlated Xc values were used to post-process all insert FEM. In addition, failure modes for the core, insert and potting adhesive are post-processed.

The FEM correctly predicted the failure mode observed in the tests in all cases. In shear, the critical failure mode is bearing failure of the skin; in pull-out, the failure mode is shear of the core with the exception of one configuration where the potting adhesive fails.

Figure 26 (shear) and Figure 27 (pull-out) compare the FEM predictions against both the ECSS predictions and the test results for each study group. It is worth noting that the ECSS predictions use the facesheet yield strength in the calculations. For the purposes of the comparison below, the baseline configurations (groups 201 to 204 in the plots) have been used to correlate an effective yield strength value for the CFRP facesheets for use in the calculations. In practice, sizing analysis is typically performed based on an initial, conservative, strength estimate. The actual performance of the facesheets, and hence insert strength, would normally only be evaluated by test specimens later in the development.

In pull-out, the FEM is able to predict core shear failure more accurately than the more conservative ECSS predictions.

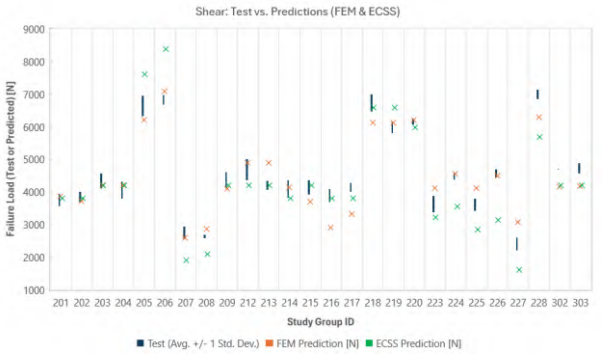

Figure 26: Shear Test Predictions vs Test

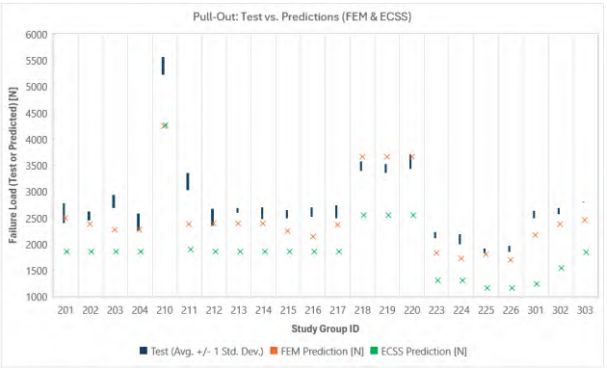

Figure 27: Pull-Out Predictions vs Test

6.1. Potting Adhesive Failure

The core is the failing component in all configurations tested in pull-out, with the exception of one study group where failure is observed in the potting adhesive at the base of the blind insert. The same failure is predicted by the FEM and is also consistent with the ECSS prediction. Figure 28 shows the stress contour plot from the FEM adjacent to the cross-section view of the failed test specimen, with a crack propagating from the insert base corners to the outer edge of the potting adhesive.

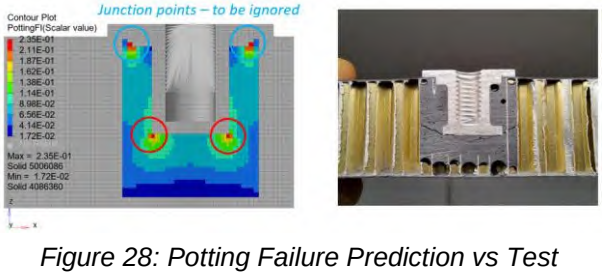

Figure 28: Potting Failure Prediction vs Test

6.2. Core Post-Processing

The core has been post-processed using the minimum, maximum and average FI from each FEM. The closest match between FEM predictions and test result was obtained using:

- Minimum core FI for configurations where a symmetric core stress distribution is expected, with no geometric disturbances
- Average core FI for configurations where edge proximity introduces a geometric disturbance

leading to asymmetry in the stress distribution
- Maximum core FI for configurations with insert proximity effects

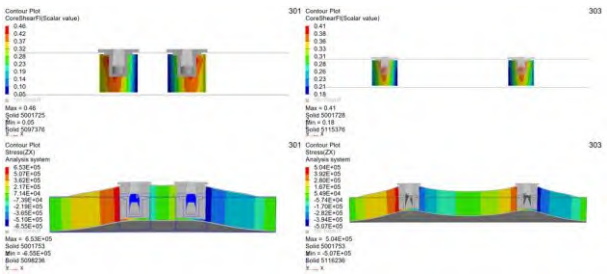

Figure 29: Core FI Distribution Asymmetry

6.3. Edge Effects

An insert potted close to a panel edge has reduced load capability in both in-plane and out-of-plane directions. The out-of-plane knockdown factor (KDF) of an insert's load-carrying capability is defined in [1] by Eq. (11), considered applicable for metallic and CFRP sandwich panels.

$$\eta_{EN} = 0.55\sqrt{\frac{e}{b_p}} - 0.05\,{}^{e}/_{b_p} \quad \text{for } e \leq 5b_p \qquad (11)$$

In the in-plane loading scenario, [1] recommends performing tests to obtain reliable data for edge coefficients in CFRP skin panels.
From the test failure loads, FEM failure load predictions, and ECSS failure load predictions, KDFs have been calculated for the edge effect study groups. These are shown in Figure 30 (pull-out) and Figure 31 (shear).
In pull-out, the KDF trend is consistent between all approaches; ECSS calculations are the most conservative, the test results the least, and the FEM providing a middle-ground between the ECSS and test values.
In shear, no discernible edge effect is noticeable from the test data; this is also predicted by the FEM for the Hashin and Tsai-Hill failure models. The Hoffman model predicts a KDF trend similar to the ECSS KDF trend.

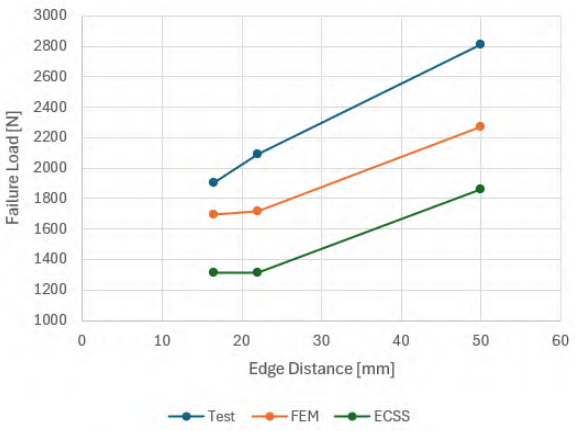

Figure 30: Edge Effect – Pull-Out

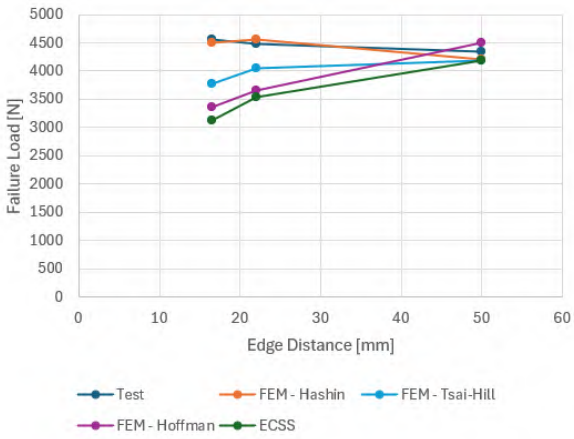

Figure 31: Edge Effect – Shear

6.4. Insert Proximity

Inserts potted in the vicinity of another insert experience a reduction in load capability in both in-plane and out-of-plane directions. In the scenario of two inserts loaded in the same out-of-plane direction – as is the case in the current study – the insert's pull-out load-carrying capacity is reduced by an interference coefficient. When the two insert potting radii are the same, the KDF equation is given in Eq. (12).

$$\eta_{IS} = \frac{1}{2}\left(1 + \frac{a}{5b_{p1}}\frac{1}{2}\right) \quad \text{for } a \leq 5(b_{p1}+b_{p2}) \qquad (12)$$

In the in-plane direction, [1] recommends performing tests to obtain reliable data in CFRP sandwich panels. In this study, insufficient two-insert specimen in-plane test data is available to draw any conclusions.
In pull-out, test failure loads, FEM failure load predictions, and ECSS failure load predictions are compared in Figure 32. The maximum core FI has been used to post-process the FEMs, due to the asymmetry in honeycomb core stress resulting from the insert proximity. A small influence of the proximity effect is visible in the test and FEM data; the KDF from both data sets is very comparable. The ECSS KDF is more conservative, however shows a similar trend.

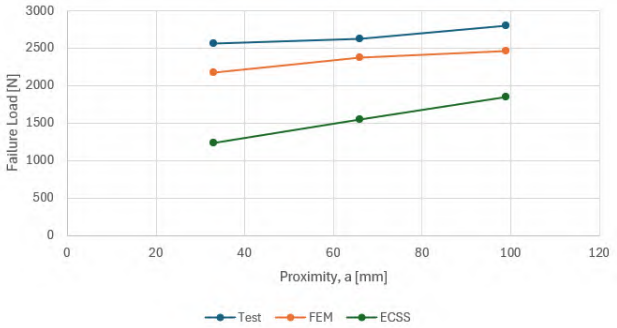

Figure 32: Proximity Effect – Pull-Out

7. APPROACHES TO MATERIAL TESTING & CORRELATION

As demonstrated in this study, for in-plane strength the fibre compression is the primary failure mode. The laminate fibre compressive strength X_c can hence be considered as the main correlation parameter for the laminate in-plane strength, when the model discretization and contact parameters are fixed. Three methods of determining X_c are identified:

- Material tests (UD compression test)
- Pin-hole bearing tests (with subsequent FE analysis and correlation of X_c to the test results)
- Insert shear tests (with subsequent FE analysis and correlation of X_c to the test results)

The X_c values obtained from these three approaches are summarized in Table 11, for both laminate manufacturers.

Table 11: Summary of X_c Values [MPa]

Manuf.	Mat. Test	Pin-Hole Bearing		Insert Test
		Double Shear	Single Shear	
OPT	774	697	906	983
ADM	380	576	722	817

The UD compression tests displayed high sensitivity, resulting in significant scatter in the obtained values. The tests may be sensitive to the test setup. Data obtained this way may therefore be unreliable; however, comparison with the correlated values shows that it is generally a conservative approach to determining X_c.

The pin-hole bearing test offers a method of determining X_c with a similar level of testing effort compared to the UD compression tests, but with results that tend to be less conservative compared to the UD compression tests, and with variation of approximately 10%. The single-shear test method results in less conservative X_c values compared to the double-shear test and is recommended over the double-shear test method, which may be influenced by the constraint of the laminate bulging in the failure zone. Some additional effort is required to setup representative FE models and correlate the analysis results to the test values compared to the material characterization test approach.

The insert tests provided the least conservative X_c values, with the smallest variation (ca. 5%). This approach therefore introduces the least amount of conservatism, however the effort to manufacture the test specimens and correlate the results is also the highest of all methods.

The selection of a test approach must take into account the usual project considerations:

- Budget and timeline
- Tools and capability within the organization to perform the analysis and correlation activities
- Desired – or acceptable – level of conservatism in the results

Note that regardless of the material testing method selected, a sufficient number of test specimens should be planned to ensure repeatability of the result, and to allow for A/B-basis value determination without a significant penalty due to a small sample size. As a minimum, 10 test samples are recommended to avoid a significant statistical penalty.

8. CONCLUSIONS

This investigation has shown that standard modelling techniques with commercial solvers are sufficient to model CFRP bearing failure and insert capability, with good correlation to both test data and ECSS predictions demonstrated.

The Hashin, Tsai-Hill and Hoffman failure models all provide similar critical load predictions for the CFRP skins and can be used interchangeably depending on the solver features or data availability.

For the studied laminates, the fibre compressive strength X_c is demonstrated to play the dominant role in the bearing and insert capability; correlation of this parameter alone is sufficient to obtain accurate insert load capability predictions.

X_c can be determined via different test methods: material characterization tests, pin-hole bearing tests, or insert specimen tests. The lower-level tests are found to provide more conservative estimates of X_c.

The analysis approach described can allow for a reduced quantity of physical tests, but does not entirely replace testing.

In shear, the edge effect data from test and the Hashin and Tsai-Hill models suggest only a minor influence. However, the Hoffman model and ECSS predictions are similar and suggest a KDF is applicable. Further data and study are necessary. In pull-out, the ECSS KDF predictions are more conservative than the FEM predictions and the test results, but all show a similar trend.

In pull-out, the ECSS KDF for two-insert proximity is shown to be conservative, and the FEM is able to provide accurate prediction of a realistic KDF.

The analysis has shown that the use of a MAT9 card to represent the core via 3D elements is viable, enabling prediction of both shear and pull-out capabilities of an insert. The core FI distribution symmetry adjacent to the potting can be used to determine which failure index approach is most suitable for a particular configuration. The minimum FI is applicable for undisturbed inserts; the average FI for asymmetry due to edge proximity; and the maximum FI for asymmetry due to insert proximity.

Environmental testing, acoustic testing, modal survey testing, experimental modal analysis

ABSTRACT

Direct Field Acoustic Noise (DFAN) testing of satellites is a proven alternative for reverberant room acoustic testing and, in certain cases, even random vibration testing. The objective of this paper is to propose a method that allows to use a DFAN setup also successfully for modal survey testing of a spacecraft, further increasing the efficiency of the testing program. Another important advantage of adopting acoustic excitation, compared to impact or shaker excitation, is that mechanical contacts with the satellite are avoided.

This paper presents the results of a large test campaign on the Structural Test Article of the Emirates Mission to the Asteroid Belt spacecraft which was tested at the Laboratory for Atmospheric and Space Physics at the University of Colorado (CU LASP). Eigenfrequencies, damping ratios, and mode shapes of the satellite have been identified from a DFAN test setup and compared with results from modal shaker excitation.

1. INTRODUCTION

There is increasing interest in the aerospace community to reduce testing cost, risk, and schedule impacts by combining as many structure-related tests as practicable into a single test setup [1,2]. One potential opportunity is to perform a modal survey test while a test article is configured for a Direct Field Acoustic Noise (DFAN) qualification test, and to verify this approach a modal survey test of the Emirates Mission to the Asteroid Belt Structural Test Article (EMA-STA) was performed using acoustic, impact, and shaker excitation.

There have been earlier successful demonstrations of applying (operational) modal analysis to data from a preliminary acoustic (system identification) test or to the acoustic qualification test data itself [3-6]. The specific objectives of the EMA-STA tests are to verify the feasibility of using acoustic excitation well below 20 Hz, to explore and compare some specific excitation signals, to compare different data processing and modal analysis strategies, and to further develop the fixed-base correction method combining acoustic excitation with additional structural excitation at the interface of the satellite. This last topic is discussed in a separate paper [7].

Uncorrelated multiple-input broadband random acoustic excitation will be compared to multiple-input random shaker excitation. Operational Modal Analysis (OMA) using satellite structural responses only will be compared to Experimental Modal Analysis using Frequency Response Functions (FRFs).

The measurement campaign and this paper have been the result of a collaborative effort from Acoustic Research Systems (ARS), ATA Engineering, and Siemens Digital Industries Software, bringing together competences on DFAN testing, acoustic devices, aerospace & defense advanced engineering, data acquisition, (MIMO) control and experimental & operational modal analysis.

This paper will discuss modal survey testing using Neutrons as acoustic excitation devices, describe the EMA-STA test setup, discuss excitation signals and measurement functions required for modal analysis. EMA and OMA results will be discussed, and modal shaker results will be compared to acoustic excitation results. Finally, the conclusions will be presented.

2. MODAL SURVEY TESTING USING ACOUSTIC EXCITATION

There has been a surge in research efforts that verify that DFAN sources can be used to excite test articles well enough to conduct modal surveys [3-8]. Experimental Modal Analysis (EMA) can be performed when FRFs are available, i.e. next to the structural responses, also signals representative for the acoustic sources need to be available. Alternatively, Operational Modal Analysis (OMA) can be applied as long as the magnitude and pattern

of the acoustic pressure varies slowly as a function of frequency such that the main assumption associated with OMA – that the input power spectra are constant as a function of frequency – is broadly true over reasonable frequency ranges.

A typical acoustic qualification test setup used by Acoustic Research Systems is shown in Figure 1. In this configuration six stacks of three ARS Neutron acoustic devices are placed around the test article. Typically, a controller that acts upon multiple field microphone signals generates incoherent broadband acoustic noise to approximate a diffuse acoustic field, which excites the article. The controller adjusts the generated drive signals such as to reproduce the target acoustic spectrum, typically expressed in full or 1/3rd octave bands.

DFAN systems consist of multiple stacked acoustic devices surrounding the test article to produce the high-intensity output required by launch vehicle acoustic qualification testing. At the same time, it is important to avoid the creation of interference patterns, non-characteristic of diffuse acoustic fields, which can over/under excite test articles.

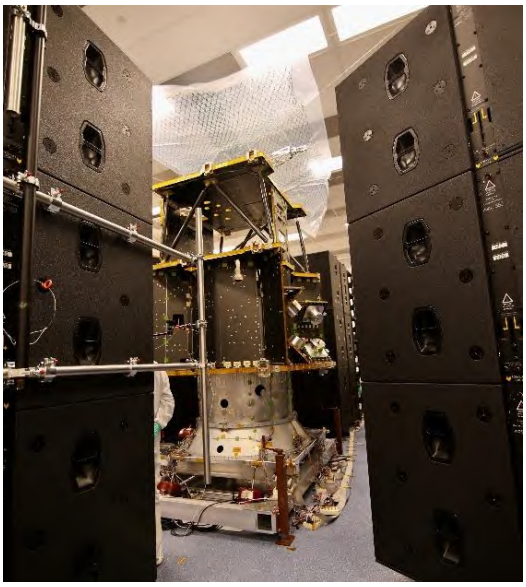

Figure 1: Acoustic qualification test setup showing ARS Neutron system in 6x3 testing configuration surrounding EMA-STA

The Neutron was designed with the highest possible initial efficiency across the frequency ranges most prominent in most launch vehicle payload fairings. Particularly in the low frequencies, the unique driver-loading mechanism in the Neutron produces equal pressure both behind and in front of the transducer. This mechanism somewhat unexpectedly allows the device to actively extend excitation into infrasonic frequencies without over excursion of the transducers.

This sort of excitation scheme is perfectly aligned with a typical multi-input/multi-output modal survey test where independent random excitation is applied to each conventional modal shaker. While many acoustic sources would be damaged if excited at low frequencies, the ARS Neutrons are designed to be robust and self-limiting. At lower frequencies when acoustic inputs are less efficient, acoustic input can be concentrated in the frequency domain to allow the acceleration response to rise above the sensor noise floor. One such excitation is a multi-sine excitation pioneered by ATA [9].

Interesting to note is that all typical shaker excitation signal can also be used to drive ARS Neutron acoustic devices: random, burst random, pseudo-random, pink noise, sine dwell, sine sweep. The Neutron has demonstrated the capability to provide effective modal excitation at frequencies above 2 Hz. Furthermore, all Neutrons utilize a common subwoofer design spanning frequencies from below 2 Hz to 400 Hz, thereby covering the complete frequency range of interest for most aerospace modal test applications.

3. TEST SET-UP

The EMA-STA is shown in Figure 1. It is connected to a reinforced isolated plate (“base plate” and “stiffening beams” in Figure 2) through a payload adapter. The isolated plate is connected to a transportation cart through four wire rope isolators. The isolated plate was reinforced to help increase its out of plane stiffness. The wire rope isolators keep higher frequency shock type loads from passing into the test article. The cart itself rests directly on the ground. The ARS Neutrons were configured in a 6x3 configuration. For this test, each stack of three Neutrons used the same input voltage for a total of 6 sets of independent acoustic sources.

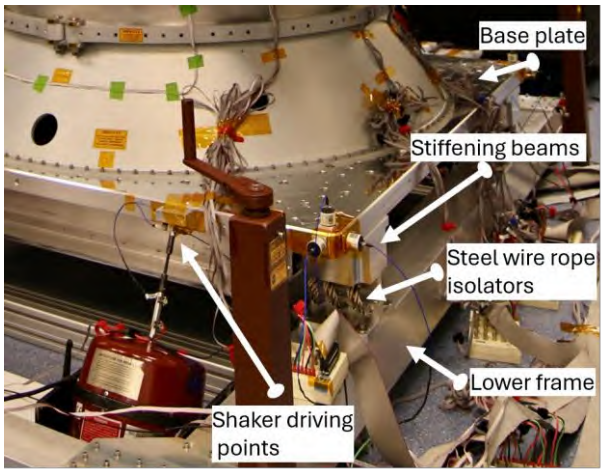

Figure 2: EMA-STA boundary condition

A total of 147 100 mV/g modal accelerometers were mounted to the test article. Twelve 1000 mV/g seismic accelerometers were mounted to the isolated plate at four corners in order to measure the rigid body motion of the plate and the primary out of plane twist mode (Figure 3). An example of a

microphone to monitor acoustic input sound pressure levels is shown in Figure 3.

Seven modal shakers were mounted at the base in a configuration to excite the six rigid body modes and the primary vertical twist mode of the isolated plate. The shaker configuration was selected for applying the fixed-base correction method [7] but in this paper the shaker data will be used to compare more classical shaker modal results with acoustic excitation modal results. A schematic of the accelerometer and shaker locations is shown in Figure 4.

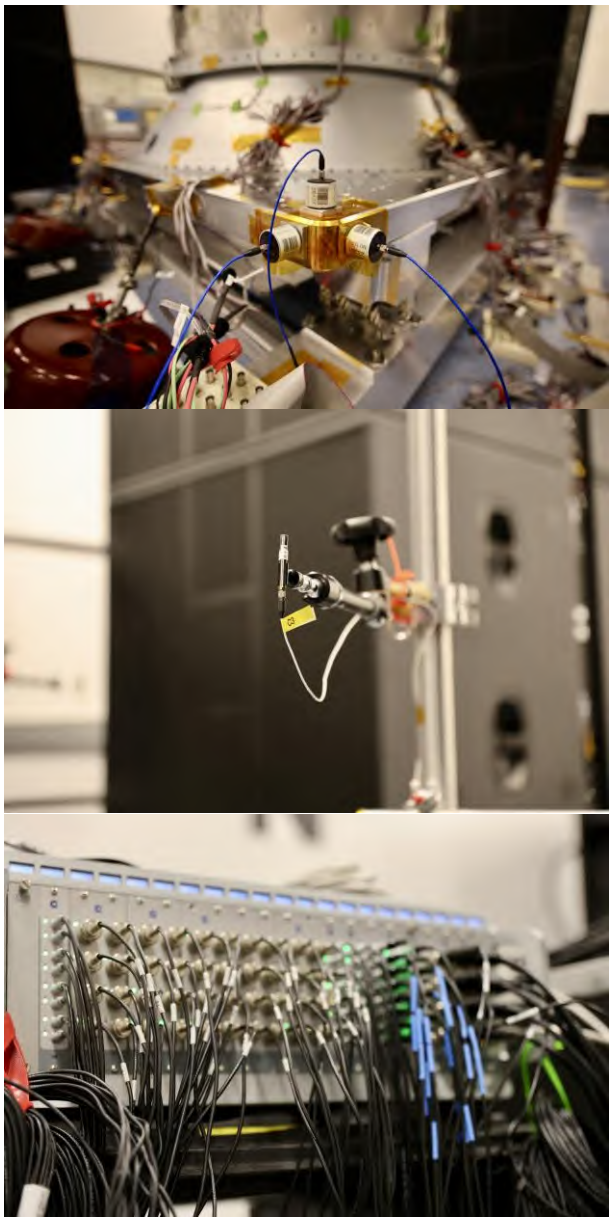

Figure 3: (Top) Modal shaker and seismic accelerometer installation; (Middle) Control microphone; (Bottom) Simcenter SCADAS

Data was collected using Siemens Simcenter Testlab software and two SCADAS Lab frames daisy-chained together with a fiber optic connection for a total of 224 channels (Figure 3). This test recorded a total of 188 channels including all accelerometers, load cells, microphones, and input voltages. Data was sampled at 6.4 kHz. Voltage signals to both the modal shakers and the Neutrons were provided by the SCADAS drive (DAC) channels. The SCADAS system provided two types of excitation signals to the shakers and acoustic sources: broadband random generated internally and digitally generated multi-sine sweep excitation provided by ATA and replayed using the “arbitrary source” capability of the SCADAS. While open-loop excitation was used for the modal survey test data presented in this paper, Testlab is also capable of MIMO control for DFAN qualification testing [10].

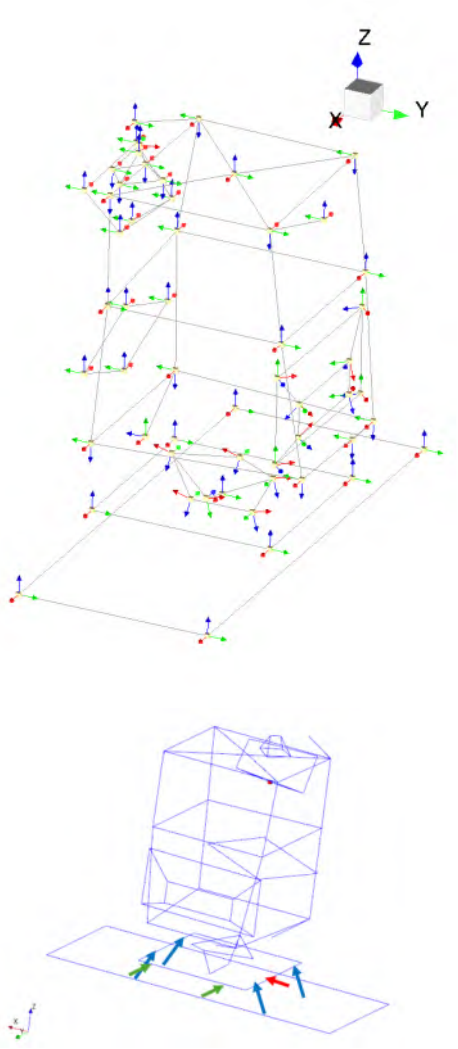

Figure 4: (Top) Accelerometer locations; (Bottom) Modal shaker excitation locations

4. EXCITATION SIGNALS AND MEASUREMENT FUNCTIONS

The 7 shakers at the base have been driven by uncorrelated white noise signals [V], which means that the 7x7 power spectrum matrix of the drives is a diagonal matrix. With shaker testing, a stinger is used to transfer a point force into the structure. This force can be measured by a force sensor that is placed between the stinger and the structure

(Figure 2). FRFs [g/N] can be computed relating structural acceleration responses [g] to the forces [N]. Classical EMA can be applied to these FRFs to identify the modes of the satellite.

The acoustic devices have been driven by 6 uncorrelated signals of the following type:

- White noise (2-200 Hz): this is a standard excitation signal that is also used in shaker testing to excite the frequency range of interest in a modal test.
- Pink noise (20-2000 Hz): this is a typical acoustic signal and is somewhat representative of the excitation during a typical DFAN test.
- Multiple parallel sine sweeps (1-25 Hz): this is a special excitation signal developed by ATA [9] where as many sine sweep signals as independent excitation devices (in this case 6) are used. Each sweep starts at a different frequency, but each sweep covers the entire frequency of interest. Idea is to focus more energy in the lowest frequency range, where acoustic devices are typically less efficient, and still obtain structural responses well above the noise floor.

Figure 5 compares the power spectral densities [V^2/Hz] of these drive signals sent to the 6 independent acoustic devices. As will be demonstrated, high-quality results have been obtained by using the standard white noise excitation signals and the data obtained using other excitation signals will not be further discussed.

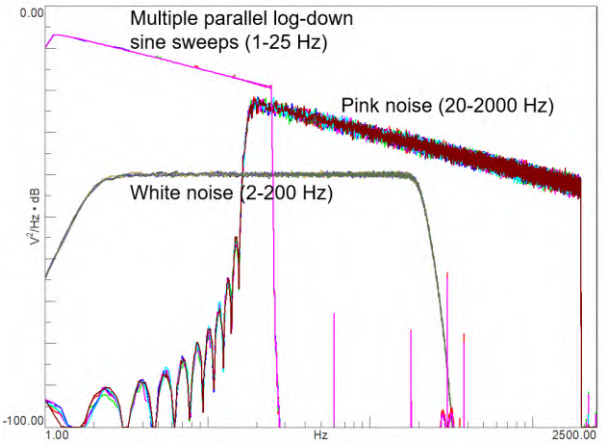

Figure 5: Power Spectral Densities of the drive signals sent to the 6 independent acoustic devices: comparing white noise, pink noise, and multiple parallel sine sweeps

When using acoustic devices as excitation, it is more challenging to quantify the forces acting on the structure. To still be able to calculate FRFs, surrogate signals can be used:

- Drives [V], although not directly representative for the actual "acoustic force"; resulting FRFs will have [g/V] as unit.
- Microphones [Pa] in front of acoustic devices; resulting FRFs will have [g/Pa] as unit.

Figure 6 (Top) shows the power spectra [V^2] of the drives and (Bottom) the drive to microphone FRFs [Pa/V]. The curves represent direct FRFs, i.e. between the microphone in front of a source and the drive sent to that source. The matrix insert shows the full 6x6 FRF matrix, indicating that the diagonal elements are the most important ones.

Although flat drives have been used, it is obvious that the acoustic pressure decreases at the lower end of the spectrum. Nevertheless, the low-frequency modes were still very well excited (lowest mode is around 7 Hz) – see further.

Both [g/V] and [g/Pa] FRFs could be used for EMA, but as an alternative, it is also possible to consider an OMA approach, where no FRFs are needed; response power and cross spectra [g^2] are used instead. EMA and OMA will be discussed in next section.

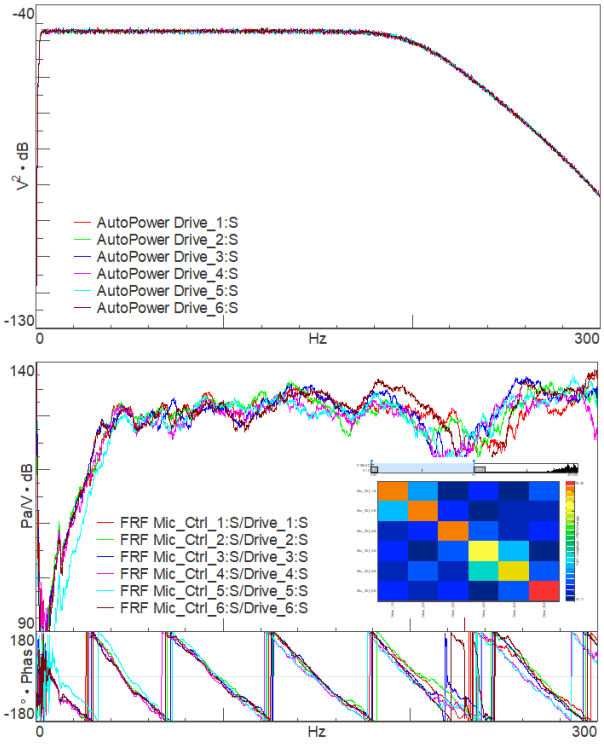

Figure 6: (Top) Power spectra of the white noise drives; (Bottom) FRFs from drives to microphones

When comparing shaker excitation FRFs [g/N] with acoustic excitation FRFs [g/V] (Figure 7), it can be observed that the acoustic FRFs have significantly lower magnitudes at the lower frequencies. Nevertheless, both types of FRFs show an identical "modal content" (same resonance frequencies are apparent in both). Owing to the high quality of the entire measurement chain, the lower frequency modes clearly exceed the noise floor for the acoustic FRFs as well.

It is also interesting to look at the phase behaviour of some measurement functions that can be processed from the shaker and acoustic excitation:

- Shaker FRFs [g/N] show the typical “modal” phase behaviour when crossing through resonances (Figure 8).
- Acoustic FRFs [g/V] show a superimposed linear phase which is caused by the time delay in the acoustic excitation path (Figure 9). Such phase behaviour is typically not accounted for in the (modal) models that are used in the curve-fitting process.
- Acoustic excitation cross spectra between structural responses [g^2] do not suffer from the time delay in the acoustic path. Again, a “modal” phase behaviour is observed (Figure 10).

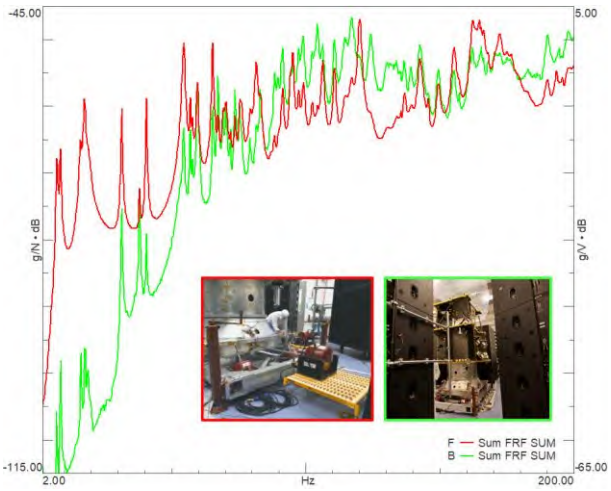

Figure 7: Sum of FRFs: comparing white noise shaker excitation (red) with white noise acoustic excitation (green)

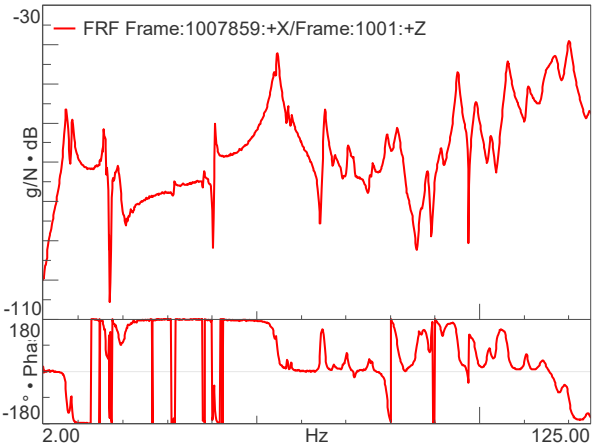

Figure 8: White noise shaker FRF [g/N] with typical “modal” phase behaviour

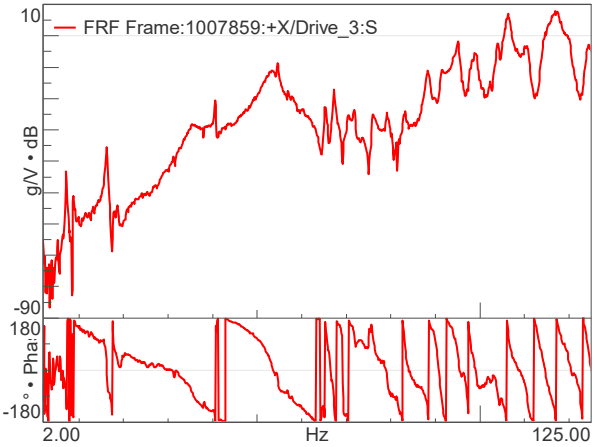

Figure 9: White noise acoustic excitation FRF [g/V] shows additional time delay (linear phase)

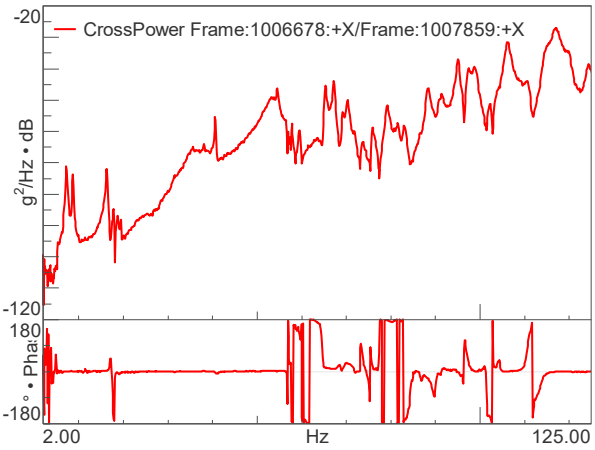

Figure 10: White noise acoustic excitation cross spectrum [g^2] without time delay

5. EMA AND/OR OMA

Next step is to estimate the modal parameters from the measurement functions calculated as explained in previous section. Experimental Modal Analysis is the process of estimating structural modes (eigenfrequencies, damping ratios, and mode shapes) based on vibration measurements in either controlled experimental or operational conditions, respectively. This happens by so-called curve-fitting techniques where a modal model is fitted to the measurement data.

When trying to estimate the modal parameters from sometimes noisy data, it is generally a good idea to over-specify the model order considerably, i.e. to try to fit high-order models that contain much more modes than present in the data. Afterwards the true physical modes are separated from the spurious numerical ones by interpreting a so-called stabilization diagram (Figure 11 – Figure 13). The poles corresponding to a certain model order are compared to the poles of a one-order-lower model. If their differences are within pre-set limits, the pole is labelled as a stable one. The spurious numerical poles will not stabilize very well during this process

and can be sorted out of the modal parameter data set more easily.

Nevertheless, the interpretation of stabilization diagrams may be intimidating for the non-expert and the selection of the “right” poles can be a time-consuming and error-prone process. Therefore, the automation of pole selection in modal analysis is important to accurately process complex datasets without user-dependent interaction and with repeatability. Such automated modal analysis method was recently proposed in [11]: a Hybrid AI method was developed using a Machine Learning (ML) density-based clustering technique, combined with domain knowledge of modal parameter selection.

Polymax [12] as implemented in Simcenter Testlab was selected as the EMA method and applied to both shaker [g/N] and acoustic FRF [g/V] data (Figure 8, Figure 9). The Polymax stabilization diagrams can be found in Figure 11 and Figure 12. The Operational Modal Analysis (OMA) variant of Polymax [13] will be used to estimate the modes from the acoustic excitation cross spectrum data. A detailed discussion on data pre-processing for Operational Modal Analysis can be found in [13] and references therein.

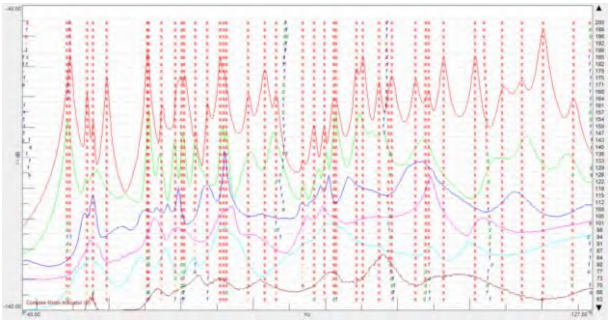

Figure 11: EMA applied to shaker FRFs [g/N] – stabilization diagram

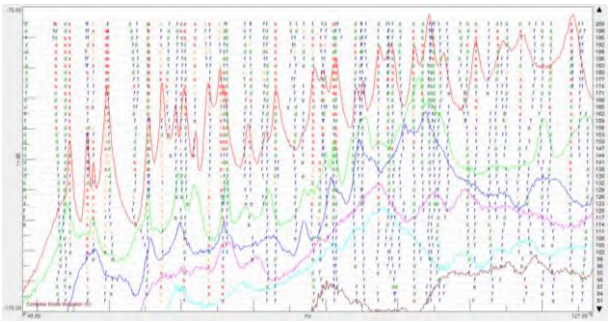

Figure 12: EMA applied to acoustic excitation FRFs [g/V] – stabilization diagram

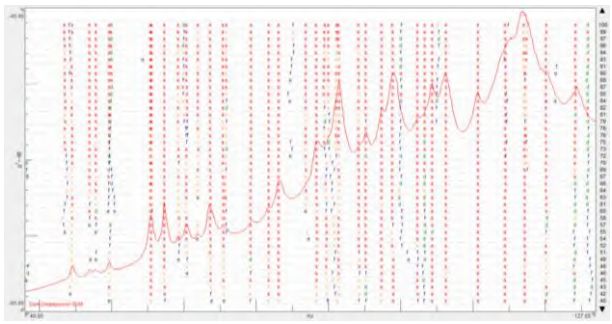

Figure 13: OMA applied to acoustic excitation cross spectra [g^2] – stabilization diagram

Following observations can be made from the stabilization diagrams:

- Polymax applied to clean (high-coherence) shaker FRFs [g/N] results in very clear stabilization diagram (Figure 11).
- Polymax applied to acoustic excitation FRFs [g/V] results in a stabilization diagram from which it is more challenging to select the poles (Figure 12). These FRFs are somewhat noisier (lower coherence) and show a linear phase behaviour (Figure 9) which is not fully compatible with the modal model that is used for the curve-fitting.
- OMA Polymax applied to acoustic excitation cross spectra [g^2] again results in a very clear stabilization diagram from which the pole selection is straightforward (Figure 13).

As one of the objectives of this work is to verify the feasibility of using acoustic excitation well below 20 Hz, OMA was also applied in the lower frequency range (2 - 25 Hz) of the white noise acoustic excitation data. The stabilization diagram in Figure 14 indicates that the lower modes could be easily found. The comparison between the measured and synthesized cross spectra (Figure 15) confirms the high quality of the OMA results in the lower frequency range.

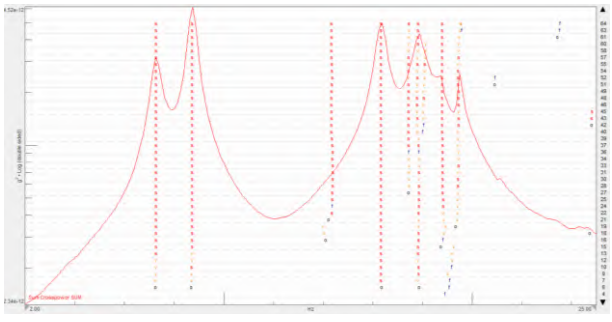

Figure 14: OMA applied to acoustic excitation cross spectra [g^2] in the lower frequency range (2-25 Hz) – stabilization diagram

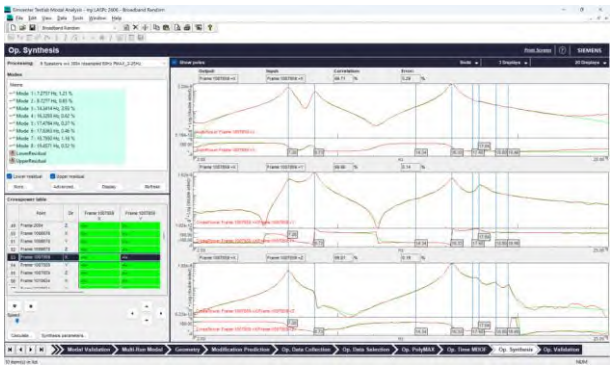

Figure 15: Comparison between measured and synthesized cross spectra (2-25 Hz)

Some acoustic excitation OMA modes are shown in Figure 16 (lower-frequency rigid body modes) and Figure 17 (some examples of flexible deformation modes).

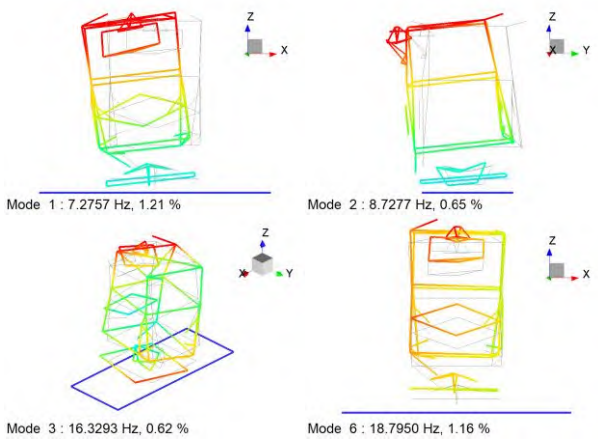

Figure 16: Rigid body modes

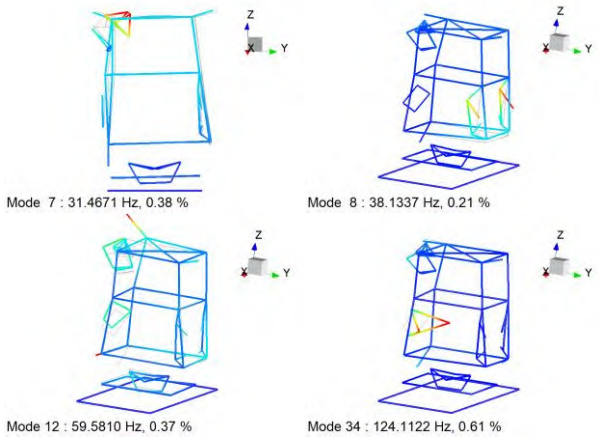

Figure 17: Examples of flexible modes

It is interesting to compare the modes obtained by applying EMA to the shaker FRFs with the modes obtained by applying OMA to the acoustic excitation cross spectra:

- Figure 18 shows the relative frequency difference [%] and the ratio between the shaker and acoustic damping ratios [-]. The first six (rigid body) modes show the largest discrepancies. In general, the frequencies and damping ratios agree very well.
- Figure 19 shows the MAC values between the shaker and acoustic excitation modes. Again, they agree very well.

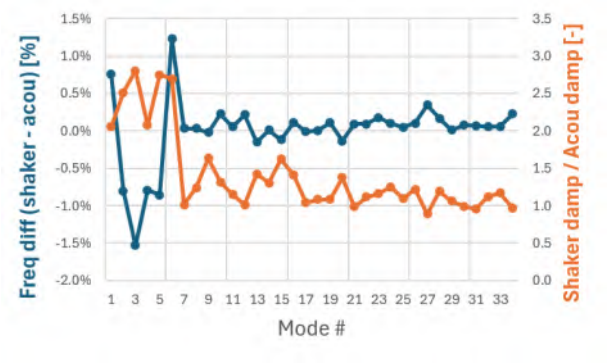

Figure 18: Frequency and damping ratio comparison between shaker EMA and acoustic excitation OMA results (34 modes in range 2-127 Hz)

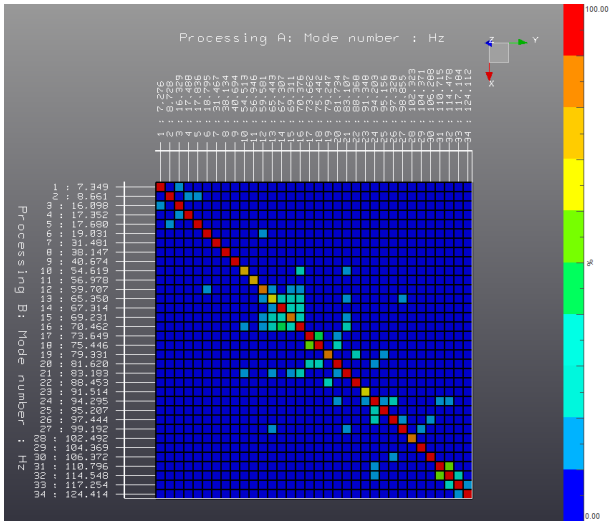

Figure 19: Mode shape comparison (MAC) between shaker EMA and acoustic excitation OMA results (34 modes in range 2-127 Hz)

6. CONCLUSIONS

- Acoustic excitation using Neutrons in a typical DFAN setup can successfully support satellite modal survey testing, extending the value of an existing acoustic qualification setup without requiring mechanical contact with the specimen.
- Despite acoustic devices being traditionally less efficient at low frequencies, white noise acoustic excitation (2–200 Hz) produced structural responses well above the noise floor, allowing reliable identification of modes down to the 2–25 Hz range.
- Both Experimental Modal Analysis (using acoustic FRFs [g/V]) and Operational Modal Analysis (using response cross spectra [g^2]) are viable for acoustic excitation data. However,

OMA on cross spectra produced noticeably cleaner stabilization diagrams than EMA on acoustic FRFs, most probably because the FRFs have a superimposed linear phase (time delay) from the acoustic excitation path that is not well captured by standard modal curve-fitting models. Cross spectra are not affected by this delay and retain the expected “modal” phase behavior.

- Modes identified via OMA on acoustic excitation cross spectra closely match those from EMA on shaker FRFs across 34 modes spanning 2–127 Hz, in terms of both frequency/damping (ratios/differences) and mode shapes (high MAC values). The largest discrepancies occur for the first six rigid body modes.
- The results validate combining DFAN qualification testing with modal survey testing in a single setup, reducing test program cost, schedule, and handling risk.

ABSTRACT

Diffuse Field Acoustic Noise (DFAN) testing is widely employed for the environmental qualification of spacecraft structures and equipment, where a sufficiently diffuse and spatially uniform acoustic field is required to provide representative excitation conditions. The size and geometry of the test article may, however, be constrained by the physical dimensions and acoustic characteristics of the DFAN facility. For large planar structures, an inclined test configuration may provide an alternative approach for increasing the effective dimensions of the structure that can be accommodated within the facility.

This study investigates the feasibility of using panel inclination in DFAN testing and assesses its effects on both the acoustic excitation and the structural dynamic response. A steel panel was considered as a representative planar structure and tested at different inclination angles under diffuse acoustic excitation. Particular attention was given to the spatial uniformity of the acoustic field over the frequency range of interest and to the possible changes in the structural response associated with panel orientation.

A finite element model was developed to evaluate the effect of gravity-induced static deformation on the natural frequencies and mode shapes of the panel for different inclination angles. The numerical predictions were validated through experimental modal analysis using impact hammer testing. Subsequently, a series of DFAN tests was performed with the panel at different orientations. Acoustic field measurements and structural response measurements were compared to assess the uniformity of the excitation and to quantify the variations in the panel response associated with inclination.

The results provide an assessment of the extent to which panel orientation affects both the acoustic excitation and the structural dynamic response. In particular, the study evaluates whether an inclined configuration can provide sufficiently representative acoustic excitation while maintaining structural behaviour suitable for qualification testing. The findings contribute to the assessment of inclined DFAN configurations as a potential approach for testing large planar spacecraft structures and provide practical guidance for their application and interpretation in environmental qualification campaigns.

1. INTRODUCTION

Diffuse Field Acoustic Noise (DFAN) testing is widely employed for the environmental qualification of spacecraft structures and equipment to reproduce the severe acoustic loads experienced during launch. The acoustic environment represents one of the principal dynamic environments considered during spacecraft qualification, and aerospace standards and launcher documentation define the requirements and procedures used to reproduce these conditions in laboratory testing [2,9,10]. Measurements performed during actual launch events have also demonstrated the complex spatial characteristics of the acoustic environment experienced by spacecraft during lift-off [15].

Traditionally, high-intensity acoustic qualification has been performed in reverberant acoustic test facilities, where multiple reflections within the chamber are used to generate an approximately diffuse sound field. A diffuse field provides acoustic energy arriving from multiple directions and is therefore intended to expose the test article to a broad range of excitation conditions. The spatial uniformity and diffuseness of reverberant acoustic fields have consequently been the subject of extensive investigation [1,12,13]. In particular, diffuseness and spatial coherence are key parameters for assessing the extent to which a measured acoustic field approximates an ideal diffuse-field condition [12,13]. These characteristics are particularly relevant when evaluating whether an acoustic test environment provides a representative and sufficiently uniform excitation of the test article [1].

An alternative approach is Direct Field Acoustic Noise (DFAN) testing, in which arrays of high-power loudspeakers are used to generate the acoustic excitation directly around the test article. DFAN offers several practical advantages over conventional reverberant acoustic testing, including reduced facility requirements, increased flexibility in test configuration, and enhanced control of the acoustic excitation [2,3]. The approach has been progressively developed and applied to spacecraft and subsystem qualification, with experimental and numerical studies demonstrating its feasibility and comparing its performance with conventional reverberant-field testing [3,14,16–19]. In particular, comparisons between direct-field and reverberant-field excitation have shown that the structural response of a test article can depend not only on the overall acoustic spectrum but also on the spatial characteristics of the incident acoustic field [3,5,14].

The achievement of a sufficiently uniform and diffuse acoustic environment therefore remains an important consideration in DFAN testing. Investigations of direct-field acoustic testing have demonstrated that the generated acoustic field can contain spatial variations and non-diffuse components depending on the arrangement of the loudspeakers, the control strategy, and the test configuration [5]. The acoustic environment generated by a DFAN system is consequently not determined solely by the prescribed overall sound pressure level. The number and position of acoustic sources, the location of control microphones, and the interaction between the acoustic field and the test article can all influence the

resulting spatial distribution of acoustic energy [3,5].

The development of Multiple-Input Multiple-Output (MIMO) control strategies has provided additional possibilities for controlling the acoustic environment generated by loudspeaker arrays. MIMO approaches allow multiple acoustic sources to be controlled simultaneously and can be used to achieve the desired acoustic spectrum at several measurement locations [4,6]. Pre-test numerical analysis can support the design of these control strategies, while experimental investigations have demonstrated the implementation and validation of acoustic devices and control systems for direct-field testing [7]. These developments have contributed to the increasing application of DFAN as an alternative to conventional reverberant acoustic qualification. Nevertheless, the characterization of the resulting acoustic field remains important, particularly when changes in the geometry or orientation of the test article may alter the spatial distribution of the acoustic excitation.

A relevant practical limitation of acoustic qualification facilities is the size of the test article that can be accommodated within the effective acoustic test volume. This limitation is particularly relevant for large planar spacecraft structures, such as solar panels, whose dimensions may exceed the nominal dimensions of the available DFAN configuration. Increasing the available test volume or modifying the facility itself may not always be technically or economically feasible. An alternative approach is to modify the orientation of the test article. In particular, an inclined configuration may allow a planar structure to make more effective use of the available test volume, potentially enabling the testing of structures whose characteristic dimensions exceed the corresponding nominal facility dimensions.

The use of an inclined configuration, however, introduces several aspects that must be experimentally assessed before it can be considered a viable approach for acoustic qualification. Changing the orientation of the test article modifies the direction of gravity relative to the structure and may therefore alter its static deformation and stress state. For a flexible structure, these changes can affect its dynamic characteristics through geometric stiffness effects, resulting in variations of natural frequencies and mode shapes. Although such effects are expected to be limited for relatively stiff metallic panels, they may become relevant when interpreting differences in structural response between different orientations.

At the same time, changing the orientation of the test article may modify the acoustic environment generated by a multi-speaker DFAN system. The specimen can interact with the incident acoustic waves through reflection and scattering, potentially affecting the local distribution of acoustic energy and the degree of spatial uniformity of the field. This effect is particularly relevant in DFAN facilities, where the acoustic environment is generated directly by discrete loudspeaker sources rather than primarily through the reverberation of a test chamber [3,5,16–18]. Consequently, any variation in the measured structural response between different orientations may result from changes in the structural dynamic properties, changes in the acoustic excitation, or a combination of both.

The objective of this work is therefore to experimentally and numerically investigate the feasibility of using inclined configurations to extend the applicability of DFAN testing to large planar spacecraft structures. A steel panel is considered as a representative structural element, and different inclination angles are investigated. The study is divided into two complementary investigations.

The first investigation addresses the structural effects associated with the change in orientation. A finite element model of the steel panel is developed to evaluate the influence of gravity loading on its static deformation and modal characteristics for different inclination angles. The numerical predictions are validated through experimental modal analysis using impact hammer testing. This analysis provides a quantitative assessment of the extent to which the structural dynamic behaviour changes as a function of panel inclination.

The second investigation addresses the acoustic aspects of the proposed configuration. The same panel is tested in the CIRA MSI-DFAT facility equipped with multiple loudspeaker columns at different inclination angles. Acoustic measurements are performed to characterize the spatial distribution and diffuseness of the acoustic field over the frequency range of interest. At the same time, the structural response of the panel is measured and compared between the different configurations. Particular attention is given to determining whether the inclined configurations maintain a sufficiently representative acoustic excitation and whether the corresponding changes in structural response can be attributed to the orientation of the panel rather than to significant modifications of the acoustic field.

The combination of finite element modelling, experimental modal analysis, acoustic field characterization, and DFAN testing provides a comprehensive assessment of the effects associated with panel inclination. The results are used to determine whether an inclined configuration can provide a sufficiently representative and spatially uniform acoustic excitation while potentially allowing planar structures with dimensions exceeding the nominal dimensions of the DFAN test volume to be accommodated. The study therefore provides a basis for evaluating inclined DFAN configurations as a potential approach for the environmental qualification of large spacecraft structures, including solar panels, and for defining practical criteria for their implementation in acoustic qualification campaigns.

2. TEST ARTICLE DESCRIPTION

The test article consists of a rectangular steel panel with overall dimensions of 2.0 m × 0.76 m. The structure comprises a flat central plate with a uniform thickness of about 1.7 mm, enclosed by a continuous peripheral flange. The flange has a thickness of 3.4 mm, approximately twice that of the central panel, and extends

15 mm out of the plane of the plate along the entire perimeter. This integral edge reinforcement increases the stiffness of the panel boundaries, enhancing the overall bending rigidity and reducing edge deformations while introducing only a limited increase in structural mass. The transition between the central plate and the peripheral flange is continuous, resulting in a monolithic configuration without cut-outs, discrete stiffeners, or other geometric discontinuities.

Figure 1: Test article investigated in this study: the rectangular steel panel with a reinforced peripheral flange installed in the Direct Field Acoustic Noise (DFAN) facility.

Owing to its simple geometry and well-defined structural layout, the panel exhibits dynamic characteristics representative of a broad class of thin-walled reinforced structures. The combination of a compliant central plate and a stiffened perimeter makes the structure particularly suitable for investigating the influence of gravity-induced orientation changes on the modal characteristics, as well as for assessing the consistency of the structural response under diffuse acoustic excitation in a Direct Field Acoustic Noise (DFAN) environment.

3. EXPERIMENTAL MODAL ANALYSIS

Prior to the acoustic testing campaign, an experimental modal analysis was performed to characterize the baseline dynamic behaviour of the panel. The identified natural frequencies and mode shapes were subsequently used as a reference for the numerical model correlation and for evaluating possible orientation-dependent variations.

3.1 Experimental Setup

The experimental modal analysis was conducted using the impact hammer method. Data acquisition and post-processing were performed with an LMS SCADAS SCM2E05 acquisition system. The structure was excited using a PCB Piezotronics 086C03 instrumented impact hammer, which was sequentially applied at all measurement locations according to a roving-hammer strategy. The structural response was measured by means of two PCB Piezotronics 356A16 triaxial ICP accelerometers, permanently mounted at grid locations P4 and P15 throughout each measurement. The use of two fixed reference sensors improved the observability of the global modes and increased the reliability of the modal parameter estimation. The acquisition system, hammer and accelerometer used for the impact testing are shown in Fig. 2

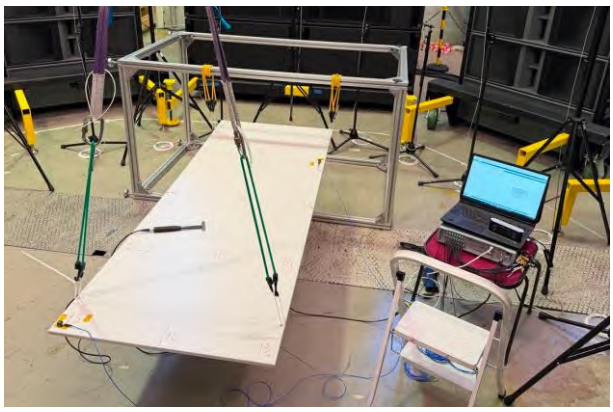

Figure 2: Experimental setup adopted for the impact modal testing, showing the suspended panel, the instrumented impact hammer, the two triaxial reference accelerometers, the LMS SCADAS SCM2E05 data acquisition system, and the Simcenter Testlab 2406 software used for data acquisition and modal analysis.

The measurement geometry consisted of a 3 × 5 grid of evenly distributed excitation points covering the panel surface. Frequency response functions (FRFs) were acquired by impacting each grid location while simultaneously recording the responses from the two reference accelerometers.
The complete experimental procedure was repeated for seven panel inclination angles (0°, 15°, 30°, 45°, 60°, 75°, and 90°) to investigate the influence of orientation on the dynamic characteristics of the structure.

3.2 Modal Identification Results

The experimentally measured frequency response functions (FRFs) were processed using the PolyMAX frequency-domain modal parameter estimation algorithm implemented in Simcenter Testlab 2406. PolyMAX was selected owing to its robustness in identifying closely spaced modes and its capability to provide stable estimates of the modal parameters from multiple FRFs.
Modal identification was performed over the frequency range 1–72 Hz, adopting a model order of 56. The stabilization diagram obtained from the identified poles was used to distinguish physical modes from numerical poles, allowing the extraction of the natural frequencies, damping ratios, and associated mode shapes. To ensure a consistent comparison between the different panel configurations, identical identification parameters were employed for all datasets, thereby minimizing the influence of the processing procedure on the identified modal characteristics. This approach enabled the observed variations in the modal parameters to be attributed solely to changes in the structural behaviour

associated with the panel orientation. An example of the stabilization diagram obtained for the 0° inclination configuration during the PolyMAX modal identification process is reported in Fig. 3. The stable poles selected for the extraction of the modal parameters are highlighted

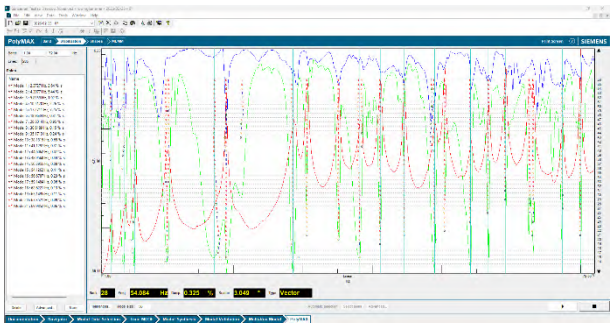

Figure 3: Representative PolyMAX stabilization diagram for the 0° inclination configuration, showing the identified poles and the stable poles used for modal parameter estimation.

The identification procedure was repeated for each of the seven panel inclination angles (0°, 15°, 30°, 45°, 60°, 75°, and 90°). Particular attention was paid to maintaining a consistent mode numbering throughout the analysis by comparing the spatial distribution of the identified mode shapes across all configurations. This ensured an unambiguous tracking of the modal evolution with increasing inclination and facilitated the subsequent comparison with the numerical predictions.

The resulting experimental modal model constitutes the reference dataset for the subsequent finite element model correlation and for assessing the influence of panel orientation on the structural dynamic behaviour. The identified natural frequencies and damping ratios are summarized in Tab. 1 and 2, while the evolution and correspondence of the identified modes with the inclination angle are reported in the modal tracking map shown in Fig. 4. Modal tracking results show an overall decrease in natural frequencies with increasing inclination angle, due to the reduction of the gravity component perpendicular to the panel surface. The frequency shift is mode-dependent, as it is influenced by the modal deformation pattern. The variation becomes more pronounced above approximately 60° inclination, as the panel approaches the vertical configuration.

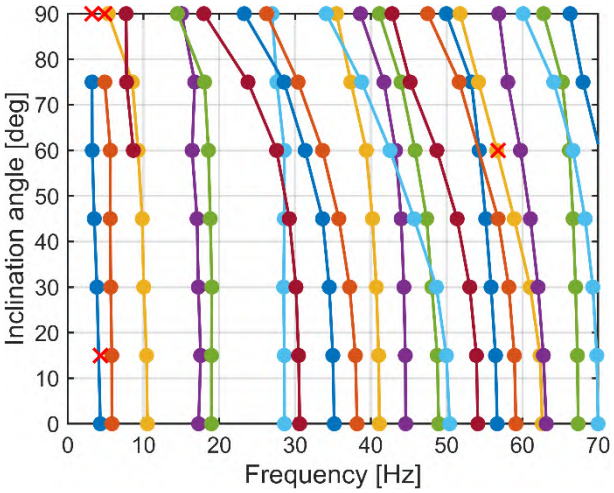

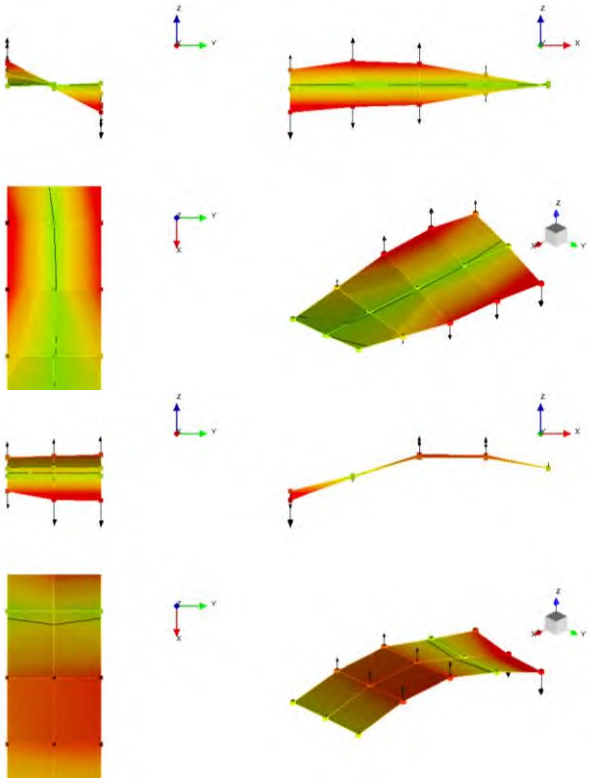

Figure 4: Experimental modal tracking map highlighting the correspondence and frequency evolution of the identified structural modes over the full range of panel inclination angles.

As a representative example, selected mode shapes measured for the panel at 0° inclination are reported in Fig. 5.

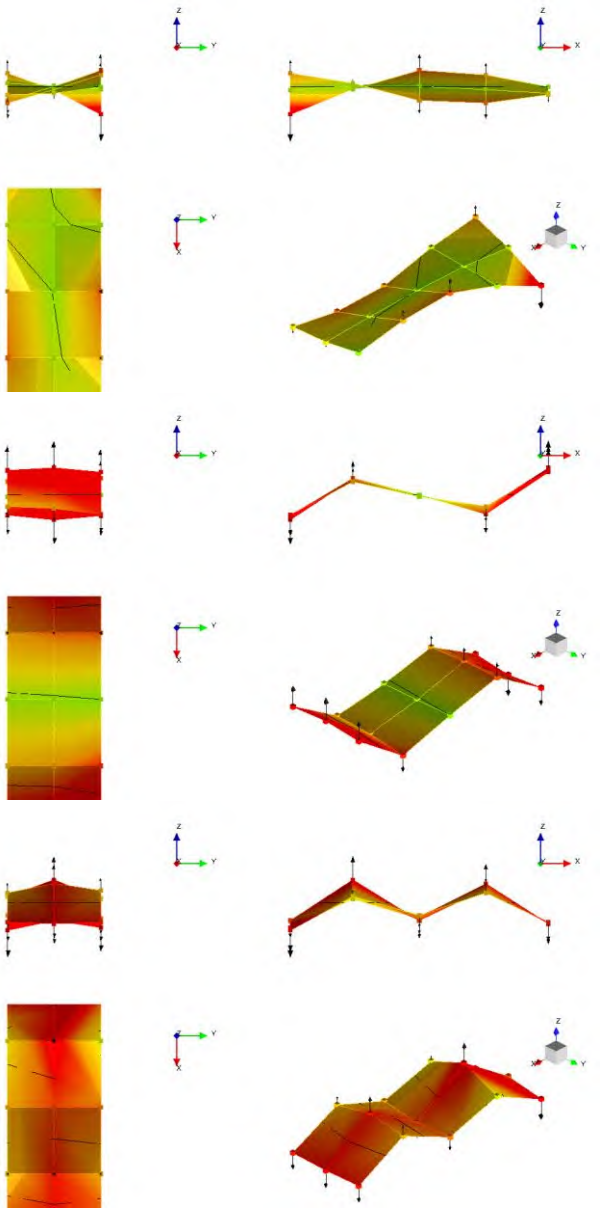

Figure 5: Representative experimental mode shapes of the panel at 0° inclination obtained from the PolyMAX modal identification. The QUAD visualization from Simcenter Testlab reports the identified modes in descending order from top to bottom, corresponding to natural frequencies of 4.31, 5.84, 10.52, 18.96, and 30.62 Hz.

4. FEM MODEL AND CORRELATION

The finite element model of the panel was developed using Simcenter Nastran. The structure was discretized using 15,992 nodes and 15,734 four-node shell elements (CQUAD4). Two shell property regions were defined to reproduce the different thicknesses of the structure: the central plate was modelled with a thickness of 1.7 mm, while the peripheral flange was represented with a thickness of 3.4 mm. The material was assumed to be isotropic steel, with a Young's modulus of 210 GPa, Poisson's ratio of 0.3, and density of 7850 kg/m³. The modal analysis was performed using the SOL

SEMODES solution sequence, with the extraction of the first 200 elastic modes through the EIGRL eigenvalue solver. The model was generated in FEMAP and subsequently solved using MSC-Nastran solver.
The initial finite element model was updated through an in-house model updating procedure to reduce the discrepancy between the numerical predictions and the experimental modal results. The procedure considered the variation of key parameters affecting the dynamic response, namely material density, elastic stiffness, and panel thickness. A Design of Experiments (DOE) methodology was first employed to construct a surrogate model relating the selected parameters to the predicted modal frequencies. The surrogate model was then coupled with an optimization algorithm to identify the parameter combination minimizing the frequency error between the experimental and numerical modes. The resulting updated FEM provided an improved correlation with the experimentally identified modal behaviour.

Table 3: Updated finite element model parameters obtained through the model updating procedure and adopted for the subsequent numerical analyses

Density [Kg/m^3]	7796
Young Modulus [Pa]	2.13E+11
Panel Thickness [mm]	1.6755
Flange Thickness [mm]	3.3352

The updated finite element model was then used to perform a modal analysis up to approximately 700 Hz. The identified natural frequencies were analysed to determine the frequency range in which the modal density progressively approaches a nearly constant value. This analysis allowed the identification of the transition between the low-frequency regime, where the structural response is governed by distinct and identifiable modes, and the higher-frequency regime, where the response becomes increasingly characterized by overlapping modal contributions under diffuse acoustic excitation. The transition was identified at approximately 90 Hz, beyond which the modal density remains nearly constant with an average value of 0.283 modes/Hz, as shown in Fig. 6

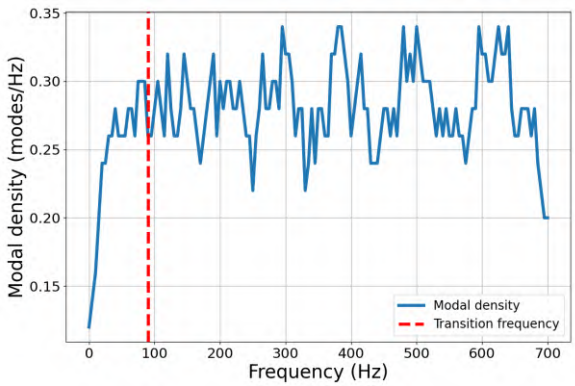

Figure 6: Modal density of the updated finite element model as a function of frequency, highlighting the transition to the nearly constant modal density region

The first two elastic mode shapes obtained from the updated finite element model are presented in Fig. 7 as a representative illustration of the finite element mesh and the numerical modal characteristics of the panel

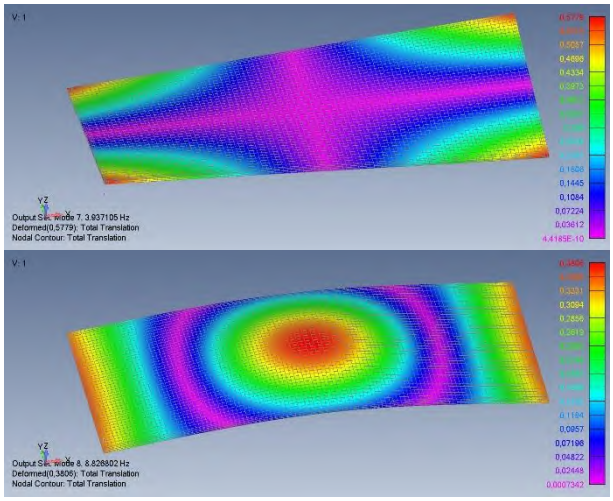

Figure 7: First and second elastic mode shapes of the updated finite element model at 3.94 Hz and 8.83 Hz, respectively.

5. DFAN TESTING AND ORIENTATION EFFECTS

Acoustic testing is a key milestone of any space-hardware mechanical qualification campaign, alongside vibration, shock, and thermal-vacuum testing. Traditionally carried out in reverberant chambers, acoustic qualification has increasingly moved toward Direct Field Acoustic Testing (DFAT) — also referred to in the literature as Direct Field Acoustic Noise (DFAN) testing — which reproduces the reverberant acoustic field using an array of loudspeakers driven by a centralized Multi-Input-Multi-Output (MIMO) closed-loop controller: most generally 16 to 32 microphones are placed randomly to cover the entire test volume. Configurations vary based on the size of test article so that every test is compliant with industry standards in terms of prescribed distance between loudspeakers and article. By removing the need for a dedicated chamber, DFAT offers substantial advantages in cost, portability, and test-schedule flexibility, and has been used to qualify flight hardware including the Orion crew module, the Nancy Grace Roman Space Telescope OTA, and the Proba-V satellite. The method is referenced in NASA HDBK-7010, and standardization work is currently ongoing under ESA/ECSS.
A specific application of DFAT concerns the acoustic qualification of solar arrays, whose large dimensions may impose geometrical constraints on the test configuration. In such cases, the test article may need to be inclined with respect to the nominal orientation in order to fit within the available test volume while satisfying the required distances from the acoustic sources. Although DFAT is intended to reproduce a diffuse acoustic field, the field generated by a finite loudspeaker array is not perfectly diffuse and may exhibit spatial variations in acoustic pressure level and direction of incidence. Consequently,

the orientation of an extended test article may affect the acoustic loading acting on its surfaces and, ultimately, its structural response. This aspect is particularly relevant for large and lightweight structures such as solar arrays, for which the acoustic loading may be sensitive to variations in the local incident sound field. The influence of the test article inclination on the acoustic response therefore represents a relevant aspect to be assessed when defining and interpreting DFAT configurations. In particular, the extent to which variations in the inclination angle modify the acoustic excitation and the resulting structural response remains to be quantified.

To investigate the influence of test article inclination on the acoustic excitation and structural response under DFAT conditions, an experimental campaign was conducted at the CIRA acoustic testing facility using the test article described in the previous sections. The campaign was specifically designed to assess the variation of the test conditions and of the resulting structural response as a function of the test article orientation. The experimental setup, the selected inclination angles, and the adopted test procedure are presented in the following sections. First, the CIRA DFAT facility and its main characteristics are described. The experimental campaign is then presented, including the test configurations, instrumentation, and measurement approach adopted for the different test article orientations. Finally, the experimental results are analysed and discussed, with the aim of assessing the extent to which the inclination of the test article affects the acoustic excitation and the corresponding structural response.

5.1 CIRA DFAN Facility

The experimental campaign was conducted at the CIRA Space Qualification Center using the Direct Field Acoustic Noise (DFAN) system developed by MSI-DFAT within the framework of the ASI-funded PNRR Space Factory 4.0 program. The facility is based on a mobile Direct Field Acoustic Testing (DFAT) system designed to reproduce the high-intensity acoustic environment experienced during launch without requiring a reverberant chamber.

The Noise Generation System (NGS) consists of high-power loudspeakers arranged in a circular configuration around the test article. The system combines 30 MP-21 low-frequency subwoofers, covering the frequency range from approximately 20 to 300 Hz, with 48 MP-150 three-way loudspeakers for the mid- and high-frequency range. The loudspeakers are driven by dedicated high-power amplifiers and are distributed around the test article to generate an acoustic field representative of the reverberant conditions required for qualification testing. The system is designed to operate over a broad frequency range, approximately from 25 Hz to 10 kHz, and to generate sound pressure levels suitable for high-intensity aerospace qualification tests.

The acoustic field is controlled through a Multiple-Input Multiple-Output (MIMO) closed-loop Noise Control System (NCS), implemented using Siemens Simcenter TestLab. Up to 24 control microphones are available for the MIMO control, with a minimum of 16 microphones required for the standard configuration. The microphones are distributed around the test article and provide the feedback signals used to control the individual loudspeaker drives. In addition to matching the target acoustic spectrum within prescribed tolerances, the control system monitors the coherence and phase relationships between microphone pairs. This allows the generated field to be optimized not only in terms of overall sound pressure level but also with respect to its spatial characteristics, thereby providing an acoustic environment that approximates a diffuse field.

The NCS is based on SCADAS hardware, providing up to 50 input channels and 16 output channels, and allows additional monitoring channels to be integrated into the test configuration. Accelerometers can also be included to monitor the structural response of the test article and, when required, to implement response limiting. The combination of the MIMO control strategy and the circular loudspeaker arrangement enables the acoustic excitation to be adapted to different test articles and configurations while maintaining a controlled and repeatable acoustic environment.

5.2 Experimental Test Campaign

The experimental campaign was performed on the test article described in the previous sections to investigate the influence of its inclination on the acoustic excitation and structural response during DFAT. Seven different test article orientations were considered, corresponding to inclination angles of 0°, 15°, 30°, 45°, 60°, 75°, and 90° with respect to the reference configuration. The same acoustic test configuration, control strategy, target spectrum, and test procedure were maintained for all orientations, with the inclination angle representing the main parameter varied throughout the campaign. This approach allowed the effect of test article orientation on the acoustic loading and resulting structural response to be assessed independently of changes in the test configuration.

The DFAT test was controlled using a MIMO random control strategy implemented in Siemens Simcenter TestLab. A total of 16 microphones were used as control microphones for the MIMO control loop. The microphones were distributed around the test article to provide feedback on the acoustic field and to enable the controller to reproduce the prescribed target spectrum. The microphones were PCB Piezotronics 378C10 ICP microphones, with nominal sensitivities close to 1 mV/Pa.

The structural response of the test article was monitored using nine accelerometers arranged in a 3 × 3 regular grid on the plate under investigation. The instrumented plate has dimensions of approximately 0.76 × 2.0 m, with the accelerometers distributed over its surface to provide spatially distributed measurements of the vibration response. The accelerometers had a nominal sensitivity of 5 mV/g. The microphone and accelerometer configurations were kept unchanged throughout the

different test conditions to ensure consistency in the comparison of the results.
The target acoustic spectrum imposed on the MIMO controller corresponded to a nominal OASPL of 130 dB. The target spectrum covered the frequency range from 15.63 Hz to 2 kHz and was defined with a frequency resolution of 3.125 Hz. The target levels, together with the prescribed lower and upper tolerances and abort limits, are reported in Tab. 4. The target spectrum was controlled within lower and upper tolerances of ±3 dB, while an abort limit of +6 dB was applied to prevent excessive acoustic excitation. The frequency resolution adopted for the control was 3.125 Hz, with 120 degrees of freedom (DOF) specified for the MIMO control configuration.

Table 4: Target acoustic spectrum and control limits used for the MIMO control

Freq. [Hz]	Target level [dB]	Lower tolerance [dB]	Upper tolerance [dB]	Abort limit [dB]
16	86.13	3	3	6
31.5	90.02	3	3	6
63	120.02	3	3	6
125	121.72	3	3	6
250	124.52	3	3	6
500	124.52	3	3	6
1000	119.52	3	3	6
2000	115.52	3	3	6
4000	112.52	3	3	6
8000	109.52	3	3	6

The acoustic test was conducted through a controlled level ramp-up procedure. Starting from a level 9 dB below the target spectrum, the acoustic excitation was increased in 3 dB steps until the full target level was reached. Once the nominal test level was achieved, the spectrum was maintained for approximately 120 s. This procedure was applied consistently to all seven test article orientations.
The test sequence consisted of three main phases: system identification, system verification, and the final MIMO random control test. During system identification, the dynamic relationship between the loudspeaker drive signals and the acoustic responses measured by the control microphones was characterized. The subsequent system verification phase was used to verify the identified model and the capability of the system to reproduce the prescribed acoustic field. Following successful verification, the MIMO random control test was performed.
During the final test, the six independent drive signals generated by the MIMO controller were distributed among the acoustic sources according to the DFAN configuration. Three signals were used to drive the MP-21 low-frequency loudspeaker stacks, while the remaining three signals controlled the MP-150 mid- and high-frequency loudspeaker stacks. The resulting acoustic excitation was therefore generated through six independently controlled drive channels, while the microphone array provided the feedback required to maintain the target acoustic spectrum and its spatial characteristics.
Fig. 8 shows the test article installed in the DFAN facility at three representative inclination angles, corresponding, from top to bottom, to 0°, 30°, and 60°. The panel is suspended using the elastic suspension system adopted for the test campaign, with the nine accelerometers arranged in a 3 × 3 grid on its upper surface. A spirit level was used during the setup procedure to accurately define and verify the inclination angle and was removed before the acoustic test. The DFAN loudspeaker stacks surrounding the test article can be observed in the background.

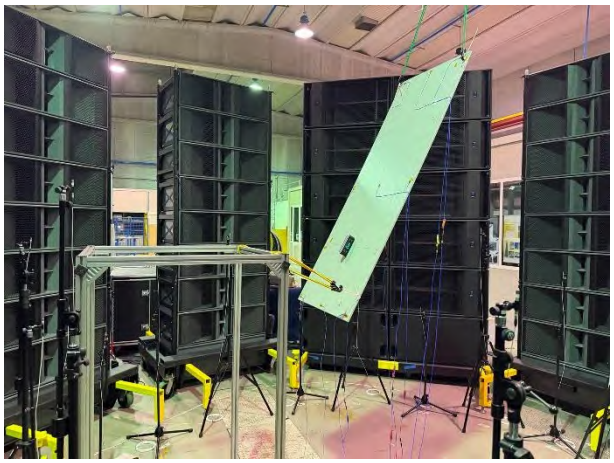

Figure 8: Test article configuration at different inclination angles: 0°, 30°, and 60° from top to bottom.

Fig. 9 presents the acoustic pressure measurements recorded by the 20 microphones during the MIMO control phase, including the 16 control microphones and four additional measurement microphones. The measurements are reported in octave bands, with the individual microphone responses shown in light grey and their arithmetic mean shown in black. The target acoustic spectrum imposed by the MIMO controller is shown in green, together with the lower and upper control limits in violet and the abort limit in red. The comparison between the measured responses and the target spectrum shows that the acoustic field generated during the test is maintained within the prescribed control limits over the considered frequency range, confirming the capability of the MIMO system to reproduce the required acoustic excitation.

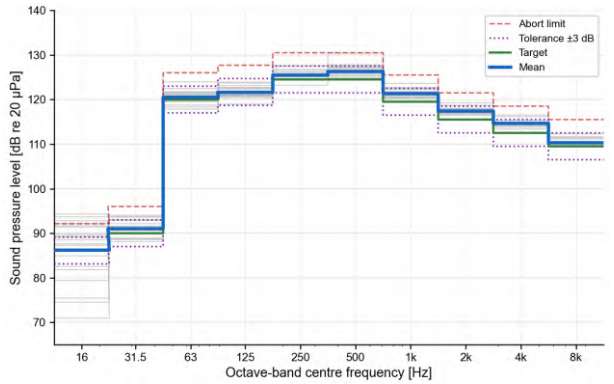

Figure 9: Acoustic pressure levels measured by the 20 microphones during MIMO control (panel inclination: 0°), together with the mean spectrum, target spectrum, ±3 dB control limits, and upper +6 dB abort limit.

5.3 Results and Discussion

To investigate the influence of test article inclination on the acoustic–structural coupling, the Vibro-Acoustic Gain (VAG) was evaluated in one-third-octave frequency bands. The VAG was calculated as the ratio of the mean structural acceleration response to the mean acoustic pressure acting on the test article. The mean acoustic pressure was obtained from the 16 control microphones and four additional measurement microphones, whereas the mean structural acceleration was calculated from the nine accelerometers distributed over the test panel. By expressing the structural response relative to the acoustic excitation level, the VAG provides a normalized indicator of the acoustic-to-structural response transfer, thereby facilitating comparison between test configurations with different acoustic field levels. The VAG obtained for the seven investigated inclination angles is reported in Fig. 10.

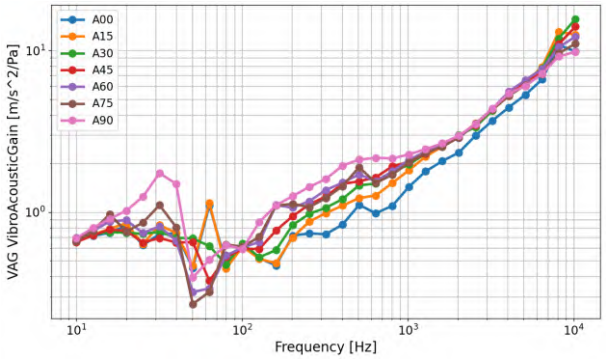

Figure 10: Vibro-Acoustic Gain (VAG) as a function of frequency for the seven investigated test article inclination angles, evaluated in one-third-octave frequency bands.

The results show a clear frequency-dependent influence of the test article inclination. Up to approximately 90 Hz, the structural response is strongly governed by the modal characteristics of the panel. In this frequency range, the relatively low modal density allows individual structural modes to dominate the response, resulting in significant differences between the investigated orientations. The change in inclination modifies the coupling between the incident acoustic field and the structural modes, leading to substantial variations in the VAG.

Between approximately 100 Hz and 1 kHz, the influence of the inclination remains evident, although the response is no longer dominated by a limited number of clearly distinguishable modes. The increasing modal density leads to a more distributed structural response, while the orientation of the panel continues to affect the efficiency of the acoustic–structural coupling. Within this frequency range, several intermediate orientations, particularly those between approximately 45° and 75°, exhibit very similar VAGs over extended frequency ranges. This behaviour is of particular interest for the practical definition of DFAT configurations, as it suggests that a relatively broad range of intermediate orientations can produce comparable structural responses.

Above approximately 1 kHz, the differences associated with the inclination angle progressively decrease, and the responses corresponding to most orientations tend to converge. This indicates that the structural response becomes less sensitive to the orientation of the test article at higher frequencies. An exception is observed for the 0° configuration, which exhibits a distinct response compared with the other orientations. This behaviour is

attributed to the influence of gravity on the structural configuration, which can modify the static state of the panel and consequently affect its dynamic response.

The limiting configurations at 0° and 90° also provide useful reference conditions for interpreting the overall trend. The large difference between these orientations, particularly at low frequencies, confirms that the inclination angle affects the efficiency with which the acoustic field excites the structure. At intermediate angles, the response progressively approaches a region in which several configurations exhibit comparable behaviour. In particular, the similarity observed between approximately 45° and 75° is relevant to the practical use of inclined configurations when the dimensions of the test article impose geometrical constraints on the DFAT setup.

The results therefore indicate that the effect of test article inclination is primarily concentrated in the low- and mid-frequency ranges. Below approximately 90 Hz, the response is strongly associated with the modal behaviour of the structure, while between approximately 100 Hz and 1 kHz the inclination continues to influence the Vibro-Acoustic Gain (VAG) despite the higher modal density. Above approximately 1 kHz, the effect of inclination becomes comparatively small, apart from the specific behaviour observed for the 0° configuration. Importantly, the analysis of the acceleration-to-pressure ratio indicates that the differences between orientations are not primarily associated with variations in the applied acoustic field, but rather with the different transfer of acoustic energy to the structure as a function of its orientation.

From a practical perspective, these findings support the use of intermediate inclination angles when the geometry of a large test article prevents testing in the nominal orientation. For example, an inclination of 45° may provide a suitable compromise between the available test volume and the resulting structural response, while the results show that orientations in the approximate range of 45°–75° can produce similar responses over a significant frequency range. However, the present analysis does not, by itself, establish that an inclined configuration is equivalent to the reference 0° configuration from a qualification standpoint. In particular, the use of averaged acceleration levels may mask local increases in vibration response, since an increase at one accelerometer can be compensated by a reduction at another location.

Therefore, a final assessment of the potential over-test or under-test associated with an inclined configuration requires a more localized comparison. The acceleration response at each measurement point should be compared, frequency band by frequency band, with the corresponding response obtained in the reference 0° configuration. Such a sensor-by-sensor analysis would allow local increases and reductions in structural response to be identified and would provide a more robust basis for determining whether an inclination such as 45° can be adopted for qualification testing without introducing unacceptable over-test or under-test conditions.

CONCLUSIONS

This work investigated the influence of test article inclination on the structural response of a large flexible panel subjected to Direct Field Acoustic Noise (DFAN) excitation. The study was conceived to assess whether inclined configurations can be used as a practical approach to accommodate large planar structures within the available test volume of a DFAN facility, while maintaining representative acoustic excitation conditions. The investigation combined experimental modal characterization, finite element model updating, and an experimental acoustic campaign performed at the CIRA Space Qualification Center.

The panel was first characterized through impact hammer testing, and the experimentally identified modal parameters were used to update the finite element model. The updated model was subsequently used to investigate the modal behaviour of the panel up to approximately 700 Hz for the different inclination conditions. The analysis identified a transition at approximately 90 Hz between a low-frequency regime dominated by distinct structural modes and a higher-frequency regime characterized by increasing modal density. Above this transition, the modal density approached an approximately constant value of 0.283 modes/Hz, corresponding to approximately one mode every 3.5 Hz.

The DFAN campaign was performed at seven inclination angles, from 0° to 90° in 15° increments, while maintaining the same acoustic control configuration. The prescribed acoustic target spectrum was successfully reproduced for the investigated configurations, and the structural response was monitored using nine accelerometers distributed over the test panel. The Vibro-Acoustic Gain (VAG), defined as the ratio between the mean structural acceleration and the mean acoustic pressure, was used as a normalized indicator to investigate the influence of panel inclination while mitigating the effect of variations in the overall applied acoustic pressure level.

The experimental results show that panel inclination has a significant influence on the frequency-dependent acoustic-to-structural transfer, particularly below approximately 1 kHz. The strongest variations were observed in the low-frequency modal regime below approximately 90 Hz, where the response is dominated by individual structural modes and is therefore highly sensitive to changes in structural configuration. Between approximately 100 Hz and 1 kHz, the influence of inclination remains evident, although the increasing modal density progressively reduces the sensitivity to individual modal variations. Above approximately 1 kHz, the VAG responses associated with most orientations tend to converge, indicating a progressively lower sensitivity of the global acoustic-to-structural response to panel inclination. Intermediate orientations, particularly between 45° and 75°, exhibited similar VAG trends over extended frequency ranges.

The numerical and experimental modal results provide a

quantitative assessment of the structural changes associated with different orientations, while the DFAN measurements demonstrate that these changes, together with possible variations in the acoustic excitation, can affect the measured structural response. The results therefore indicate that an inclined configuration cannot in general be assumed to be equivalent to the reference 0° configuration solely on the basis of the applied overall acoustic spectrum. Both the frequency-dependent structural response and the spatial characteristics of the acoustic excitation must be considered when defining and interpreting DFAN configurations for large planar structures.

From a practical perspective, the results support the feasibility of using inclined configurations as a potential approach for accommodating planar structures whose dimensions may exceed the nominal dimensions of the DFAN test volume. In particular, the intermediate orientations investigated in this study, including the 45° configuration, showed promising behaviour over significant portions of the frequency range and may provide a practical compromise between geometrical accommodation and structural response. However, the present results do not by themselves establish the equivalence of an inclined configuration with the reference configuration for qualification purposes.

In particular, the spatially averaged VAG is not sufficient to demonstrate that an inclined configuration provides an equivalent qualification environment. A sensor-by-sensor comparison with the 0° reference configuration, performed over appropriate frequency bands, is required to identify local increases or reductions in structural response and to assess potential over-test or under-test conditions. Such an analysis should be complemented by an assessment of the spatial characteristics of the acoustic field for each orientation, in order to distinguish variations associated with the structural dynamics from those arising from changes in the acoustic excitation.

Overall, the study demonstrates that panel inclination is a promising approach for extending the practical applicability of DFAN testing to large planar spacecraft structures, including solar panels, potentially allowing structures whose dimensions exceed the nominal geometrical envelope of the test facility to be accommodated. The results provide an experimental basis for the development of acceptance criteria for inclined DFAN configurations. Future work will focus on establishing quantitative limits for structural response variation, including sensor-level over-test and under-test criteria, and on correlating these limits with the spatial characteristics of the acoustic field. This will support the definition of a robust methodology for selecting and qualifying inclined configurations for the environmental testing of large spacecraft structures.

ABSTRACT

This paper presents a Multi-SISO (M-SISO) one-third-octave acoustic control architecture for direct field acoustic noise (DFAN) testing. The method uses multiple broadband random drives, each assigned to a control microphone and a one-third-octave feedback loop, rather than a narrowband phase-targeted multivariable controller. The objective is to regulate the broadband spectrum while allowing the global field to result from the statistical superposition of uncorrelated sources. The paper focuses on the control philosophy, loop structure, signal processing, representative test configuration, and field-quality observations. Data from a 32-device DFAN system with separate control and monitor microphone positions show close agreement between the two microphone groups and consistent exposure over time. The results demonstrate the practical viability of M-SISO control for DFAN applications in which a spatially uniform, low-coherence acoustic field is an appropriate test objective. The work does not provide a direct performance comparison with narrowband MIMO control and does not claim that low coherence alone constitutes a complete diffuse-field qualification.

1. INTRODUCTION

Acoustic qualification testing for spacecraft and other launch-borne hardware seeks to reproduce the broadband sound-pressure environment inside a launch-vehicle fairing [1]. Reverberant chambers remain an established reference technology, while direct field acoustic noise (DFAN) systems offer a portable alternative that can be deployed without a dedicated reverberation facility [2]. DFAN systems have commonly used narrowband multivariable control, selected microphone locations, and partially coherent source arrangements. These methods can be effective, but phase-sensitive summation and standing-wave effects may influence the spatial field and the structural response of a device under test [3,4].

The present paper examines a different control philosophy: a Multi-SISO one-third-octave architecture in which many locally controlled loops regulate filtered sound-pressure levels while the global field is formed by the superposition of uncorrelated broadband sources. The target is a stable and repeatable broadband test environment rather than a prescribed narrowband pressure pattern. The paper therefore concentrates on the architecture and on field-quality observations. Detailed structural-response comparisons are outside its scope.

2. BACKGROUND AND CONTROL PHILOSOPHY

2.1 Diffuse-field objective

For the purposes of this paper, field uniformity and field diffusivity are treated as related but distinct properties. Uniformity describes the spatial variation of sound-pressure level over the test region. Diffusivity describes the statistical and directional character of the acoustic field. Low spatial coherence is consistent with reduced dominance of persistent coherent wavefronts, but it is not, by itself, a complete measure of diffusivity. In a direct field system, these properties must be influenced through source arrangement, source independence, and controller behavior because they are not generated by the long reverberation time of a chamber.

2.2 Architectural rationale

If the acoustic devices provide sufficient broadband output, the system need not rely primarily on coherent summation between separate low- and high-frequency source groups to reach the required level. Each device, or small group of devices, can instead be assigned an independent broadband drive and a dedicated feedback loop. The controller regulates one-third-octave sound-pressure levels and does not prescribe phase relationships between source groups. This paper treats that choice as an architecture decision rather than as a tuning variation. Previous work has demonstrated octave-band DFAN control and purpose-built broadband acoustic devices [6,7].

3. M-SISO ARCHITECTURE

3.1 Loop structure

In the M-SISO architecture, each loop contains an independent broadband random source, an acoustic device or device group, a logically assigned control microphone, and a band-domain feedback controller. The control microphone is dedicated to that loop in the controller configuration, although its measured pressure contains

contributions from all acoustic sources in the field. The microphone signal is analyzed in one-third-octave bands and compared with the target spectrum. The resulting band-level error is used to adjust the drive amplitude of the associated source. Additional source groups are accommodated by repeating the same loop structure. Figure 1 illustrates an example in which the acoustic devices are divided into independently controlled groups around the test article.

The loops are locally controlled rather than acoustically isolated. They interact through the common sound field, and practical operation therefore includes an inter-loop gain-stabilization mechanism that prevents individual source groups from moving toward extreme operating points in response to local deviations. The present paper describes the function of this mechanism but does not disclose implementation-specific controller gains or update equations. Consequently, the work should be read as an architecture and experimental-observation paper rather than as a complete reproducible controller specification.

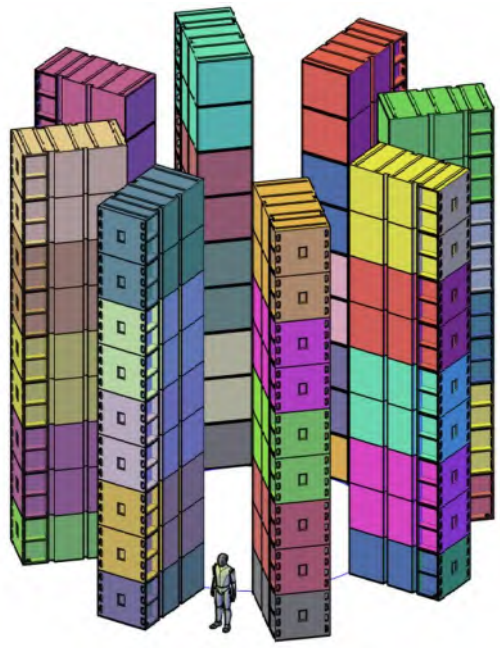

Figure 1: Example arrangement of independently controlled acoustic device groups in an M-SISO system.

3.2 Signal processing and control law

The controller operates in the one-third-octave domain using filter banks compliant with ANSI S1.11 [5]. The controlled quantity is the filtered one-third-octave sound-pressure level at each assigned control microphone. Band levels are updated at a fixed control interval and compared with the target spectrum. This processing avoids the need to use FFT-based cross-power and phase-correlation terms in the acoustic control law. It also permits short update intervals without requiring long narrowband averaging windows. No prescribed phase alignment is maintained between source groups, and no narrowband interference pattern is intentionally synthesized at selected microphones. The actual reaction time, loop gains, saturation logic, and convergence behavior are implementation-dependent and are not quantified in the present data set.

3.3 Interface to protection and notching

The absence of narrowband acoustic control does not preclude narrowband structural protection. High-resolution acceleration monitoring may be operated in parallel with the octave-band acoustic controller. In that arrangement, the M-SISO loops generate the acoustic field, while warning, abort, or notching actions are derived from a separate structural-monitoring path. Structural notching performance was not evaluated in the data presented here and is included only to define the interface between acoustic control and test-article protection.

4. EXPERIMENTAL SETUP

The representative setup used 32 acoustic devices arranged as eight stacks of four around the device under test. The acoustic control system provided 32 source outputs and 60 microphone inputs. A total of 51 microphones was used: 32 microphones positioned in front of the acoustic devices served as control microphones, and 19 additional microphones served as independent monitors. Of the monitor microphones, 12 were placed at positions representative of conventional narrowband control layouts and seven were placed outside the principal target region. The distinction between control and monitor positions allows the field to be assessed both where the controller directly measures it and at locations that do not contribute to the feedback law. The physical 32-device installation is shown in Fig. 2.

Figure 2: Representative 32-device DFAN system used for architecture validation.

The system was exercised with launch-derived target spectra up to approximately 145 dB overall sound-pressure level and exposure durations of one or two minutes. Three source-patching configurations were used in the broader test

programme: 32, 16, and 8 independent drives. The 32-drive arrangement assigned one drive to each acoustic device. The lower-drive-count configurations grouped devices and therefore introduced increasing source coherence. Figure 3 shows the 8x4 arrangement together with the approximate control and monitor microphone locations. The present paper uses these configurations only to illustrate field consistency and temporal behaviour; their structural-response consequences are outside the present scope.

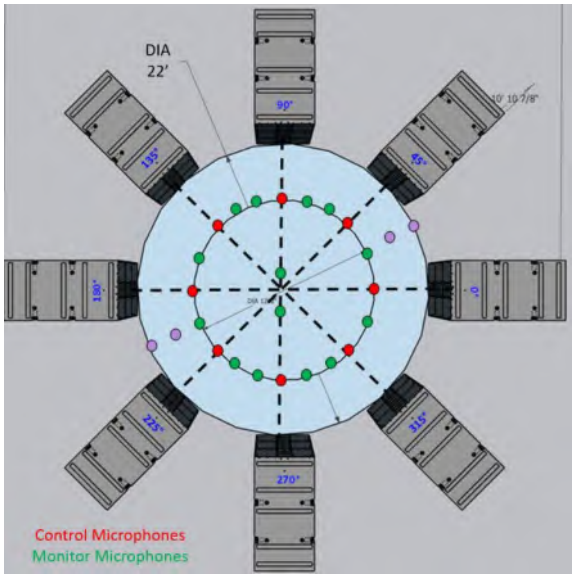

Figure 3: Representative 8x4 DFAN configuration with control and monitor microphone locations.

5. RESULTS

5.1 Control and monitor response

The first result of interest is the relationship between the control microphones and the independent monitor microphones. During representative 32-drive M-SISO operation, both microphone groups followed the target spectrum closely in the one-third-octave presentation. In several frequency regions, the monitor traces grouped as tightly as, or more tightly than, the control traces. This control-to-monitor agreement is illustrated in Fig. 4. Because the monitor microphones were not part of the feedback loops, this observation indicates that acceptable spectral agreement was not confined to the directly controlled locations.

The corresponding power spectral density representations show a similar relationship between the controlled and monitored positions. These narrowband plots are used as an independent description of the generated field; they are not the basis of the octave-band control law. The current data support a qualitative conclusion of broad field agreement. A formal statistical acceptance criterion, including spatial standard deviation or maximum deviation from the target, was not applied in this paper and remains a subject for further work.

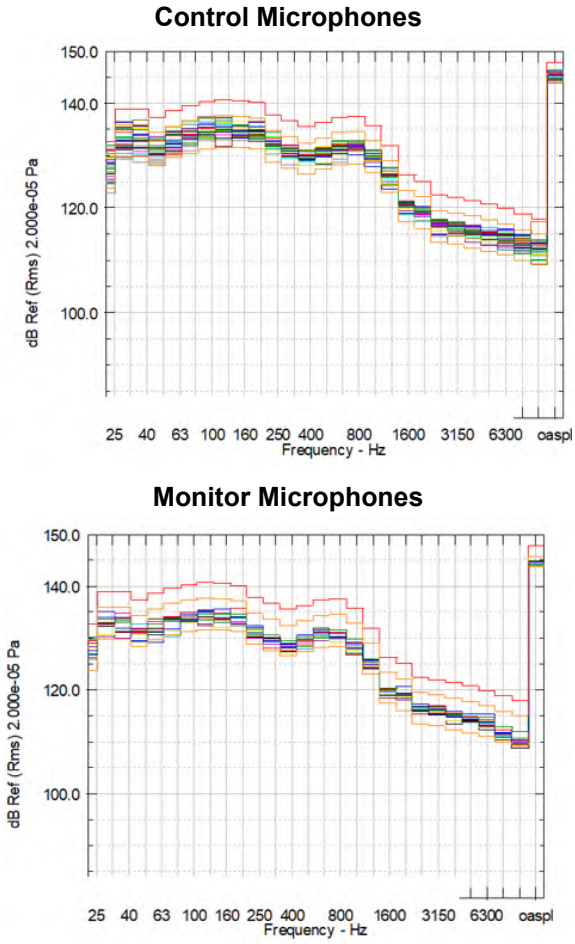

Figure 4: Representative control and monitor microphone agreement during 32-drive M-SISO operation.

5.2 Field diffusivity and coherence

A second observation concerns spatial coherence. Because the source signals are intentionally uncorrelated, coherence between spatially separated microphones remains comparatively low over most of the measured frequency range. This behaviour is consistent with reduced dominance of persistent coherent wavefronts. It does not, on its own, prove that the field is ideally diffuse, because coherence also depends on microphone separation, estimator settings, signal-to-noise ratio, and the selected reference channel.

The coherence plots in Fig. 5 are therefore used as a diagnostic indicator rather than as a complete field-qualification metric. They complement the comparison of control and monitor spectra by showing that acceptable spectral agreement is obtained without intentionally maintaining narrowband phase relationships between source groups. A future qualification method should combine coherence with spatial level variation, control-to-monitor agreement, and temporal stability.

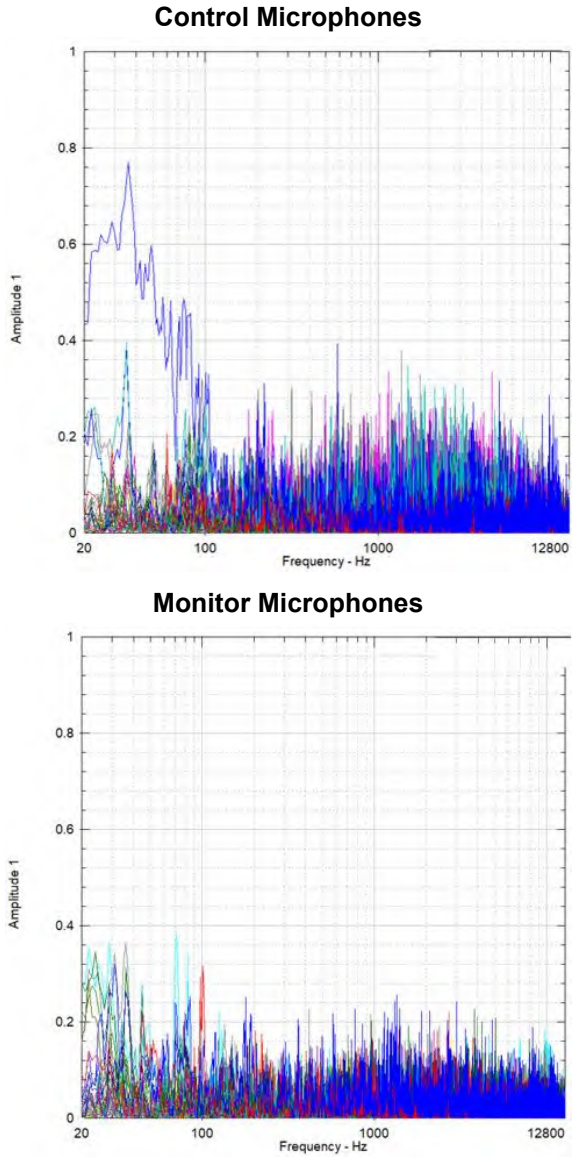

Figure 5: Representative control and monitor coherence plots for M-SISO operation.

5.3 Controller stability and temporal consistency

Temporal consistency was evaluated using short-duration linear averages calculated at five-second intervals over the exposure time. The rolling-average results for the different drive configurations are shown in Fig. 6 and show no obvious drift or loss of target tracking during the displayed runs. The 16-drive case contains more averaging intervals because that exposure lasted 120 seconds. These plots demonstrate stable operation for the tested cases, but they do not constitute a dynamic step-response or disturbance-rejection measurement. No quantitative rise time, settling time, or overshoot is claimed.

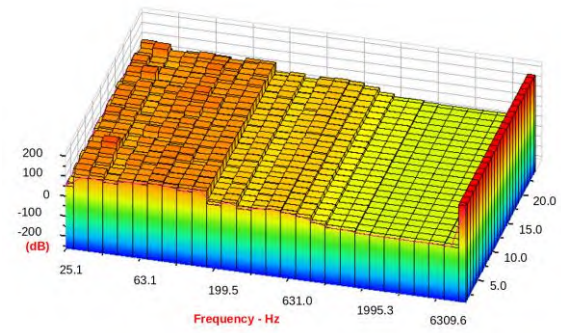

Figure 6: Representative rolling averages showing stable M-SISO behavior for multiple drive configurations.

6. DISCUSSION

The main distinction of the proposed method is architectural. Traditional narrowband MIMO DFAN control attempts to manage a coupled, phase-sensitive multivariable problem. The M-SISO approach instead decomposes the system into many independent broadband energy-control loops and accepts that the global field should be evaluated statistically rather than as a deterministic narrowband construct. That shift offers several practical advantages: simpler system implementation, straightforward scaling, fast loop updates, and reduced dependence on exact source, microphone, and DUT placement.

These benefits do not imply that M-SISO is a universal replacement for every acoustic control problem. The method is best suited to applications in which a diffuse acoustic field is an appropriate objective and where broadband qualification levels are more important than fine-grained line-by-line phase shaping. It also assumes acoustic hardware capable of producing the required levels without excessive reliance on coherent summation. Where structural protection is critical, a separate monitoring and notching path remains advisable. Within those bounds, however, the results support M-SISO as a robust and practical DFAN architecture.

An additional advantage is communicability. Because the architecture is conceptually simple, it is easier to explain, validate, and maintain than a highly coupled controller whose behaviour depends on multiple hidden interactions between loops. This has practical value for test preparation, review with customers, and troubleshooting during a campaign. A system that is easier to reason about is often also easier to trust in operation.

From a test-campaign perspective, the decentralized structure also simplifies commissioning. Each loop can be verified locally, source by source, without first solving a high-dimensional coupled control problem. This makes it easier to identify problematic channels, microphone issues, amplifier limitations, or local acoustic anomalies during setup. In a practical program, that reduction in diagnostic effort can translate directly

into shorter preparation time and more confidence before the first full-level run.

The architecture also scales cleanly. Adding devices does not fundamentally change the controller philosophy; it increases the number of repeated control elements. That characteristic is attractive for large or reconfigurable DFAN systems in which the physical arrangement may change from campaign to campaign. It also supports a more modular software and hardware implementation, which is useful for maintenance, future feature development, and transparent communication of system behavior to review boards and customers.

At the same time, the architecture has clear boundary conditions. It depends on acoustic devices that can produce the necessary broadband output without excessive reliance on coherent summation, and it does not eliminate the need for structural monitoring when the DUT is sensitive to narrowband resonance effects. These are not weaknesses of the concept so much as design assumptions that should be stated explicitly. Future work can therefore focus on quantifying the boundaries of applicability rather than on re-establishing the basic viability of the control approach.

This risk is not merely theoretical. A related large-scale test of a representative satellite mass model found that column-coherent drive—equivalent to a single drive per stack, as used in traditional line-array DFAN systems—produced 11% higher overall structural acceleration than a fully incoherent M-SISO configuration, concentrated below 200 Hz [8]. At a 148 Hz solar-array mode, the column-coherent drive left the solar array almost unexcited while the main structure responded strongly, an outcome inconsistent with impact-modal predictions; the fully incoherent drive excited both consistently and in agreement with the modal survey (Fig. 7). Avoiding this kind of unpredictable, geometry-dependent blind spot is one of the motivating principles behind the M-SISO architecture's preference for independent, uncorrelated sources over coherent summation.

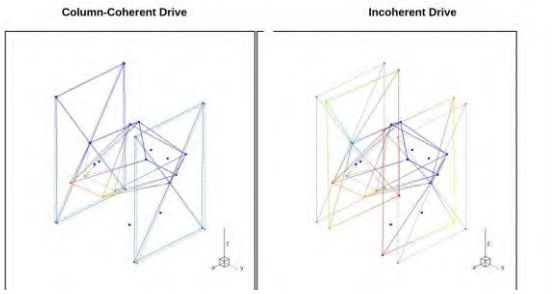

Figure 7: 148 Hz solar-array mode excited by column-coherent drive (left) vs. fully incoherent drive (right). Reproduced from [8].

The reverse outcome is equally plausible. Because coherent summation creates spatially fixed interference patterns rather than a statistically uniform field, a structural mode could just as easily coincide with a pressure anti-node and be overexcited, rather than left dormant, depending on how the mode's spatial distribution (its joint acceptance) aligns with the interference pattern. In either direction, the excitation a given mode receives becomes a matter of geometric coincidence rather than a predictable, bounded quantity, further favoring a statistically diffuse field over deterministic coherent summation whenever the DUT's response is not fully characterized in advance.

7. CONCLUSIONS

A Multi-SISO one-third-octave control architecture provides a credible and technically coherent alternative to narrowband phase-targeted DFAN control. By pairing independent broadband sources with dedicated control microphones and one-third-octave feedback loops, the method generates the acoustic field through statistical superposition rather than deliberate phase enforcement. Representative system data show good agreement between control and monitor locations together with stable exposure over time. These characteristics make the architecture well suited to direct field acoustic noise testing when the target is a practical, repeatable, and sufficiently diffuse acoustic environment.

The next step for this line of work is targeted consolidation. Because the core architecture has now been framed clearly, follow-on studies can evaluate one additional dimension at a time without broadening the paper again. Suitable next studies include loop-dynamics characterization, microphone-placement sensitivity, scalability with larger numbers of channels, and field-qualification procedures that combine monitor positions, coherence measures, and rolling averages into a compact acceptance framework.

That staged validation path is one of the strengths of the architecture-based presentation. It allows the M-SISO concept to be assessed first on its own terms and then extended systematically. In that sense, the present paper is intended not only as a report of a controller implementation, but also as a foundation for a family of focused DFAN papers that address performance, robustness, and qualification methodology in a structured way.

Direct field acoustic test (DFAT), stacked spacecraft, constellation satellites, structural response, finite element analysis (FEA), experimental modal analysis (EMA), Vibroacoustic gain

Abstract

Direct Field Acoustic Testing (DFAT®) is widely used to reproduce launch acoustic environments for spacecraft qualification. With the increasing demand for high-volume spacecraft production, particularly for constellations, testing throughput has become an important consideration. Rather than running N acoustic tests on N articles, one could envision performing a single acoustic test on N articles stacked together, saving the time and cost of N-1 tests, which may be substantial. However, both launch authorities and OEMs raise a key question: Would the vibroacoustic excitation experienced by a single unit remain representative when multiple units are stacked? In addition, spacecraft are often integrated and launched in a stacked configuration within a rocket fairing, where adjacent units are mechanically connected to one another, which alters the acoustic loading and structural response. This physical coupling increases the effective mass that each spacecraft's structure must support, shifting its dynamic response to lower frequencies relative to a single, isolated unit.

This study investigates the feasibility of simultaneously testing multiple spacecraft in a stacked configuration during DFAT while maintaining a representative acoustic and structural environment for each unit. Three identical panels, used as simple spacecraft models, were tested first singularly and then in stacked configurations of two and three units. Experimental modal analysis (EMA) and vibroacoustic (DFAT) testing were performed for each case and the results were compared.

1. Introduction

The purpose of these tests is to characterize the acoustic and structural dynamics of an individual constellation satellite simulator during DFAT, and to observe how those dynamics change when multiple simulators are stacked and tested simultaneously. This study does not aim to determine whether stacked acoustic qualification is feasible: that determination belongs to spacecraft analysts, qualification authorities, and launch providers, and can only be established through testing of representative flight hardware with mission-specific analysis. Instead, the goal is to document the general trends that emerge when multiple spacecraft simulators are stacked and tested together, informing future qualification decisions.

A MATLAB finite element analysis (FEA) of the constellation satellite simulator was performed to characterize its structural dynamics; damping was excluded from this model. The FEA results directly informed the panel separation distance used in testing, as detailed in Section 2.

A circular array of loudspeakers surrounded the test article, with an annulus of control microphones feeding a MIMO controller to produce a spatially uniform, quasi-diffuse acoustic field. Monitor microphones tracked the local field around the panel of interest, which carried 20 accelerometers to measure structural response. Experimental modal analysis identified natural frequencies and mode shapes for the single panel and three panel configurations, tracking how structural dynamics changed as panels were added to the stack.

2. Test Configuration

The tests were conducted using a 6×6 DFAT speaker stack configuration: a speaker circle with a height of 3.66m (12ft) and an inner test radius of 3.66m (12ft) surrounding the test article, with six low-frequency stacks (one MP-40 speaker below four MP-21 low-frequency speakers) and six mid/high-frequency stacks (six MP-150 speakers each). Sixteen control microphones were deployed in an annulus around the test article, numbered 1-16 clockwise beginning at 0°, as seen in *Fig. 1.*

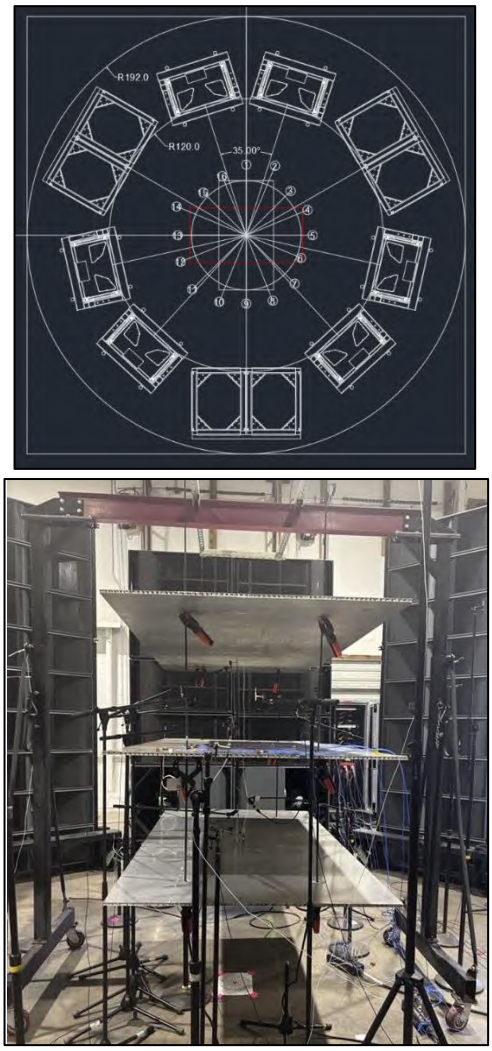

Figure 1: CAD top-down view of the speakers, test article, and control microphones (top) and panel stack suspended from the gantry suspension fixture inside the DFAT speaker circle (bottom).

The SpaceX Falcon 9 acoustic spectrum was selected as the basis for the test profile because the Falcon 9 family currently performs more orbital launches per year than any other launch vehicle, making its environment broadly applicable to the spacecraft community [1]. The spectrum was extended down to the 1/3-octave band centered at 16 Hz, see Fig. 2, since the pre-test FEA placed the panel's fundamental bending mode near 15 Hz. A Siemens SCADAS MIMO controller generated correlated drive signals to maintain the target quasi-diffuse environment. Although the specification was defined in 1/3-octave bands, control was performed in narrowband 3.125-Hz bands.

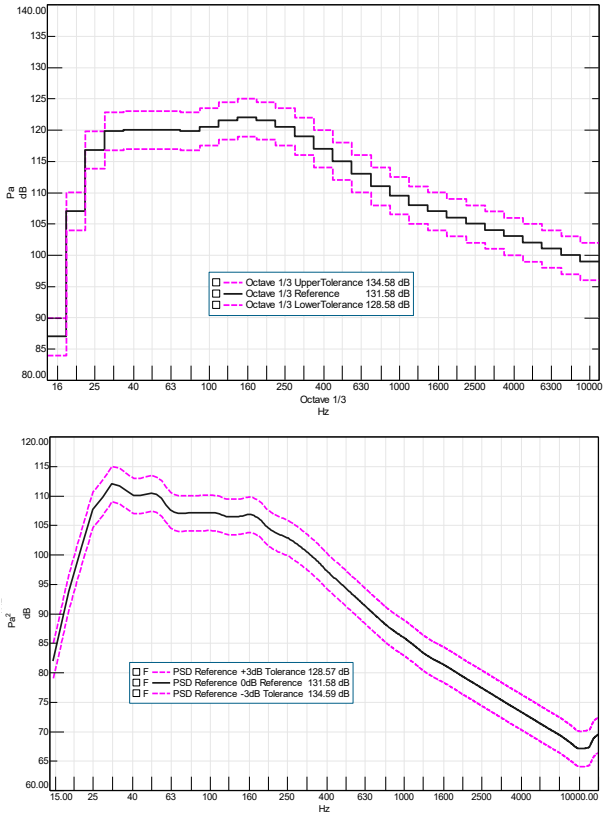

Figure 2: Modified Falcon 9 reference spectrum in 1/3-octave bands (top) and narrowband (bottom).

The test article (TA) was a 1.27cm thick (0.5in), 1.21m (4ft) × 2.43m (8ft) aluminum honeycomb panel. A simple panel geometry was chosen because the study targets dynamic trends associated with stacked testing in general, not a specific spacecraft program, and its simplicity makes the acoustic and structural behavior easier to interpret. This panel had also been studied by Underwood and Lamparelli [2], allowing reuse of established instrumentation and methodology, though direct comparison with their findings is not possible due to differences in boundary conditions and panel orientation relative to the incident field.

In Fig. 1, a gantry fixture suspended the panels in air: bungee cords passed through holes drilled in each panel, with the panels resting on clamps attached to the cords. This suspension was assumed to approximate a free-free boundary condition with minimal constraint from the support structure.

Each panel was tested individually, then in stacked configurations of two and three panels on the same bungee system. In all configurations, only one panel, referred to as the test panel, was instrumented with accelerometers, as seen in Fig. 3; the remaining panel(s) are referred to as auxiliary panels. Monitor microphones 17–24 maintained a fixed geometry relative to the test panel throughout testing. For the single and two panel configurations, the test panel sat 0.91m (36in) above the ground; for the three panel configuration, it occupied the middle position and was raised, together with all monitor microphones, by 0.59m (23.5 in) to a final height of 1.51m (59.5in).

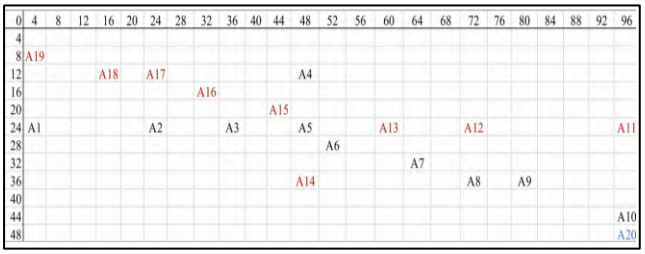

Figure 3: Accelerometer (A1–A20) layout on the test panel.

Panel Separation Distance

The separation distance between panels was selected on acoustic grounds: to generate a standing wave between adjacent panels at a targeted low-frequency panel mode, since low-frequency excitation carries most of the acoustic energy at launch and drives much of the vibroacoustic loading on spacecraft structures. Normalizing separation by panel thickness was rejected because the panel's aspect ratio is unrealistic relative to flight hardware, and representative spacing information from operational constellation stacks were not available.

The FEA, using free-free boundary conditions and simplifying the honeycomb plate to an isotropic plate of equivalent stiffness and mass, was studied using Irvine's honeycomb plate techniques [3]. The 285-Hz mode was chosen as the basis for plate separation for three reasons: it lies in the lower-frequency regime where acoustic energy is concentrated; it corresponds to an even panel mode, simplifying interpretation; and its half wavelength gives a separation of 0.601m (23.68in), reasonably representative of spacing between neighboring spacecraft in a stacked launch configuration. Assuming a one-dimensional standing wave in the vertical direction and considering only the first acoustic mode of the cavity between panels [4], the 3D standing wave equation

$$p_{lmn} = A_{lmn}\cos(k_{xl}x)\cos(k_{ym}y)\cos(k_{zn}z)\,e^{j\omega_{lmn}t} \quad (1)$$

reduces, for a one-dimensional standing wave in the vertical z-direction with n = 1, i.e. mode (0,0,1), to

$$p_{0,0,1} = A_{0,0,1}\cos(k_{z1}z)\,e^{j\omega_{0,0,1}t} \quad (2)$$

so that a standing wave is created when

$$\omega_{0,0,1} = \frac{c\pi}{L_z} \rightarrow f_{0,0,1} = \frac{c}{2L_z} \rightarrow L_z = \frac{c}{2f_{0,0,1}} \quad (3)$$

Substituting the 285-Hz target and a speed of sound of 343m/s (1125ft/s) results in

$$L_z = 0.601m\ (23.68in) \quad (4).$$

Due to fixture and hardware limitations, the realized spacing was adjusted to 0.600m (23.625in). The derivation assumes rigid, stationary panel surfaces. The selected spacing was expected to reduce the response of the targeted even mode through interaction between the standing wave and the panel's transverse motion; this hypothesis is evaluated by comparing the single-panel and stacked configurations. The targeted mode is shown in Fig. 4.

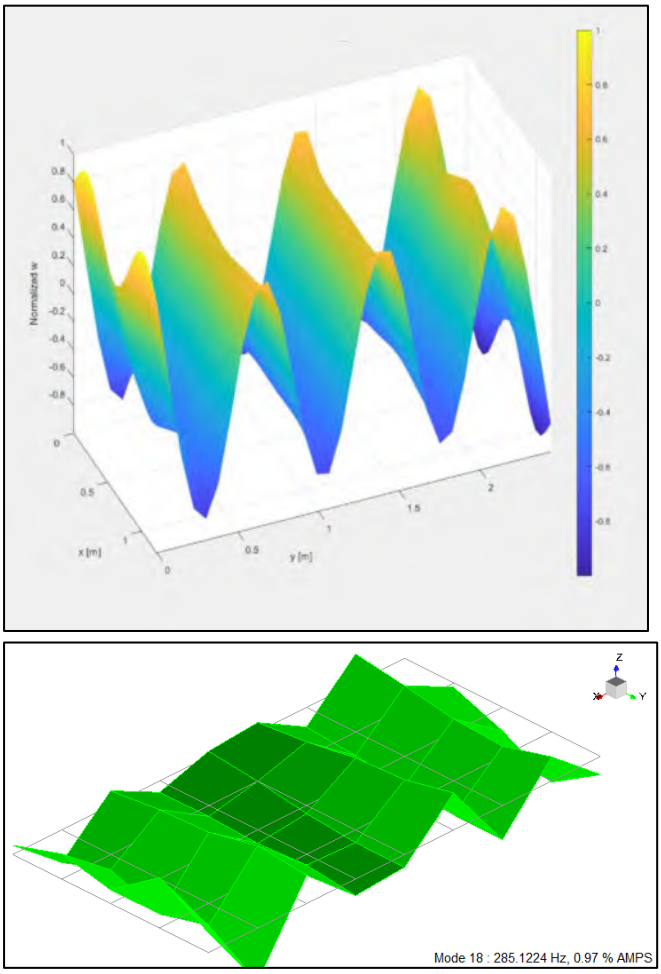

Figure 4: Honeycomb FEA prediction at 285Hz (top) and the even panel mode near 285Hz (bottom) from the EMA.

3. Results

In the microphone PSD plots that follow, control microphones are blue, monitor microphones orange, the control average green, the reference spectrum black, and the ±3 dB tolerance bands pink. In all other graphs, the green, red, and blue curves display the results from the single panel, two panel, and three panel tests, respectively.

The microphone PSDs for all three configurations, Figs. 5-6, together with the Sinc Indicator Function (SIF) results, Fig. 6, (bottom), which is a proxy measure for the diffuseness of the acoustic field [5], show that the input acoustic fields were nearly identical in SPL uniformity and diffuseness. Variations at the monitor microphones or accelerometers can therefore be attributed to the stacked configuration rather than the input field, and the analysis below compares the single panel response with the two and three panel responses.

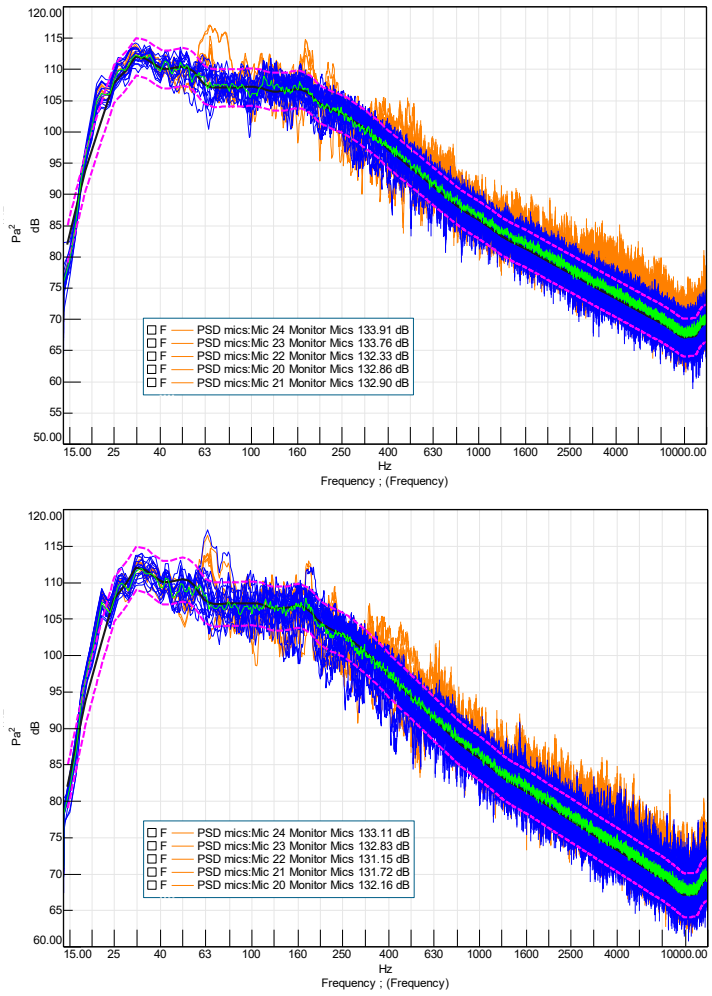

Fig. 5: Control and monitor microphone narrowband PSDs: single-panel (top) and two-panel (bottom) configurations.

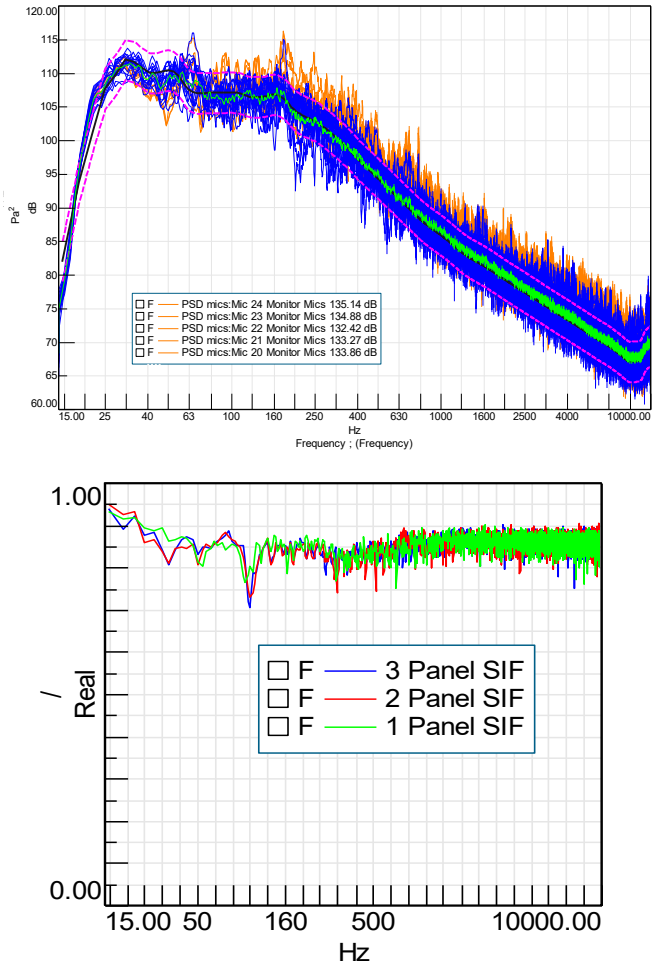

Fig. 6: Three-panel microphone PSDs (top) and Sinc Indictor Function of the control field for the three configurations (bottom).

Average monitor microphone levels exceeded control levels in all configurations, as expected: the panel acts as an acoustically rigid surface, reflecting incident energy and raising local SPL. The excess in average monitor OASPL grew from about 1 dB (single panel) to 1.25 dB (two panels) and 2 dB (three panels), attributable to the proximity of reflective surfaces: in the two-panel test the panel sat 0.91m (36in) above the ground and 0.59m (23.625in) below the auxiliary panel, while in the three-panel test it sat 0.59m (23.625in) from reflective panels both above and below.

While several individual frequencies exceeded the +3 dB tolerance band, monitor OASPL stayed within test tolerances for all configurations. The largest amplifications occurred near 64, 175, 678, and 779 Hz, peaking 6-8 dB above reference. The 64-Hz amplification was most pronounced in the single- and two-panel tests, while the others peaked in the three-panel test. These amplifications are not consistently tied to panel count; rather, they are governed by the geometric arrangement of panels and acoustic field.

The test panel's acceleration response generally tracked the monitor microphone PSDs, with dominant peaks at frequencies of elevated local SPL (Fig. 7), though not perfectly: some frequencies with elevated monitor levels produced little structural response, possibly because the associated modes have odd shapes or limited net pressure loading (speculative, pending further analysis). Notably, the single-panel configuration consistently showed the highest acceleration response, with the two and three panel configurations lower and similar in magnitude, consistent with the standing wave between panels reducing transverse panel motion near the targeted frequencies. Several peaks also shifted modestly in frequency between configurations, suggesting added structural coupling from the supports and neighboring panels.

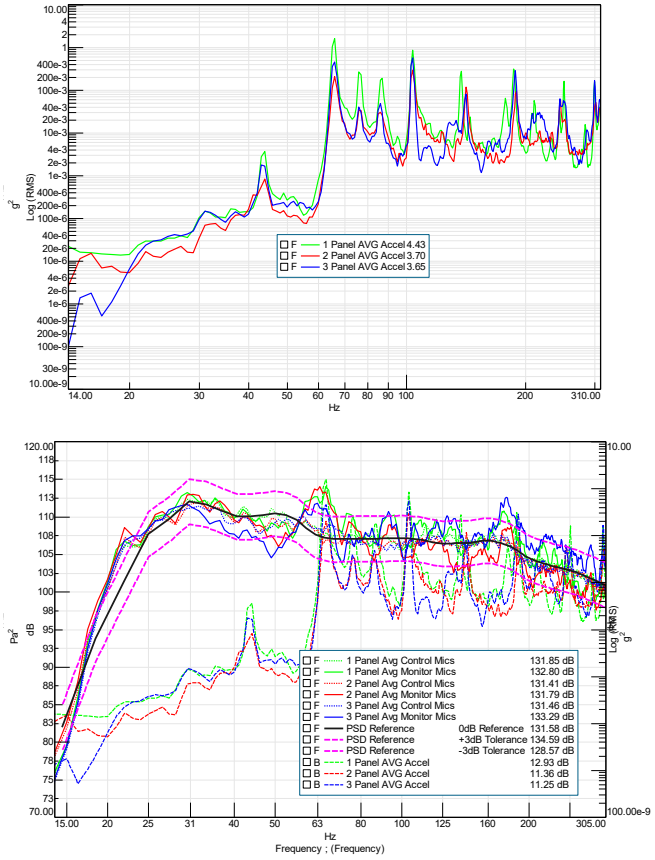

Fig. 7: Single-panel microphone PSDs overlaid with the average panel acceleration response.

Vibroacoustic gain (acceleration response normalized by acoustic input) was calculated as a direct measure of acoustic-structural coupling efficiency (Fig. 8). Distinct gain peaks began near the fundamental bending mode at approximately 15 Hz and continued through the upper test frequency range; above roughly 1000 Hz, individual modal peaks became difficult to distinguish from broadband response and noise. The single-panel configuration showed the highest overall gain, followed by the three-panel and then the two-panel configuration, an ordering that was somewhat unexpected: a monotonic decrease with panel count might have been anticipated if the panels simply constrained transverse motion. Instead, the interaction between panel spacing, local acoustic field formation, and structural coupling appears configuration-dependent rather than a simple function of panel count. This also underscores that structural response cannot be inferred from local acoustic pressure or acceleration alone: gain captures how effectively acoustic energy transfers into structural motion.

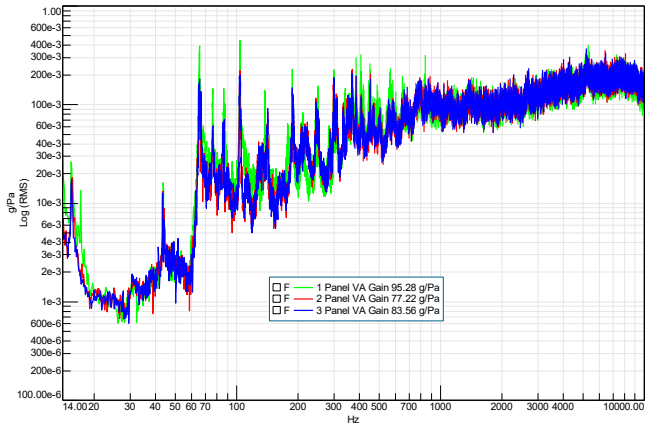

Fig. 8: Vibroacoustic gain of the test panel for the three configurations.

The behavior near the targeted 285-Hz standing wave is of particular interest (Fig. 9). The acceleration PSD shows a pronounced, well-defined single-panel response near 285 Hz; the three-panel peak is broader, less pronounced, and more heavily damped; and the two-panel response is almost entirely absent, making the mode effectively unobservable. Vibroacoustic gain tells a different story: well-defined peaks remain near 285 Hz for all three configurations, with the single panel still highest, so the mode was not eliminated by stacking; rather, the efficiency with which the field excited it changed substantially. The monitor PSDs complicate the picture further: the three-panel test had the highest local pressure near 285 Hz while the single- and two-panel environments were nearly identical, yet their structural responses differed dramatically. Local SPL alone is therefore insufficient to explain the response; acoustic loading distribution, mode shape, and structural coupling all play significant roles.

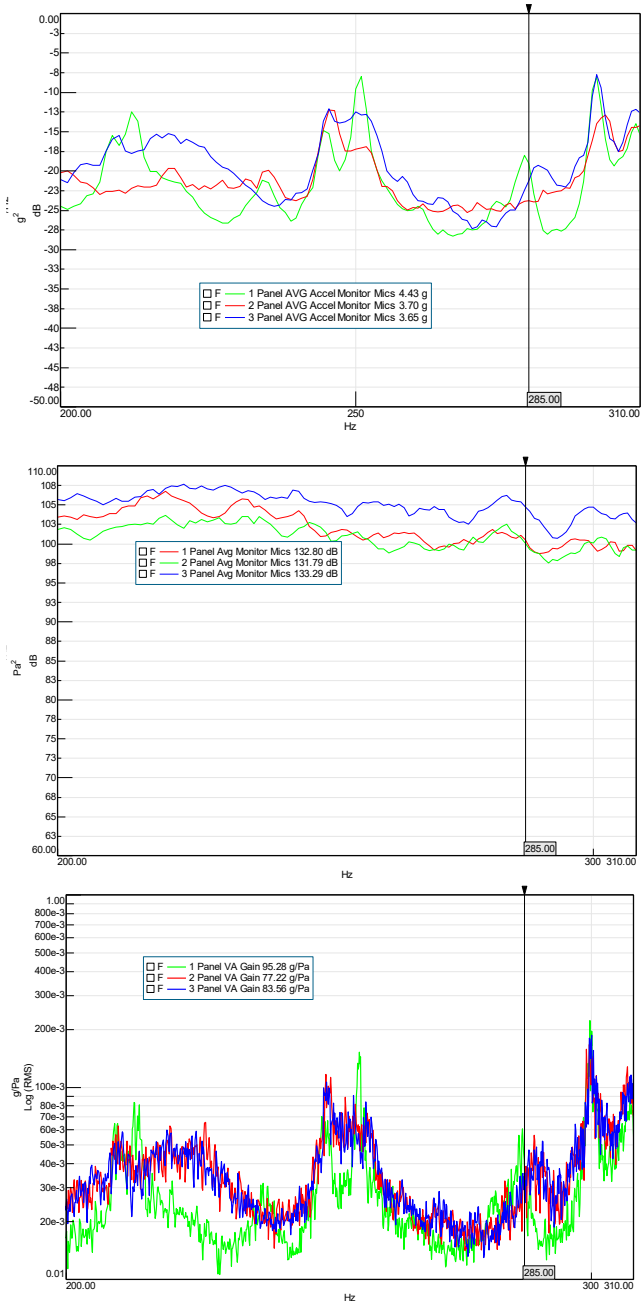

Fig. 9: Detail near 285 Hz: average acceleration response (top), monitor microphone PSDs (middle), and vibroacoustic gain (bottom).

The EMA results showed strong correlation between the single-panel and three-panel configurations, per the MAC comparison in Fig. 10 and the frequencies in Tab. 1. High diagonal MAC values indicate that the test panel's dominant mode shapes remained largely consistent after adding auxiliary panels, while several modes shifted modestly in frequency: the auxiliary panels altered effective dynamic properties while preserving deformation patterns. The mechanisms behind these shifts cannot be determined definitively from the present data, particularly since the boundary conditions were designed to minimize structural coupling. One exception: a single-panel mode at 216.9 Hz was not identified in the three-panel EMA, and the 293.7-Hz single-panel mode shifted down to 285.1 Hz in the three-panel configuration, landing on the intentionally selected standing-wave frequency. This may indicate interaction between the inter-panel acoustic cavity and the structure, though additional analysis would be needed to establish causality.

4. Analysis and Conclusions

This study asks a practical question: When spacecraft are stacked and tested together, does the vibroacoustic environment each unit experiences stay representative? The goal was not to establish blanket feasibility of stacked DFAT qualification, but to document the general trends that emerge when spacecraft are tested in a stacked configuration.

Control microphone and SIF measurements confirmed the input field was highly repeatable across configurations, so observed changes in monitor levels, acceleration, and vibroacoustic gain are attributable to the neighboring panels, not the DFAT control field.

Neighboring panels alter the local acoustic environment through reflections and cavity effects, but these effects are strongly frequency dependent with no simple relationship to panel count. Structural response likewise can not be predicted from sound pressure levels alone: loading distribution, mode shapes, and acoustic-structural coupling all matter. This was clearest at the standing-wave frequency the test was deliberately tuned to target, where the single-panel configuration responded strongly, the two-panel configuration nearly suppressed the mode, and the three-panel configuration fell in between, suggesting standing-wave/structural-dynamics interaction can meaningfully affect stacked spacecraft behavior. EMA results reinforce this: mode shapes stayed largely consistent despite

frequency shifts, so stacking alters modal excitation and acoustic coupling more than the spacecraft's underlying structure.

If adopted, stacked acoustic testing would function as a workmanship test and should be run at the OEM facility, so a failing unit can be reworked without shipping delays. The mock-up support structure should also match the dynamics of the actual flight stacking structure, since a mismatch would undermine test fidelity. Stacked testing may also be more flight-accurate than testing units individually, since stacked spacecraft do not fly as isolated bodies, and the added mass introduces low-frequency content closer to actual flight dynamics.

Frequency-specific sensitivities from standing waves can be response-limited with narrowband control, which notches a single structural or room mode without affecting the rest of the band, unlike 1/3-octave control, which would notch the whole band. Since test requirements are typically written in 1/3-octave terms, a configuration can pass tolerance while still carrying a meaningful narrowband variation, so a detailed vibroacoustic FEA is needed to judge whether that variation matters.

Overall, stacked DFAT testing is highly configuration dependent and cannot be evaluated by spacecraft count alone. RMS acceleration response decreased with stacking, but this should be verified with mode-specific FEA rather than taken at face value. No disqualifying behavior was observed, and the concept warrants further study with representative hardware and mission-specific analysis. If validated, stacked DFAT testing could meaningfully cut schedule and cost for high-volume constellation production, saving N-1 acoustic tests per stack.

ABSTRACT

In Direct Field Acoustic Noise (DFAN) testing, large arrays of high-powered loudspeakers are used to produce a high intensity acoustic environment for payload qualification and/or pre-flight assurance-testing purposes. Over the past two-decades, this has become an increasingly popular alternative to equivalent tests performed in Reverberant Acoustic Test Facilities (RATFs). Nonetheless, there remains a need to qualify the similarity of the sound fields produced by these two types of tests to ensure equivalence of the two approaches and de-risk the transfer between one testing technology and the other. There is, therefore, a continued demand for evidence that the sound field produced by a DFAN system is – or can be – equivalent to that produced by a RATF. By design, both produce sound fields that are inherently random, so what is required to compare them is metrics that capture & quantify the key characteristics of these random sound fields.

This paper will report some recent developments in the modelling of diffuse sound fields, as both types of test aim to achieve, including in metrics that aim to quantify how 'diffuse' a produced sound field is. The effectiveness of these approaches will be illustrated through two case studies – one at smaller scale and lower SPL and a second at full scale and full test SPL – via which recommendations for best practice going forwards will be suggested.

1. INTRODUCTION AND MOTIVATION

The space-launch industry has an established need for acoustic environmental testing. This aims to replicate, in a precisely controlled way, the structural response that would occur during launch due to its extreme acoustic environment [1]. Such testing is used to qualify new payload designs and for pre-flight assurance testing purposes.

Traditionally, such acoustic tests have been performed in Reverberant Acoustic Test Facilities (RATFs), but these have disadvantages including high construction and operation costs, and the logistical challenge of moving the payload to the test facility, which can be costly and/or risky when large payloads and/or distances are involved.

Since the mid-1990s, Direct Field Acoustic Noise (DFAN) testing – also known as Direct Field Acoustic Testing (DFAT®) – has existed as an alternative. In this technology, large arrays of high-powered loudspeakers are used to produce the necessary acoustic environment. The scope of what sound field DFAN testing systems could render is broad, enabled by the powerful control systems they use [2,3], but demand from the space launch industry has, to date, been for them to replicate the sound field produced by RATFs, since this derisks the transfer from one test technology to the other.

Since RFAT is an accepted test method within the space industry, and tests are likely to continue in parallel with DFAN systems, it is highly desirable to show equivalence. As both test methods are designed to produce diffuse random sound fields, what is required are metrics that can fully characterise these acoustic environments.

1.1. The UK National Satellite Test Facility

The UK National Satellite Test Facility (NTSF) at RAL Space in Harwell, Oxfordshire, opened in May 2024. DFAN was selected as the Acoustic testing technology for this facility, allowing acoustic and vibration testing to share clean room space. This leads the Dynamics Group to have an interest in developing and utilising appropriate sound field metrics, with the purpose of both demonstrating that

Figure 1: The UK National Satellite Test Facility Left: Exterior view. Right: Elevated view of a mid-sized DFAN test in the clean room.

theirs is a well-proven test system capable of providing an acoustic environment equivalent to a RATF test, and for quality assurance of individual tests. Moreover, being part of the UK STFC, RAL Space's mission includes furthering fundamental knowledge, motivating collaboration on research studies such as the ongoing one reported herein.

1.2. Outline of this paper

The remainder of this paper is organised as follows:

- Section 2 gives an overview of diffuse field theory and metrics, including recent developments.
- Section 3 then reports some work that was done in 2024 on the design of linear microphone arrays for quantification of sound field 'diffuseness', including some updated perspectives.
- Section 4 reports full-scale tests where the array from 3 was used, including some unintended properties of it that have recently been identified.
- Section 5 relates this to DFAN 'drive matrices', leveraging findings from a scale-model 'mini-DFAN' test conducted at the University of Salford.
- Finally, section 6 draws conclusions and reflects on areas where further research is needed.

2. DIFFUSE FIELD THEORY AND METRICS

A diffuse field is a theoretical sound field commonly defined as being one in which sound energy arrives from all directions with equal probability [4]. Further requiring that the waves arriving from differing directions are incoherent leads to several well-known properties, such as the coherence between pressure signals at a pair of spaced microphones and homogeneity of Sound Pressure Level (SPL), given sufficient time-averaging.

Before getting into diffuse field metrics, however, it is worth noting that the commonplace starting assumption of RATFs – that they produce a diffuse field – is not strictly true, since they largely contain the same sound recirculating. With sufficient scattering objects and distance from boundaries, the sound field is chaotic and isotropic enough to be effectively diffuse above a specified frequency, but even then, deviations from diffuse can be detected if long time-averaging is done in specific ways [5]. Thus, when discussing the metrics used later in this report, it should be born in mind that many are capable of showing up flaws in RATF too [6].

The other 'elephant in the room' is that it highly unlikely that the sound field inside a rocket fairing is diffuse; limited data is available on this but that which is shows different characteristics [7]. Indeed, a fairing is a relative tight-fitting air volume where the acoustic energy source is incoherent vibration of its external boundary (due to chaotic aerodynamic loading), a scenario that a DFAN system would arguably be better able to simulate than a RATF.

Nonetheless, a diffuse field remains a useful target for environmental acoustic testing because panel structures are usually most susceptible to acoustic excitation from specific angles, and a diffuse field includes all of them. It is also the testing requirement specified in launch manuals, so from a pragmatic perspective is what DFAN systems must achieve.

2.1. Diffuse field metrics prevalent in DFAN

An established method for assessing how close a sound field produced by a DFAN system is to diffuse is to compare measurements of coherence between spaced pairs of microphones to the theoretical trend that would occur if the sound field truly was diffuse. This approach has been in use for around 14 years, with one of the first appearances being [8] in 2012. Notably, it is extremely versatile; since no special arrangement of microphones is in principle required, existing monitor and control microphone signals can be analysed in this way.

The coherence $\gamma(f)$ between a pair of microphones is the ratio of the cross Power Spectral Density (PSD) between the signals they capture, normalised by the square root of the product of their auto PSDs. These PSDs are dependent on frequency f, hence coherence γ also is. In a diffuse field it is well know that this – like the signals' covariance [5,10] – follows a $\mathrm{sinc}(kr)$ trend. Here r is the separation distance between the microphones in meters and $k = 2\pi f / c_0$ is the acoustic wavenumber, where c_0 is the speed of sound in meters per second.

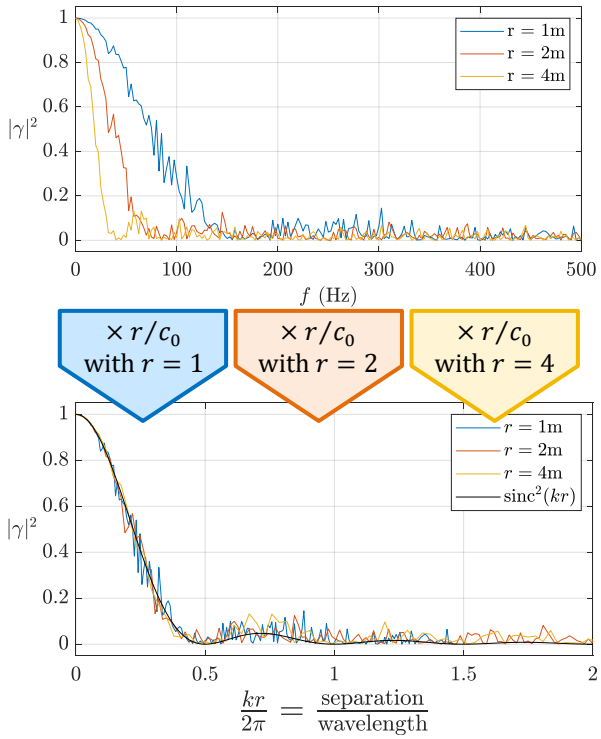

Figure 2: Coherence for three microphone pair spacings in a simulated diffuse field. Top: versus frequency. Bottom: versus separation / wavelength, with the theoretical trend overlaid.

In practice, it is more common for the Magnitude Squared Coherence (MSC) $|\gamma|^2$ to be plotted, which follows a $\mathrm{sinc}^2(kr)$ trend due to the squaring.

Simulated diffuse field microphone MSC data is plotted in Fig. 2 for three example microphone spacings. Each line contains a natural randomness because a diffuse field is a random field, and here – as is representative of measurement – it has been observed for a finite period of time (64 FFT blocks).

The main thing to note is that in the top plot, where MSC is plotted against frequency, the lines do not lie on top of one another due to the differing spacing. In the bottom plot, however, plotting the same data w.r.t. kr has compensated for the differing spacing such that the lines do align both with each other and the theoretical trend line (black). This is the benefit of kr plots when viewing coherence data.

Some practitioners have anecdotally voiced some hesitation about the use of kr as the abscissa axis, since the physical meaning of it is far less immediate than frequency f. But here, normalisation by 2π (as plotted) is helpful since it can be readily shown that $kr/2\pi = r/\lambda$, the ratio of separation to wavelength, which has an immediate physical meaning.

Another barrier perceived by some is the scaling of MSC data w.r.t. frequency $|\gamma(f)|^2$ by $2\pi r/c_0$ in its abcissa to give $|\gamma(kr)|^2$ (or by r/c_0 for the plotted normalized version), because r is another array of data (of size $N_{\mathrm{mics}} \times N_{\mathrm{mics}}$). This is somewhat tedious in a spreadsheet, but in a scripted array language* such as Matlab™ or NumPy it is trivial.

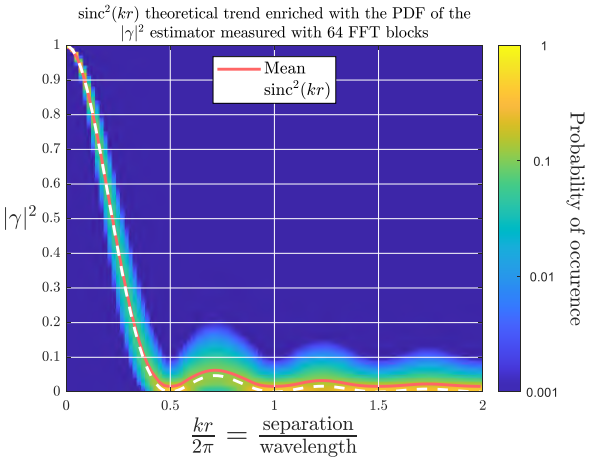

Figure 3: Theoretical $sinc^2(kr)$ trend (white dashed line) enriched with the PDF of $|\gamma|^2$ (colourmap) when 64 FFT blocks are used in its calculation. Mean of the distribution is in red.

In terms of a quantitative metric, Carrella and Mayne proposed the "Sinc Indicator Function (SIF)" in 2022 [10]. This computes the magnitude of the difference between $|\gamma(f)|^2$ measurements and the theoretical trend $\mathrm{sinc}^2(2\pi fr/c_0)$, then averages this over microphone pairings to produce a single figure of merit. The purpose of this is well-meaning and the scale and notion of averaging over microphone pairs – being joint spatial samples of the coherence statistics – are well-founded, but concerns have been anecdotally raised over the heteroscedastic properties of the MSC, on which it is based.

The Probability Density Function (PDF) of the MSC, as explored in [6], captures the root of this concern. Since that paper, the lead author of this manuscript has found a new use for this PDF, in 'enriching' theoretical results computed based on 'Expected' values (what would be seen if observing forever) to capture the distribution of values likely to be measured in a finite time. Fig. 3 shows a simple example of this – enriching the $\mathrm{sinc}^2(kr)$ trend – but the same approach can also be applied to more sophisticated Finite Element or Boundary Element Method based models, which – being based on the Expected values of the Cross-Spectral Density Matrices (SDMs) [11,12], normally fail to capture the variance due to finite-time measurement windows.

The heteroscedastic properties of the MSC are clearly visible in Fig. 3. When the theoretical line (dashed white) is close to 1, the variance (vertically as plotted here) of the PDF tends to zero. But when the theoretical line tends to zero, the variance is significant and – potentially more problematic for the SIF – has a biased mean (red versus white lines).

A solution to this bias comes in the form of complex coherence, which has recently been championed by Allen and co-workers at NASA [13], and for which the theoretical curve $(\mathrm{sinc}(kr))$ is known and the mean is unbalanced. This paper presents results as both magnitude-squared and complex coherence for comparison, additionally using histogram plots in the style of Fig. 3 to show the proportion of mic pairs achieving a given value more clearly than line plots do. Moreover, as a thought experiment, the SIF is computed on this complex data† for comparison too.

A correction for the vanishing variance of measured coherence as true coherence approaches unity is discussed in Section 5 of [6]. A slight modification of this appears applicable to complex coherence too, potentially leading to almost uniform variance and a quasi-Gaussian PDF over the full range, but further research on this is required; it is not presented here.

* There are strong benefits to choosing such languages over spreadsheets in terms of reproducibility and quality assurance too, since they lead to processes that are more easily audited and less prone to human error.

† To be precise, it is computed on the signed magnitude-squared real part of coherence; it was found that the imaginary part added relatively little information, and squaring was necessary to achieve the same scale

2.2. Other Diffuse Field Metrics

Outside the DFAN community, the spaced-mic coherence trend above is known [5] but not widely utilised. Instead, a metric involving the ratio of the magnitude of the real part of acoustic intensity to the acoustic potential energy (a scaling of magnitude-squared pressure) attracts attention; see, e.g., the two recent review articles by Zotter et al [14,15]. Another metric is isotropy, as developed by Nolan and co-workers to study room acoustic RATF; see section 2.3.3.2 of [1] for an overview of this and refs. Zotter notes that isotropy is a stricter measure than the intensity measure since the former compares energy levels arriving from all directions, while the latter only requires opposite pairs to be equal.

A potential concern for the DFAN community raised by [14] is that it concludes that the intensity metric and homogeneity of SPL can only be achieved by a loudspeaker array concurrently in 3D if the array is spherical. This is in opposition to standard DFAN practice where, for practical reasons, arrays are cylindrical. But an important caveat is that the analysis in [14] only considers direct sound from theoretical source layers, and scattering from the DUT and array hardware is ignored. Such scattering has the potential to increase diffusivity beyond the predictions in [14] and is even done deliberately in some cases (e.g. in EP4260039A4). However, more research is required to validate this hypothesis.

As is unsurprising given the spherical homogeneity of directional energy comprising a diffuse field, metrics have also been suggested that leverage spherical harmonics decomposition in various ways. These assume use of a spherical microphone array. Perhaps the most sophisticated of these is the COMEDIE metric of Epain and Jin [16], which is defined based on covariance but could be adapted to coherence. Use of spherical harmonics also overcomes some limitations of the more widespread 'sum of plane waves' model, on which Tanaka and Otani [17,18] have made recent useful fundamental contributions. This gets to the nub of the problem of many of the metrics above: they are designed so they return 1 for a perfectly diffuse field and 0 for a plane wave, but their behaviour between these limits is not well understood because there is no universally accepted way to synthesise a sound field that is diffuse to some arbitrary percentage. In the view of the leading author, more research is required to bottom this issue out before any metrics can have their properties fully understood.

2.3. Other considerations

Another consideration is that no measurements to quantify sound field quality should be taken too close to the loudspeaker or DUT, since these respectively have evanescent nearfield properties and cause scattering that disrupts the sound field's statistical properties [19]. However, putting a limit on exactly where this effect becomes insignificant is difficult since it depends on the size of objects and the mic spacing compared to wavelength, and the object's boundary properties (surface impedance, often likely to be non-locally reacting) and the analysis frequency bandwidth (e.g. 3Hz PSD or fractional octave bands). Measuring 1 meter from a boundary is standard in outdoor environmental acoustics and can be shown to be sufficient for spacing more than half a wavelength if the analysis is done in full octave bands (narrower bandwidth analysis requires a greater distance to stabilise). But these results are based on reflections from an infinite rigid plane (such as a chamber floor) and more relaxed constraints are likely to be sufficient for DFAN tests due to scattering and diffraction.

3. MICROPHONE ARRAY DESIGN FOR SPACED COHERENCE MEASUREMENT

While a benefit of spaced microphone coherence measures is that they can be applied to arbitrarily placed microphones, this section explores if array designs can be conceived that optimise the quality and discriminating power of the analysis. Moreover, if the microphones are attached to an array structure then their relative positions are fixed, meaning that the data processing can be repeatedly run for different placements easily (to use control & monitor mics, position data must be measured).

There is precedent for using fixed spacing mic arrays for DFAN sound field quantification. Kolaini and co-workers used a planar array of microphones [8], though the focus there was mainly on checking for arena modes. Arrays with four microphones in a cartesian configuration – one in a corner and three offset in perpendicular directions by an identical distance – have also been shared in personal communications with the leading author.

The motivation behind the design report here was the observation (inspired by conversations with Dr. Marcos Underwood at ECSSMET2024) that the comparison of MSC to $\mathrm{sinc}^2(kr)$ is most informative in the range $1/8 \leq kr/2\pi \leq 3/8$. Referring again to Fig. 3, it can be seen that: i) the variance is very small for $kr/2\pi < 1/8$, with almost all coherence data likely to lie very close to unity; ii) the variance is very wide and the mean value biased for $kr/2\pi > 3/8$, leading to wide, skewed confidence intervals that make drawing conclusions difficult. Since $1/8 \leq kr/2\pi \leq 3/8$ spans less than 2 octaves for a single mic separation value r, it is clear that multiple mic spacings would be required to ensure that some coherence data always lies in this optimal kr region.

This suggests microphone arrays designed to give a wide distribution of differing spacings. A caveat to this objective is that using complex coherence now makes the data with $kr/2\pi > 3/8$ more useful, but the design approach is reported here, nonetheless.

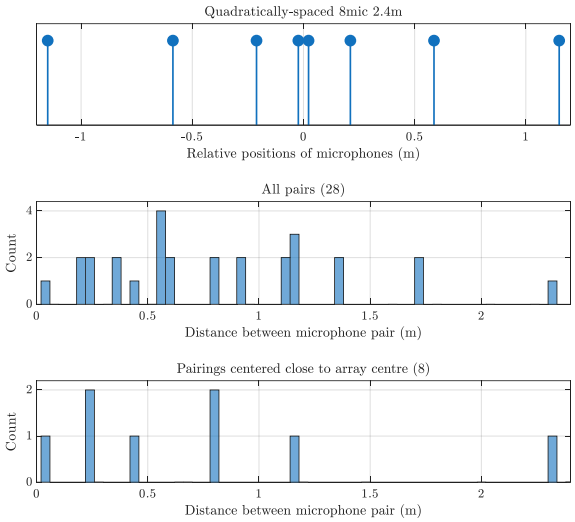

Figure 4: Mic placements (top) and spacing histograms (middle and bottom) for the manufactured quadratically-positioned array.

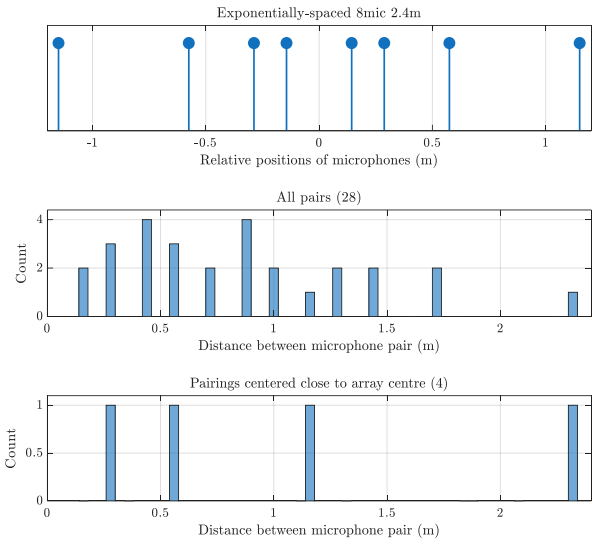

Figure 5: Mic placements (top) and spacing histograms (middle and bottom) for an array with exponential spacings.

For practical reasons a linear array was considered. This only has the capability to measure sound field statistics in a single direction, but it was felt to be a suitable test of the design principles, and full 3D characterisation could be achieved either by manufacturing multiple arrays to form a 2D or 3D cross, or by reorienting the array and repeating.

The array was made quite long – the maximum mic spacing was 2.3m – to ensure that the 25Hz third-octave band, as is typically the lowest frequency band in a DFAN SPL specification, could produce coherence data with $kr/2\pi \geq 1/8$. A quadratic positioning rule was followed, leading to the nearest mic pair being only 4.6cm apart, which satisfies $kr/2\pi \leq 3/8$ up to 2.8kHz. The positions can be seen in the top subplot of Fig. 4. Clearly this is a large array, but the aim was to devise a highly discriminating device with a wide bandwidth.

At the time, the quadratic rule was selected by considering the spacing statistics of all mic pairs (Fig. 4, middle subplot), but it was later realised that this led to a significant number of pairs having their centre away from the array centre. To address this the selection of pairs used was revised, leading to 8 pairings being analysed (Fig. 4, bottom subplot).

An intuitive way of visualising the contribution of these different microphone spacings is to consider a certain analysis bandwidth and display where the differently spaced pairs contribute data on a kr plot. This is shown for a full octave band in Fig. 7. The $\mathrm{sinc}^2(kr)$ trend is overlaid in black and the range $1/8 \leq kr/2\pi \leq 3/8$ is highlighted in yellow. The top and middle plots both pertain to the quadratically spaced array in Fig. 4 that was constructed; the top plot shows the 80Hz octave band and the middle shows the 250Hz octave band, illustrating how these contribution areas shift with frequency.

It is clear from this, however, that even with the reduced set of pairings used, there is often a lot of overlap, and there is also a gap present (which would close with a wider analysis bandwidth, but if analysing in octave bands then is present). Noting that an octave is a doubling in frequency, it makes sense to also space microphones according to an exponential rule, where each mic spacing is a doubling of the preceding one. This design is shown in Fig. 5, in which the doubling of spacing trend is visible in the bottom subplot; only symmetrical mic pairings centred on the array centred are utilised. The bottom panel of Fig. 7 shows how this makes the kr ranges each pairing contributes data for line up optimally on the kr plot, with the upper corner of each pair meeting the lower corner of the next. This array design has not been tested but is the logical next generation if linear arrays tests are continued.

The next section reports data gathered with the quadratically spaced design in Fig. 4.

4. FULL SCALE TEST RESULTS AT THE UK NATIONAL SATELLITE TEST FACILITY

This section reports tests conducted at the UK NSTF during two campaigns; one in April 2025 and the other in August 2026. Both used the microphone array shown in Fig. 6, which was constructed following the specification in Fig. 4. Note that a ball joint is present at top of the stand to allow changes in orientation around a common centre position.

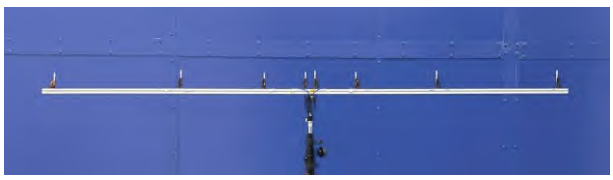

Figure 6: Photograph of the quadratically spaced mic array constructed at the NSTF

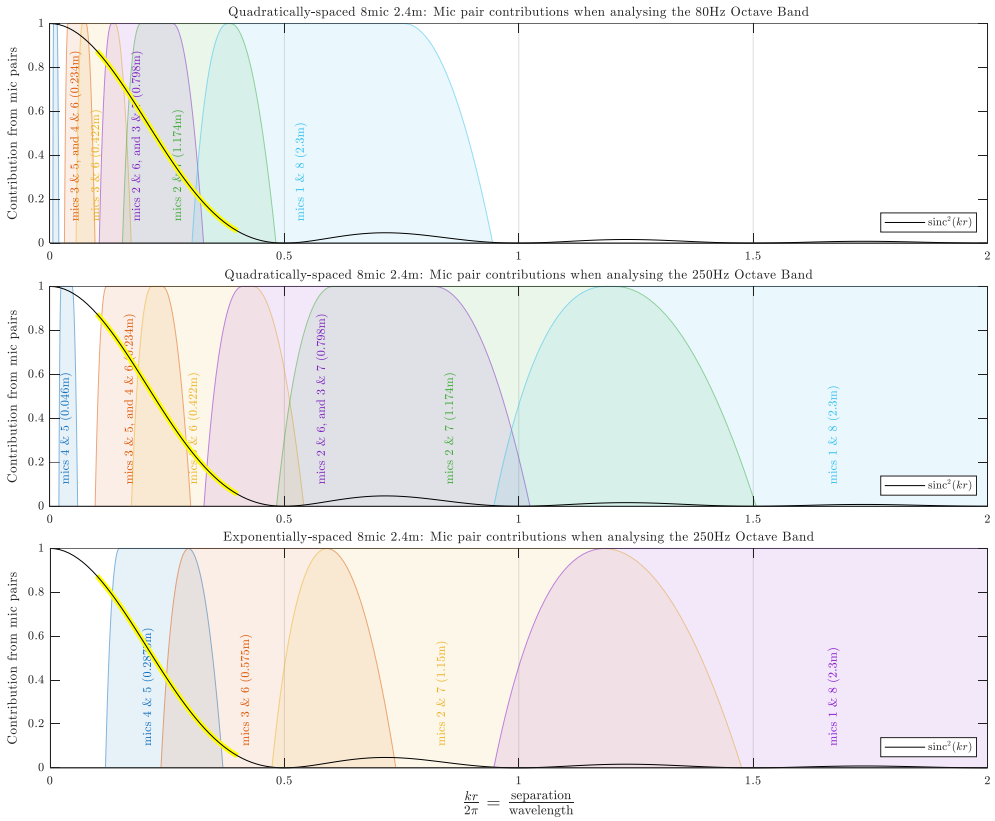

Figure 7: Contribution from different mic pairs displayed graphically on a kr plot, illustrating where they contribute data for the specified Octave Band (OB). Top: Quadratically spaced for 80Hz OB; Middle: Quadratically spaced for 250Hz OB; Bottom: Exponentially spaced for 250Hz OB.

The microphones were ¼" PCB Piezotronics model 378A12 (max SPL = 194dB), held in custom 3D printed holders on 2cm square linear extrusion. These were connected to a National Instruments NI-9231 8-channel input module in a cDAQ9181 caddy, which communicated via ethernet directly with the data acquisition toolbox in Matlab, allowing direct and immediate analysis of the captured data.

Both tests used an ARS Neutron system with six stacks, driven by an m+p control system. The stacks were raised 20cm off the floor on wheel boards and the arena diameter was 3.3m in both tests.

Mic array data was processed identically in both these tests and the Salford tests that follow in Section 5, except that data was captured for 50 seconds in these tests and only 30 seconds in the Salford ones. The sampling rate of the NI module was 51.2kHz. PSDs were computed by Welch's method, with an FFT length of 2^{14} samples, 50% overlap and a Hanning window; these settings give a frequency resolution of 3.125 Hz, as is often used for DFAN test control and analysis. For 50 seconds duration this leads to averaging of 311 FFT blocks. Third-octave filtering to compute SPLs was done using the octaveFilterBank object from the Matlab Audio Toolbox, with its filter order set to 6. With this setting, these filters satisfy BS EN 61260-1:2014.

To compute the histogram plots that mimic the PDF in Fig. 3, bins stepped by 0.01 and 0.02 were used for the ordinate coherence and abcissa $kr/2\pi$ axes respectively. To avoid the measure being biased by

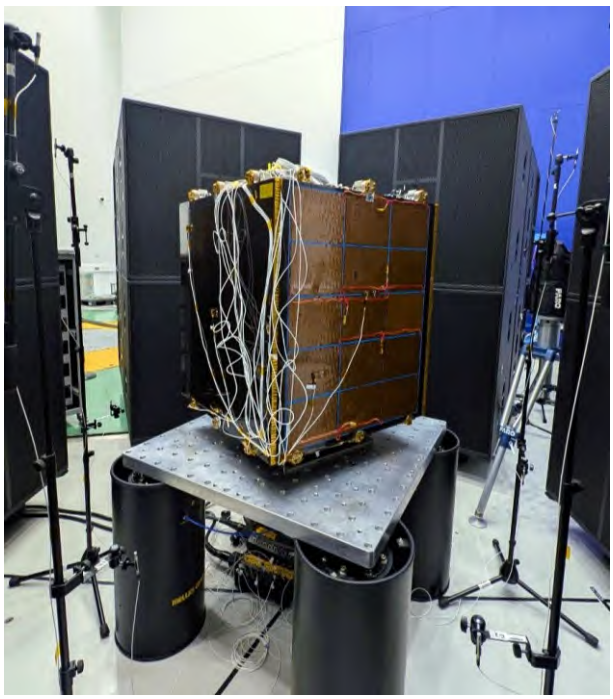

Figure 8: Photograph of the PROBA-V STM in the DFAN test area at the NSTF, mounted on a structural isolation table.

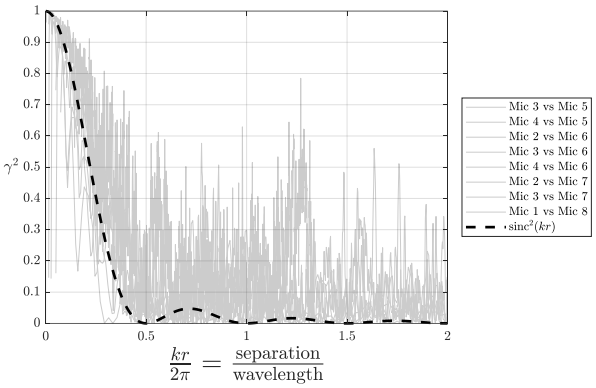

Figure 10: MSC between selected microphone pairs for the PROBA-V test as lines versus kr

the differing number of FFT lines in each kr bin, which is affected by spacing r, the histogram was first computed for each microphone separately, then combined. These were also weighted by 6th-order high & low pass filters at the limits of the frequency analysis range (25Hz – 10kHz). Bin counts were normalised per kr bin, yielding a probability distribution over each vertical stripe. The mean was then computed as the first moment of this. The same processing was applied to magnitude-square and complex coherence, but with differing ranges.

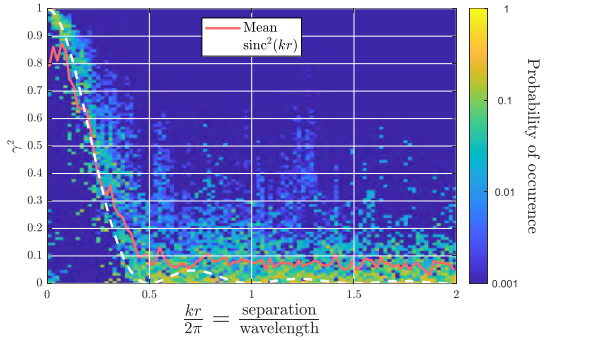

Figure 11: MSC between selected microphone pairs for the PROBA-V test as a histogram vs. kr

4.1. Proba V Test April 2025

This test campaign used the Structural and Thermal Model (STM) of the PROBA-V satellite as the DUT, as has been used in several comparative studies, e.g. [21, 22]. This is shown in Fig. 8. The Neutron loudspeakers were stacked two high, which – with the 20cm spacing off the floor – meant the top of the stacks were 2.4m from the floor (each Neutron is 1.1m high and 1.2m wide). The mic array could not be positioned in the middle of the test arena due to the presence of the DUT (a limitation due to its length). In the data presented here it was above the DUT and slightly tilted, meaning mic 1 was slightly higher than 2.4m. Other positions and orientations were also tested.

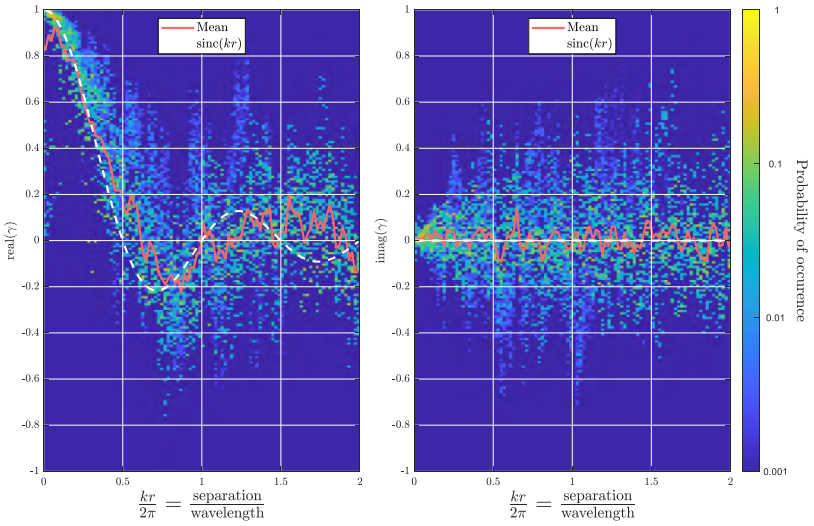

Figure 12: Complex coherence between selected microphone pairs for the PROBA-V test as histograms vs. kr.

Figures 9-12 all show the same coherence data. Fig. 9 shows it as MSC lines versus frequency, mainly to illustrate the point from Fig. 2; that plotting it this way does not allow trends to be seen. Fig. 10 shows the same lines but versus $kr/2\pi$; trends can now be seen but one can only estimate visually, and very crudely in a way dependent on plot line thickness, the density of data at different ordinal MSC values.

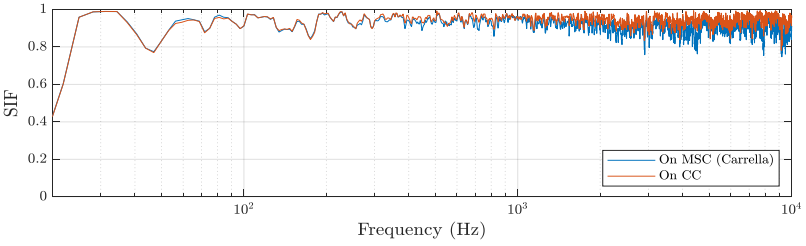

Figure 13: The Sinc Indicator Function (SIF), on MSC as per [10] (blue line) and adapted to complex coherence (orange).

Fig. 11 addresses this issue by plotting the same data as a histogram. Now the portion of data close (or not so close) to the theoretical trend line can be clearly read from the plot. Note that data in this plot appears rather scattered; increasing FFT resolution to narrower than 3Hz improves and smoothes this. The mean line is also shown in pink, which is – as expected – biased above the most commonly occurring data due to the highly skew distribution.

Fig. 12 shows the same data as histograms of the real and imaginary parts of complex coherence. The real part is seen to roughly follow the theoretical $\mathrm{sinc}(kr)$ trend, while the imaginary data clusters around zero because the theoretical trend is purely real. Now, because of the reasonably symmetrical distribution, the pink mean line follows the most commonly occurring data.

Fig. 13 shows the SIF, both the definition in [10] and an adaption of this (see footnote on page 3) for complex coherence. Both metrics behave very similarly, but the adapted version based on complex coherence is able to get slightly closer to unity at high frequencies because it is not deflected from this by the skew distribution of the MSC estimator.

In summary, it can be seen that:

- The properties of the sound field produced by the DFAN system for this test were appropriate.
- Plotting coherence data gathered form multiple mic pairs as a histogram aids interpretability.
- Working with complex coherence eliminates the bias in the mean that occurs due to skew when data is predominantly incoherent ($|\gamma| \to 0$).

4.2. Further Testing August 2026

Further testing of the linear array was conducted in August 2026, still with the mic spacing in Fig. 4. This was undertaken with an empty arena, the rationale being that it is more appropriate to assess the sound field the system produces against the diffuse field theoretical target when a DUT is not present, since the sound field statistics around the DUT would not match free-field theory even if the incident sound field were perfectly diffuse, because it's scattering would perturb them*. The test was otherwise like that in the previous section, except that: i) a higher and different SPL target spectra was used, and ii) the stacks were of three Neutrons, rising 3.5m tall.

Numerous tests were conducted varying the drive pattern to be all independent, all the same, or group by stack or ring / tier. These are not included here, however, since they show trends similar to those in section 5.1 but less clearly.

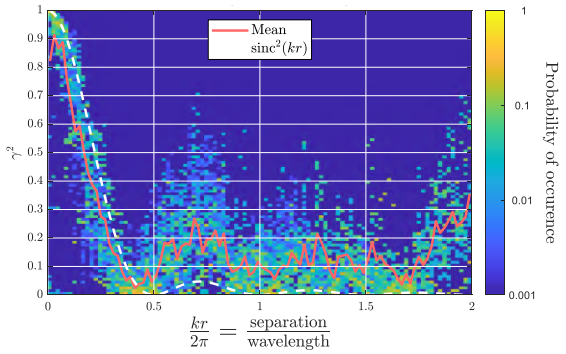

Figure 14: MSC histogram for an empty arena with array level & aligned to two loudspeaker centres.

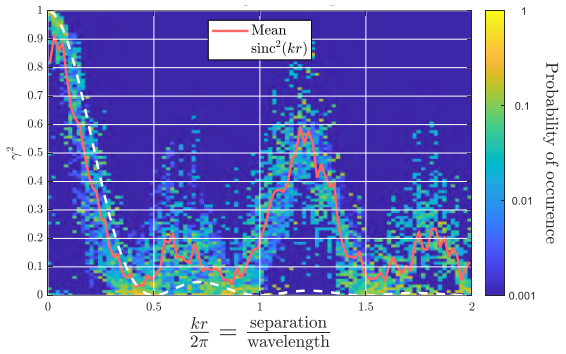

Figure 15: As Fig. 14, but with array rotated 30° horizontally to be aligned with a pair of gaps.

What is worthy of mention is the result in Figs. 14 & 15 that appears to show an issue with the use of the linear array. This is visible with all loudspeakers driven independently – so maximally diffuse – and depended on array orientation. In Fig. 14, when the array was aligned with a pair of speakers, the MSC trend looks mainly as expected. But in Fig. 15, when it is rotated 30° to align with a gap, a significant anomaly occurs at $kr/2\pi \approx 1.2$. Note that it is not a mode. Mics with different spacings see it at different frequencies; it is a sound field correlation property. While the physical meaning of this anomaly is yet to be fully explained, it is clear that it is due to the symmetry of the test arena – this hypothesis was validated by performing Boundary Element Method simulations, which showed the same trend.

This result does not mean that DFAN system and arena symmetry is undesirable; diffuse fields are symmetrical and [14] showed that this means loudspeaker systems should be symmetrical too.

What it shows is that a linear array has no ability to discriminate across its width, and instead achieves a sort of 'super-resolution' in the direction it is oriented, which highlights some sound field properties to a disproportionate extent. This may be

* On this, we note that no simple model currently exists for how the presence of a DUT changes a diffuse field. Such a model would be valuable both to corroborate or deny this assumption, and to inform more realistic sound field targets when a large DUT means a test arena has a high fill factor.

useful in some cases, where the desire is to closely scrutinise certain directional behaviour (examples follow in the next section), but it suggests that a long linear array such as this is not ideal for providing a general sense of sound field diffuseness. Thus, it is not ideal for generic DFAN quality assurance.

It also casts questions over empty area testing, though with a less directionally biased mic array this practice should still be informative in relevant cases.

5. 'MINIDFAN' SCALE MODEL TEST RESULTS AT THE UNIVERSITY OF SALFORD

These tests were conducted in April 2025, two weeks before those reported in Section 4.1. The system, which is shown in fig. 16, comprised 16 loudspeaker 'stacks', each 1.18m high, around a 1.8m diameter test arena. Each stack contained 8 KEF Ci100QR coaxial loudspeakers, each with their own internal chamber, driven by Cloud CX-A850 amplifiers and RME audio interfaces. A unique feature of the setup was that all 128 loudspeakers could be fed audio independently from Matlab via MADI, hence the drive matrices – the effect of which was the main research question – could be changed in software on the fly. Eleven drive patterns were tested; the four reported here plus seven orthogonal Fourier-Legendre patterns. Note that there was no controller in use; the system ran open-loop.

A linear array was also used to gather data here, comprising 12 GRAS model 40PQ ¼" mics. The spacing of these was fixed at 5cm due to mounting hardware restrictions, so 55cm was the maximum spacing. Signals were fed into three 4-channel NI-9234 input modules in a cDAQ-9174 frame, which fed audio data directly into Matlab via USB. In addition, a 48 mic spherical array from a gfai Acoustic Camera system was used to capture data; this was exported to .wav and imported into Matlab for processing. This was done primarily to measure isotropy, but here coherence data from it is reported instead. A Microflown Scan & Paint 3D Acoustic Intensity Mapping system was also used, and a structural response simulator, but page limits prevent reporting on that.

5.1. Linear Array Measurements

Selected results from the linear array are shown in fig. 19. Here the array's ability to interrogate the directional sound field properties is exploited to show the different effects that drive patterns have vertically and horizontally. Note that the plots here use an earlier version of the histogram analysis than the other plots in this paper, causing them to show slightly different scatter. Unfortunately, the raw data was corrupted so these cannot be updated with the latest version of that analysis.

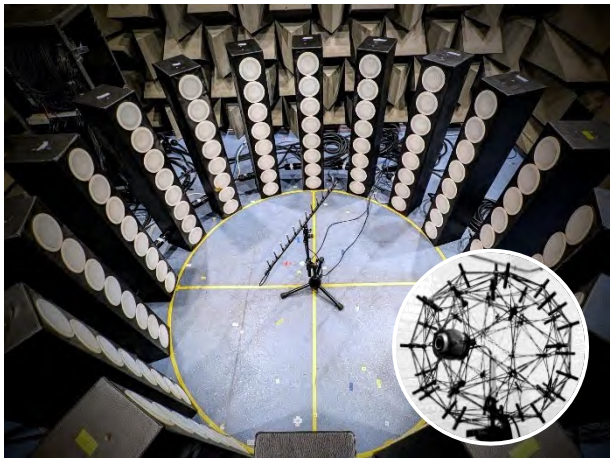

Figure 16: 'MiniDFAN' scale model test setup at the University of Salford. Photo shows linear mic array in horizontal central position. Circular inset shows the 48 mic spherical array also used.

The results clearly show that 'all independent' drive is most diffuse whereas using a single drive produces a field that is not diffuse at all. Additionally, it can be seen that correlating drives by stack or ring greatly reduces diffuseness in the corresponding direction. This suggests that if one groups drives too systematically then this will likely affect the structural response of the DUT. For example,

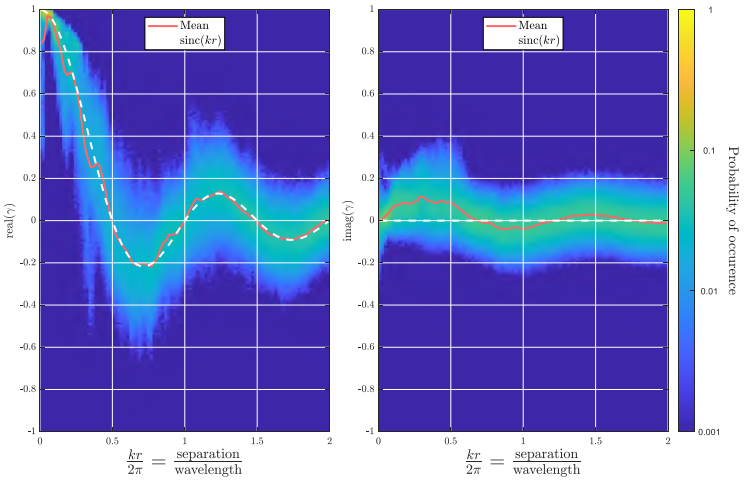

Figure 17: Complex coherence for the 'MiniDFAN' with LS driven independently, measured with the spherical array.

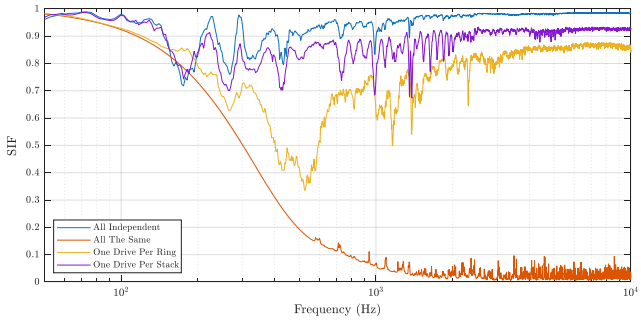

Figure 18: SIF versus frequency for the 'MiniDFAN' measured with the spherical array, comparing drive types.

grouping loudspeakers by stack is likely to greatly change the excitation on the top face of the DUT.

5.2. Spherical Array Measurements

Fig. 17 shows complex coherence results from the mic pairs from the spherical array. Its 48 mics yield 1128 unique pairings, with their separations differing in length and orientation. This provides excellent averaging over angle especially, leading to a distribution of data whose mean almost exactly tracks the $\mathrm{sinc}(kr)$ trend in its real part.

This suggests that spherically symmetric arrays may be a good choice for DFAN quality assurance.

Fig. 18 shows the MSC SIF [10] calculated from the spherical array data for the four drive patterns. At low frequencies all lines tend towards unity; this is because the array – which is 40cm diameter – is too small to discriminate effectively and all signals are coherent in all cases. But at higher frequencies it discriminates between the drives, albeit with all taking quite high values that don't entirely reflect the extent of differences seen with the linear mic array.

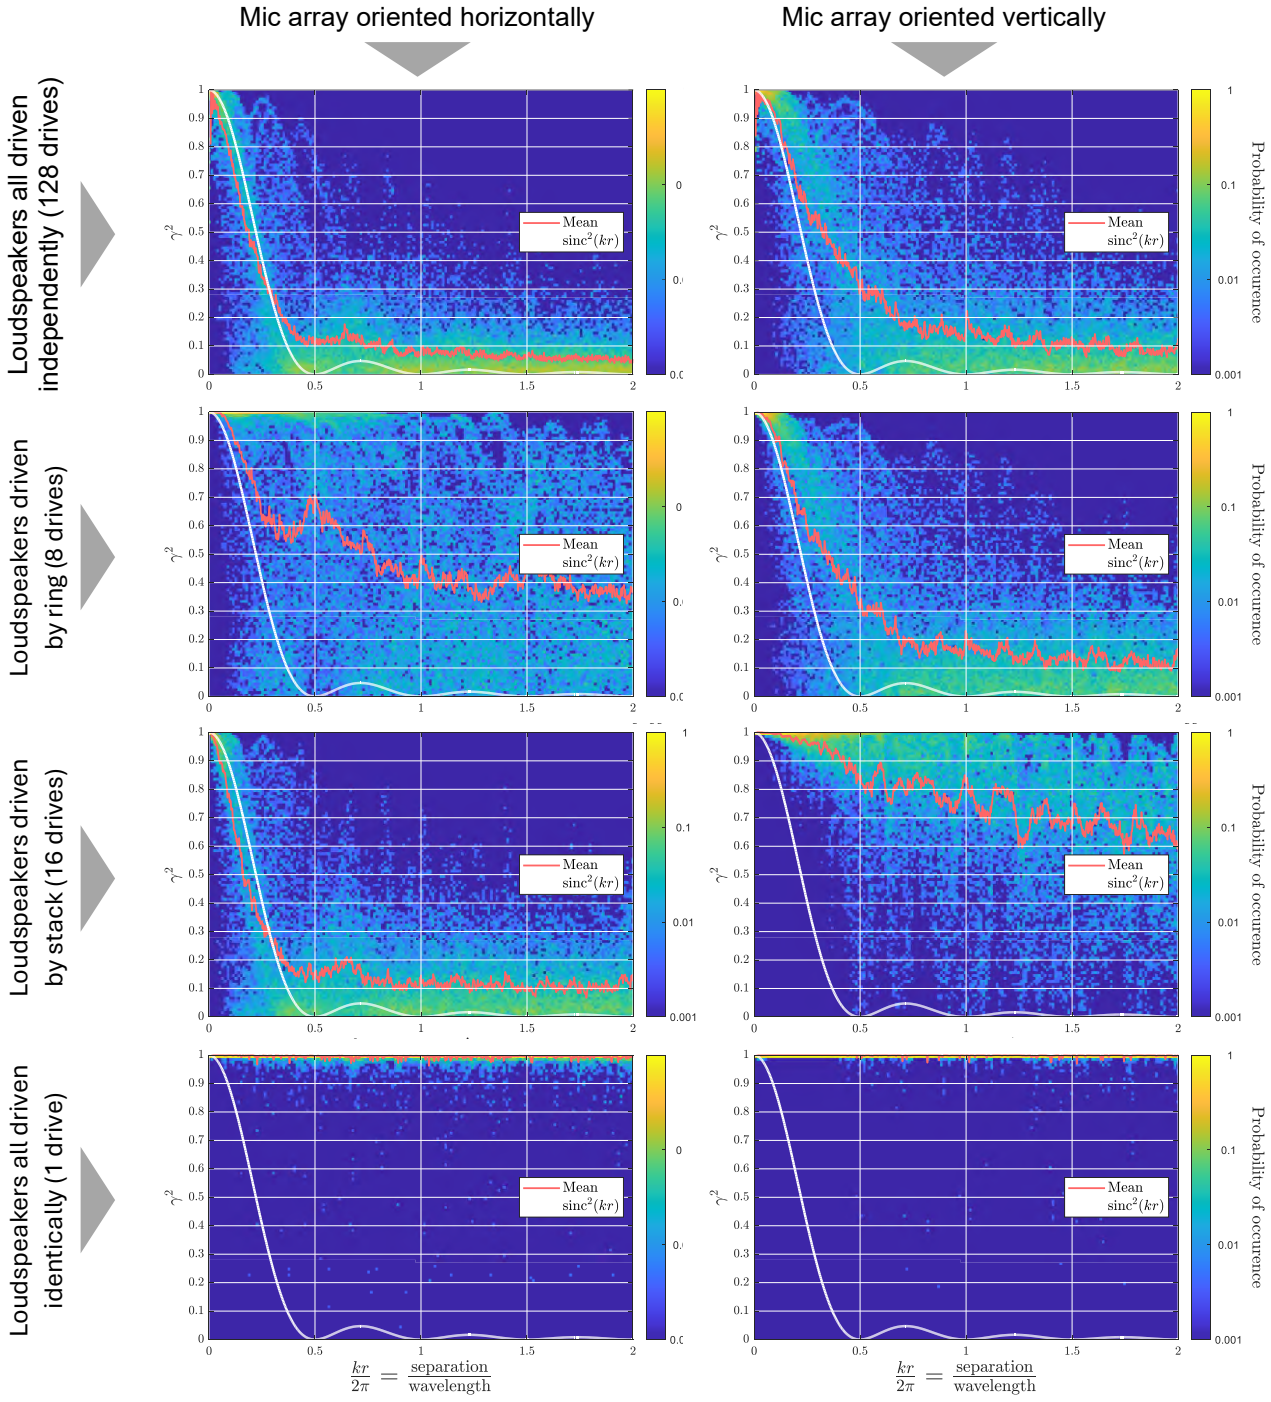

Figure 19: MSC histograms for the MiniDFAN with four differing drive patterns, as measured by the linear array in horizontal and vertical configurations. Individual subplots show combinations as labelled.

5.3. Outlook for scale model testing

More data exists from these scale model tests, and from other diffuse field comparison tests conducted in Sept 2022, which are currently being collated and prepared for journal publication. This is intended to also include isotropy measures, scanned intensity maps and metrics, structural response comparisons and corroborating simulations.

Nonetheless, the limited amount of data presented here already shows that a good deal can be learnt about sound field fundamentals while testing at smaller scale, notably in which the reduced size, weight and SPL expedite laboratory practices.

6. CONCLUSIONS AND FURTHER WORK

Coherence between spaced microphone pairs is an established and practical means of quantifying how similar a DFAN sound field is to a diffuse field. This paper has suggested improvements to how that data might be processed and displayed, notably using complex coherence – or its signed real part at least – and histograms instead of line plots to show results aggregated from many microphone pairs.

A new paradigm for designing microphone arrays tailored to this metric has also been presented. This was demonstrated with a linear array, which was successful but proved to be more useful as a diagnostic tool for querying directional properties of sound fields in great detail, than it was for general sound field diffuseness quantification. For DFAN sound field quality assurance it is suggested that a smaller spherical 3D array might be more suitable.

The linear array did, however, prove useful in demonstrating the significant changes that drive patterns have on the sound field produced by a DFAN system. The conclusion is that the drive 'matrix' – being the mapping from M controller outputs to N loudspeakers, where $N > M$ typically, should always be detailed in DFAN test reports.

6.1. Areas requiring further research

This work, and the review of recent literature it contains, shows that more fundamental research is needed if the properties of the various diffuse field metrics that exist are to be fully understood.

Firstly, a means of synthesising a field with a given % 'diffuseness' is required in order for terms such as 'diffuseness' or 'diffusivity' to move from being qualitative descriptors to quantitative metrics. As noted in [18], summation of plane waves is not the ideal model for this, and variable partial coherence between energy from different directions also needs to be captured in the model somehow.

On coherence, progress has been made on better understanding its properties in [6], but similar needs to be done for complex coherence, as is presented herein and in [13]. Such understanding will allow more informed design of metrics that avoid issues caused by its heteroscedastic estimator properties.

Specific to DFAN applications, better understanding is required of the effect of DUT scattering on diffuse field metrics and targets, and of how this and loudspeaker proximity cause local changes that mean control and monitor microphones should be positioned a certain distance away into the cavity. These effects depend on obstacle geometry and acoustic properties, so would need to be quantified by a parametric sweep of representative geometrics, ideally including or informed by nearfield loudspeaker radiation and impedance data.

Extension of the array design paradigm herein to 3D arrays would also be desirable, ideally with analysis tools informed by the improved models of partially diffuse fields discussed above. Arrays with spherical symmetry seem desirable, which for low/moderate microphone counts can be based on Platonic solids.

7. ACKNOWLEDGEMENTS & IP

The authors acknowledge the contribution of Finn Alderson, a student studying at the University of Salford, who helped conduct the measurements at Salford that are reported in section 5.

The initial linear microphone array design in section 3 was funded by RAL Space in 2024, so its IP is co-created by RAL Space and the University of Salford. The measurements undertaken at the National Satellite Test Facility (reported in Section 4) are the IP of RAL Space. All other material is the IP of the leading author and the University of Salford; RAL Space has kindly funded dissemination of this work at ECSSMET 2026, but the research itself was undertaken without external funding.

The gfai 'Sphere 48' Acoustic Camera system used in section 5 is property of the (now defunct) STFC Equipment Loan Pool that was funded by EPSRC.

ABSTRACT

This paper is based on the methodology of a recent paper presented at the 2026 AIAA SciTech Forum [1] but instead is used to simulate representative test results presented by the paper (and its references) published in the 2023 Volume 66: Issue 1 of the IEST Journal [2]. That paper contains a study of the vibroacoustic response of an aluminum honeycombed 2.44m x 1.22m (8'x4') test-panel that results from using advanced MIMO acoustic control of Direct Field Acoustic (DFA) tests [3] to create multiple types of acoustic fields consisting of a near-diffuse and four other non-diffuse fields with various panel orientations, for a total of 30 tests, where all DFA tests were specified to have the same OASPL and 1/3-Octave spectrum test reference [2].

Each discussed test uses the same 24 randomly arranged approximate circle of control microphones that are in turn surrounded by an approximately concentric outer circle of 8x8 MSI DFAT loudspeaker stacks that contain the described test article at their mutual center. The test panel's experimental modal analysis (EMA) results were used as the basis to determine how well each of the five types of acoustic fields, described in [2], excited the EMA identified modes of the test panel.

The vibroacoustic test results from three of the five described DFA tests [2] were selected for this paper, where each test creates a different acoustic field that will be discussed first. This will be followed by a discussion of the vibroacoustic response simulation from the same DFA test's acoustic fields exciting the test panel, which are compared to the described test results and to the EMA and FEM based modal analysis, by its ability to create and analyze the various fields and associated panel vibroacoustic responses using numerical simulation [1]. These two sets of discussions in the paper are jointly designed to demonstrate the importance of conducting DFA testing using a near-diffuse acoustic field.

1. INTRODUCTION

1.1 Overall Testing Goals of Selected DFA tests

The purpose of previous testing [2,4-5] was to further justify the advantages and need to have a Near-Diffuse [3] acoustic field that can fully excite the structural modes of a test article. The tests were designed to compare the vibroacoustic response of a test article (TA) under test using MSI-DFAT 8x8 loudspeaker stacks, shown in Fig. 1, where the TA is shown by Figs. 1 and 2, is a 2.44m x 1.22m (8'x4') rectangular test-panel (panel) that is instrumented with 20 accelerometers. Figs. 1 and 2 illustrate the location of the 20 accelerometers that were used and Fig. 2 (bottom) shows their coordinates relative to the Panel in inches (2.54 cm/inch).

The analyses in [2,4] used PSDs with Δf = 0.1563 Hz for Experimental Modal Analysis (EMA) and Δf = 0.1953 for their other analyses of the panel to better distinguish between closely spaced panel modes. This paper will instead use a unified Δf = 0.78125 for all PSD analyses and simulations performed to simplify the following presentations, for which the frequency range used in this paper, in the interest of shortening the simulation time, will be either 20 or 30 Hz to 200 Hz, instead of the 20 Hz to 10 kHz or 40 Hz to 300 Hz used by [2,4], for microphone (mics) and accelerometer (accels) data analyses.

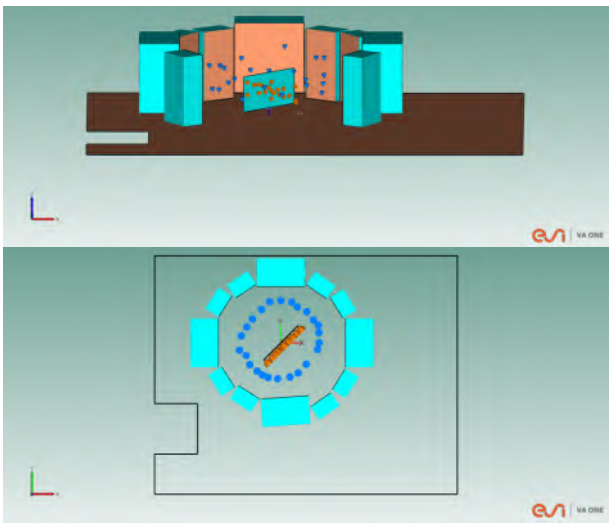

Figure 1: (top) elevation & (bottom) plan views of 8x8 Stack configuration with 8 or 1 independent drives; 24 control Mics; 8'x4' Test Panel & Accels

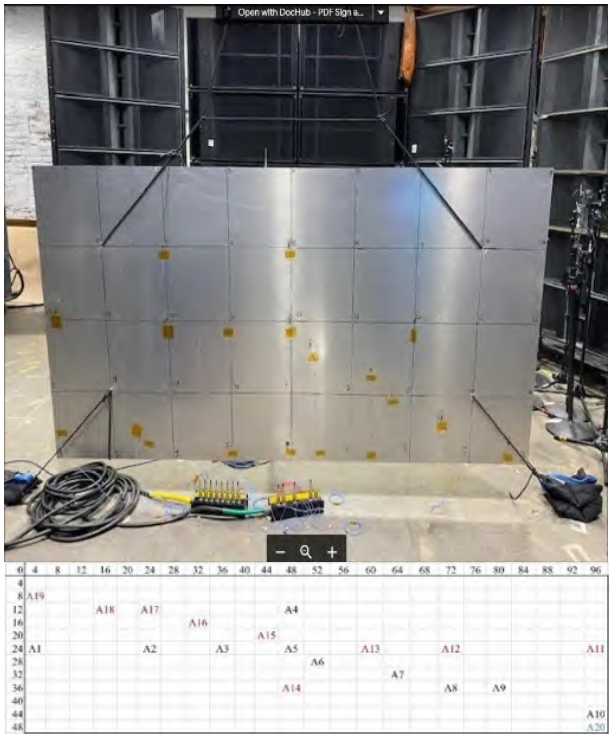

Figure 2: (top) 2.44m x 1.22m (8'x4') Test Panel; and (bottom) Coordinates of Panel Accelerometers

The test panel and accelerometers shown in Figs. 1 and 2 are at the center of the microphone circle in its 45° orientation, which is the only test panel configuration discussed in this paper. The panel, on the other hand, was tested in [2,4] using three rotational configurations, 0°, 30°, and 45° with respect to the speaker and microphone circle.

1.2 Importance of Nearly Diffuse Acoustic Fields

It is generally recognized [2-5] that only a nearly diffuse acoustic field will properly excite all the modes of the structure under test and that an acoustic field with measured coherence between microphones throughout the acoustic field differing "significantly" from a theoretical sinc^2 function is not nearly diffuse, and in general, not capable of similarly exciting all its structural modes [2-5].

Similarly, it is also known that if an acoustic field is excited with uncorrelated drive signals for the loudspeakers, the response of a test article and control microphones may not be consistent with the response from a diffuse acoustic field due to the underlying acoustic modes that may be excited by uncorrelated drives without MIMO control [2-5].

The test campaign in [2,4-5] was designed to demonstrate that only a Near-Diffuse acoustic field created using modern optimal adaptive MIMO methods to control the test-facility's acoustic modes [3] can properly excite the test panel in general, for which the use of non-diffuse acoustic fields may not provide, by employing a more comprehensive suite of tests as used for the testing described by [2].

1.3 Test Configuration Used for this Paper

The testing in [2,4] used two configurations of MSI-DFAT's loudspeaker 8x8 stacks with five acoustic fields, whereas this paper uses only one form that is based on 8 full stacks of MP21's for the lowest frequencies and 8 of MP150's for the mid and high frequencies and three fields. Stacks are driven by the control system using either 8 independent drives for two tests using MIMO to create Near-Diffuse and Directed-Coherent acoustic fields and one test with 1 drive using MISO control [2,4], to excite the panel in the 45° configuration as illustrated by Fig. 1.

The Panel is instrumented with 20 Accelerometers. Their locations are illustrated by Fig. 2 using the colors black, red, and blue. Accelerometers A1-A10, in black, were used for the first testing [5] and A11-A19 in red were added for the newer test campaigns [2,4]. Accelerometer A20 in blue was used for operational modal analysis (OMA), as a test performance metric [2,4], which is not used here.

Three types of acoustic tests are described and simulated that were performed to excite the test panel using three types of acoustic fields: 1) Near-Diffuse to approximate a theoretically diffuse field with zero mean random phase between control-microphones, as described in [2-5], using multiple-input-multiple-output (MIMO) control [3]; 2) to approximate a Directed-Coherence Field using a "push-pull" configuration with MIMO control [2-5]; and 3) to drive all the loudspeaker stacks with a single drive, which is controlled with multiple-input-single-output (MISO) control, where MISO uses the average of the 24 control microphones for control, whereas MIMO controls each of the amplitudes of the 24 control microphones as well as the relative coherence and phase between all microphones, i.e., by controlling the microphone's spectral density matrix (SDM) by finding the proper drive's SDM [3].

1.4 Experimental Modal Analysis Results

Before testing, an experimental modal analysis (EMA) was performed on the panel to determine its structural modes between 10 Hz and 300 Hz. Table 1 contains the obtained EMA results [2,4].

Table 1: 22 EMA Panel Modes

Mode	Natural Frequency (Hz)	Damping Ratio (Hz)	Damping Ratio (%)	Damped Resonant Frequency (Hz)	Observed Resonant Frequency (Hz)	Observation Discrepancy (%)
1	15.71	0.14	0.86	15.71	15.6	-0.70

21	249.77	0.56	0.23	249.77	249.8	0.01
22	285.08	0.57	0.2	285.08	285.2	0.04

- The 22 Mode's f_n and ζ_n were used to determine the Damped Resonant Frequencies.
- A Roving Hammer Technique and Star Modal [2] provided the 45-Point EMA, where only Modes 3 to 22 are used.

1.5 DFA Test's Reference Amplitude Spectra

The references are shown in Fig. 3 that follows.

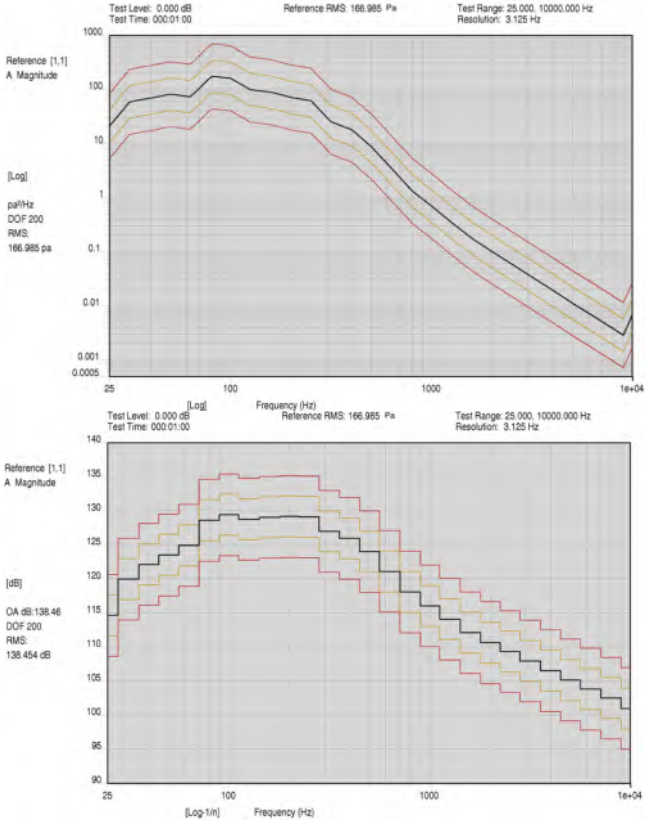

Figure 3: (top) Reference PSD and (bottom) 1/3 OB Spectrum Used for 24 Control Microphones for DFA Tests

2. TEST RESULTS

2.1 Comparison of the Acoustic Fields Used

The measured acoustic characteristics of the three fields used to excite the test panel under the described conditions, and their summary response results are discussed, which [2-6] cover in detail.

The degree of diffuseness of the fields will be assessed by examining typical plots of coherence compared to the sinc^2 function vs. Kr, which adjusts coherence for differing delays between microphone pairs, and the variations of the 1/3 OB SPL Spectra of all 24 control microphones between each other to assess the uniformity of the three acoustic fields.

These comparisons also assess how well the 3 tests agree in acoustic levels and spectra and how well the measured coherence approximates that of an ideal diffuse field and how uniform the field is, where both are required for a field to be Near-Diffuse [2,4].

2.2 Near-Diffuse Field

Fig. 4 contains the plot of the 24 1/3 Octave SPL spectra for each of the 24 Control Microphones, from 25 Hz to 200 Hz, on its top, where the alarm tolerances are +/- 3dB and the abort tolerance are +/- 6dB. Notice how uniform the spread between the spectra of control microphones is in the Fig. 4 (top) plot, i.e., mostly within the +/- 3dB tolerance, except at 25 Hz.

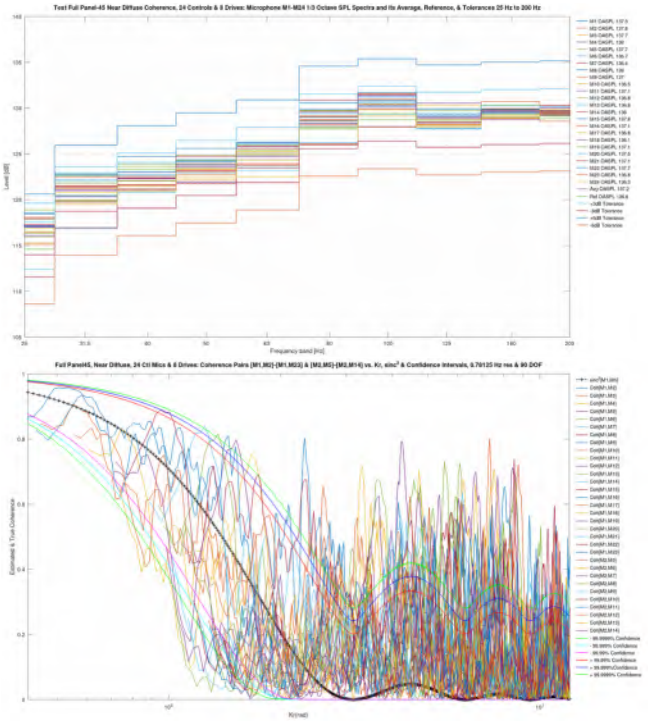

Figure 4: (top) 1/3 Octave SPL Spectra of the 24 Control Mics & (bottom) Relative Coherence vs. Kr

The plot of Fig. 4 (bottom) is of 32 typical coherence spectra between control microphones 1 and 2 to 23 and between microphones 2 to 14, which uses Kr (in radians of the sinc^2 function shown), as further discussed in subsection 3.1 and [6], as the x-axis, which compensates for the differing delays between them [6], which allows all the coherences plotted to be compared to a single sinc^2 function [6], which represents the plot of the ideal coherence for diffuse fields [6]. This plot shows how close to an ideal diffuse field the Near-Diffuse acoustic field is, which is validated by the fact that most of coherence spectra in the first lobe of the sinc^2 are within the +99.9999% confidence intervals of coherence [6], in spite of the fact the coherence spectra were measured with a low 90 DOF and FFT Δf=0.78125 Hz, which allows the high coherence spikes we see just above Kr=2, which didn't occur when at least 200 DOF and Δf=3.125 Hz were used [2,4].

This indicates that the Near-Diffuse field coherence spectra estimate approximates the ideal coherence well. Additionally, the Optimal Adaptive MIMO Control [3] that is used reduces the coherence between the displayed microphone pairs below the -99.9999% confidence intervals of the ideal sinc^2 coherence curve, where the plot on the bottom of Fig. 4 demonstrates this less than theoretical effect.

2.3 Non-Diffuse Directed-Coherence Field

The 24-control microphone 1/3 Octave SPL spectra and Coherence vs. Kr results in Figs. 5 (top and bottom) match what is expected from a Directed-Coherence acoustic field [2,4-5]. It is further shown that this field does not excite all expected test panel resonances properly in what follows and in [2,4-5]. This is a result of the response enhancement-

cancellation effects discussed for this field in [2,4-5], upon which subsection 2.4 will further elaborate.

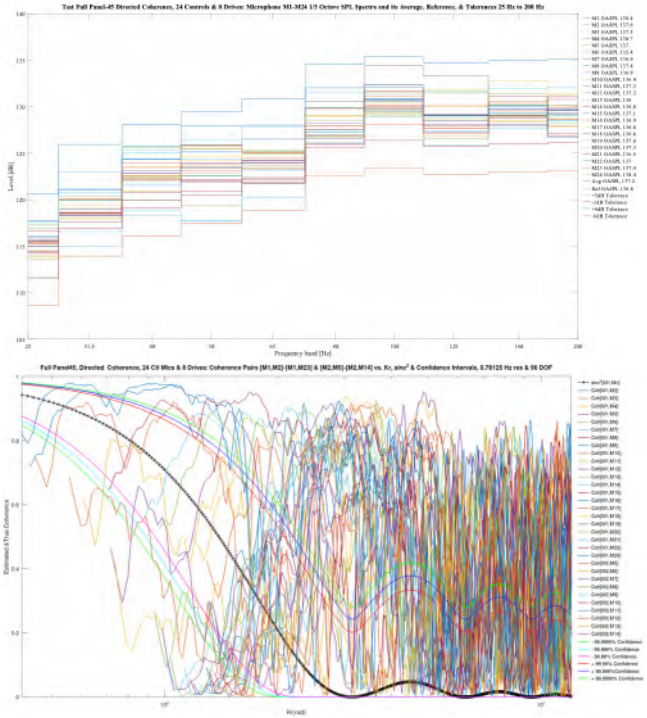

Figure 5: 1/3 Octave SPL Spectra of the 24 Control Mics & (bottom) Relative Coherence vs. Kr

Note that the uniformity in Fig. 5 (top) is not as good as what we see in Fig. 4 (top) for the Near-Diffuse field. Also, Fig. 5 (bottom) is quite different than what we see in Fig. 4 (bottom). Thus, the Directed-Coherence field is not Near-Diffuse. This is by design since its MIMO control is programmed with judicious choices for the setting of the off-diagonal coherence and phase terms [5] in its reference SDM [3] to have a higher coherence as the plot in Fig. 5 (bottom) shows, but by having its SDM set to create a push-pull sound pressure condition by the setting the phases between the front to 0° and front and rear microphones to 180°, i.e., as the front of panel loudspeaker's sound pressure waves push, the rear of panel loudspeaker's sound pressures pull the panel, effectively in theory doubling the pressure force on the panel, which becomes apparent above 137 Hz and continuing above 200 Hz as discussed in [2, 4-5]. This will be discussed further in the following subsection 2.5 describing the panel's vibroacoustic responses to the 3 acoustic fields.

2.4 Non-Diffuse MISO Field

As compared to the Directed-Coherence test, the Fig. 6 (top) 24-control microphone 1/3 Octave SPL spectra are much less uniform and the (bottom) Coherence vs. Kr results are mostly 1, which demonstrate the MISO created acoustic field [2,4-5] is not diffuse, where [2,4-5] demonstrate in detail that as a result this field performs the poorest, by not being able to excite all expected test panel resonances properly, which will be briefly discussed in following section.

The poor performance largely results from the in-phase, shown in [2,4-5], high coherence sound pressure waves being measured by the control microphones response shown in Fig. 6 (top and bottom) causing more significant enhancement-cancellation effects due to their interaction with plate mode's relative phase that is explained for this field in [2,4-5]. This field simply cannot match what is expected from an acoustic field that was created using MIMO, which instead uses a multiple-input-single-output (MISO) control, which has no ability to control the relative phase and coherence between sound waves coming from the speaker stacks, which are driven by a single drive. The result is that this field provides the poorest proper excitation of the expected test panel modes by the 3 discussed fields, as will be discussed later and as described in detail in [2,4-5].

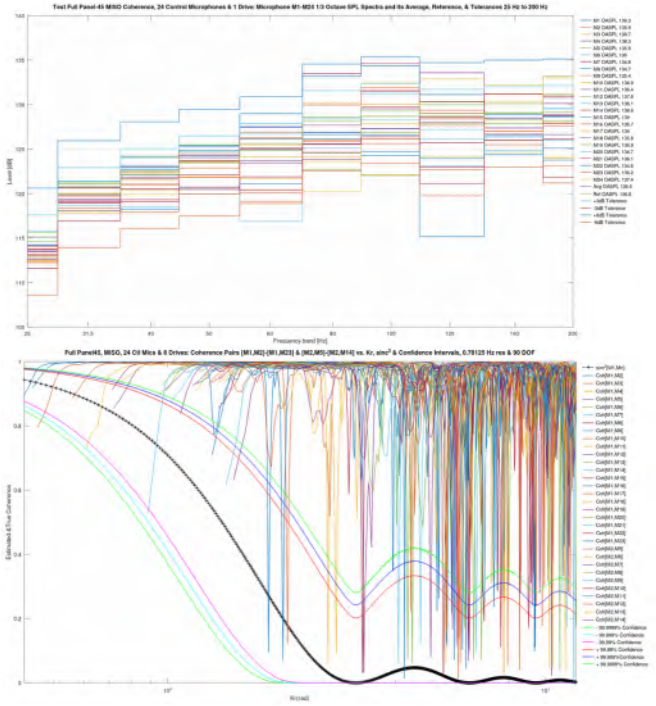

Figure 6: (top) 1/3 Octave SPL Spectra of the 24 Control Mics & (bottom) Relative Coherence vs. Kr

2.5 The 3 Field's Panel Response Comparison

Comparison is not detailed, since [2,4] has details. The following Fig. 7 provides a simpler comparison.

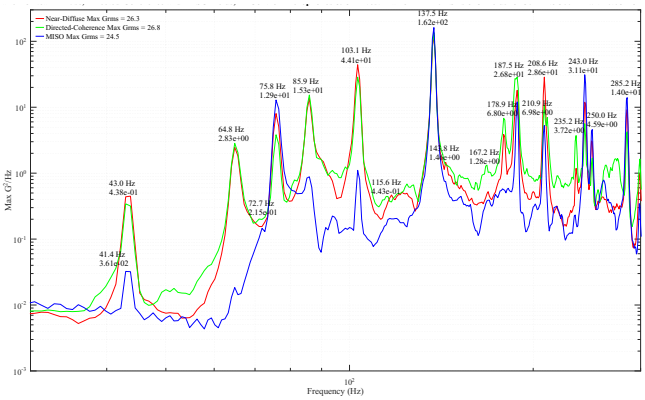

Figure 7: Comparison of the Maxima of the PSDs from the 20 Accels A1-A20 from each of 3 Fields

Note that Fig. 7 displays the comparison of the

three fields to 300 Hz, to be more consistent with [2,4] and because that is needed by section 3. Consequently, Fig. 7 also better demonstrates the differences between the 3 Acoustic Fields.

The MISO Field (in blue) is shown by Fig. 7 to have the lowest maximum response in general, except for also creating the highest responses for the 75.8 Hz, 137.5 Hz, 243 Hz, 250 Hz, and 285.2 Hz panel modes, which are examples of response enhancement [2,4-5]. In contrast, MISO excites the rest of the panel's modes the least, with the 43 Hz, 64.8 Hz, 85.9 Hz, 103.1 Hz, 167.2 Hz, 178.9 Hz and 235.2 Hz modes barely responding, which are examples of response cancellation [2,4], where both results are inconsistent modal responses not directly linked to the spectral and OASPL specified for the acoustic test, which are not present in the responses due to the Near-Diffuse Field. This behavior is most likely caused by the high coherence and in-phase behavior [2,4-5] demonstrated by the response of the control microphones, which characterizes the acoustic field that excites the panel modes.

Fig. 7 also indicates that the Directed-Coherence Field (in green) performs better in this regard than MISO due to the higher sound pressure force exerted by this field on the panel at the same OASPL as that of MISO and the Near-Diffuse Fields, where its responses exceed those due to the Near-Diffuse field for the 64.8 Hz, 85.9 Hz, 167.2 Hz, 178.9 Hz, 187.5 Hz, and 235.2 Hz modes, but interestingly not so for the 75.8 Hz, 103.1 Hz, 208.6 Hz, 243 Hz, 250 Hz, and 285.2 Hz modes, where they are at lower g^2/Hz level than what the Near-Diffuse field achieves, as Fig. 7 demonstrates, even though there is a doubling of sound pressures acting on the panel due to its push-pull excitation, where this lack of consistency is not present with the Near-Diffuse Field.

Also note in Fig. 7 that for the modal responses above 137.5 Hz, the Directed-Coherence Field has a consistent response growth trend, where the modal responses rise to higher levels, as the modal frequencies increase to 187.5 Hz with significant drop in g^2/Hz level of the following 208.6 Hz mode, where thereafter that trend changes into a more hit and miss pattern as far the modal responses go. Also note the response levels between the modes is highest for the Directed-Coherence field, as displayed in Fig. 7, which starts at 37 Hz persisting throughout the 37 Hz to 300 Hz range, but increasing significantly above the 137.5 Hz mode to 300 Hz. This set of phenomena appears to be caused by the enhancement-cancellation effects discussed earlier for the Directed-Coherence and MISO cases, but which also appear more consistently in the modes after the 137.5 Hz mode, which is also where the differences between the Near-Diffuse and Direct-Coherent fields become more apparent. This phenomenon, which Fig. 7 demonstrates, is explained more fully in the following subsection 3.4 of the following section in conjunction with Fig. 22.

Other significant differences between the vibracoustic response of the panel's mode between the Near Diffuse and the other two fields are discussed in more detail, along with 2 other non-diffuse fields that were used for DFA testing, in [2,4-5]. These demonstrate that the Near Diffuse field is more effective in exciting the panel's modes in a consistent manner, by using various performance comparison metrics using pseudo-velocity (PV) based Partial Damage time-domain [2]; PV VAG and PSD frequency domain [4]; and Acceleration PSD comparison [5] methods.

As seen, Fig. 7 is also useful to compare the 3 maximum acceleration PSDs obtained from each of the 20 PSD panel accelerometers from each of the 3 fields and annotates the overall maximum g^2/Hz level and frequency for each of the 20 modes. The comparison also supports the view that the Near-Diffuse field excites the panel modes more consistently than the other fields [2,4-5], since the Near-Diffuse field does not, like the Directed-Coherent field, switch from being the highest performer at 64.8 Hz to the lowest performer at 75.8 Hz and again above the 137.5 Hz mode to the 187.5 Hz mode being the highest performer and then low again at the 208.6 Hz mode and then again the lowest for the 243 Hz, 250 Hz and 285.2 Hz modes. This behavior is consistent with response enhancement-cancellation we see to a greater extent for MISO. In [2,4-5] similar behavior for the other non-diffuse fields that were tested was demonstrated.

2.6 Conclusions about the DFA testing results

- This section presented the control microphone 1/3 OB spectra and a typical set of coherence vs Kr spectra of the Near-Diffuse, Directed-Coherence, and MISO Fields using the same OASPL and spectrum from Testing in 2021.
- It also presented the comparison of the vibroacoustic response that resulted from exciting the panel with those Acoustic Fields. The comparison and the references cited demonstrated the coherence settings for the 3 tests, which differed as explained in the paper, created significant response level differences that showed that the Near-Diffuse field is more effective in exciting the panel's modes in a consistent manner than the other two fields.
- The 2021 test data provided an opportunity to test digital vibroacoustic simulation systems, since we had both the vibroacoustic acceleration response SDMs and Acoustic Field excitation sound pressure level SDMs. These are imported into the VA One simulator to compare its simulated panel vibroacoustic response PSDs and other analyses with the test results. These will be discussed in the following section 3 on simulation.

3. COMPARISON OF NUMERICAL SIMULATION AND MEASURED RESULTS

The DFAT panel test was modelled using the VA One vibroacoustic simulation software, and the results of the simulation were compared to the measured data for the same three cases: Near-Diffuse, Directed-Coherence, and MISO. Fig. 8 shows the complete model. The aluminum honeycomb test panel was modelled as a finite element structure and the speakers and test volume were modelled with the Boundary Element Method (BEM) technique. The frequency domain was limited to 200 Hz with a constant analysis bandwidth of 0.78125 Hz in order to capture the low-frequency structural modes while keeping the run time of the BEM solution reasonable. The results are however constrained by the 200 Hz upper limit, and should be viewed with that constraint in mind.

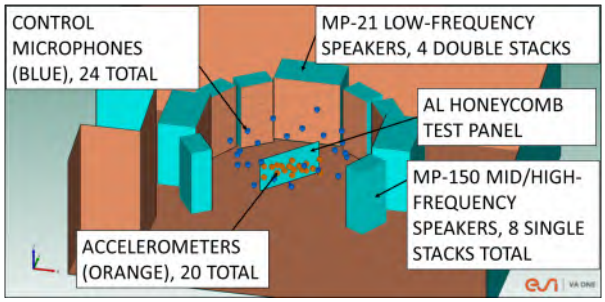

Figure 8: Complete VA One Model

The measured data below about 30 Hz, where the microphone signals had rolled off significantly, appeared unreliable due to instrumentation noise at low SNR and possible ambient sound and vibration. For this paper, we have presented SPL data above 20 Hz and acceleration data above 30 Hz to avoid confusion from the unreliable low-frequency measurements.

There were 24 control microphones distributed around the test panel and 20 accelerometers attached to the panel. The room in which the tests were performed was included in the model.

For each of the three simulation cases, the Spectral Density Matrix (SDM) that was measured during the actual test was imported into VA One and applied to the 24 control microphones. VA One solved for the speaker output that matched the SDM at those 24 microphones, and then solved the coupled vibroacoustic problem to get the structural response of the test panel. The comparisons shown here are between the measured and simulation SPLs and acceleration PSDs.

An Experimental Modal Analysis (EMA) was performed on the test panel in 2021, and the mode frequencies and shapes from the current FE model of the panel were checked against the EMA results (Tab. 1). Below 200 Hz, all 16 panel modes were in agreement, but there was a reversal of the order of modes 15 (187.0 Hz) and 16 (188.3 Hz), which were the two highest frequency modes. That reversal was ignored for this paper.

3.1. Near-Diffuse Field Case

The simulation of the Near-Diffuse Field case produced microphone and accelerometer responses that were very similar to the measured test data.

Virtually all DFAT tests and tests in Reverberant Acoustic Test Facilities (RATFs) are either explicitly or implicitly required to approximate a diffuse field. For aerospace vibroacoustic tests, the primary exception to this historically has been progressive wave testing with a Progressive Wave Tube. There has also been interest in fields with other spatially varied characteristics, but the primary field of interest is an approximately diffuse field. An ideal diffuse field is spatially homogeneous, and at any frequency, provides a uniform intensity in all directions. The coherence between a pair of microphones in an ideal diffuse field will have a $\text{sinc}^2(kr)$ shape [6] and the phase will be 0 or pi, where k = wavenumber and r = microphone separation distance. Actual test fields can only approximate an ideal diffuse field. The Near-Diffuse Field case was such an approximation. Graphs of measured coherence vs. kr for the three cases are shown in Fig. 4, 5, and 6. In Fig. 4 for the Near-Diffuse case, the measured coherence is shown for a number of microphone pairs, and generally follows the $\text{sinc}^2(kr)$ function.

The Near-Diffuse test used MIMO (Multiple-Input Multiple-Output) control [3], where the 24 control microphones were the multiple inputs to the controller, and the outputs were 8 drive signals that were mixed and used to drive the speaker stacks. Each double stack of low-frequency MP-21 speakers was driven by the same signal over its height, and each single stack of mid/high-frequency MP-150 speakers was driven by the same signal over its height. The Near-Diffuse simulation used the same MIMO control configuration of 24 control microphones and 16 speaker stacks as the actual tests, but the specific generation and mixing of the drive signal between the controller and the speakers was not modelled. Rather, for the simulation, VA One matched the SDM at the 24 control microphones by adjusting the speaker stack outputs.

The measured SDM for the Near-Diffuse case was imported into VA One and the model was solved to match the SDM at the 24 control microphones. Fig. 9 shows the SPL reference spectrum, the measured average spectrum for the 24 control microphones, and the average spectrum from the VA One simulation. All three spectra are essentially identical. There is a small hump in the measured and VA One spectra at 90 Hz.

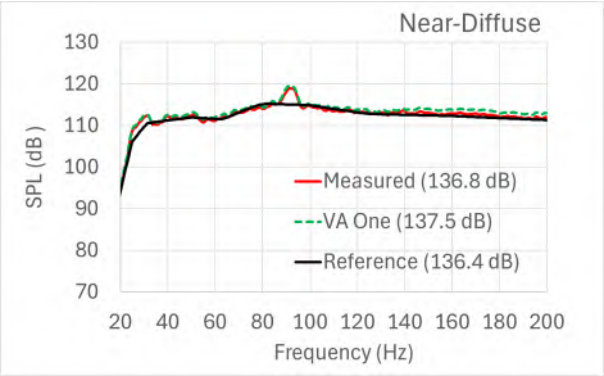

Figure 9: SPL Spectra for Near-Diffuse Case

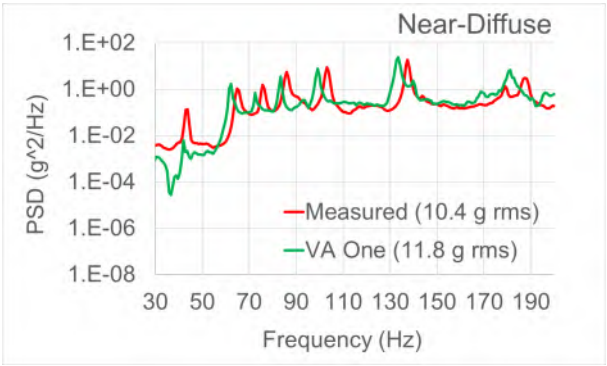

Figure 10: PSDs for Near-Diffuse Case

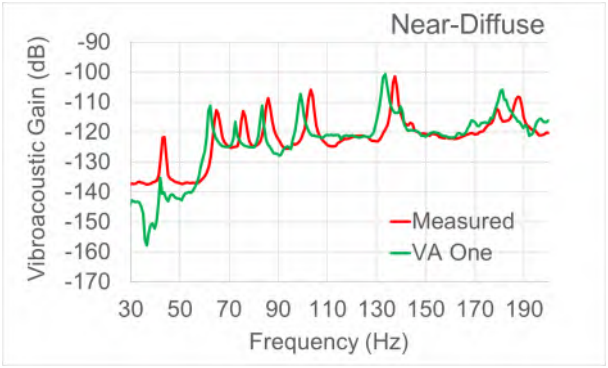

Figure 11: Vibroacoustic Gain for Near-Diffuse Case

Fig. 10 shows the measured average PSD for the 20 accelerometers and the average PSD from the VA One simulation. The two spectra are very similar. Above 50 Hz, the amplitudes of the modal responses are similar. The frequencies of the modes from the simulation are slightly lower than the measured frequencies, but the modes from the simulation still correspond well to the measured data.

Fig. 11 shows the Vibroacoustic Gain (VAG) calculated from both the measured data and the VA One simulation. The VAG is defined here as the acceleration level in dB ref. 1 g minus the SPL in dB ref. 20 microPa, and its purpose is to normalize only the acceleration response with respect to SPL. The VAG does not normalize the response with respect to coherence and phase, so differences in VAG can be attributed to joint acceptance. The measured and simulation values of VAG in Fig. 11 are very similar. The measured VAG is higher than the simulation values below about 40 Hz, and this could be due to instrumentation noise or ambient sound and vibration. Unfortunately, we did not make measurements of the ambient environment for comparison.

3.2. Directed-Coherence Case

The simulation of the Directed-Coherence case produced microphone and accelerometer responses that were very similar to the measured test data and also very similar to the Near-Diffuse case.

The intent of the Directed-Coherence case was to produce a field that had different coherence and phase on each side of the test panel, but the same SPL spectrum as the other two cases. That illustrates the effect of coherence and phase on the panel response independent of SPL. The coherence and phase were defined for the Directed-Coherence case to produce a sort of push-pull effect on the panel. Fig. 5 shows the measured coherence vs. kr for the Directed-Coherence case, which differs significantly from the coherence of the Near-Diffuse case (Fig. 4).

Fig. 12 shows that the average control microphone SPL spectra for the measured and simulation Directed-Coherence cases were essentially identical and very similar to the reference spectrum. The slight hump at 90 Hz is still evident, as for the Near-Diffuse case. So, the change in cases was not the SPL but rather coherence and phase, as intended.

Fig. 13 shows the measured, average PSD for the 20 accelerometers and the average PSD from the VA One simulation. The two spectra are very similar, and both are similar to the PSDs for the Near-Diffuse case (Fig. 10).

Fig. 14 shows the VAG calculated from both the measured data and the VA One simulation. As with the PSDs, the two VAG spectra are very similar, and both are similar to the VAG curves for the Near-Diffuse case (Fig. 11). The measured VAG is higher than the simulation values below about 40 Hz, similar to the other two cases.

The overall, average acceleration for the 20 accelerometers increased for both the measured data and the simulation (Fig. 10 and 13), by 1.1 g rms for the measured data and 1.8 g rms for the simulation, but the responses for the Directed-Coherence and Near-Diffuse cases show that the two fields had a very similar effect on the test article. This was not true for the MISO case, which had the most different field and will be discussed next.

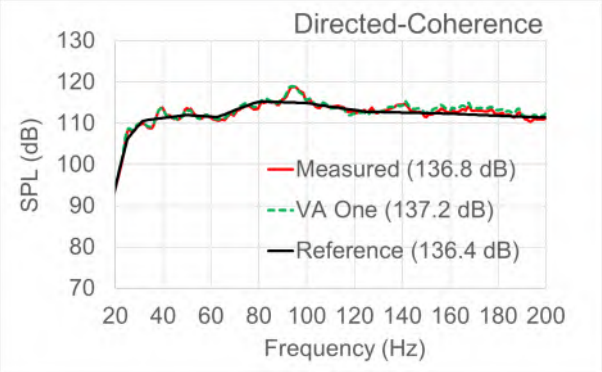

Figure 12: SPL Spectra for Directed-Coherence Case

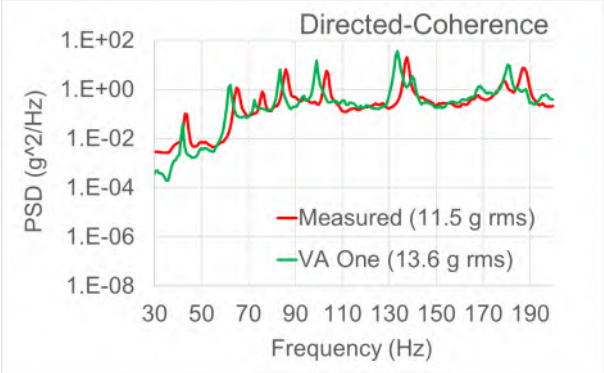

Figure 13: PSDs for Directed-Coherence Case

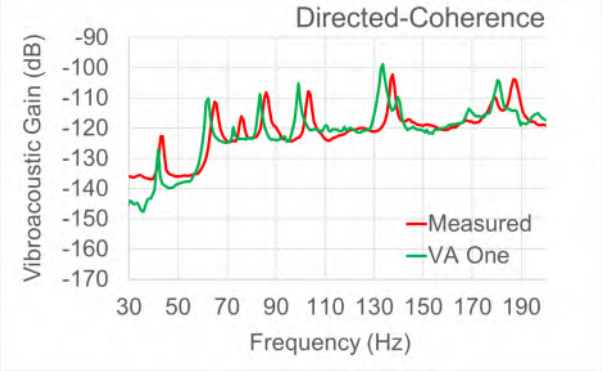

Figure 14: Vibroacoustic Gain for Directed-Coherence Case

3.3. MISO Case

The simulation of the MISO case produced microphone and accelerometer responses that were similar to the measured data, but that differed significantly in some respects. The MISO field was the most different of the three cases and the most atypical for aerospace vibroacoustic testing, so it was expected that the MISO case would exhibit significant differences.

The MISO test used Multiple-Input Single-Output control. The multiple inputs were the 24 control microphones. Their signals were averaged and input to the controller. The controller produced a single drive signal output that was band-passed and used to drive all speakers within a given frequency band. This is the way early DFAT tests were controlled before the transition to the higher-fidelity MIMO rectangular control that was used for the Near-Diffuse and Directed-Coherence cases. The simulation of the MISO case was similar to the simulation of the MIMO cases in that VA One matched the SDM at the 24 control microphones by adjusting the speaker stack outputs.

The drawback to a MISO field for testing is that its symmetry produces large spatial variations in SPL (even if they aren't reflected in the average) and a much less diffuse test field. This was the motivation for transitioning to MIMO control during the early development of DFAT.

Fig. 15 shows that the measured, average SPL spectrum for the MISO case was similar to the reference spectrum. The average spectrum from the simulation was also similar to the reference and measured spectra, but had lower SPLs in the range of 80-120 Hz, and a significant local minimum at 113 Hz. The MISO spectrum did not show the small hump at 90 Hz that was in the Near-Diffuse and Directed-Coherence spectra. As for the Directed-Coherence case, the intent for the MISO case was to maintain the SPL spectrum while changing only the phase and coherence of the field. Fig. 6 shows the measured coherence vs. kr for the MISO case, and in comparison to Fig. 4 and 5, can be seen to differ significantly from the coherence of the other two cases. The differences in the MISO SPL spectra are normalized away by the VAG.

Fig. 16 shows the measured, average PSD for the 20 accelerometers and the average PSD from the VA One simulation. The two spectra differ significantly. Above 60 Hz, the measured curve is lower than the simulation curve, and the actual test essentially did not excite the modes at 62 Hz and 99 Hz (frequencies per the VA One results), which were excited in the simulation. Below 60 Hz, the measured response is significantly higher than the simulation response. This difference is also evident for the other two cases, and again may have been due to instrumentation noise or ambient sound and vibration.

Fig. 17 shows the VAG calculated from both the measured data and the VA One simulation. The VAG spectra exhibit the same differences as the corresponding PSDs. The measured VAG is higher than the simulation values below 60 Hz, similar to the other two cases.

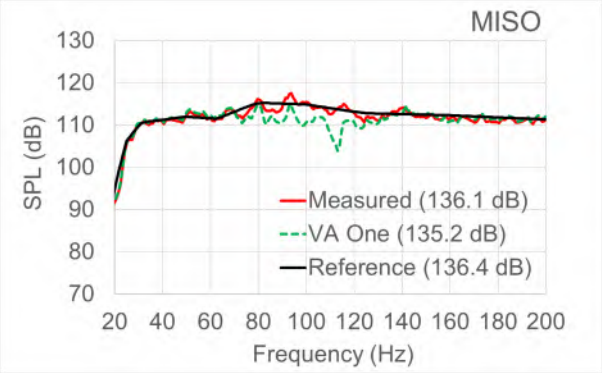

Figure 15: SPL Spectra for MISO Case

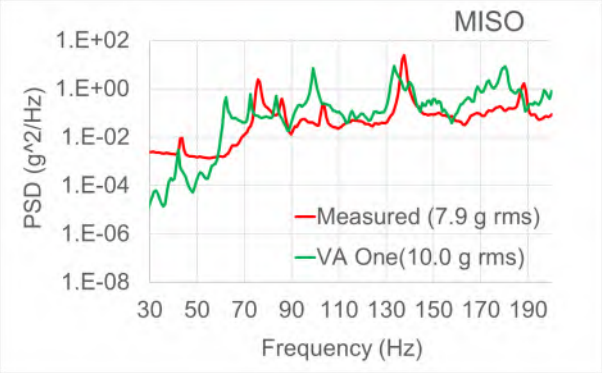

Figure 16: PSDs for MISO Case

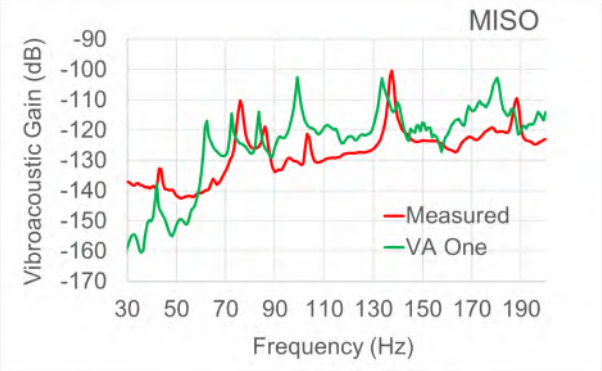

Figure 17: Vibroacoustic Gain for MISO Case

The measured responses for the MISO case were quite different than for the Near-Diffuse and Directed-Coherence cases, as was expected (Fig. 18 and 20). However, the simulation responses for the MISO case were different than the measured responses, which was unexpected (Fig. 16 and 17).

In particular, the simulation did excite the modes at 62 Hz and 99 Hz but the measured field did not. The differences in the measured and simulation SPL spectra shown in Fig. 15 don't really explain this. The model may not have been configured right for the MISO case, or perhaps the 24 control microphones were insufficient to capture some important aspect of the field. The agreement between the measured and simulation data was good for the Near-Diffuse and Directed-Coherence cases, which implies that the fidelity of the basic model is good. We have not drawn any specific conclusion about the differences.

3.4. Comparison of PSDs and Vibroacoustic Gain

Fig. 18 shows the measured acceleration PSDs for the three cases. The curves for the Near-Diffuse and Directed-Coherence cases are essentially identical. There are some differences, but they are small. This similarity was somewhat unexpected, but was repeated in the simulation PSDs shown in Fig. 19. The similarity is probably due to limiting the analysis domain to 200 Hz coupled with the size of the test article, and that the SDMs for the Near-Diffuse and Directed-Coherence cases, while quite different as shown in Fig. 4 and 5, weren't different enough to cause significantly different responses below 200 Hz. The response of a structure to a field is not only a function of the field characteristics (SPL, coherence, and phase), but also a function of the ratio of the size of the structure to the wavelength of the acoustic excitation. Reference 7 by Sutherland has an excellent discussion of this in Chapter 8. Fig. 22 is an example for a baffled, simply-supported beam, and was taken from that reference. Note that at low L/λ, the values of joint acceptance are about the same for both a diffuse field and a progressive wave for a given value of L/λ (particularly for the odd modes). However, these are distinctly different fields. In contrast, at high values of L/λ, the joint acceptances for the diffuse and progressive-wave fields differ significantly. In Fig. 22, λ is equal to the actual acoustic wavelength for a diffuse field, and equal to the trace wavelength across the length of the beam for a progressive wave. Fig. 22 is for a beam, and so is only an example, and does not apply directly to the test panel, except with regard to the overall concept.

If we had extended the domain to a higher frequency, then the acceleration responses for the Near-Diffuse and Directed-Coherence cases would have shown more differences [2,4]. In Fig. 7, the maxima of the PSDs are plotted for those cases, and more significant differences between them are evident at 150-300 Hz.

The measured PSD for the MISO case in Fig. 18 is different than the other two cases, as expected, since the field control and SDM were much different (Fig. 6). Again, the measured MISO field did not excite the mode at 62 Hz and poorly excited other modes. However, for the simulation PSDs in Fig. 19, the curves for all three cases are similar, and excite all the modes to similar levels. This includes the simulation MISO PSD curve, which makes it different than the measured MISO PSD curve.

Fig. 20 and 21 show the vibroacoustic gain for the measured and simulation data respectively. The

relationships between the curves are similar to Fig. 18 and 19.

3.5. Conclusions about Measured vs. Simulation Data

Some conclusions concerning the comparison of the measured and simulation data are listed here.

- The VA One simulations provided results that were good approximations of the measured results. The authors always learn things about the tests from the simulations, and this project was no different.
- The Near-Diffuse and Directed-Coherence responses were quite similar, and this was probably due partly to the frequency domain being limited to 200 Hz, coupled with the panel dimensions. It would not be correct to conclude that all fields excite the test article similarly, and the MISO case shows clearly that this isn't true. Extending the analysis and simulation beyond 200 Hz would show more differences between the Near-Diffuse and Directed-Coherence cases.
- We recommend that ambient sound and vibration be measured and taken into consideration for these types of investigations. Ambient sound at very low frequencies is not audible, so it has to be measured. Also, the simulation assumes a noise floor of zero, which won't be true in practice.
- The measured response for the MISO case was different than for the other two cases even though the measured, average SPL spectra for all three cases were very similar and also similar to the reference spectrum. This reinforces the idea that the test article can show different responses depending on the spatial correlation of the field, even if the SPL spectra are the same. It is not theoretically sufficient to specify only an average SPL spectrum for a test.
- The difference between the measured and simulation responses for the MISO case could indicate that the model was not configured right for the MISO case or that the spatial resolution of the microphones was insufficient, but the specific cause wasn't investigated and warrants further analysis.

ABSTRACT

The structural qualification of solar arrays requires high confidence in numerical predictions under launch environments due to complex fluid-structure interactions in stowed configurations. This paper presents an integrated methodology developed and validated at INVAP's facilities to close the gap between structural modeling and environmental testing.

A detailed finite element model of a carbon fiber/Honeycomb solar array was developed using a two-way vibro-acoustic coupling formulation to account for entrained air mass and radiation damping. Validation involved a sine sweep test to correlate structural modes via modal projection, followed by Direct Field Acoustic Testing (DFAT) simulated as a diffuse acoustic field.

Results show an exceptional match in Power Spectral Density (PSD) levels across the 20-2000 Hz band. This study validates the diffuse field assumption for DFAT and demonstrates how two-way coupling establishes a highly predictive digital twin for spacecraft qualification.

1. INTRODUCTION

Structural qualification during the launch phase represents a critical risk-reduction milestone in spacecraft mission design. Due to high surface-area-to-mass ratios, lightweight appendages like stowed solar arrays (SAs) are particularly vulnerable to high-intensity acoustic excitation and the resulting fluid-structure interactions. While these environments are traditionally simulated in Reverberant Acoustic Test Facilities (RATF) to achieve a uniform sound field, the aerospace industry has increasingly adopted Direct Field Acoustic Testing (DFAT) – or Direct Field Acoustic Noise (DFAN) – as a flexible, cost-effective alternative ([1]). By deploying high-power loudspeaker arrays directly around the flight hardware within a standard test bay, DFAT bypasses the logistical transportation risks and massive infrastructure costs associated with fixed acoustic chambers, ensuring the direct sound field heavily dominates over room reflections ([2]).

A comprehensive literature review compiled by [3] establishes the engineering maturity and remaining challenges inherent to contemporary DFAN frameworks. Modern DFAT methodologies, operating under institutional guidelines like [4] and [5], utilize Multi-Input Multi-Output (MIMO) control strategies to translate narrow or third-octave test specifications into wideband drive commands. However, achieving precise spatial field diffusivity and managing low-frequency modal coupling remain persistent technical difficulties. Because the enclosing loudspeaker stacks physically form an open-topped cylindrical cavity around the test article, they introduce distinct acoustic cavity modes ([2]). In the absence of significant damping, these modes generate severe peaks and nulls in the sound pressure level (SPL) spectrum, leading to spatial non-uniformity and temporal ringing [2]. Reference [3] highlights historical validation campaigns, including the Orion European Service Module, where structural components like the SA wing exhibited severe coupling with acoustic cavity environments and local boundary effects, risking localized over-testing or under-testing.

Addressing these phenomena requires robust numerical predictive tools. The Salford review specifically identifies the Finite Element Method (FEM) and the Boundary Element Method (BEM) as the primary standard industrial approaches for low-frequency vibro-acoustic simulation, alongside advanced cross-spectral density control schemes designed to overcome theoretical diffuse field limitations ([3], [6]).

Despite these advancements in numerical modeling, standard industrial workflows frequently oversimplify fluid-structure coupling by treating the acoustic field as purely uncoupled or ignoring the boundary layer constraints between closely packed structures. This frequently results in either overly conservative design margins or non-conservative physical predictions.

This study addresses these limitations through an integrated numerical and experimental framework developed and executed within INVAP's specialized simulation and testing facilities. By implementing a high-fidelity, two-way coupled vibro-acoustic formulation in NX Siemens software (version 2312), the proposed methodology explicitly accounts for the entrained air mass, radiation damping, and acoustic cavity resonance trapped within stowed panel configurations. This predictive model is sequentially validated against a low-frequency modal sine sweep campaign and a full-scale DFAT

qualification run. The results demonstrate how a predictive "digital twin" can accurately capture complex structural-acoustic responses under high-intensity, diffuse acoustic field assumptions, offering a verifiable path toward reducing safety factors on advanced flight hardware.

The remainder of this paper is organized as follows. Section 2 details the mathematical and numerical formulation of the fully coupled fluid-structure model. Section 3 focuses on the low-frequency mechanical qualification, describing the shaker slip table sine sweep configuration, the structural model tuning, and the custom spatial visualization tool used to track mode shapes. It also analyzes the amplitude-dependent mechanism damping extracted from the final high-level test runs. Section 4 covers the high-frequency acoustic qualification, establishing the analytical frequency limits of the simulation before detailing the physical DFAT setup, its compliance with [4] instrumentation guidelines, and the final g_{RMS} response correlation results. Finally, Section 5 presents the conclusions of this study and outlines directions for future work.

2. NUMERICAL FORMULATION AND BASELINE MODEL

This finite element modeling section can be broken down into different subsections. First, a description of the structural model of the solar array (SA) is addressed. Then, the fluid setup for the vibro-acoustic analysis is discussed, and last but not least, the general assumptions made regarding dynamic settings of the solutions are detailed.

2.1. The Structural Setup

The properties and element types used to model the main components of the SA are summarized in Tab. 1, including the carbon fiber reinforced polymer (CFRP) and aluminum honeycomb sandwich panels, the Restrain Release (RR) towers, the yoke and the hinges. The composite facings are modeled as orthotropic laminates using shell elements, while the aluminum honeycomb core is represented via equivalent core properties to capture out-of-plane shear flexibility. The resulting FE model consists of ~248k elements and ~372k nodes, and is depicted in Fig. 1.

Table 1: Properties and Element type of the main components of the SA

Component	Property	Element Type
Sandwich Structure	2D Laminate Shell	CQUADR
RR towers	Shell	CQUADR
Yoke	Solid/Beam	CTETRA10/Beam
Hinges	Rigid/Spring	RBE2/CBUSH

To represent the launch configuration, the RR towers and the yoke are rigidly constrained (all six degrees of freedom fixed) at their respective base interface to the satellite structure, establishing a fixed-base boundary condition. Furthermore, the mass of the solar cells, wiring harness, and surface components is accounted for by applying a uniformly distributed non-structural mass (NSM) across the facesheet elements, ensuring the model's total mass and center of gravity match the physical properties of the hardware.

A preliminary normal modes analysis (NX Nastran SOL 103) was conducted to extract the baseline structural natural frequencies and effective modal mass in the stowed configuration. Tab. 2 compiles the dominant normal modes that capture more than 5% of the effective modal mass up to 150 Hz. Notably, only three modes fall strictly within the operational sine sweep range (5-100 Hz). However, the first fundamental in-plane mode along the X-direction lies immediately adjacent to the upper frequency boundary, indicating a high probability of structural excitation during physical testing.

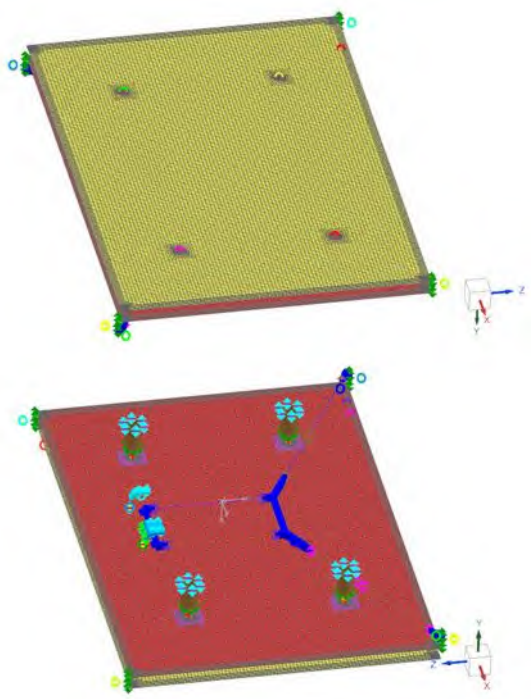

Figure 1: Solar Array's FE model – The Structural Mesh

Table 2: Modes with >5% of associated effective modal mass

2.2. The Fluid Setup

To capture the complex fluid-structure interactions (FSI) driving the SA's vibro-acoustic response, a dedicated acoustic fluid domain was modeled surrounding the stowed panels. The acoustic

environment is simulated as a high-intensity diffuse sound field, reflecting the operational assumptions of the full-scale qualification test. Rather than using multiple nested fluid volumes, a continuous, single acoustic FE mesh was generated. This fluid domain encapsulated the highly confined air cavities trapped between the stowed composite facesheets and extends outward to an external radiation boundary.

To prevent artificial acoustic reflections from the truncation boundary of the FE air volume back to the structure, an Automatically Matched Layer (AML) boundary condition was applied to the outer faces of the fluid domain. The AML formulation dynamically simulates an acoustic free field, allowing radiated acoustic energy to pass through the boundary without reflection, while explicitly capturing the entrained air mass effects and radiation damping within the narrow inter-panel gaps. The fluid elements are populated using standard ambient properties for air, with a nominal density of $\rho_0 = 1.21\ kg/m^3$ and a speed of sound $c_0 = 343\ m/s$.

During the physical qualification campaign, the SA is mounted vertically within the cylindrical loudspeaker array using specialized Mechanical Ground Support Equipment (MGSE) designed and manufactured at INVAP's facilities, replicating its flight-stowed orientation in the satellite structure. To mirror this experimental architecture, the MGSE geometry and its structural interface stiffness were explicitly incorporated into the simulation boundary conditions. Due to its reticulated, frame-like architecture, the MGSE is efficiently discretized using one-dimensional beam elements, which accurately capture the global bending and torsional stiffness of the fixture without introducing unnecessary computational overhead. Concurrently, the MGSE adapter plate – which interfaces directly with the SA and represents the localized stiffness of the satellite body – is modeled using two-dimensional shell elements due to its high surface-area-to-thickness ratio. Fig. 2 depicts the fully integrated FE mesh of the SA mounted onto the hybrid beam-and-shell representation of the MGSE.

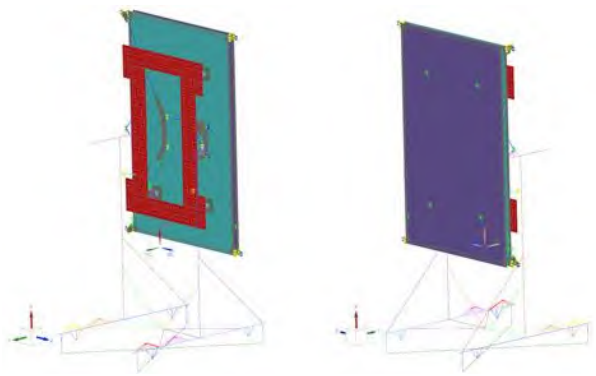

Figure 2: FE model of the SA mounted on the MGSE

The FSI across the wet faces of the composite panels is enforced via a fully coupled, two-way surface-to-surface acoustic coupling card. As illustrated in Fig. 3, the acoustic solid fluid mesh tightly envelopes all structural components characterized by a high surface-area-to-thickness ratio, including both the laminate facesheets and the MGSE adapter plate. Under this bi-directional formulation, the micro-vibrations of the structural panel facesheets generate localized acoustic back-pressure within the fluid mesh, while the pressure waves from the diffuse acoustic field simultaneously act as a surface force driving structural excitation. This localized coupling logic is critical for accurately capturing the radiation damping and entrained air mass effects inside the narrow stowed cavities, which directly govern the low-frequency modal responses of the array during the test.

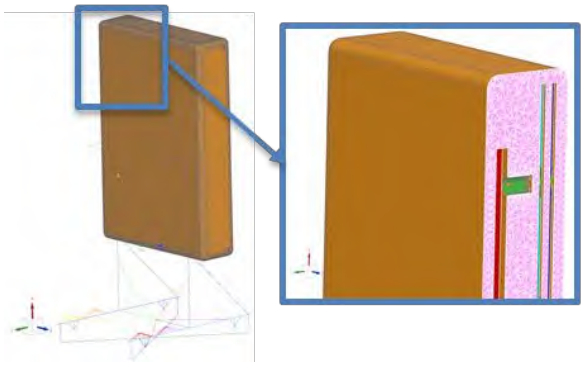

Figure 3: Detail on the acoustic fluid mesh

2.2.1. Coupled Governing Equations

The bi-directional FSI is mathematically discretized at the wetted boundary interfaces. Following the definitive unsymmetrical finite element formulation utilized by NX Nastran, the coupled system of equations governing the combined structural-acoustic domain is expressed in block matrix form as:

$$\begin{bmatrix} M_s & 0 \\ -A^T & M_f \end{bmatrix} \begin{Bmatrix} \ddot{u} \\ \ddot{p} \end{Bmatrix} + \begin{bmatrix} B_s & 0 \\ 0 & B_f \end{bmatrix} \begin{Bmatrix} \dot{u} \\ \dot{p} \end{Bmatrix} + \begin{bmatrix} K_s & A \\ 0 & K_f \end{bmatrix} \begin{Bmatrix} u \\ p \end{Bmatrix} = \begin{Bmatrix} P_s \\ P_f \end{Bmatrix} \quad (1)$$

Where:

- Subscripts s and f represent the structural and fluid partitions of the system, respectively.
- $\{u\}$ is the structural nodal displacement vector, and $\{p\}$ is the fluid nodal acoustic pressure vector.
- $[M_s], [B_s]$, and $[K_s]$ are the structural mass, damping, and stiffness matrices.
- $[M_f], [B_f]$, and $[K_f]$ represent the acoustic fluid compressibility, boundary impedance damping, and mobility stiffness matrices, respectively.
- $\{P_s\}$ and $\{P_f\}$ denote the external structural load and fluid acoustic source vectors, respectively.
- $[A]$ is the fluid-structure coupling (area)

matrix mapping the shared degrees of freedom across the wetted interface.

A key practical advantage of this solver architecture is that the structural and fluid mesh topologies are permitted to be completely non-conformal at the interface. The coupling matrix, $[A]$, is automatically computed via surface-to-surface projection algorithm (governed by the ACMODL bulk data entry). This computes a conservative spatial interpolation that bridges the dissimilar nodal boundaries. Consequently, the cross-coupling term $[A]\{p\}$ projects the fluid pressure fields into localized equivalent face forces on the structural elements, while the structural acceleration coupling term $-[A]^T\{\ddot{u}\}$ enforces complete kinematic continuity by driving pressure fluctuations back into the acoustic mesh domain.

This fully coupled matrix block is solved simultaneously across the frequency range of interest when executing a strong two-way coupling. However, within the modal frequency response framework of NX Nastran (e.g. SOL 111), the solver handles this computation via a multi-stage workflow: the uncoupled normal modes of the structure and the fluid domain are initially extracted separately and sequentially, after which they are projected into modal coordinates to assemble and solve the coupled matrix system. This approach drastically optimizes solver times while capturing true two-way entrained air mass variations and radiation damping effects.

2.3. Dynamic Settings and Solution Assumptions

To validate the analytical predictions against experimental data, two distinct numerical solution paths were configured within the NX Siemens architecture: a low-frequency structural modal response analysis for the sine sweep campaign, and a broadband coupled modal frequency response analysis for the acoustic field simulation.

2.3.1. Structural Sine Sweep Configuration

The structural sine sweep analysis is implemented using an NX Nastran SOL 103 normal modes solution, with the dynamic output subsequently evaluated via the Response Dynamics module to simulate multi-directional base excitation. The frequency sweep is evaluated from 5 Hz up to an upper limit of 250 Hz; extending the solution range well beyond the nominal test band ensures that out-of-band high-frequency modal contributions and residual vectors are fully captured.

The frequency resolution is defined using a hybrid discretization approach: a baseline linear step size of 1 Hz is maintained, supplemented by localized modal clustering (Cluster 2 configuration) that injects 10 additional frequency points between adjacent natural frequencies to precisely resolve sharp resonant peaks. Energy dissipation across the assembly is modeled using a uniform critical damping ratio of $\zeta = 1\%$ across all structural modes.

2.3.2. Vibro-Acoustic Analysis Configuration

The broadband diffuse acoustic simulation is executed via the NX Nastran SOL 111 Modal Frequency Response solver, coupling the structural panel modes with the fluid cavity modes. The operational frequency range spans a broad spectrum from 20 Hz to 2000 Hz. To match standard acoustic data reduction formats while optimizing computational efficiency, the solution frequency steps are discretized using a 1/12-octave band fractional distribution, resulting in a true analytical frequency sweep ranging from 19.4 Hz to 2050 Hz. Consistent with the structural validation path, a critical damping ratio of $\zeta = 1\%$ is applied to the modal basis.

The high-intensity diffuse sound field environment is numerically simulated by applying a Distributed Acoustic Plane Wave load card across the outer boundaries of the fluid domain. This boundary condition models a superposition of randomly oriented, spatially uncorrelated plane waves that uniformly envelop the vertically mounted assembly, as displayed in Fig. 4. This loading strategy ensured an omnidirectional acoustic energy distribution that accurately replicates the diffuse field characteristics generated within the loudspeaker array during physical qualification.

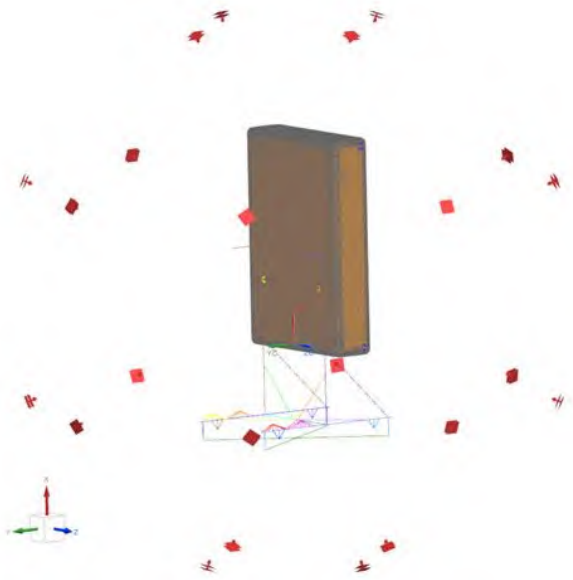

Figure 4: Distributed Acoustic Plane Wave load

3. LOW FREQUENCY QUALIFICATION: THE SINE SWEEP CAMPAIGN

3.1. Experimental Configuration

The physical sine sweep qualification campaign was conducted to verify the structural integrity of the stowed SA and ensure compliance with launcher launch environment requirements. Unlike the vertical layout planned for the acoustic campaign, the SA was mounted directly to the shaker table utilizing only the specialized MGSE adapter plate. This adapter plate was secured flat against the

shaker's slip table for horizontal axes and onto the head expander for vertical testing, bypassing the reticulated frame to establish a direct, rigid interface with the moving armature, as depicted in Figs. 5 and 6.

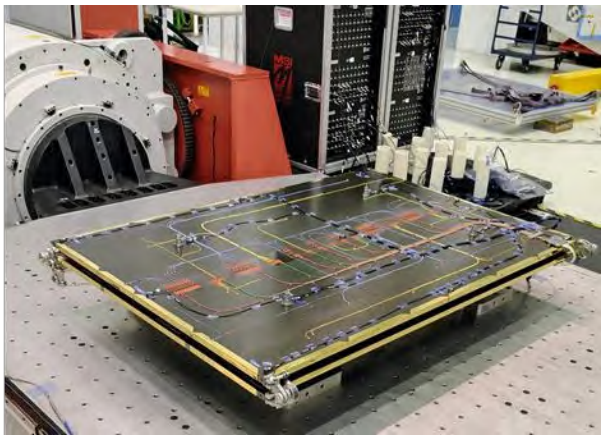

Figure 5: SA mounted onto the shaker's slip table for in-plane Z-direction Sine Sweep Test

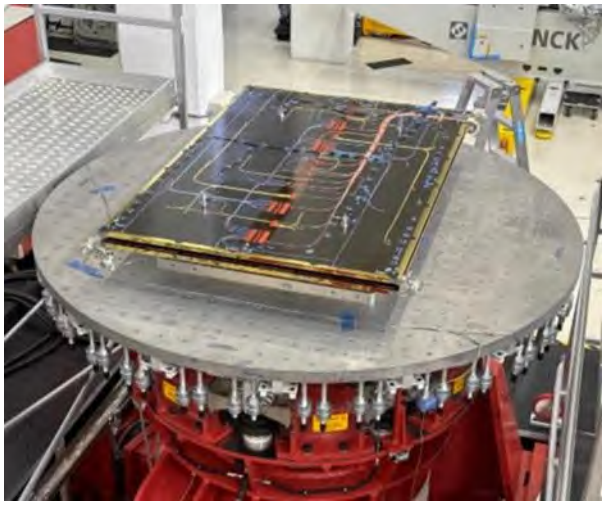

Figure 6: SA mounted onto the head expander for out-of-plane Y-direction Sine Sweep Test

Base-excitation testing was executed sequentially across the three orthogonal axes following a strategic order: first along the in-plane Z-direction, followed by the in-plane X-direction, and concluding with the out-of-plane vertical Y-direction. The horizontal Z-direction was intentionally selected as the initial testing axis because it represents the least responsive axis of the stowed assembly. Starting with this axis allowed the team to isolate and extract a cleaner, less coupled set of initial normal modes, baseline transfer functions, and signature markers before moving to the more highly coupled axes.

To monitor localized dynamic responses, the hardware was instrumented with a dedicated array of triaxial accelerometer affixed to the composite facesheets, the RR towers, and the yoke interfaces. Prior to exposing the flight hardware to full qualification-level loads, a low-level signature sweep (0.1g, 5-250 Hz) was executed at the start of each axis run to experimentally extract the baseline natural frequencies and transfer functions of the undegraded assembly.

Rather than subjecting the flight-critical hardware directly to full qualification-level loads, the excitation profile was increased incrementally through a series of intermediate scaled testing levels. This progressive step-up approach provides two vital technical advantages. First, evaluating intermediate-level telemetry allows the engineering team to closely monitor response trends and proactively characterize structural non-linearities or amplitude-dependent damping behaviors that are fundamentally absent or un-excited during the baseline 0.1g signature sweep. Second, tracking the response scaling across these intermediate stages enables highly accurate, empirical predictions for force-limiting, critical location "notching", and shaker abort thresholds. This ensures that as the input spectrum safely approaches full qualification intensity, the hardware is tightly protected against inadvertent over-testing or destructive resonance peaks.

Crucially, low-level signature sweeps were repeated between each consecutive intermediate and high-level run. These intermediate checks allowed for an immediate, direct comparison of the transfer functions against the baseline signature. A primary criterion for verifying structural health was ensuring that no significant frequency shifts occurred in the peak responses at the main resonant frequencies. Any unexpected downward shift in frequency would serve as an immediate indicator of structural degradation, limit exceedance, or joint slippage, signaling that the test must be halted to prevent hardware damage.

3.2. Model Correlation and Tuning Methodology

To provide an accurate structural baseline for subsequent broadband vibro-acoustic simulations, a systematic model tuning workflow was carried out sequentially based on the initial testing phases. Discrepancies between the initial finite element predictions and the physical test signatures were addressed by focusing on parameters with inherent manufacturing or assembly tolerances.

1. **Mass Profile Refinement**: Prior to the dynamic vibration runs, a physical mass properties test was executed to determine the precise total weight and center of gravity (CoG) of the hardware assembly. The non-structural mass (NSM) distributed across the composite facesheet elements was adjusted to match these measured physical properties, correcting minor mathematical discrepancies in the cable harnesses and adhesive layers.
2. **Pre-load Interface Stiffness Tuning**: Following the completion of the first dynamic run (Z-direction), the experimental transfer functions revealed a slight frequency shift in the primary modes associated with the RR mechanism. To resolve this, the stiffness

values of the CBUSH spring elements located at the top of the RR towers (see Fig. 7) – which model the high-tensile pre-loaded RR bolts – were fine-tuned. Adjusting these localized axial and shear stiffness values successfully captured the true contact compliance and tension state of the flight-release hardware.

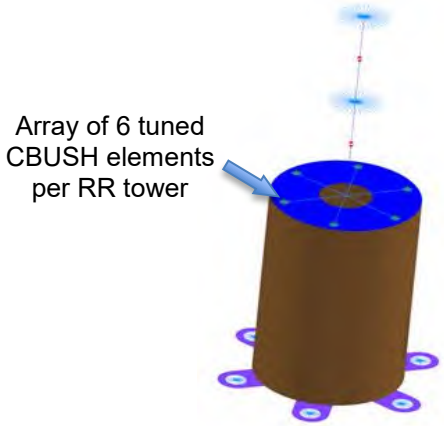

Figure 7: CBUSH elements with tuned stiffness

While these targeted physical updates significantly improved the overall model representation, the highly coupled and dense nature of the spectrum meant that a perfect ±0.5% frequency deviation criteria (see [7]) could not be strictly met for every single secondary or higher-order mode across the wide 5-250 Hz sweep.

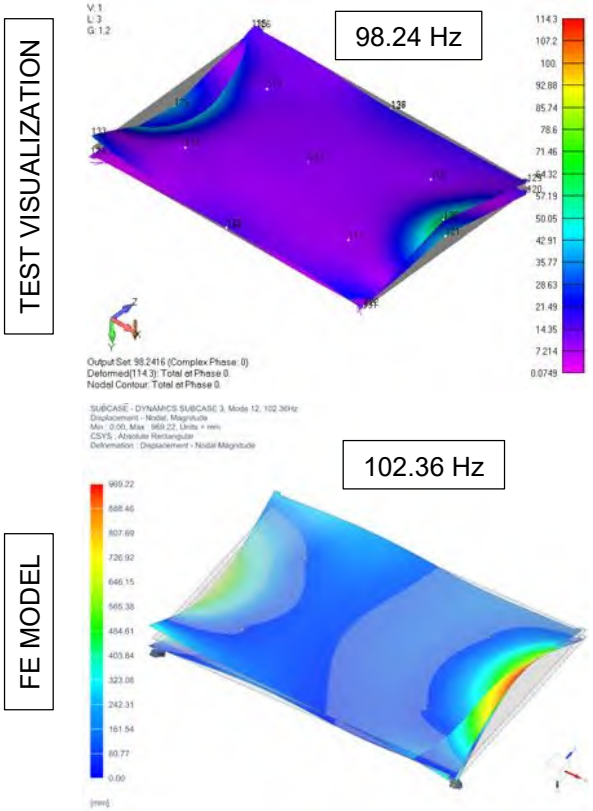

Figure 8: Example of mode shape comparison between FE model and Test visualization – First fundamental mode for Sine Sweep in X direction

To overcome this limitation and ensure complete confidence in the model's predictive capabilities, an advanced, custom mathematical visualization technique was developed. This method directly projected the discrete physical accelerometer frequency response functions (FRFs) captured during the test onto the model's analytical modal eigenvectors. By transforming the experimental response vectors into the analytical mode space, the team achieved a direct spatial comparison of the mode shapes despite the discrepancies in absolute resonant frequencies. As an example, Fig. 8 illustrates a side-by-side comparison of the first fundamental mode shape captured during the X-direction sine sweep, showing excellent correlation between the FE model's prediction and the test visualization. Notably, even when minor frequency shifts occurred, this spatial tracking technique allowed the primary modes to be confidently identified and tracked throughout the remainder of the testing campaign.

This spatial correlation approach definitely proved that the physical modes were structurally tracking the analytical ones. Armed with this rigorous spatial verification, the team was confident that the response limits set to protect the flight hardware were mathematically sound. This allowed the qualification campaign to safely proceed to the high-level sine sweep tests with full validation authority, bypassing the rigid frequency deviation constraint.

3.3. Post-Test Damping Characterization

Because structural damping in complex space mechanisms is inherently amplitude-dependent, a definitive evaluation of energy dissipation could not be established using only the low level 0.1g signature sweep. Instead, the real damping ratios were characterized via post-processing the transmissibility curves obtained directly from the high level qualification runs using the half-power bandwidth method.

Due to high modal density and closely spaced, coupled responses in certain accelerometer channels, clean isolated peaks were not universally present, preventing a global automated extraction. However, localized evaluations revealed significant amplitude–dependent energy dissipation near key deployment mechanisms – such as the hinges and synchronism cables – where local modal damping values reached up to 2.5% around 46 Hz (Fig. 9). In contrast, the clean sandwich panel structure consistently exhibited damping values around or below 1% (see Figs. 10 through 12).

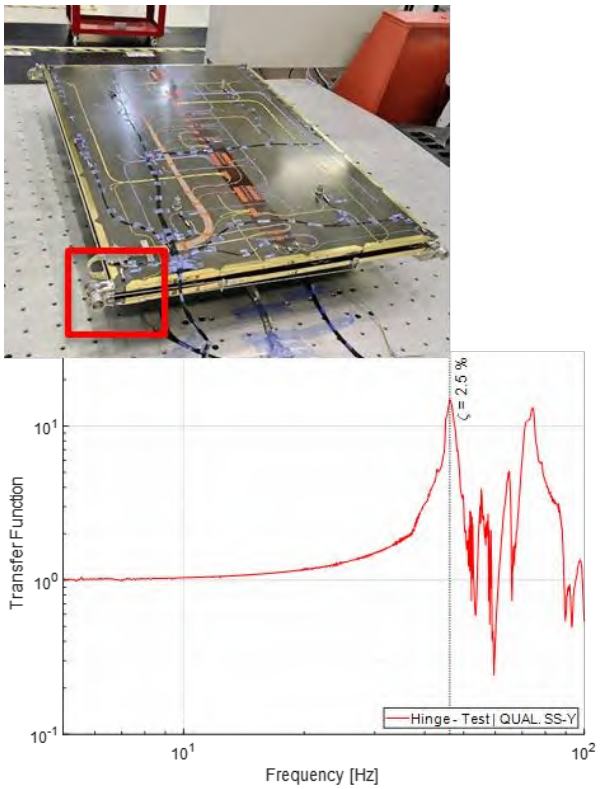

Figure 9: Local Damping @ Hinge | Sine Sweep Y-Direction Qual-level transmissibility

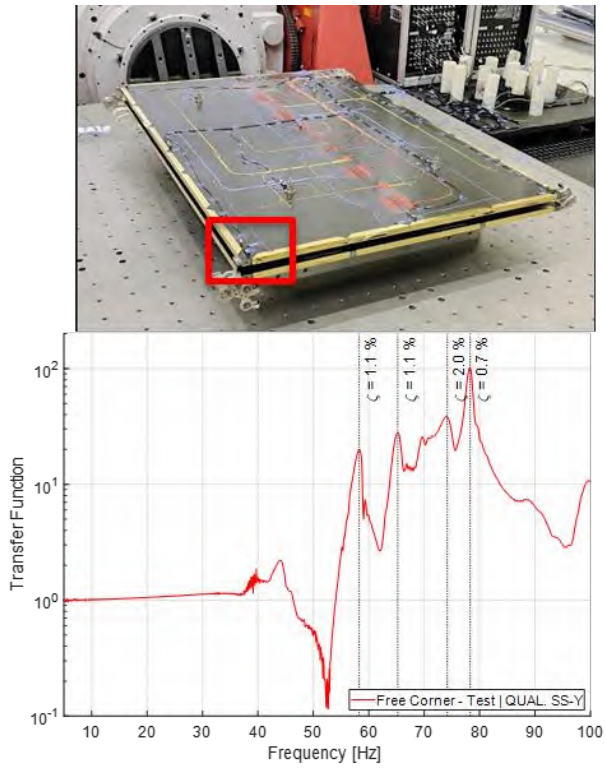

Figure 10: Local Damping @ Free Corner | Sine Sweep Y-Direction Qual-level transmissibility

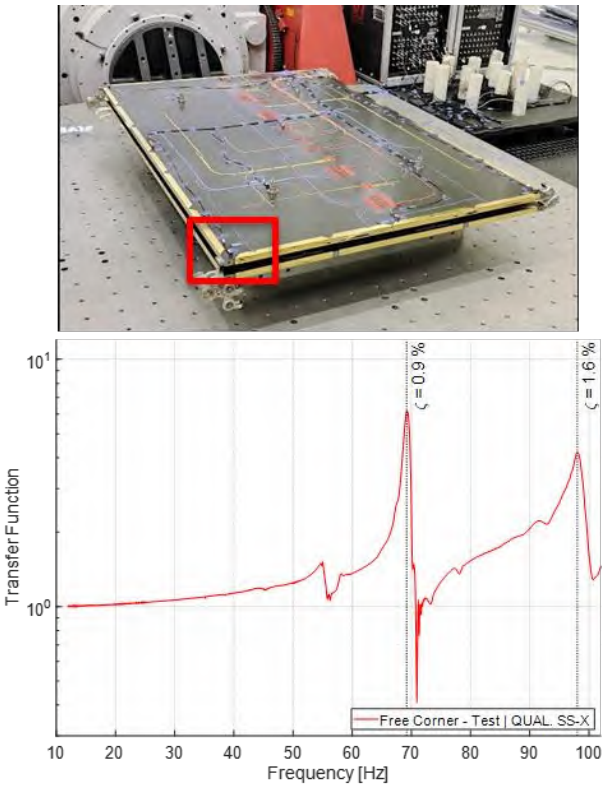

Figure 11: Local Damping @ Free Corner | Sine Sweep X-Direction Qual-level transmissibility

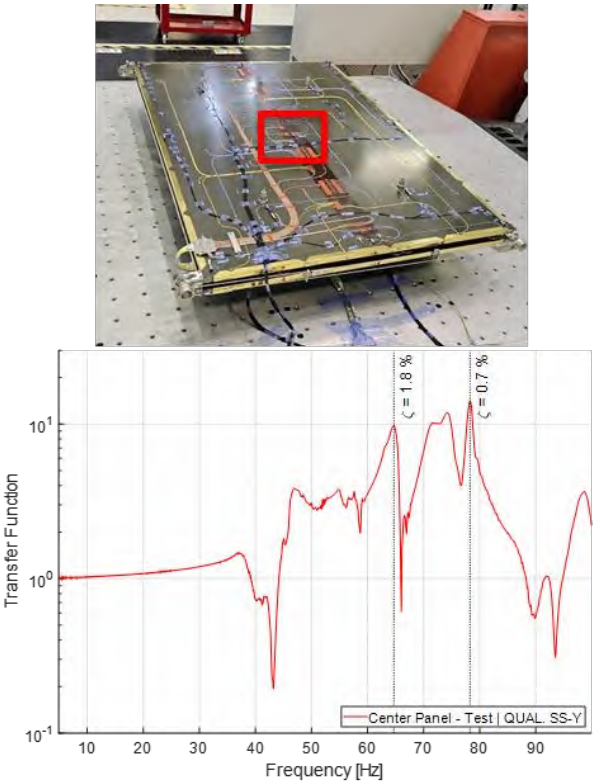

Figure 12: Local Damping @ Center Panel | Sine Sweep Y-Direction Qual-level transmissibility

A post-test cost-efficiency and safety analysis confirmed that implementing a spatially varying, non-uniform damping matrix was computationally expensive and unnecessary for global predictions. Retaining a uniform critical damping value of $\zeta = 1\%$ across the entire frequency spectrum was justified as a safe engineering approach, establishing a reliable, conservative upper bound for the responses at critical mechanism locations.

4. HIGH FREQUENCY QUALIFICATION: THE DFAT CAMPAIGN

4.1. Analytical Scope and Model Limitations

Prior to evaluating the experimental correlation, two fundamental modeling assumptions must be established regarding the scope and kinematic boundaries of the vibro-acoustic simulation.

First, a deliberate constraint was placed on the analytical bandwidth of the fully coupled FE model, capping the simulation spectrum strictly at 2000 Hz despite the physical DFAT campaign capturing telemetry up to 10000 Hz. This truncation is dictated by the fundamental physics of numerical discretization and modal density in deterministic methods. As the excitation frequency exceeds 2000 Hz, the acoustic wavelengths in air contract significantly, requiring an exponentially higher mesh refinement to prevent numerical dispersion errors.

Furthermore, in this high-frequency regime, the modal density of both the thin composite panels and the internal air cavities increases dramatically, making deterministic, phase-retaining predictions (like SOL 111) highly sensitive to microscopic manufacturing variations and physically non-representative. Truncating the numerical model at 2000 Hz captures the entirety of the macroscopic, high-energy global interactions while keeping computational solve times efficient.

Second, because the sandwich panels are mathematically idealized using 2D shell elements, the model lacks a physical thickness profile or cross-sectional surface area along its edges. Consequently, the solver's surface-to-surface projection algorithm cannot apply acoustic pressure forces in the in-plane directions (X and Z). In a pure acoustic simulation, this representation would typically result in a significant under-prediction of in-plane responses.

Thankfully, the low-frequency sine sweep campaign definitely demonstrated that the structural assembly's primary response axis is overwhelmingly dominated by the out-of-plane Y-direction, regardless of the input excitation axis. Because the physical cross-coupling drives almost all critical acoustic energy into out-of-plane panel bending, the 2D shell modeling limitation has a negligible impact on the global accuracy of the qualification predictions.

4.2. Acoustic Test Configuration

To evaluate the structural resistance of the stowed SA against the extreme broadband acoustic loads encountered during the launch phase, a Direct Field Acoustic Testing (DFAT) qualification campaign was performed. Unlike the horizontal slip-table configuration used in the low-frequency sine campaign, the SA was tested in its true vertical, flight-stowed orientation. The assembly was integrated onto the full, specialized MGSE – incorporating both the interface adapter plate and the primary reticulated frame structure – and positioned centrally within a high-power cylindrical loudspeaker array (see Fig. 13).

Figure 13: Vibro-Acoustic Test Setup

Fundamentally, a circular array of acoustic drivers generates a direct acoustic field. However, to closely simulate the diffuse, reverberant sound field characteristic of a launch vehicle fairing, the system was optimized to achieve maximum spatial diffusion and field uniformity around the specimen. The excitation spectrum covered a broadband frequency range running up to 10000 Hz, matching the launcher's most probable environment (MPE) specifications. The testing campaign followed a highly controlled, incremental acoustic loading sequence: beginning with a very low-level acoustic signature run, progressing to a low-level acoustic signature, followed by the flight level and culminating with the qualification level (0 dB). For both the flight and qualification runs, the scaling was applied progressively. This step-up sequence was vital to closely monitor and control microphone convergence – ensuring the closed loop controller established a stable, uniform target Power Spectral Density (PSD) spectrum before exposing the flight hardware to maximum acoustic power.

To monitor and regulate this environment in real time, a specialized control ring comprising 12 independent control microphones was deployed. These microphones were distributed on the ground at varying heights around the perimeter of the SA.

To mitigate localized near-field acoustic anomalies, boundary absorption errors, and speaker acoustic-center reflections, the positioning of the instrumentation strictly adhered to the standardized spatial clearance boundaries recommended in [4]. Specifically, the microphones were placed with a minimum clearance threshold of 0.6 m away from the responsive surfaces of the solar array, and no closer than 0.9 m from the face of the loudspeaker drivers. The drive signals to the acoustic drivers were dynamically regulated via a closed-loop controller utilizing the narrow-band average of this 12-microphone cluster.

4.3. Vibro-Acoustic Response Evaluation & Correlation Results

The predictive accuracy of the fully coupled fluid-structure FE model (SOL 111) was validated by comparing the analytical acceleration PSD responses directly against the experimental accelerometer telemetry. The spatial distribution of these physical accelerometers across the solar structure is illustrated in Fig. 14.

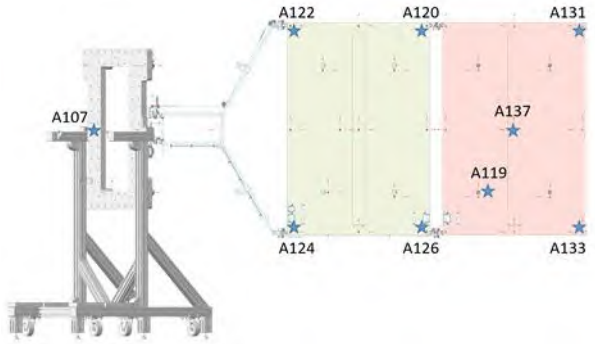

Figure 14: Spatial distribution of accelerometers

Table 3: Structural Acceleration g_{RMS} Correlation (FE model vs. Experimental Test)

Accel ID	Location	FEM	Test	% Error	Test - Capped	% Error - Capped
A107X	Adapter Plate	0,5603	0,7217	28,81%	0,5825	3,96%

A126Z		7,7082	10,0651	30,58%	7,9317	2,90%
A137X	Center Outer Panel	3,4215	6,3621	85,94%	5,4043	57,95%
A137Y		25,8886	33,3349	28,76%	32,293	24,74%
A137Z		3,7038	6,7951	83,46%	5,5678	50,33%
A122X	Hinge - Panel&Yoke	7,0207	7,1581	1,96%	6,7987	3,16%
A122Y		18,8102	19,2701	2,44%	19,155	1,84%
A122Z		8,7508	8,3747	4,30%	7,3438	16,08%
A124X	Hinge - Panel&Yoke (Sync. Cables)	6,9497	6,6784	3,90%	6,3817	8,17%
A124Y		19,4256	15,4833	20,29%	14,335	26,21%
A124Z		7,9518	7,6395	3,93%	7,3438	7,65%
A133X	Free Corner (Sync. Cables)	7,6067	10,9964	44,56%	10,568	38,93%
A133Y		21,05	16,9805	19,33%	15,924	24,35%
A133Z		8,357	10,1134	21,02%	9,4412	12,97%
A120X	Hinge	8,396	9,8585	17,42%	9,2587	10,28%
A120Y		20,3083	19,4906	4,03%	19,051	6,19%
A120Z		7,5379	10,8224	43,57%	9,5938	27,27%

The evaluation utilizes overall root-mean-square acceleration (g_{RMS}) values, assessing both the full physical test spectrum and the strictly capped analytical bandwidth (20-2000 Hz) across all three orthogonal directions. Tab. 3 outlines the complete correlation dataset. Notably, highlighting green indicates a highly successful structural correlation within standard engineering limits.

4.3.1. Direct Load Path & Out-of-Plane Validation

Analysis of the complete dataset strongly validates the mathematical foundations and boundary conditions established in the modeling phase. Specifically, the model exhibits high predictive capability along the primary structural load path of the assembly.

As shown in the layout in Fig. 14, accelerometer A119 is physically positioned on the outer sandwich facesheet in the immediate vicinity of a RR bolt, representing the direct load path from the satellite interface adapter plate into the SA's structural panels. In this highly critical region, once high-frequency noise is capped to the model's analytical limit, the correlation is exceptionally tight: 1.57% error in X and 3.25% error in Y. This provides strong empirical validation of the localized joint stiffness tuning detailed in Section 3.2.

Furthermore, the primary out-of-plane response (Y-axis) shows excellent global correlation in standard structural zones. The unconstrained free corner (A131Y) tracks with a near-perfect 0.11% capped error, while the structural panel-to-yoke hinge (A122Y) matches within 1.84%. These results demonstrate that the numerical formulation captures the global bending modes of the panels with high fidelity.

4.3.2. Physics-Based Analysis of Divergence Trends

Where the numerical and experimental results diverge, the variations can be attributed to three well-defined physical behaviors:

- **Z-Axis Cylindrical Boundary Variations**: The Z-axis corresponds to the vertical, axial axis of the cylindrical loudspeaker array. In a physical DFAT setup, the cylinder's open top and bottom boundaries naturally prevent the acoustic field from achieving perfect, uniform spatial diffusivity along the axial direction. This boundary leakage introduces real-world axial pressure variations that an idealized, perfectly diffuse-field model cannot reproduce, explaining the higher Z-axis correlation discrepancies (such as A107Z and A137Z), even though the absolute response magnitudes remain relatively low compared to the dominant bending axis.
- **In-Plane Shell Truncation**: Because the sandwich panels are modeled using 2D shell elements, the FE model lacks the true physical cross-sectional edge area required to capture in-plane (X and Z axis) shear and compression

wave pressures. However, because the structural assembly's response is overwhelmingly dominated by out-of-plane bending (with Y-axis acceleration magnitudes reaching up to 300% higher than the orthogonal in-plane axes), these in-plane deviations have no detrimental impact on the global structural verification.

- **Localized Cable Energy Dissipation**: The FE model systematically over-predicts out-of-plane (Y) responses in zones with synchronization cables (e.g., A124Y at 26.21% and A126Y at 37.94%). Under intense acoustic excitation, the synchronization cables act as localized, highly non-linear damping mechanisms through friction and cable-guide sliding. Because the simulation employs a globally uniform, conservative 1% damping ratio, it safely over-predicts these localized peak responses, maintaining a reliable safety envelope for the flight hardware.

4.3.3. Spectral Density Alignment and Modal Trends

While integrated g_{RMS} scalar values in Tab. 3 provide a useful macroscopic validation metric, evaluating spectral distribution across the frequency domain is vital to proving the model's physical fidelity. To this end, Figs. 15 and 16 compare the analytical and experimental acceleration PSD curves for two distinct structural zones representing the extreme bounds of the correlation envelope.

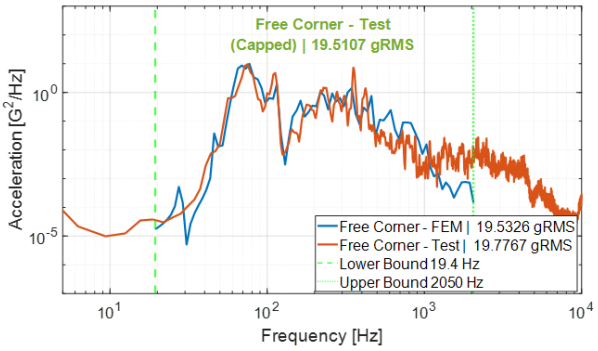

Figure 15: Acceleration PSD comparison at the Free Corner – A131Y

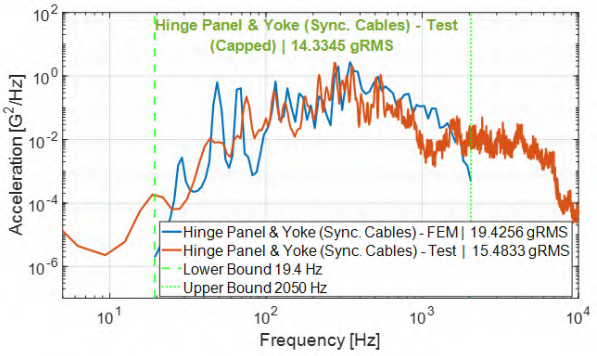

Figure 16: Acceleration PSD comparison at the Hinge with Sync. Cables – A124Y

Fig. 15 illustrates the out-of-plane (Y-direction) response at the unconstrained free corner (A131Y). The spectral alignment is exceptionally tight, with the primary global structural mode near 75 Hz matching perfectly in both frequency and peak amplitude. Throughout the mid-frequency band up to the 2000 Hz analytical threshold, the FE model faithfully tracks the physical modal density, validating the distribution mass and stiffness. The plot also visually justifies the high-frequency capping strategy: beyond the vertical green boundary marker (2050 Hz), the physical hardware's response is dominated by high-frequency, low-energy residual modes that do not significantly contribute to the global g_{RMS} area.

Fig. 16 displays the PSD comparison at the panel-to-yoke hinge near the synchronization cables (A124Y). Despite the 26.21% numerical over-prediction in total g_{RMS}, the structural tendencies of the curves are remarkably similar. The FE model accurately captures the distribution of resonances and anti-resonances across the entire three-decade logarithmic scale. However, the visual comparison reveals that the analytical resonant peaks (blue curve) are systematically narrower and taller than the corresponding experimental peaks (orange curve). This behaviour provides direct, visual proof of the local damping mismatch theorized in Section 4.3.2. Because the global model utilizes a conservative 1% damping ratio, it under-predicts the localized dissipative effects of the synchronization cables, resulting in higher simulated peaks while still preserving the correct physical modal behaviour of the assembly.

5. CONCLUSIONS AND FUTURE WORK

5.1. Summary of Achievements

This paper presented a comprehensive, sequentially validated structural and vibro-acoustic qualification framework for a flight stowed solar array assembly. By bridging the gap between deterministic FE analysis and experimental boundary realities, the study demonstrated a highly reliable methodology for protecting flight hardware under severe launcher environments.

The primary contributions drawn from this engineering campaign include:

- **Advanced Spatial Correlation**: The development of a custom visualization technique – which directly projected experimental frequency response functions onto analytical modal eigenvectors – successfully bypassed the rigid limitations of traditional absolute frequency deviation metrics. This spatial mapping proved that physical mode shapes closely tracked the analytical predictions, providing the mathematical justification needed to safely execute high-level sweeps with total confidence in the hardware's safety margins.
- **Effective Data-Driven Assumptions**: Post-

test characterization using the half-power bandwidth method on high-level transmissibilities isolated localized, amplitude-dependent mechanism damping reaching up to 2.5% near the hinges and synchronism cables. Applying a conservative, uniform 1% critical damping value across the global model proved to be a highly efficient, computationally cost-effective engineering approach, yielding excellent predictive accuracy while maintaining safe, conservative upper-bound envelopes in highly damped mechanism zones.

- **High-Fidelity Multi-Axis Validation**: The fully coupled fluid-structure model utilizing a non-conformal fluid mesh achieved exceptional alignment with physical Direct Field Acoustic Testing (DFAT) telemetry across multiple monitoring zones. Within the modeled 20-2000 Hz bandwidth, the primary out-of-plane response (Y-axis) at the free corner of the panel correlated with a near-perfect 0.11% error. Furthermore, the model exhibited high predictive capability along the direct structural load path near the RR interfaces, capturing the experimental response within 1.57% in the X-axis and 3.25% in the Y-axis.
- **Characterization of Boundary and Kinematic Mismatches**: Expanding the dataset to all three orthogonal axes successfully isolated and justified localized modeling discrepancies. The higher errors observed along the in-plane axes (X and Z) were physically matched to the 2D shell element modeling assumptions, while the localized over-predictions near the hinges (up to 37.94%) were directly mapped to energy dissipation from the physical synchronization cables. Additionally, the Z-axis correlation trends highlighted the real-world pressure variations introduced by the open boundaries of the cylindrical loudspeaker array, which are omitted by idealized diffuse-field assumptions.

5.2. Future Work

While the deterministic FE approach proved highly accurate for the low-to-mid frequency regimes, extensions of this work will focus on addressing the high-frequency boundaries beyond 2000 Hz. Future research will explore the integration of Statistical Energy Analysis (SEA) or hybrid FE-SEA methods to capture the high-density, localized acoustic response spectrum up to 10000 Hz without inducing expensive computational costs. Additionally, further investigations will be directed toward explicitly modeling non-conformal, amplitude dependent mechanism damping and localized non-linear boundary conditions directly within the frequency domain to adaptively update joint properties as acoustic loading levels increase.

Spacecraft Testing, Vibration Control, Environmental Testing, Virtual Shaker Testing.

ABSTRACT

Vibration control tests are used to verify that a spacecraft and its sub-systems can withstand the specified launch vibration environment. Because these campaigns are executed under severe schedule constraints and involve high-value hardware, early, reliable and risk-free predictions of test responses are essential. A Digital Twin of the complete test set-up (spacecraft, shaker, and controller) can be used to replicate the physical campaign in a virtual environment for test de-risking. This approach - known in the dynamic environmental testing community as Virtual Shaker Testing (VST) - is particularly important when transient phenomena should be captured. One typical example is a sine control of a full spacecraft, where accurate simulation of primary and secondary notch behavior can support both notch definition and the optimal tuning of the controller parameters.

This paper proposes a new VST workflow that completely changes the traditional paradigm of Virtual Shaker Testing. Rather than building a simulation of the test, we propose a workflow that allows to test a simulation.

Test engineers first identify an onsite, executable Digital Twin (xDT) of the excited system and then use this stable model to generate high-fidelity VST predictions. The methodology is demonstrated on a full-scale industrial case study, where the proposed framework accurately predicts notch levels during a sine test of a spacecraft-representative mass model.

Finally, preliminary results indicates that the approach can be coupled with Frequency Based Substructuring to predict key test outcomes much earlier in the spacecraft development cycle.

1. INTRODUCTION AND OBJECTIVES

Environmental testing in spacecraft (S/C) engineering is critical to demonstrate and verify the global integrity of the designed structure, to screen the flight hardware for workmanship errors, and to validate mathematical models. In particular, vibration control (VibCo) testing is a mandatory part in the S/C development process to qualify the mechanical designed structure for launch as defined in several handbooks and standards by the National Aeronautics Space Agency (NASA) [1] and European Space Agency (ESA) [2].

During VibCo tests, dynamic coupling between the test specimen, the vibration testing facility, and the vibration controller can critically affect test outcomes [3,4], particularly in the presence of transient phenomena. The shaker (including amplifier), the Device Under Test (DUT), and any additional equipment such as fixtures and force measurement devices (FMDs) cannot be treated as independent systems; instead, the coupled dynamic ensemble must be accurately represented. To better assess control deviations and beating effects at structural resonances [5-8], Virtual Shaker Testing (VST) approaches have been developed to numerically simulate the entire closed-loop test environment [8-10].

Previous VST implementations have relied on detailed finite element models [7-8] or experimental data-driven approaches [9-12]. However, these often require deep simulation and testing expertise, which can generate challenges in translating information from one domain to the other. Moreover, they also require extensive data sharing among manufacturers, which can pose confidentiality challenges and impede industrial application. Despite its clear advantages, the widespread implementation of VST is often hindered by high computational costs and the lack of transparent, accessible mathematical models shared between spacecraft manufacturers and testing facilities.

2. REAL-TIME VIRTUAL SHAKER TESTING

To address these challenges and bridge the gap between test engineers and simulation specialists, this work presents a real-time VST framework where the physical twin (amplifier + shaker + DUT) is replaced by an executable digital twin (xDT) [13-

14], as illustrated in Figure 1.

There are three main actors in a real-time VST setup:

1. A vibration controller (e.g. Siemens Simcenter SCADAS and Testlab) for spacecraft qualification testing. This shall be the same system used during the physical shaker tests.
2. A real-time platform (e.g. Simcenter Testlab RT) connected to analogue input-output (I/O) modules via EtherCAT, where the virtual replica of the system can run in real-time.
3. A discrete state-space model of the coupled shaker-DUT system, exported as a Functional Mock-up Unit (FMU), capable of running in real-time with the required numerical stability.

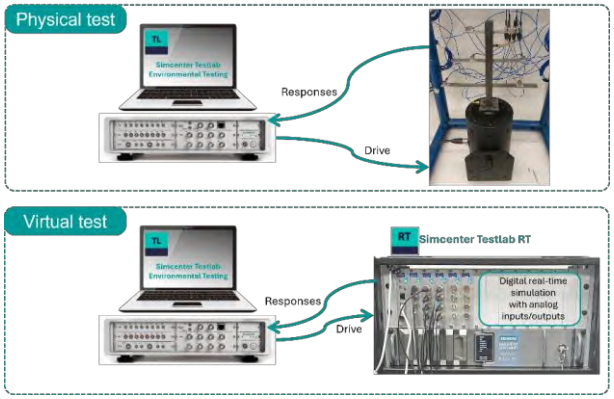

Figure 1 - Physical shaker test and real time Virtual Shaker Test

In the proposed approach, the vibration controller interfaces with the digital twin running on a real-time platform instead of the physical shaker facility and sensors. The output signal from the controller, which would normally drive the shaker amplifier, is then connected to the analogue input of the real-time platform. Similarly, the simulated sensor responses are fed back from the analogue output to the SCADAS input channels, in the same way a physical sensor is connected during the physical test. This approach enables the controller to drive a virtual replica of the test in real-time, accurately predicting transient responses and enabling optimization of control parameters.

There are two primary use-cases for the VST:

1. *Onsite derisking:* using stable experimental data driven model derived from System Identification to tune the controller settings and predict notches, including potential overshoots. This use-case requires the physical system in its final test configuration.
2. *Offsite derisking and test-informed design*: using hybrid or fully virtual multi-physics models to address test performances of a system early in the development cycle. The goal is still to allow test-engineers to run their vibration controller as they would do with the physical system.

This approach has been introduced and validated by Siemens and Thales Alenia Space Italy (TAS-I). Preliminary results were presented in previous works on small scale models the onsite derisking use-case, e.g. [15] and [16].

The idea of this paper is to demonstrate that the real-time VST can be used to predict sine control test results with a full-scale system. The data for the validation were provided by TAS-I.

3. REAL TIME VIRTUAL SHAKER TESTING PREDICTION FOR ONSITE DERISKING

The main goal of this work is to predict control, notch and measure responses of a sine control run performed on the LDS V994 shaker of TAS-I (Rome Tiburtina).

The different steps for the real time VST are reported in Figure 2 for the onsite derisking use-case.

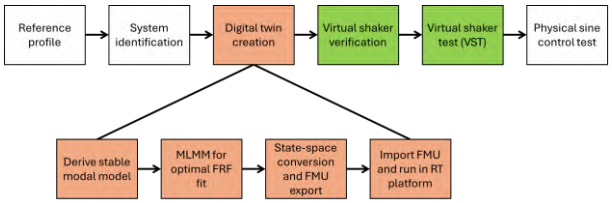

Figure 2 - Schematic of a sine control test workflow including the VST steps in orange and green.

TAS-I provided several runs performed for the characterization and the acceptance of their facility in longitudinal test configuration with a slip table. The runs and the System Identification data are here adopted to validate the onsite derisking use-case for the real-time VST.

In this exercise, the physical sine control tests were performed before the real-time VST predictions. This of course does not hinder the validation of the approach since the sine control settings could also be loaded to define the VST setup from the physical setup.

3.1. Physical Test setup

The physical test setup is shown in Figure 3. Figure 4 (top view) provides a visual representation of the location of the 4 pilots (P1, P2, P3 and P4). The excitation axis is the longitudinal axis X.

Figure 3 – LDS V994 shaker at Thales Alenia Space in Rome (via Tiburtina) and test setup adopted for the validation.

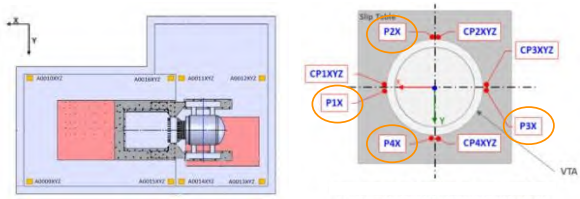

Figure 4 – Top view of the test setup. Slip table instrumented with 4 pilots (circled in orange).

The Device Under Test (DUT) is shown in Figure 3 and illustrated in Figure 5. It is an assembly of a conical structure and a cylindrical mass designed to replicate the mass and the modal properties of Sentinel-type spacecrafts.
The total mass of the device is 2390 Kg and its CoG is located at approximately 1.615 m from its base. The structure is axial-symmetric and attached to the shaker via a payload adapter.

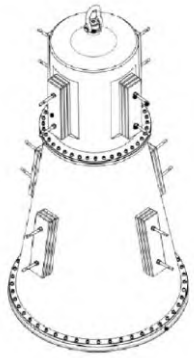

Figure 5 - Conical structure and a cylindrical mass designed to replicate the mass and the modal properties of Sentinel type spacecrafts.

The DUT was also instrumented with different accelerometers. The 4 locations illustrated in Figure 6 were identified as of interest by the experts of TAS-I. The sensors A10, A11 and A12 were connected on the cone in proximity of the attachment flanges. The sensor A14 is located on top of the cylindrical mass.

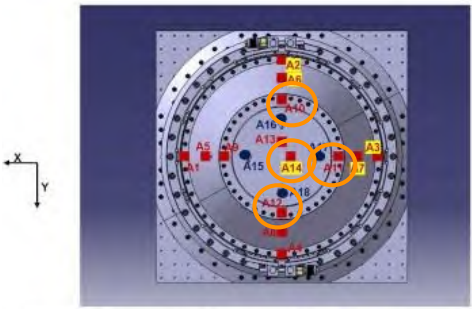

Figure 6 – instrumentation of the DUT (the sensors used for the validation are circled in orange).

As mentioned, different tests were recorded during the characterization, and the acceptance of the facility. Some of these runs were also replicated virtually. We will focus on a complete case of a longitudinal run with an activated notch to show the capability of the VST to also predict notch overshoots. The Sine Control setup for this run is illustrated in Figure 7. The main settings are also reported here below for completeness

- Sweep Mode: logarithmic
- Sweep Rate: 4 Oct/min
- Compression Factor = 4
- Control estimator: harmonic
- Control strategy: maximum

A flat 1.8 g notch profile was applied to the response channel A14:+X. The definition of the limit followed the application of an acceleration method that translates the interfaces force and moment to accelerations of the DUT. The notch profile is reported in Figure 8.

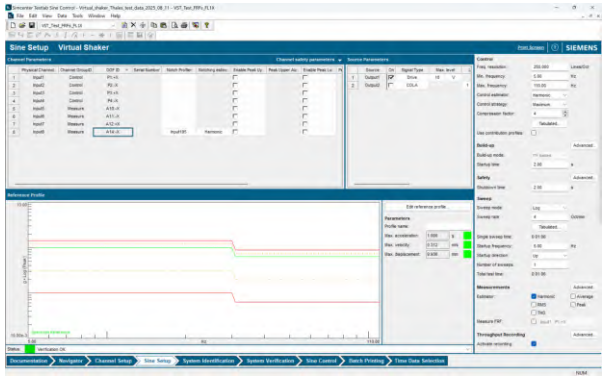

Figure 7 – Sine control setup

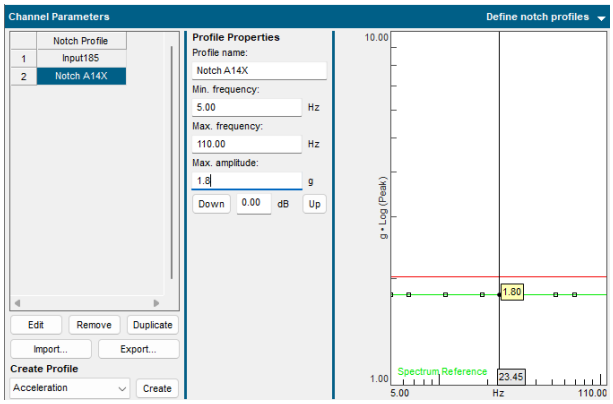

Figure 8 - Notch Profile applied on A14:+X

3.2. Virtual Shaker Test setup

Figure 9 shows the real-time VST system at the TAS-I facility in Rome Tiburtina.

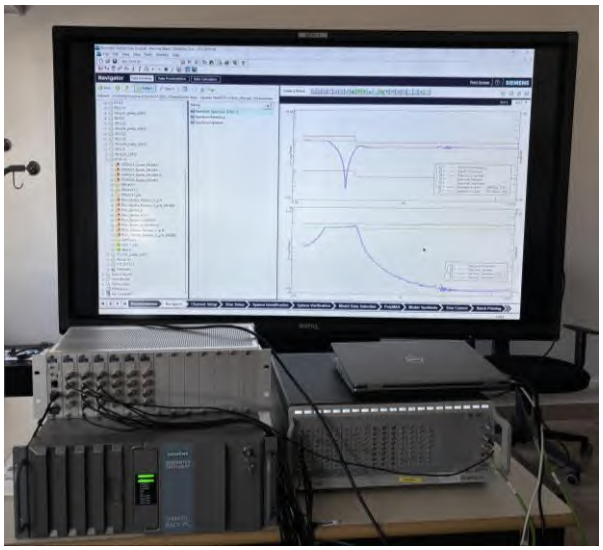

Figure 9 - Virtual Shaker Test setup in Thales Alenia Space Italy (Rome, via Tiburtina).

In this configuration, the vibration controller (Simcenter SCADAS and Testlab) is connected to the analog inputs and outputs slave devices that are connected via EtherCAT to the Simcenter Testlab RT Simatic IPC master device. Simcenter Testlab RT will execute a real time model derived from the physical test setup. When starting a test from Simcenter Testlab, the inputs and outputs of this model will be the drive voltage and the responses coming-from/going-to the Simcenter SCADAS.

3.3. Derivation of the executable digital twin

The main difference between the onsite and the offsite derisking use-cases is the origin of the model that is executed in real-time.

For the onsite derisking use-case, System FRFs obtained from a low-level System Identification runs (SI) can be used to derive the executable digital twin of the entire system under test as a state space model.

The algorithm developed in [9] and [10] can be used to derive a stable model directly from the System FRFs measured during System Identification.

- The Polymax algorithm is executed on the System FRF to synthetize a modal model. This step guarantees a stable system.
- The modal model obtained by Polymax is then modified into a maximum likelihood modal model (MLMM) [17]. This step is critical, because it optimizes the match between the System FRFs and the FRFs synthetized from the modal model and preserves its stability.
- The synthesized optimal stable model can then be converted to a discrete-time state-space model with a specified sampling frequency.

Figure 10 shows the results of applying this approach to the recorded SI data.

The results of the modal synthesis (green) and the derived state-space model (in blue) are shown in Figure 10 for the pilots, but comparable results can be obtained for the measure.

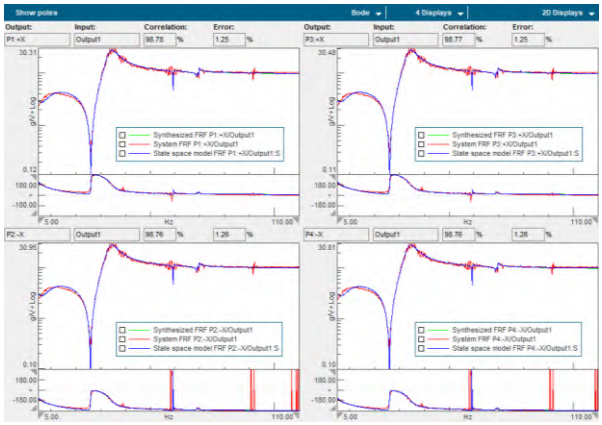

Figure 10 – State Space model (in blue) obtained from synthetized FRFs (green) fitting a stable modal model. In red measured FRF.

The state space model can then be exported as an fmu, uploaded in Simcenter Testlab RT (Figure 11) and executed in real time in the Siemens Simatic

IPC.

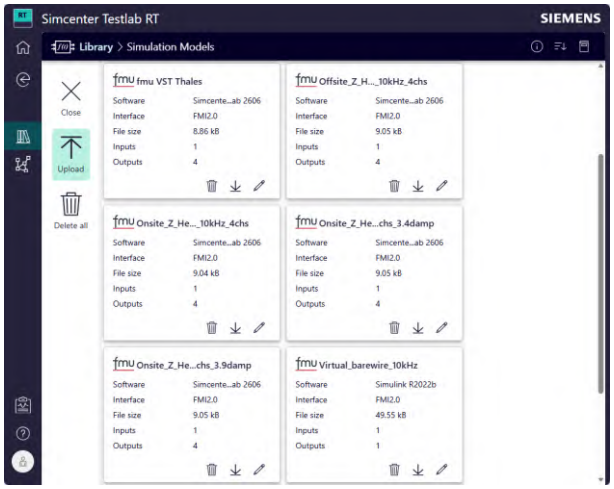

Figure 11 – the state space model can be uploaded and executed in real time in Simcenter Testlab RT

The setup can now be used to run tests virtually, optimize control settings and evaluate the effects on the test results, without exciting the spacecraft and adopting the same control hardware and software that are used during the physical tests.

3.4. Test Results

To validate the workflow, the settings of the virtual test described were loaded directly from the physical Sine Control run (see section 2.1). It is worth remembering that this is the inverse of what would be done during real test preparation, because the physical runs were chronologically executed earlier.

As a verification step of the VST setup, it is preferable to run a system identification on the virtual system. This is done to check that the test engineer has correctly defined the real-time settings, uploaded the right model and/or correctly mapped the sensors in the channel setup of the virtual test. These checks can be done by comparing the virtual System FRF from SI to the physical one. Figures 12 and 13 show the comparison between the System Identification results of the physical (magenta) and the virtual (blue) test. The figures show that the System FRF are matching accurately over the entire frequency range for the pilot and the measure channels.

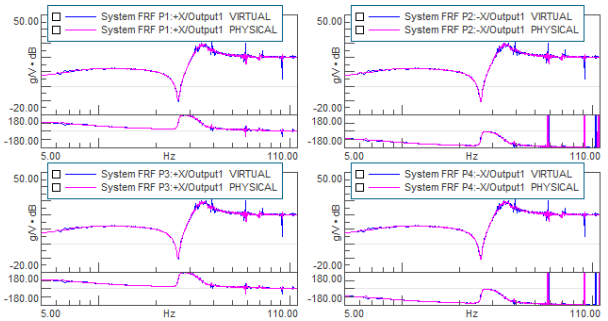

Figure 12 – Pilots system FRFs. Comparison between the SI on the physical (magenta) and virtual (blue) model.

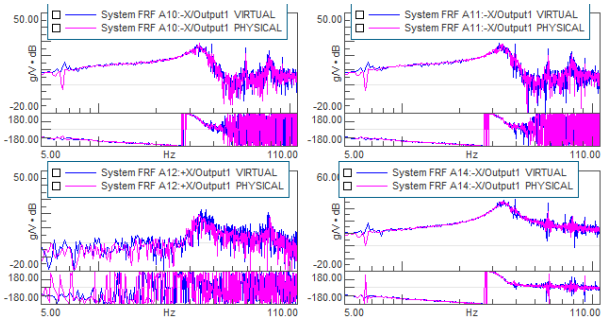

Figure 13 - Measure channels system FRFs. Comparison between the SI on the physical (magenta) and virtual (blue) model.

The comparison of the virtual (blue curves) versus the physical (magenta curves) sine control tests are finally shown in Figure 14, 15, 16 and 17. The results show that the VST can accurately predict the behavior of the physical test within the entire frequency range of interest. Transient phenomena that are characteristic of sine control runs, and that also depend on the control settings, are also well captured by the VST. Figure 17 shows for example how the proposed approach can capture notch overshoots. If needed, this overshoot could be mitigated with a local modification of the compression factor or ultimately a local negotiation on the sweep rate. Experimenting such changes would traditionally require at least a low-level sine test. The spacecraft will be subjected to the sine excitation, and the operators will be left with the uncertainty of what will happen at full level when sweeping through a local or global resonance and triggering a notch. The proposed VST approach provides the extra possibility of experimenting on a simulation model considering the transient nature of the test and the sensitivity to the control parameters.

4. HYBRID COUPLING FOR THE OFFSITE DE-RISKING USE-CASE

The present work focuses on a validation of the onsite derisking use-case. Validation of the off-site de-risking with the described full-scale setup is unfortunately still ongoing at the time of this publication.

Also in this case, the approach that is being developed tries to take a significant step forward compared with traditional methods. The idea is to perform off-site derisking adopting the real-time VST in combination with hybrid models, as shown in Figure 18**Error! Reference source not found.**.

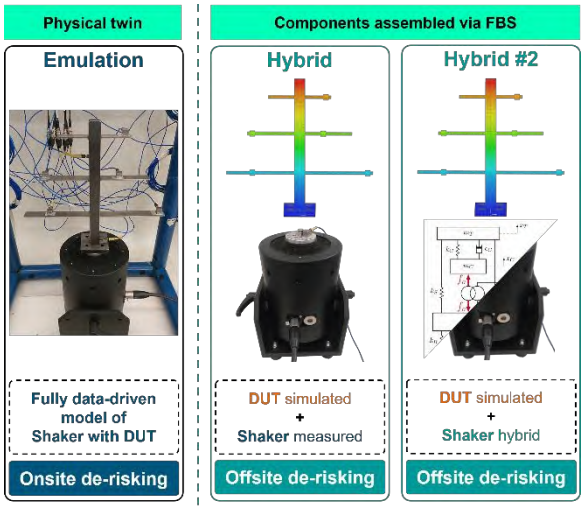

Figure 18 - Build a digital twin starting from a physical twin or a hybrid assembly of components.

Instead of requiring the physical assembly for system identification, the method developed combines:

- Experimental characterization of the shaker facility using multi-axis FRF measurements and Virtual Point Transformation (VPT) to extract complete 6-DoF dynamics.
- Numerical models of the head expander and DUT from Finite Element Analysis (FEA).
- Frequency-Based Substructuring (FBS) to couple these models in the frequency domain [18].

This approach offers several critical advantages:

- early-stage test predictions: virtual tests can be performed before the physical DUT is available, enabling test-informed design decisions during the spacecraft development process.
- Intellectual property preservation: only interface FRFs need to be shared between manufacturers and test facilities, not complete FE models, addressing confidentiality concerns.
- Ease of use and accessibility: the FBS-based workflow enables rapid assembly of FRFs from various sources without requiring deep expertise in both simulation and testing domains.
- Multi-DoF accuracy: the systematic application of VPT captures 6-DoF dynamics including rocking modes, essential for off-

centered or asymmetric spacecraft configurations that are common in practice.

The proposed method and the results on the small-scale setup shown in Figure 18 were recently published in [19] and are hereby reported for completeness.

The virtual tests for offsite derisking were performed on a hybrid system: experimentally measured shaker (force rating: 300 N) coupled with an FE model of a head expander and a DUT (a resonating structure with high COG).

Figure 19 presents the comparison of three scenarios for a centered DUT mounting.

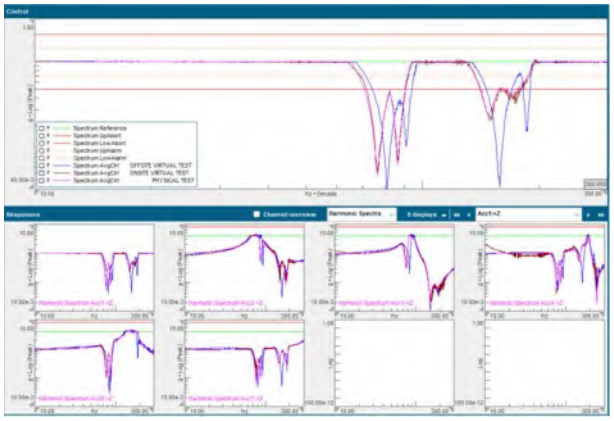

Figure 19 - Comparison of the Average control harmonic spectrum (top) and of notch channels (bottom). Offsite derisking (blue), onsite derisking (brown), and physical test (magenta).

The blue curve represents the harmonic spectrum of the control accelerometer (and the notching channels in the lower part of the picture) during the offsite de-risking virtual shaker test, performed with the hybrid coupled system. The brown curve, instead, shows the response of the virtual shaker test during the onsite derisking, hence using a fully experimental system identification of the physical twin to derive the FMU. The physical test is shown with the magenta curve, which confirms an excellent agreement when compared with the VST. The minor discrepancies are observed mainly for the offsite de-risking virtual test. Those can be attributed to the assumptions and approximations made in the FEM modelling of the DUT. As an example, the modal damping has been set to 1.5% for all modes, which is clearly not the case as the notch visible in Figure 19 shows that a higher damping is present. It is important to highlight that this exercise has been done without model updating of the FEM of the DUT in order to preserve the same scenario that test engineers will be confronted with in case of off-site de-risking, i.e. prediction potentially performed before the DUT is even built.

Figure 20 compares the harmonic spectrum of the control accelerometer for the virtual and the physical tests with an off-centered DUT configuration.

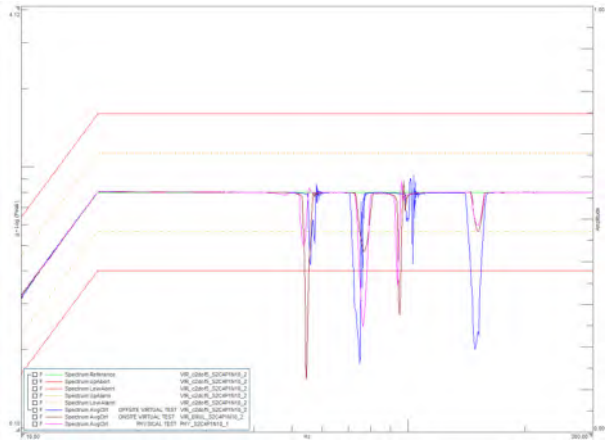

Figure 20 - Comparison of harmonic spectrum of control accelerometer. Offsite derisking (blue), onsite derisking (brown), and physical test (magenta) for the 3 scenarios with the off-centred DUT.

The blue curve represents the offsite VST, the brown curve shows the onsite VST and lastly the magenta curve reports the result of the physical test. This represents a more challenging test case where significant rocking modes are excited, and the cross-axis coupling is pronounced. The results demonstrate that the hybrid FBS approach successfully predicts the primary features of the dynamic behavior of the system even though some notches have significant discrepancy in terms of amplitude with respect to the onsite virtual shaker test and the physical test. Nevertheless, this approach allows to investigate such a complex scenario in advance of the physical test execution and can then be fine-tuned by running an onsite virtual shaker test prior to the physical test.

5. CONCLUSIONS

This work demonstrates on a full-scale system the application of a new real-time Virtual Shaker Testing workflow for onsite derisking. The physical system is replaced by an executable digital twin driven by the same vibration control hardware and software used during the physical test campaign. For the onsite de-risking case, a stable state-space model is derived from low-level System Identification FRFs.
Virtual sine-control runs accurately matched the physical tests in the control bandwidth in terms of average control, response at the individual pilots and notch behavior, including transient overshoots.

These results confirm that the proposed workflow can support test engineers in tuning the vibration controller and assessment the response at the notch channels before exposing a spacecraft to a sine excitation, particularly at full level.

Preliminary offsite de-risking results obtained on a small-scale system and based on hybrid coupling and Frequency Based Substructuring (FBS) indicate that early test predictions (before the complete physical system is available) are possible and can be accurate, considering the limited fidelity of early models. The proposed methodology for off-site derisking presents also several practical advantages derived from the fact that it combines via FBS an experimental characterization of the shaker facility using multi-axis FRF measurements and numerical models of the head expander and the DUT.

6. FUTURE WORK

It is the intention of the authors to apply the methodology described in [19] and section 4 to the full-scale setup described in section 3.

7. ACKNOWLEDGMENT

The authors would like to acknowledge the Agenzia Spaziale Italiana (ASI) for supporting this project as part of the Space Smart Factory initiative.

Flow induced vibrations, flexible line hoses.

ABSTRACT

This paper presents the phenomenon of flow induced vibrations in flexible hoses. The hitorical origins and the risks of the resulting mechanical behaviour are explained. The phenomenon is described using basic mathematical relations for the various mechanical modes. The overall engineering approach is based on the state-of-the-art literature. Coming out of A5 experience the phenomenon of FIV was considered in Ariane 6 development since the very beginning. The particular application to the development in Ariane 6 launcher is presented using both analysis and test, as well as a dedicated toolset developed for this purpose.

1. INTRODUCTION

Flow induced vibrations (FIV) is a phenomenon that occurs due to a turbulent flow interacting with a structural part. In an unsuitable case FIV can generate a strong mechanical response in the structural part that finally can lead to its disintegration. In broader terms, FIV can be understood as a subset of various flow-structure phenomena.

In the context of launchers the FIV is of a particular concern in the design of flexible lines (hoses) and compensators made of convoluted bellows. Under unsuitable conditions, the fluid conveyed by those parts excites the bellow convolutions. By their dynamic response, the convolutions in turn reinforce the vibrations fluctuations in the fluid itself.

In certain operational ranges of the fluid flow, this interaction can generate unsustainable stress amplitudes in the convolutions, resulting in failure by high cycle fatigue and consequently a leak or burst.

In space history the FIV phenomenon was the cause for the failure of Saturn V spark igniter of the J2-S engine [1,2].

Figure 1: FIV induced failure of a flexible [2].

Figure 2: Failure of the J2-S engine due to FIV anomaly in a flexible [2].

As of today, the design methods to assess the risk of FIV and the critical conditions are well established in [3,4]. Due to the high complexity of the phenomenon the design methods have their natural uncertainties and limits. In such cases, additional verification by a realistic test is essential.

In the current paper, the verification of FIV was performed in the frame of A6 hot firing tests with specific measurements. The verification by test concentrated in particular on flexible hoses, which were considered at risk of unacceptable FIV. A dedicated passenger test was performed in the hot firing test campaings in order to assess the response for few critical flexible hoses. Finally, the stress amplitudes in the convolutions were determined. A positive assessment for all flexible hoses could be achieved.

Among the known analytical challenges, the damping factor in the transfer function between the measurement sensors and the displacement at the convolutions plays a major role. While measurements for some specific test configurations are available, the information in the literature is scarce, cf. [5,6,7], often supported by NASA.

2. MODELIZATION

In this section the concept of the modelization of the FIV is outlined. For detailed description the reader should refer to state-of-the-art literature in [3,4].

Flow induced vibrations (FIV) occur due to a turbulent flow interacting with a structural part. For a convolution the vibration generates due to periodic vortex formation and shedding. This causes a periodic pressure difference, which is exerted on the convolutions, Figure 1.

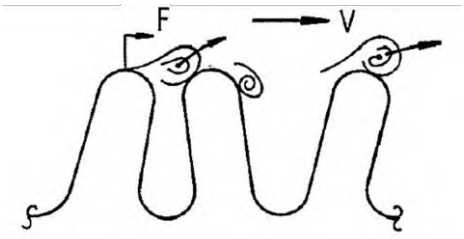

Figure 3: Generation of excitation force F on the convolution, due to flow of velocity V and the resulting vortex shedding, picture adapted from [3].

The main characteristic parameter is the dynamic pressure, defined as:

$$p_{dyn} = \frac{1}{2}\rho_f V^2 \qquad (1)$$

where ρ_f is the fluid density at a given temperature and V is fluid flow velocity. The excitation force on the convolution can be determined as:

$$F = C_x A_p p_{dyn} \qquad (2)$$

Where C_x is a product of characteristic coefficients, and A_p is the convolute height area (pressure excitable area). The total cofficient Cx largely depends on the the local geometry of the convolution and its response to the vortex sheding. That coefficient is determined experimentally.

This excitation force is resisted by the convolution, for which the displacement is:

$$x = C_m Q \frac{F}{k_A} \qquad (3)$$

where k_A is the spring rate, C_m is a vibration mode coefficient, and Q is the dynamic amplification factor. The vibration mode factor C_m describes the participation of the convolutions to the longitudinal vibration of the hose. The dynamic amplification factor Q depends on the type of the hose and the conveying fluid. This factor is derived from large experimental knowledge and it strongly influences the analytical predictions.

Finally, the maximum stress in the convolution can be determined as:

$$Stress = \left(C^*, p_{dyn}, SSR, V, geometry\right) \qquad (4)$$

where C^* is a specific coefficient, SSR is a specific spring rate based on ka, and V is flow velocity.

Beyond the state-of-the-art method, AG has historically developed an in-house relation for the determination of the stress amplitude. That model is based on the same concept of dynamic pressure and convolution stiffness, and it has a slightly different geometry definition. The resulting stress is similar to the state-of-the-art model.

Depending on the operational regime (mass flow and temperature) the convolutions may respond in three modes:

- In-phase longitudinal mode, where all convolutions vibrate in the same direction.
- Out-of-phase longitudinal mode, where convolutions vibrate in opposite direction to each other.
- Bending mode, where the walls of the convolute develop a higher order local response.

The mechanical natural frequencies of the convolutions are different for the three modes. The natural frequency can be expressed as:

$$f_m = \frac{1}{2\pi}\sqrt{\frac{2k_A}{m_m + m_{fl}}} \qquad (5)$$

where m_m is the mass of the metal and m_{fl} is the mass of the fluid active in the convolution in the studied mode.

The natural frequency and the velocity are related via the Strouhal number defined as:

$$St = \frac{fd}{V} \qquad (6)$$

or

$$f = \frac{St\,V}{d} \qquad (7)$$

where d is a characteristic (normalized) dimension of the hose. The critical Strouhal number were intensively investigated by NASA in the 1960's [4]. Depending on the definition of the characteristic dimension, and for the first mode, the St values are ca. between 0.2 and 0.5.

The last FIV excitation to be considered is the acoustic interaction, for which the first acoustic mode frequency is:

$$f = \frac{FNCO \cdot C_{\Phi}}{2\pi r_i} \qquad (8)$$

Where *FNCO* is a non-dimensional acoustic mode coefficient, C_{Φ} is the speed of sound in the fluid, and r_i is the internal diameter of the hose.

It is important to note that the mechanical modes may overlap in the operational regime, and that the acoustic excitation can occur together with a mechanical excitation.

The detailed formulaic description as well as application examples can be found in [3,4].

3. VERIFICATION APPROACH

In the chapter above the various elements to the modelization have been presented. The actual verificaiton approach and criterion will be described herewith.

The main uncertainty in the modelization is the Strouhal number, which is experimentally based, and depends mainly on the particular convolution geometry.

Therefore, the risk of excitation needs to be investigated with an uncertainty factor applied to that number. An uncertainty of +/-50% is applied on the Strouhal number. The risk of excitation is investigated over the whole uncertainty field, and not only at the two extremes.

Hence, the excitation frequency is determined based on Eq.7 for a range of Strouhal numbers.

The mechanical frequency for each mode is compared to the excitation frequency. Due to various uncertainties a safety factor is required: the mechanical frequency shall be below the excitation frequency by factor 2, which means:

$$f_m < 0.5f \qquad (9)$$

If this requirement is violated, a matching of the frequencies and self-induced excitation is assumed. In that case the assessment of the stress amplitude is mandatory. Due to further uncertainties a safety factor of 2.5 is applied. In case that acoustic mode occurs simultaneously, another safety factor of 1.5 is applied on top, Eq. 10.

The resulting stress shall be lower than the safety reduced fatigue limit of the convolution material, and its welds, at the operational temperature.

$$Stress < \frac{1}{2.5\ (\cdot\ 1.5)} \cdot fatigue\ limit \qquad (10)$$

4. ACTIVITIES PERFORMED ON ARIANE 6

The above described analytical approach developed by NASA is based on numerous test evidence. As described, many uncertainties need to be considered, which requires the implementaiton of significant safety factors.

However, over the history of various space projects, including the Ariane launchers, this approach proved to be viable and useful for the verification of the flexible hoses without extensive tests.

During the Ariane 5 development and operational accompaniment various tests of flexible hoses were performed, where the validity of the state-of-the-art approach was confirmed. Therefore, for the development of A6 the criticality of the flexibles was assessed first with the same approach, i.a. using an analytical framework.

Prior to the physical design definition the basic operational regime was defined including the temperature and mass flow ranges. Also, the various fluid end consumers were initially only linearly added.

Based on those inputs the particular geometry of the suitable flexible hoses was selected, and the risk of FIV was analytically assessed in full detail.

An efficient analysis was possible thanks to a dedicated toolset developed for this purpose. The main feature of it is the capability to assess the FIV iteratively over a range of the various input parameters, and not only at their extremes. Beyond the temperature and mass flow, the various parameters include the Strouhal number, dynamic amplification factor, as well as geometry parameters.

This process was repeated in several loops up to MG11 (launcher QR), along with the increasing precision of the predicted operational ranges as well as procured hardware properties.

As mentioned in Section 2 the dynamic amplification factor is one of the most influencing factors. Therefore, and beyond the literature data, additional effort was invested in this point.

A passenger test was organized on the hot firing test model of the ULPM stage (Upper Liquid Propulsion Module) for selected flexible hoses, to measure local vibration responses during the engine firing and other events in the propulsive system.

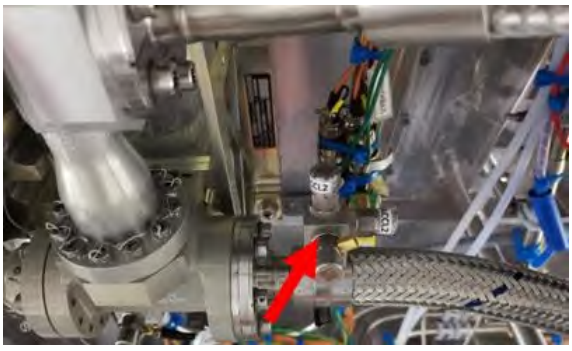

Figure 4: Example of dedicated vibration sensors on a flexible.

Beyond the usual tasks in performance of such test, one of the major challenges was to guarantee a high data acquisition rate. This is necessary as frequencies of the flexibles in order of magnitude of 10kHz are not unusual.

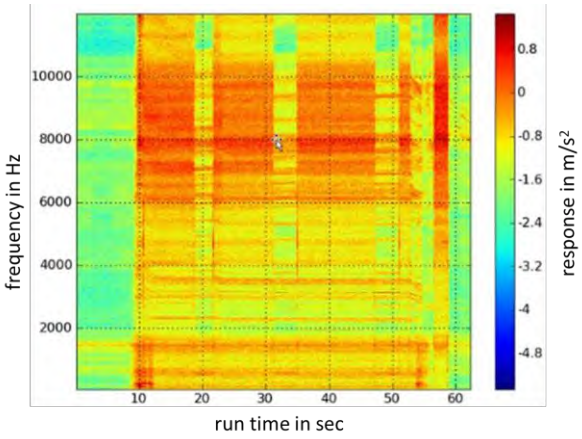

Figure 5: Example of evaluation of a test with a flexible. The response is spread over a range of frequencies, with high intensity at approx. 8kHz.

Concerning the signal post-processing, the determination of modal damping properties from measured operational vibration responses is a non-standard task. As a part of the toolset a software package was developed to extract modal damping properties from measured operational vibration responses.

In the second step, the determined excitation was post-processed to reconstruct the (maximum) amplitude in strains. With this information, the maximum stress was caclulated, both with a dedicated FEM model and with the state-of-the-art analytical solutions.

The results out of this approach and the predictions based on NASA related work [3,4,5] were in fairly good agreement, considering the large uncertainties in the assumptions.

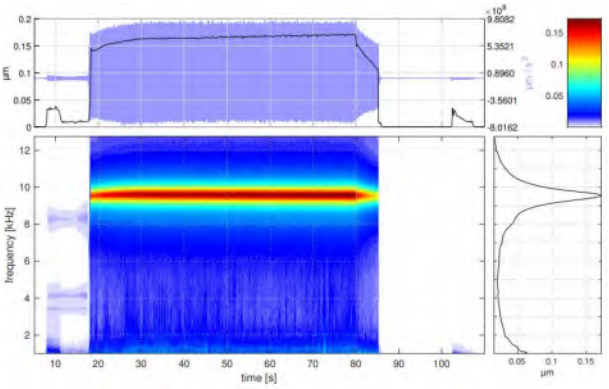

Figure 6: Example of the post-processing for the convolution amplitude. The maximum response at approx. 10kHz is well visible.

In result, it was possible to verify that none of the A6 flexible hoses coincided with the critical FIV frequencies. However, in the final design configuration the safety factor was slightly violated for few hoses, i.e. $f_m \prec 0.5f$. Using the toolset the maximum stress amplitudes were always evaluated and available for comparison to the material fatigue limit.

Due to the various uncertainties the good practice at AG is to keep the analytical stress amplitude at very low level, typically much below 10MPa. Only in cases for which test evidence is established, higher values are accepted, up to a few dozens of MPa.

This was the case for few impacted flexibles, for which investigations by test were additionally performed in the stage hot firing test, described above.

5. CONCLUSION

With A5 heritage and A6 development AG has gained deep industrial knowledge of the FIV phenomenon in flexible hoses. A comprehensive toolset was developed in orded to assess the phenomenon quickly and to avoid the risk of FIV since the beginning.

For future designs the following recommendations can be formulated:

- Risk of FIV should be avoided in the early design stages.
- The preliminary inputs should be defined with possibly large reserves, as the operational range of the propulsion subsystem is bound for modifications along the development.
- In engineering terms, it is sufficient to dimension the flexible hoses by the state-of-the-art analytical approach.
- Fatigue regime should be avoided completely. Normally, this is possible at no added mass/cost by selecting an appropriate design.

- For potentially critical flexibles a test evidence is recommended at propulsion subassembly level (test as you fly).
- Sophisticated diagnostics is necessary to evaluate the test and the risk of FIV in detail.

For future activities the characterization of local damping in the convolutions would help for deeper modelling of the dynamic behaviour.

As of writing this article, Ariane 6 has a record of eight successful operational flights since its maiden qualification flight. Fully nominal operation of the flexible hoses has been observed.

ABSTRACT

The verification of spacecraft units against launch and specifications environments is typically performed using a coupled load finite element analysis in which payloads and secondary units are assembled with the structure models by employing Craig-Bampton reduced order models. Tight schedules and the growing availability of off-the-shelf components results in situations that these models are often not available. In these cases, it is common to model the payloads with a simplified approach consisting of a lumped mass and rigid connections. This simplification makes the assessment of the random vibration response of the units more challenging.
This paper proposes a practical methodology based on the Random Response Spectrum (RRS) which allows for a simple assessment of the compliance of units when limited information is available. The proposed workflow is demonstrated through a simple example that highlights the strengths and the limitation of the simplified approach.

1. BACKGROUND

In the context of structural design and verification of a spacecraft, one of the many requirements that needs to be satisfied is the compliance of subsystems to the different load environments experienced during the mission. This includes, to name a few, quasi-static, vibrational and thermo-elastic loads. The nature of space missions is such that subsystems and payloads are typically designed as stand-alone units and follow a parallel product cycle to the spacecraft's one. As a result, they can be designed and qualified separately. The requirement of compliance is then translated into assuring that the loads experienced during the mission (or the tests) are compliant with the qualification loads of the units. This paper focuses on the evaluation of the response of units due to random vibration loads and the comparison against the tested qualification specifications.

The most common way of performing this assessment is by implementation of a Finite Element Model (FEM), comprising the primary structure (e.g. the spacecraft) and all the secondary structures and payloads attached to it. In the ideal case, a representative FEM of the different modules is available, and the structural performance can simply be assessed by the coupled analysis.

However, despite the continuous increase in computational capabilities, the implementation of fully representative FEM is complicated by the overall size of the models and the complexity of the configuration control. Furthermore, detailed models are sometimes subjected to intellectual property restriction.

The widely accepted way around this is to make use of Craig-Bampton reduced models [1]: the reduced models maintain the dynamic behaviour while significantly reducing the computational time. During the reduction process key elements such as nodal accelerations and elemental forces can be preserved so that they can be monitored during the coupled load analysis. In this way, it is possible to assess directly whether units' responses are compliant with their qualification loads. For instance, one can directly compare peak interface force with the design limit load of the component.

However, reduced models may not always be available. Common reasons are project scheduling constraints, development limitations and the increasing availability of off-the-shelf components for which FEM do not exist. The result is that a dynamically representative model cannot be used and a much simpler modelling approach needs to be adopted: a common approach is to use a rigid element connecting the interfaces between unit and spacecraft and a lumped mass positioned in the unit's centre of gravity. This simplified modelling can be effectively used to assess the compliance of static loads resulting from the coupled analysis with the quasi-static loads the units have been qualified (or sized) to.
The absence of any dynamic information on the units' side, however, complicates the comparison between the dynamic responses between simulations and qualification.

2. ASSESSMENT WITH SIMPLIFIED MODELS

Assuming that modal information (such as main frequencies) are known and that the qualification specifications are available, a first simplified approach would be to extract the RMS interface force or the equivalent interface acceleration from the FE random vibrations analysis and compare it with the Power Spectral Density (PSD) applied during the qualification testing.

Lacking a better option, the simplified rigid element-lumped mass model can still be used to compare the random response from the analysis to the qualification loads.

This approach in practice consists in comparing the input load from qualification (the PSD) with the interface acceleration response from the random vibration analysis as shown in Figure 2-1. As such, exceedances of the response with respect to the qualification input could be interpreted as not-compliance whereas a response fully enveloped by the PSD indicates compliance. A rule that is commonly adopted in the presence of exceedances is the peak clipping, which consists in ignoring sharp peaks, or peaks with a relatively small bandwidth, if they exceed by a maximum of 3dB the input profile.

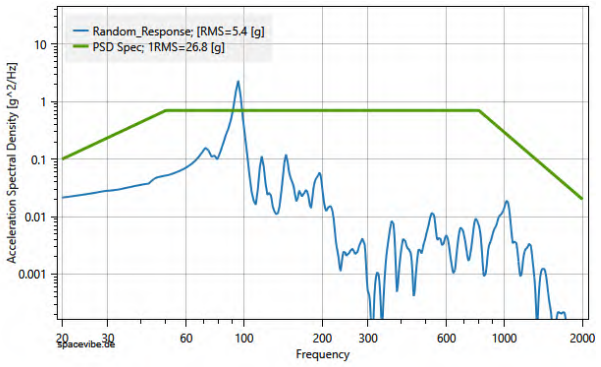

Figure 2-1:Interface Acceleration Response vs Qualification PSD of an antenna

By not considering the modal content of the unit, this approach treats PSD exceedances purely based on their amplitude. By doing so, exceedances occurring in frequency ranges far from the main modes of a unit (where the dynamic amplification occurs) are mistakenly interpreted as non-compliance, leading to excessive redesign or requalification.

A more appropriate evaluation of the response can be done by means of the Random Response Spectrum (RRS).

2.1. Random Response Spectrum Section

The Random Response Spectrum (RRS), also known as Vibration Response Spectrum (VRS) allows to consider the modes of the units when comparing the PSD with the random vibration response.

The RRS can be interpreted as the response of an array of independent single-degree-of-freedom (SDOF) oscillators with same damping assuming different natural frequency. The RRS function gives the RMS response of each oscillator to a fixed input [2].
The RRS function is a generalisation of the Miles Equation:

$$\ddot{x}_{GRMS}(f_N,\xi)=\sqrt{\sum_{i=1}^{N}\frac{1+(2\xi\rho_i)^2}{(1-\rho_i^2)^2+(2\xi\rho_i)^2}\hat{Y}_{ASPD}(f_i)\Delta f_i} \quad (1)$$

Where:

ξ	critical damping
f_i	assumed frequency
$\hat{Y}_{ASPD}$	base input acceleration PSD
ρ_i	f_i/f_N

And x is the solution of the SDOF problem with base excitation y, stiffness k and damping c. Figure 2-2 shows how the response PSD is translated into a curve for which each point is the total gRMS seen by the simplified SDOF model at an assumed natural frequency (f_N).

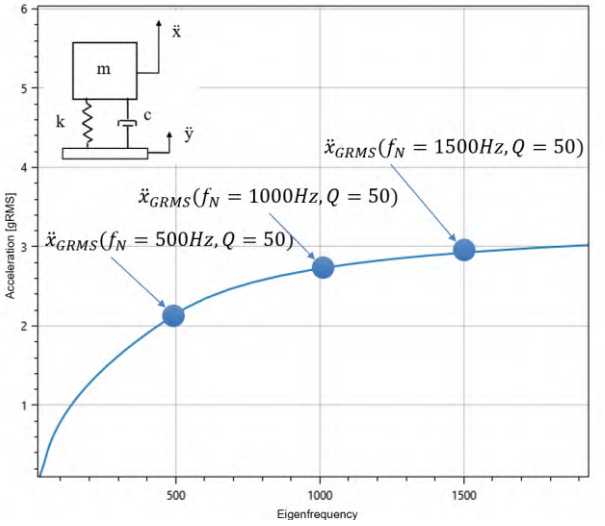

Figure 2-2: Random Response Spectrum (RRS) Plot

The VRS is extensively described in [2], where it is also demonstrated how the Shock Response Spectrum can be efficiently adapted to the random vibration environment: the RRS is used to compare different random vibration specification and to identify critical frequency ranges based on the available response. At the same time, it is shown how the RRS can be useful for test data assessment, derivation and revision of test specifications.

The RRS method is also described in [3] where it is highlighted how the method can provide a rational

approach to derive test specifications from measured data and to assess the random response of a unit based on acoustic test measurements.

Indeed, Eq. 1 can be applied to the RMS acceleration response of a unit obtained from the random vibration analysis: the output, combined with the info about the unit's modes and qualification loads, offers a practical tool to evaluate the response's compliance.

In simple words, the RRS function returns the equivalent interface force (expressed in net-g) that a unit would experience assuming that the full unit mass is excited at a certain frequency with specified Q. The equivalent interface force is a key parameter used for units sizing and strictly relevant to assess the structural integrity.

The critical difference between the response of the simplified lumped model with the reduced model is that for the latter the force spectral density at the interface can be integrated (giving the cumulative RMS) capturing all modal content and accounting for the difference in interface stiffness. This provides a significantly more representative interface force estimate.

In practice, the assessment consists in a comparison of the RRS of the specification PSD (from the qualification test) and the RRS of a unit's random response. In the next section, a workflow is proposed to efficiently interpret the results.

2.2. Suggested Workflow

The first step is to compare the interface acceleration response against the Qualification Loads PSD: if the first is enveloped by the second, the response can be considered as compliant.

If the response exceeds the PSD, the RRS function can be applied to the Qualification Loads PSD and the interface acceleration response obtained from the random vibration analysis. The comparison of the resulting curves, combined with minimal qualification data, provides a practical tool to assess the compliance of a unit. In particular, four main scenarios can be identified:

No Exceedances
The RRS of the Qualification Loads PSD completely envelopes the RRS of the random response. In other words, there are no exceedances (Figure 2-3a). In this case, the qualification loads cover the response of the unit independently of the unit's modes and the unit can be considered compliant.

Exceedances
The RRS of the random response exceeds the RRS of the Qualification PSD. Three sub-scenarios can be identified:

1) **Exceedances below the unit's main modes:** exceedances occur at frequencies sufficiently lower than the unit's primary modes (Figure 2-3b). In this case, the unit's dynamic is not excited, and it is possible to assume that the response is quasi-static. A practical rule is to consider a $\sqrt{2}$ factor between exceedance and main mode.
2) **Exceedance at (or near) the main modes:** the exceedances coincide with the primary modes (Figure 2-3c) meaning that the total Qualification Loads do not cover the predicted response. Actions such as design changes or unit's requalification shall be considered.
3) **Exceedances above the unit's main modes:** In this situation (Figure 2-3d) the interpretation of the results becomes less trivial and the assessments needs to account for data such as secondary modes or, if available, the qualification test results.

In the first case, the simplified approach can be expanded to assess the unit's compliance: since the exceedances are below the unit's primary modes, the response can be approximated as quasi-static. Therefore, the total gRMS calculated from the random response can be compared against the larger between: (i) quasi-static qualification loads and (ii) the gRMS of the qualification PSD below the unit's primary mode. If the response's gRMS is lower, the unit can be considered compliant.

The workflow is simplified in Figure 2-4.

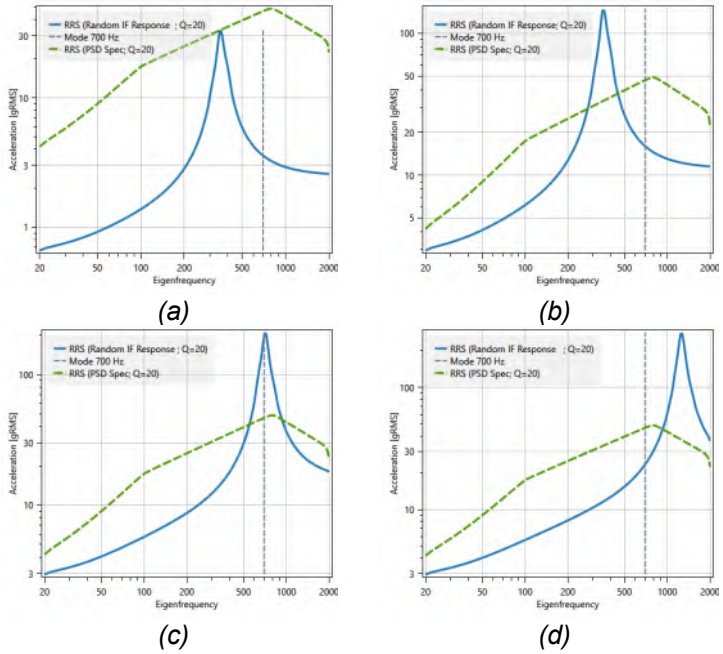

Figure 2-3: Subcases

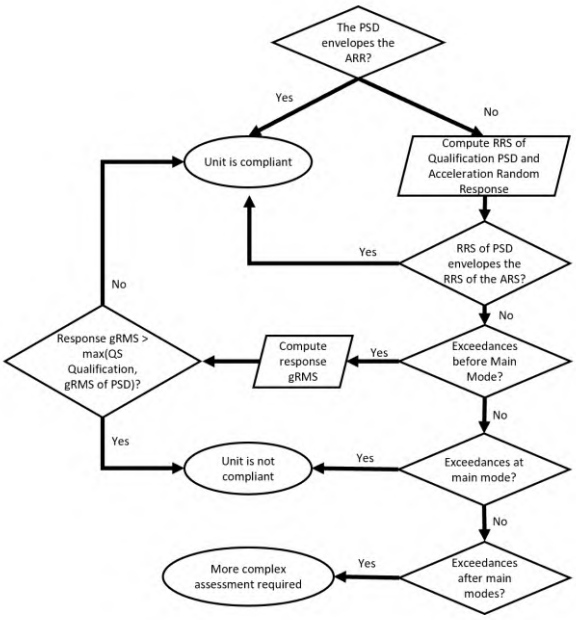

Figure 2-4: Simplified Workflow Chart

2.3. Practical Example

In this section, the approach is put to practice. In the example, an electronic box is mounted on the side of a spacecraft as shown in Figure 2-5.

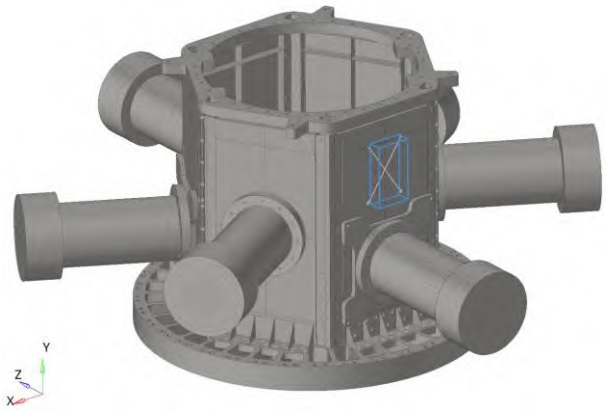

Figure 2-5: Example Structure FEM

The e-box's mechanical characteristics are listed in Table 2-1, while its primary modes are summarised in Table 2-2.

Table 2-1: E-Box Properties

Mechanical Properties		
Mass	2.3 kg	
Centre of Gravity	[0.0; 0.0; 0.016] m	
#Interfaces	4	
Qualification		
Quasi-static Loads	20g	
	Frequency [Hz]	PSD [g^2/Hz]
Random Loads	20	0.0584
	50	0.5
	400	0.5
	2000	0.0584

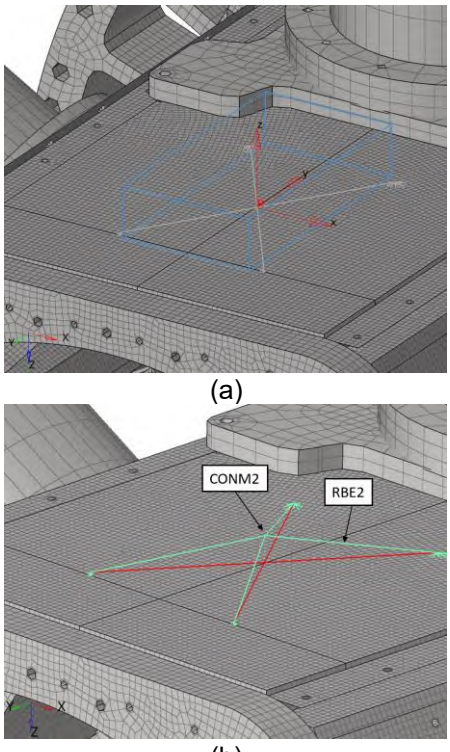

Table 2-2: E-Box Main Modes

Mode #	Frequency [Hz]	Mass fraction X	Y	Z
1	730.04	0.06%	0.07%	21.91%
2	954.77	0.25%	0.00%	32.50%
3	1040.25	0.00%	0.01%	0.01%
4	1448.14	6.91%	0.05%	3.27%
5	1472.78	7.67%	0.13%	3.76%
6	1575.97	34.65%	24.86%	0.20%
7	1591.74	19.07%	49.66%	0.12%
8	1696.40	0.60%	15.28%	0.22%
9	1829.13	0.01%	0.67%	1.13%
10	1859.41	6.40%	0.00%	1.15%

Two modelling approaches are followed:

- Model 1: the unit is attached to the platform as a reduced model (Figure 2-6a)
- Model 2: the unit is modelled as an RBE2 element connecting a CONM2 element positioned at the unit's Centre of Gravity (Figure 2-6b)

In both models, an RBE3 element has been defined at the unit's interface to retrieve the average interface acceleration. The element is expressed in the unit's coordinate system.

(a)

(b)

Figure 2-6: E-box's modelling

The random vibration analysis is performed with NX Nastran applying the Random Vibration Environment specified in [4] (shown in Table 2-3) at the fixed base of the structure with the box mounted on it. For the sake of this example, the analysis is performed in the Z (lateral) axis only.

Table 2-3: Random PSD Input

Frequency [Hz]	PSD [g²/Hz]
20	0.01
50	0.015
700	0.015
800	0.03
925	0.03
2000	0.00644
Total gRMS	**5.57**

The response of both models is plotted in Figure 2-7 against the PSD from the unit's qualification loads (Table 2-1), while the RRS is plotted in Figure 2-8.

When considering the simplified model, the interpretation of the exceedances in Figure 2-7 is not trivial as the peaks would indicate that the response is non-compliant even when applying the 3dB clipping method.

When switching to the RRS domain (Figure 2-8), the picture is cleared: all the exceedances (140 Hz, 250 Hz, 434 Hz and 508 Hz) happen in a dynamic range that is sufficiently far from the unit's own dynamics: following the approach described in §2.1, the maximum acceptable exceeding peak is at 730/√2=516Hz. It can also be appreciated how the RRS of the response after this threshold is below the RRS of the PSD, meaning that the loads induced by the primary structure are enveloped by the qualified random loads.

The response can be then assumed to be quasi-static, and the total gRMS seen due to the random loads (13 gRMS, see Figure 2-7) are compared with the quasi-static loads reached in the qualification tests: according to the qualification data shown in Table 2-1, the unit has been tested to 20g, which corresponds to 6.7g when considering 3σ values, or 15.2 gRMS when computing the gRMS up to 508Hz using the PSD specs. The response is considered compliant.

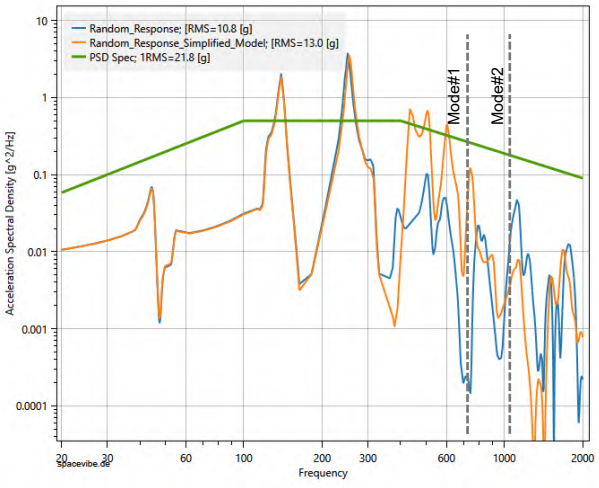

Figure 2-7: Acceleration Response and Qualification PSD

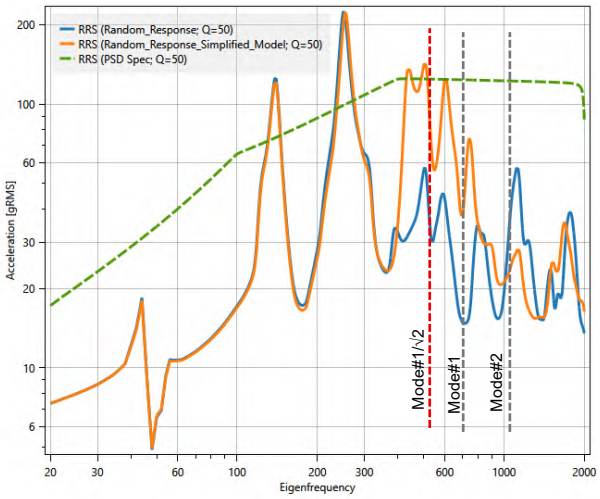

Figure 2-8: RRS of Acceleration Response and Qualification PSD

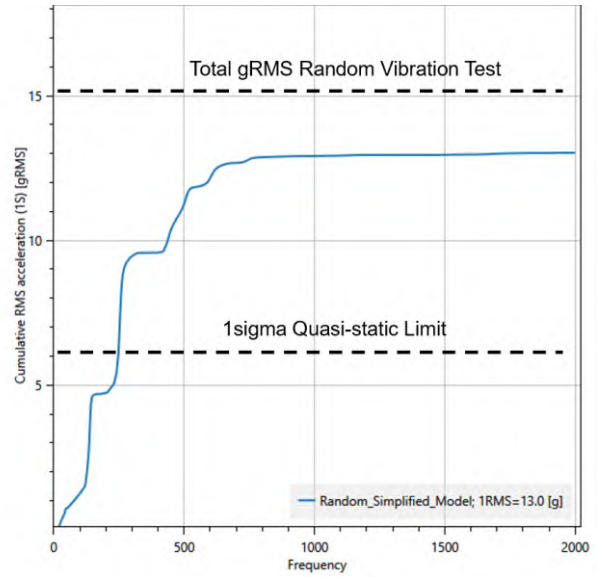

Figure 2-9: Cumulative gRMS of the simplified model

The response of the reduced model confirms what observed for the simplified model: the two main peaks at 125 Hz and 254 Hz are related to the main structure local modes and the e-box's own dynamic is not excited. Hence, the random vibration qualification covers the dynamic response and the compliance can be assessed on a quasi-static basis.

2.4. Method Limitations

The example highlights how the RRS approach is effective in assessing the random vibration response in absence of a detailed reduced model: with a limited amount of information (mass, unit's COG and qualification data) the RRS domain allows for a quick evaluation of whether the response excites the unit's dynamic and if the qualification loads envelope it.

The proposed methodology is based on several assumptions that shall be considered when performing the assessment. In the first place, the rigid element/lumped mass modelling by definition has no own dynamic and an infinitely rigid interface: this results in the peaks seen in Figure 2-8 at 434 Hz and 508 Hz. The peaks are absent from the response of the reduced model which is not infinitely rigid.

At the same time, the RRS itself comes with its own limitation:

- Eq. 1 is also dependent on the damping factor which significantly affects the RRS curve and therefore the assessment.
- As also highlighted already in [2], the method is valid as long as the modes are not coupled.
- Following Eq. 1, in the RRS domain each peak (or each point) represents the total gRMS of a SDOF model with one single mode i.e. the method assumes that the whole modal mass goes in one single mode, neglecting that this is not a realistic case.

Keeping these limitations in mind, the approach can still be used to assess the compliance of units and it offers an alternative where more detailed information is lacking.

3. CONCLUSION

This paper has shown that the Random Response Spectrum is a useful tool that can be employed to assess the random response of spacecrafts' units when detailed information or reduced order models are not available.

The proposed workflow combines the response of a simplified lumped mass/rigid element model from the finite element analysis with basic information such as the primary modes of the units and its qualification loads. The comparison between response and qualification loads in the RRS domain allows to identify whether the units' dynamics are excited by the primary structure and whether the response can be approximated as quasi-static.

The methodology has been applied to the simple example of an electronic box mounted on the side wall of a spacecraft: the results shown that a simple comparison between response and qualification loads can be wrongly interpreted and that the RRS approach allowed to determine that the qualification environment actually covered the predicted response.

The proposed methodology is subject to limitations implicit to the simplified modelling of the units and with the hypothesis at the basis of the RRS method. Nevertheless, when taking into account these limitations the proposed methodology provides a simple and practical approach that can be streamlined to efficiently assess the compliance of the unit against random vibration loads using a limited set of inputs.

ABSTRACT

This paper presents the on-going activities in maintaining the correlation of the launcher/spacecraft Coupled Loads Analysis (CLA) tool for Vega-C at the European Space Agency (ESA). A first paper on this topic was presented during ECSSMET 2024, where the Lares-2 flight measurements were compared to the ESA internal CLA tool predictions and used to adjust the forcing functions of the ignition and pressure oscillation load cases. This paper presents an overview of the correlation status based on Biomass flight measurements and will identify whether any additional tuning of the previously correlated CLA tool is required.

This case presents an added value for the correlation status check, as Biomass is a spacecraft of a different mass class and presents dynamic properties more typical of a single launch mass class, unlike the Lares-2 configuration, which is lighter and for which the main modes lie above the sine frequency range.

A brief summary of the CLA tool update in terms of methodologies and software tools is also provided. The CLA tool update has been taking place in parallel of the correlation activity and the benefits are presented in view of the Biomass flight exploitation. Two powerful capabilities that can be used together to deepen the understanding of the dynamic behaviour of the coupled launcher/spacecraft system are the modal gain tool and mode shape recovery. While the first is still under development, the usefulness is mentioned in view of this correlation exercise.

The interest of ESA missions with this launcher for medium mass class payloads is very high and early compatibility with its mechanical environment is of outmost importance. CLA is in turn a key element in spacecraft testing and qualification to support the assessment of this compatibility in the quasi-static and low-frequency range dynamic loads. The ESA internal CLA tool is used in support to ESA projects in early stages of development or after design changes. The tool complements but does not substitute the CLA of the launcher authority. It allows an agile assessment of structural loads and identification of potential criticalities in the design of the spacecraft when on-board the Vega-C launcher.

Keywords: Coupled Loads Analysis, Correlation, Forcing Function, Vega-C, Flight Measurements, Superelement Method

INTRODUCTION

The ESA CLA experience started in the 90s with the Space Shuttle and Ariane-5 launcher. The CLA tool relied on FABE (Fluid Analysis with Boundary Elements) [1] software to model Fluid-Structure Interaction (FSI) and used a combination of MSC Nastran and direct matrix abstraction programme (DMAP) for the reduction of the physical Finite Element (FE) models to Craig-Bampton (CB) models [2] and for the implementation of forcing functions, assembly of the different CB models, damping methods, and the solution of transient and frequency response analysis. From 2001 onwards, the CLA experience from Ariane-5 and the Space Shuttle programs was used to create a new CLA tool for the Vega launcher. The final CLA tool for Vega used MSC Nastran v2005.0 and all DMAPs were written to be compatible with this version. Starting in 2018, the tool was adapted to be used for Vega-C, keeping the same methodology and software. The goal of the ESA CLA tool is to support ESA projects in an agile risk assessment before a CLA with the launcher authority is possible, or to evaluate the impact of design changes in the spacecraft. Starting in 2024, the Vega-C CLA tool has undergone a major update in terms of the software used. The step to move from MSC Nastran 2005 in combination with extensive DMAP library to more recent versions of Nastran was taken, and today, the CLA tool is running in MSC Nastran 2023.1, with a very reduced need of DMAPs, making the updated CLA tool easily compatible with following versions of Nastran.

CLA TOOL UPDATE

After the CLA tool correlation based on VC01, Lares-2 flight, the ESA internal CLA tool was updated in terms of software. As described in the previous section, the CLA tool for Vega-C was developed based in MSC Nastran 2005 combined with an extensive DMAP library. The DMAPs were used to perform the launcher FEM reduction to Craig-Bampton models, including filtering of modes with effective masses below a pre-defined threshold, generation of equivalent damping matrices and running transient and frequency response analysis, extracting the generalized responses to then multiply by the payload or launcher OTMs.

With the CLA tool update, the library of DMAPs used is reduced to a minimum and only to perform specific operations. The current CLA tool after its update uses MSC Nastran 2023.1 and can be easily updated due to the minimal usage of DMAPs. The largest part of the previous DMAP library is replaced by Nastran standard Superelement method for Craig-Bampton model and OTM generation. Mode filtering based on modal effective mass and equivalent viscous damping matrix based on structural damping and modal damping is performed via dedicated python scripts. The extraction of the generalized responses is done by including the generalized response list as part of the OTMs.

With the Nastran Superelement method, mode shape visualization is straightforward with the inclusion of PLOTEL elements in the launcher and spacecraft reduced FEM.

FSI capabilities have been studied to evaluate if it is possible to implement for Vega-E, since the third stage will be a liquid propulsion stage. It has been concluded that Nastran Superelement method has the necessary capabilities to re-introduce FSI in the CLA tool [3].

The methodology followed in the CLA process remains the same: the CLA driver script in python is the same, with only a few adaptations, and the same MATLAB post-processing scripts to compute equivalent sine, QSL and min-max tables are used.

FEM MODELS

The launcher FEM used in the CLA tool have been provided by AVIO. The FEM models have been used without modification until the correlation exercise with VC01, Lares-2 flight.

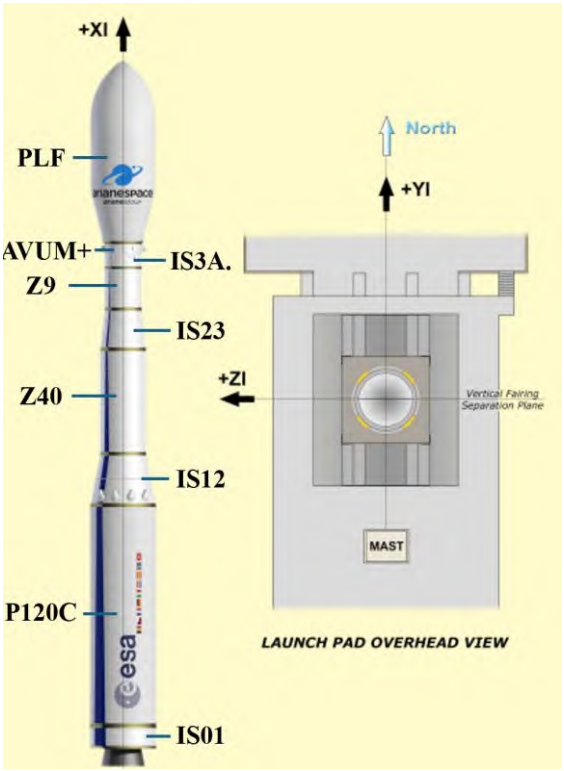

Figure 1: Vega-C Coordinate System [4] and its main components

After the correlation exercise, minor adaptations have been introduced in terms of introducing structural damping in the nozzle flexible joint of the Zefiro 9. In this paper, other launcher FEM adaptations are presented for the correlation to Biomass flight, VC04.

FORCING FUNCTIONS

The ESA internal CLA tool uses forcing functions that have been developed independently from AVIO.

For the Solid Rocket Motors (SRMs), P120C, Zefiro 40 and Zefiro 9 ignition cases are driven by the fast build-up of internal pressure in the propellant cavity and rupture of the nozzle membrane. The forcing functions were originally derived from CFD analyses and when static firing tests became available, these were also used to improve these forcing functions. Since Zefiro 9 was also used on Vega, for this case, the same forcing functions were kept for Vega-C. The ignition forcing functions are pressure and force time histories applied inside the propellant cavity, the igniter, the nozzle and the floaters (space between the domes and the propellant). For each SRM, the different internal pressure time histories are applied in different sections of the SRM.

Because the Zefiro 9 forcing functions remain the same as for Vega, but the Vega-C FEM is different, the only necessary adaptation was to update the mapping of the loads to the new Zefiro 9 FEM mesh. With the VC01 flight correlation, the forcing functions of the SRMs were updated. The effect of changing the different pressure time histories in the different sections was evaluated and it was seen that mainly the pressures in the floaters of the SRMs were affecting the acceleration outputs at the payload interface. For the particular case of the P120C ignition, also lateral forces were added to the nozzle, to be able to cover the lateral responses measured in flight at the payload interface.

On the other hand, the SRMs pressure oscillations (POs) result from the acoustic modes of the propellant combustion gases inside the propellant cavity which induce oscillations in the internal pressure, in the thrust, and excite the launcher longitudinal modes. The forcing functions are also pressure and force time histories applied in different sections of the SRMs and have been developed based on the SRMs static firing tests. Before the VC01 correlation the CLA tool included the PO of the P120C, 3 seconds after ignition and of the Zefiro 40, 15 seconds after ignition. The Zefiro 9 does not present significant pressure oscillation events. Despite the P120C and Zefiro 40 presenting more pressure oscillations, only the sizing ones for each SRM were initially considered in the CLA tool. After the VC01 correlation activity, an additional PO case was included for the P120C, around 31s after ignition. Although with lower amplitude than the PO 3 seconds after ignition, it was seen that it could happen simultaneously with the wind gust at Mach1 case.

Lastly, the CLA tool includes wind gust cases that occur at Mach1 and at Maximum Dynamic Pressure (MaxQ). These are cases which induce a worst case wind gust to maximize the bending moment at the spacecraft interface and take into account the aerodynamic instabilities at Mach1 and MaxQ. The forcing functions are based on CFD analyses performed at different Mach numbers and at different angles of attack and the two mentioned cases were selected as dimensioning. The lift and drag coefficients for these cases are considered and translated to forces applied on the external surfaces of the launcher.

LOAD CASES

As described in the previous section, there are several forcing functions applied on the launcher FEM which simulate the following load cases:

- P120C ignition
- P120C PO at 3 seconds
- Wind gust at Mach 1
- P120C PO at 31 seconds, added after Lares-2 correlation
- Combination of the two above as result of Lares-2 correlation
- Wind gust at MaxQ
- Zefiro 40 ignition
- Zefiro 40 PO at 15 seconds
- Zefiro 9 ignition

PO cases are treated by means of frequency response analysis while all the others cases are treated as transient analysis [5].

SUMMARY OF LARES-2 (VC01) CORRELATION

In 2024 the correlation of the ESA CLA tool predictions with Lares-2 flight, VC01, was presented. The objective of this correlation was to improve the prediction of the dynamic behaviour at the spacecraft interface, based on the equivalent sine (EQS). This was focused on ignition load cases and pressure oscillation load cases. Wind gust cases were not targeted as each flight will be subject to different weather conditions.

The correlation exercise was based on adjusting forcing functions of the different load cases rather than updating the launcher FEM provided by AVIO. For the Vega CLA tool correlation, it was performed differently going through three steps: SRM mass and static stiffness correlation, SRM SFT correlation, flight correlation. In the first step only the FEM was correlated, in the second step both FEM and forcing functions were correlated. In step 3 only the forcing functions were adjusted only by factoring and/or by introduction of additional forcing functions in specific frequency bands [6], [7]. The following methodology was followed for the ignition cases:

- Compute the EQS predicted by the ESA CLA at spacecraft interface.
- Compute the EQS based on the flight measurements in the same location.
- Compare the EQS and identify frequency ranges where the CLA is underpredicting or overpredicting the flight.

- Sensitivity analysis to identify which forcing functions are affecting the EQS in the target frequency (each load case has several forcing functions applied in different areas of the launcher).
- Apply a band-pass filter to the identified forcing functions and introduce this new forcing function, with an adequate scaling factor, as an additional forcing function.
- Only if needed, adjust damping parameters in specific areas of the launcher.

For the ignition cases, it was concluded that the forcing functions with the most impact on the correlation where the pressures applied in the floaters (area between domes and propellant grain). For P120C ignition particular case, lateral forces on the nozzle were added to cover other events such as possible blast waves and launch table detachment, which are not modelled as separate load cases. For the pressure oscillation cases, the correlation methodology is simpler:

- Compute the sine environment predicted by the ESA CLA at spacecraft interface.
- Compute the EQS based on the flight measurements in the same location.
- Compare the sine with the EQS and compare the frequency range where the pressure oscillation occurs and its amplitude.
- Adjust the frequency range and amplitude of the pressure oscillations to better predict the flight measurements, using pressure measurements when possible.

An important point to consider is that the Lares-2 payload is lightweight and does not present dynamics in the sine frequency range, acting as a rigid payload. For this reason, a correlation with a more typical single launch payload, with eigenfrequencies within the sine frequency range was required to verify the correlation status of the ESA CLA tool with this type of payload.

BIOMASS (VC04) CORRELATION OBJECTIVES

The Biomass flight correlation objectives are:

- Improve the CLA prediction of the dynamic behavior at the spacecraft interface, based on the EQS/sine, for SRMs ignition and pressure oscillation cases.
- Improve launcher FEM representativity of the 1st, 2nd bending and 1st longitudinal modes.
- Improve prediction of lateral QSL for wind gust cases.

While the first objective is the same objective taken for the Lares-2 correlation, two additional goals are targeted for this correlation exercise. For the second objective, there is the need to update the launcher FEM to achieve the intended correlation. This is a difference with respect to Lares-2 flight correlation, where the main correlation parameters were the different load cases forcing functions.

CORRELATION METHODOLOGY

The correlation methodology for Biomass flight is partially the same as for the Lares-2 flight. As discussed previously, it will go further and include the launcher FEM as a correlation parameter, instead of focusing only on forcing functions. For the forcing functions correlation, the same procedure as described for Lares-2 case is used.

For the launcher FEM correlation, the first step is to identify at which frequency the 1st and 2nd bending and 1st longitudinal modes are predicted to occur. For this, the mode shapes of the launcher including the Biomass payload are visualized to properly identify the modes.

The second step is to identify the same modes based on the flight measurements. Waterfall plots which show the measurements amplitude as function of time and frequency are generated for accelerometers located not only on the spacecraft interface but also along the launcher. Since these modes are global modes of the launcher, these should be identified in accelerometers along the launcher and not only on the spacecraft interface. This allows to exclude that the identified modes are local modes.

With the FEM predictions and flight measurements, it is possible to determine the error between the two. The last step is to identify which properties need to be tuned in the launcher FEM to change the frequency of the identified modes to match the flight measurements. For this, PRIMODAL software is used, in particular, the POST module. In this module, it is possible to perform a sensitivity analysis where the launcher FEM properties and materials can be varied and the change in each of the eigenfrequencies is estimated. This methodology requires the computation of the distribution of modal strain energy and modal kinetic energy on the launcher [8]. Therefore, only a few selected properties and materials are targeted as correlation parameters.

Based on the described procedure for forcing functions and FEM correlation, the actual steps taken for each family of load cases is described below.

SRM ignition:

- Original CLA comparison to VC04
- Forcing Functions (FFU) tuning
- Updated FFU CLA comparison to VC04
- FEM tuning
- Updated FFU+FEM CLA comparison to VC04
- Forcing Functions fine tuning
- Updated FFU+FEM+FFUv2 CLA comparison to VC04

Pressure Oscillations:

- Original CLA comparison to VC04
- Updated FEM CLA comparison to VC04
- Forcing Functions fine tuning
- Updated FEM+FFU CLA comparison to VC04

Wind Gusts:

- Original CLA comparison to VC04
- Updated FEM CLA comparison to VC04
- Forcing Functions fine tuning
- Updated FEM+FFU CLA comparison to VC04

The described process requires several iterations on each step and, furthermore, there is a dependency between the different tuning parameters. For example, tuning the launcher bending and longitudinal modes after tuning the forcing functions will affect the correlation achieved by tuning the forcing functions alone, making it necessary to have a second step of iterations to fine tune the forcing functions. This makes the correlation exercise very time consuming.

FEM CORRELATION

The waterfall plots show an example of the result in an accelerometer measuring in the lateral direction and in an accelerometer measuring in the longitudinal direction. It is worth noting that the same behaviour is seen in other accelerometers along the launcher, confirming that the identified modes are global modes.

While the bending modes are identified during Mach1 flight event, the longitudinal mode is identified during lift-off. As a confirmation that the identified modes are the global bending and longitudinal modes, the flight measurements were imported to PRIMODAL software, in particular, the TOMA module. In this module, an “experimental mesh” can be visualized. This is, the flight accelerometers represented in space and connected via artificial PLOTEL elements (elements used for visualization only), are displayed and the mode shapes based on the flight data can be visualized. These modes did resemble the targeted bending and longitudinal modes of the launcher, with the only drawback that the measurement locations are very limited. Still, a visual confirmation could be obtained. For the FEM bending and longitudinal modes identification, this is done visually by plotting the corresponding mode shapes.

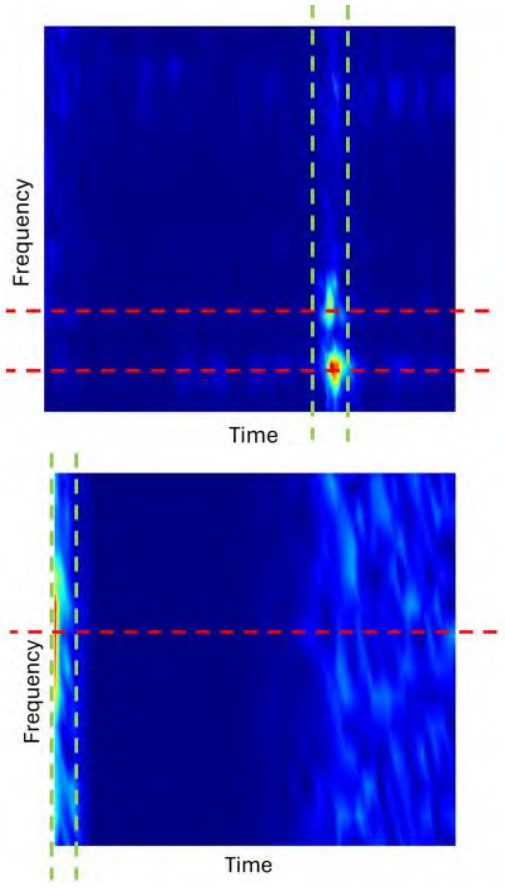

Figure 2: Waterfall plot of accelerometer measurements in lateral direction (top) and longitudinal direction (bottom) to identify launcher bending and longitudinal modes. Red lines identify the frequency, green lines the transonic and lift-off

After identifying which launcher FEM properties are driving the frequency of the identified modes, these properties were tuned in an iterative process until the FEM prediction is close enough to the flight measurement.

Table 1: Error in frequency prediction before and after correlation

Error in frequency	Initial	Correlated
1st bending mode	14.6%	0.2%
2nd bending mode	9.9%	1.0%
1st longitudinal mode	11.8%	0.6%

The achieved correlation is very satisfactory, as the launcher updated FEM is predicting the targeted bending and longitudinal modes with an error within 1%. However, to achieve this correlation, some material properties had to be changed quite significantly. Without more detailed FEM updating, for example, by remeshing areas of the FEM or updating the connections between different components of the launcher, the needed correlation requires significant FEM properties changes.

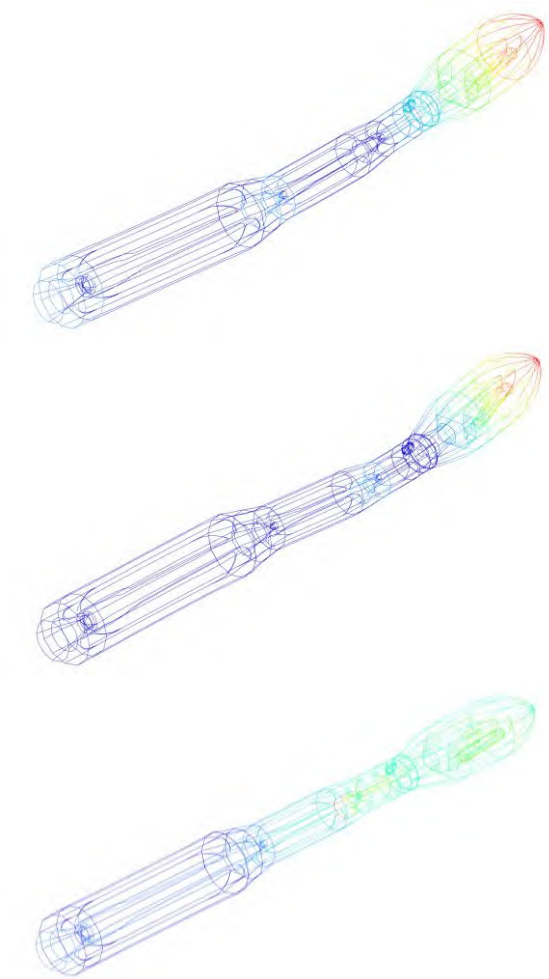

Figure 3: Mode shape of launcher first and second bending modes (top and middle) and first longitudinal mode (bottom)

FORCING FUNCTIONS CORRELATION

The steps taken to perform the forcing functions correlation will be described in this section.

P120C Ignition

1. Forcing Function tuning: Adjust amplitude of existing forcing functions (pressures) inside the P120C SRM. Adjust amplitude of lateral forces acting on the nozzle to cover blast wave and launch table detachment at lift-off. Remove frequency content from forcing functions to remove nonexistent peak at mid-frequency.
2. Effect of FEM correlation: the load case is ran with updated FFU and FEM.
3. FFU fine tuning: Adjust amplitude of lateral forces acting on the nozzle to cover blast wave and launch table detachment at lift-off.

The EQS based on flight measurements is shown in the plot in black and the EQS from the initial CLA is in green. The effects of applying point 1, 2 and 3 are represented by the curves in yellow, purple and red, respectively.

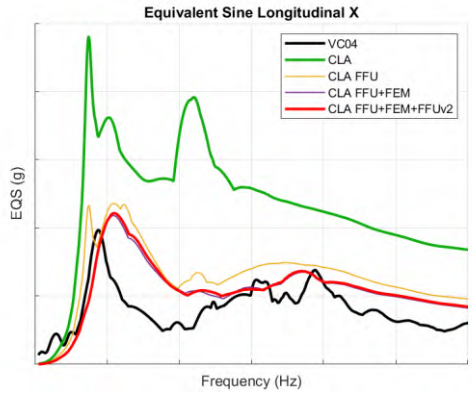

Figure 4: P120C ignition flight longitudinal X EQS comparison to CLA

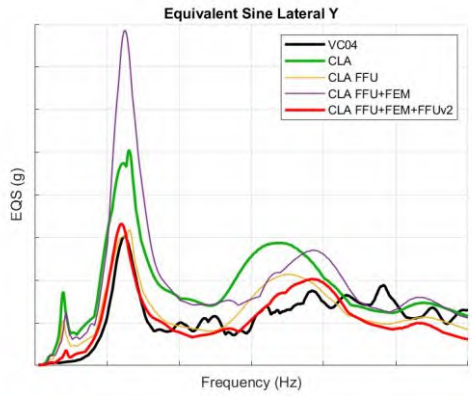

Figure 5: P120C ignition flight lateral Y EQS comparison to CLA

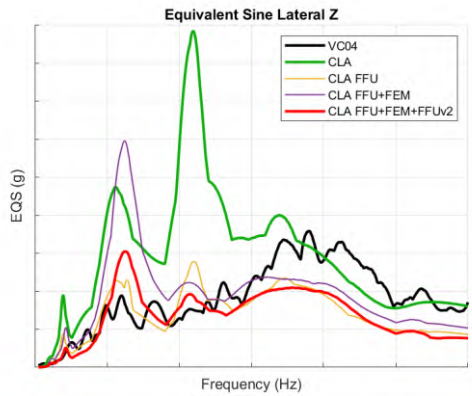

Figure 6: P120C ignition flight lateral Z EQS comparison to CLA

The following plot shows an example of the adjustment of the forcing function applied on the forward floaters of the P120C. The green function is subtracted from the black to obtain the red FFU.

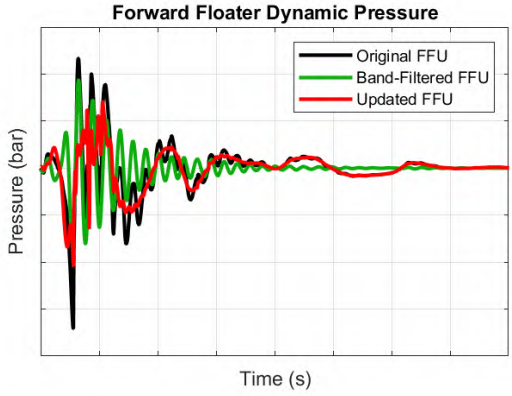

Figure 7: Pressure loads applied on the forward floater for P120C ignition case

Zefiro 9 Ignition

1. Forcing Function tuning: Adjust amplitude of existing forcing functions (pressures) inside the Z9 SRM. Remove frequency content from forcing functions to reduce 1st peak.
2. Effect of FEM correlation: the load case is ran with updated FFU and FEM.

For the Zefiro 9 ignition, the FFU fine tuning step was not required, as the updated FEM model did not affect significantly the spacecraft interface EQS. As a note, the lateral Y direction is overestimated while the lateral Z direction underestimated. The Z direction has lower amplitude (plots with different scales), so the correlation is acceptable. In the future, an attempt to tune the two lateral directions independently should be pursued, possibly based on the modal gain tool which still needs to be implemented in the updated CLA tool. The modal gain tool allows to select target responses per degree of freedom and identify which launcher and spacecraft coupled modes drive the selected responses.

The EQS based on flight measurements, EQS based on CLA before correlation, after FFU tuning and after FEM correlation are shown in the plots, in black, green, yellow, and red, respectively.

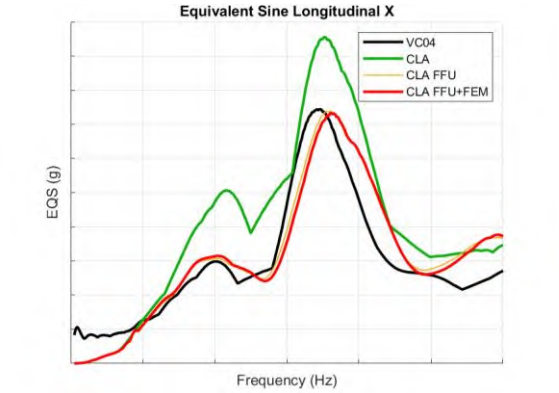

Figure 8: Zefiro 9 ignition flight longitudinal X EQS comparison to CLA

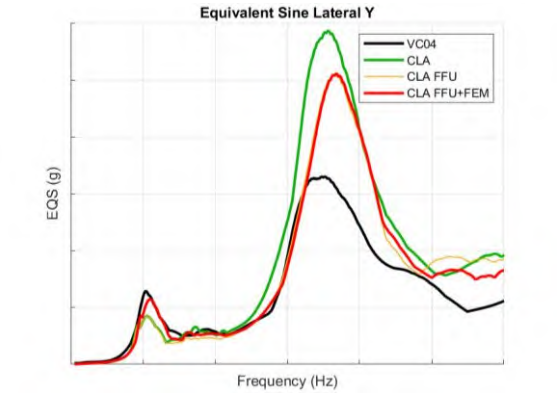

Figure 9: Zefiro 9 ignition flight lateral Y EQS comparison to CLA

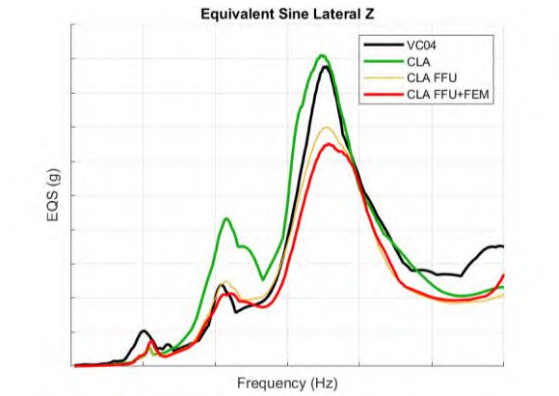

Figure 10: Zefiro 9 ignition flight lateral Z EQS comparison to CLA

The following plot shows an example of the adjustment of the forcing function applied on the forward floaters of the P120C.

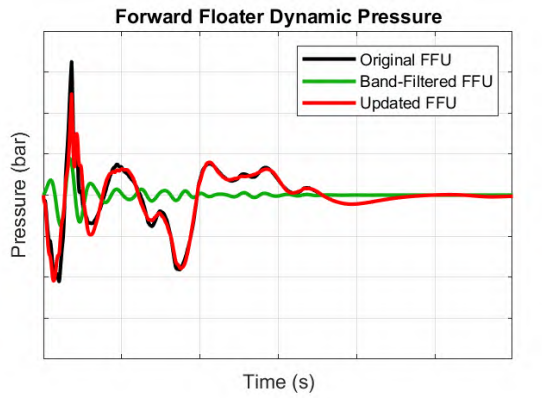

Figure 11: Pressure loads applied on the forward floater for Zefiro 9 ignition case

Zefiro 40 Ignition

The Zefiro 40 ignition flight event shows lower EQS amplitude, therefore, no dedicated correlation was envisaged. The flight measurements EQS, initial CLA EQS and CLA after FEM correlation EQS are shown in the following plots in black, green and red, respectively.

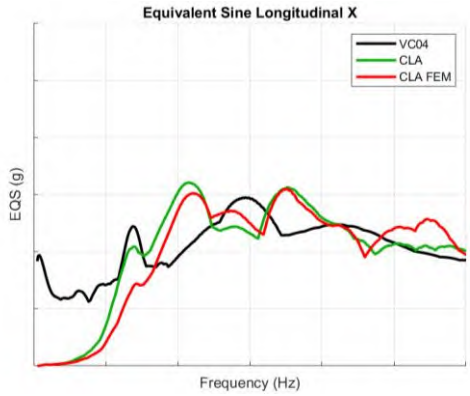

Figure 12: Zefiro 40 ignition flight longitudinal X EQS comparison to CLA

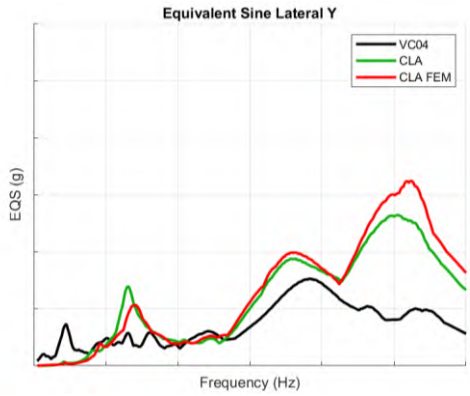

Figure 13: Zefiro 40 ignition flight lateral Y EQS comparison to CLA

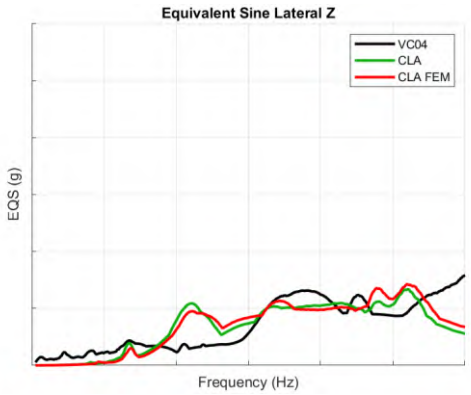

Figure 14: Zefiro 40 ignition flight lateral Z EQS comparison to CLA

P120C PO@3s and @31s

The pressure oscillation amplitude is slightly reduced for the occurrence at 3s, and for the occurrence at 31s the reduction is higher. The tuning of the amplitude is implemented with the delta-pressure measured in flight, but the acceleration at the payload interface is overestimated, as seen in the following plots. The frequency range of the forcing function is not changed, as it is according to flight.

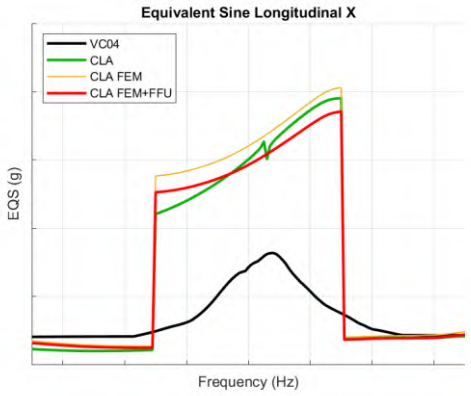

Figure 15: P120C PO@3s longitudinal X EQS / sine comparison to CLA

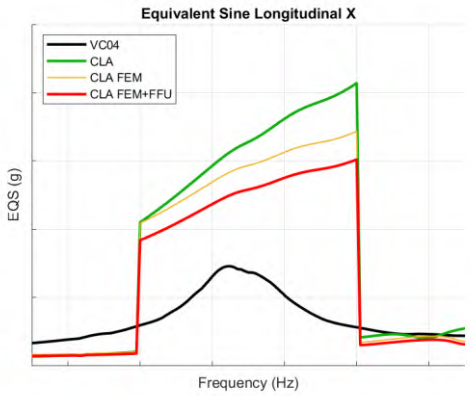

Figure 16: P120C PO@31s longitudinal X EQS / sine comparison to CLA

Zefiro 40 PO@15s

For the Zefiro 40 pressure oscillations, the frequency range of the excitation was changed. This is because the flight data shows several pressure oscillation events in time, with increasing frequency. This is shown in the waterfall plot below.

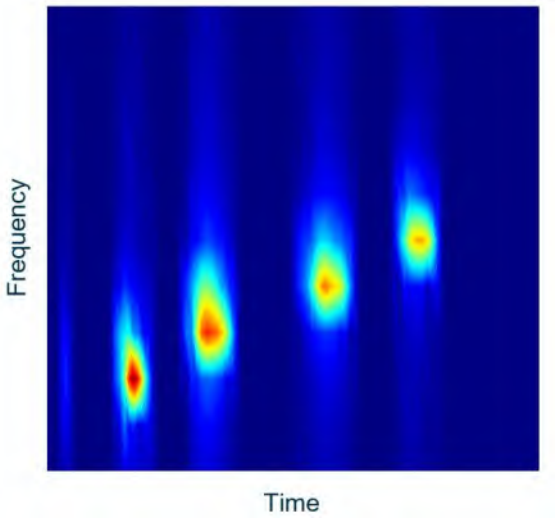

Figure 17: Waterfall plot of dynamic pressure measured inside the Zefiro 40 SRM, showing several pressure oscillation events with increasing amplitude.

To cover all the pressure oscillation events, it was decided to take the centre frequency of the excitation as the mid-frequency of all the events. This leads to a shift of the CLA curve to higher frequency, as shown in the following plot.

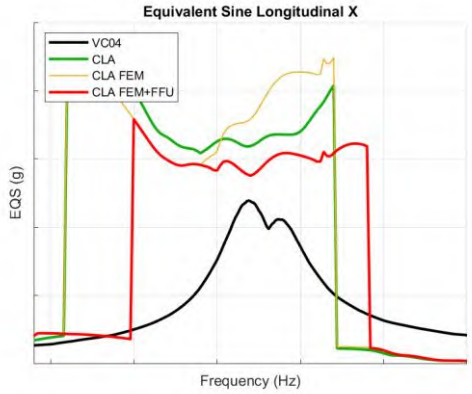

Figure 18: Zefiro 40 PO@15s longitudinal X EQS / sine comparison to CLA

Wind Gust @Mach=1 and @MaxQ

The initial CLA without correlation predicts the lateral QSL based on flight measurements. However, due to the launcher FEM correlation, the lateral QSL predicted is reduced and does not cover the flight measurements. The forcing functions for the wind gust cases are therefore increased by using a global scale factor of the forcing function, to recover the initial lateral QSL prediction. The equivalent sine for the wind gust cases is not targeted for the correlation goals because it is covered by other flight events.

OVERALL CORRELATION STATUS

The correlation status before Biomass flight correlation is shown in the following plots.

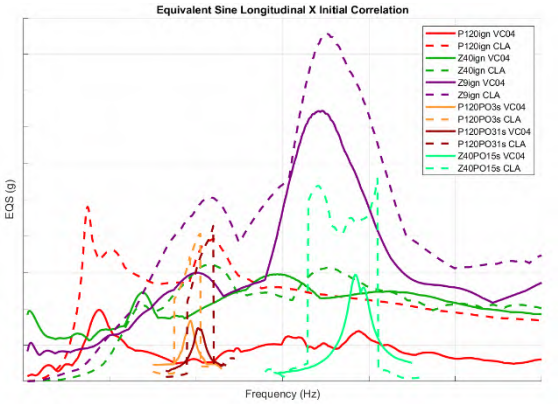

Figure 19: CLA (dashed line) vs Flight measurements (full line) EQS / sine in longitudinal X direction, before correlation

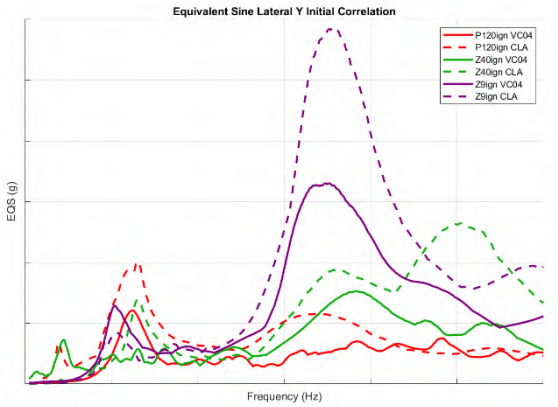

Figure 20: CLA (dashed line) vs Flight measurements (full line) EQS / sine in lateral Y direction, before correlation

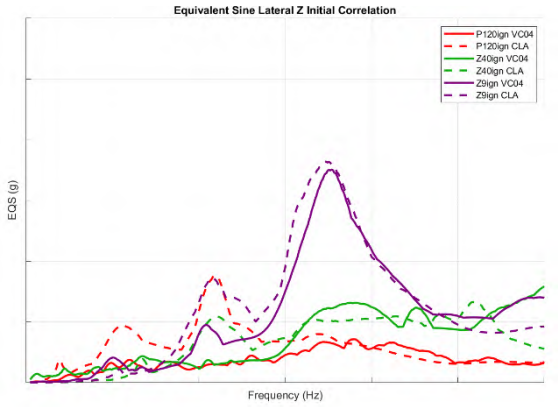

Figure 21: CLA (dashed line) vs Flight measurements (full line) EQS / sine in lateral Z direction, before correlation

The correlation status after Biomass flight correlation is shown in the following plots.

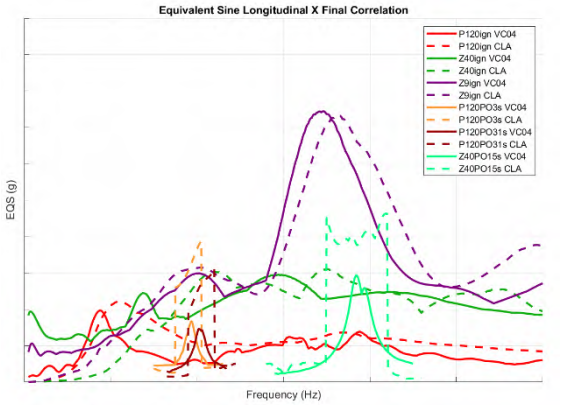

Figure 22: CLA (dashed line) vs Flight measurements (full line) EQS / sine in longitudinal X direction, after correlation

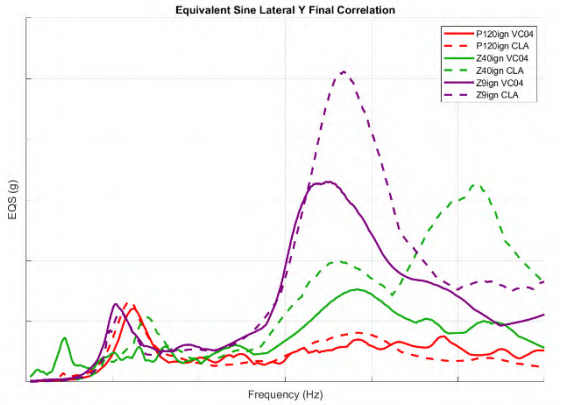

Figure 23: CLA (dashed line) vs Flight measurements (full line) EQS / sine in lateral Y direction, before correlation

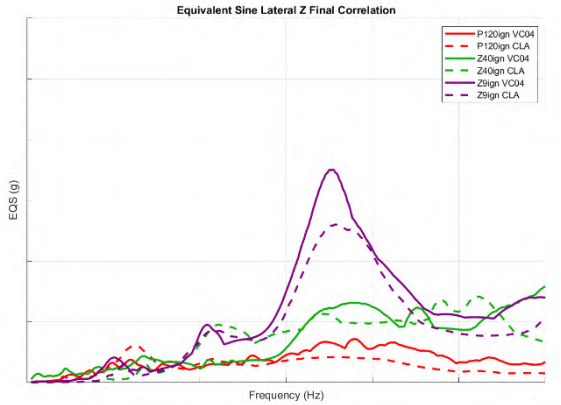

Figure 24: CLA (dashed line) vs Flight measurements (full line) EQS / sine in lateral Z direction, before correlation

The plots presented in this section show the different EQS comparing the initial CLA prediction to flight and the final CLA prediction to flight. It is seen that there are overall improvements.

For the longitudinal direction:

- For the low frequency environment, most of the overpredictions with respect to flight have been resolved by correlating the P120C ignition case (red plots).
- For the mid-frequency range, the overpredictions for the Zefiro 9 ignition have also been resolved (purple plots).
- The pressure oscillations are slightly less conservative (orange, bordeaux and light green plots) and the frequency range of the Zefiro 40 occurrences is better correlated to flight (light green plots).

For the lateral directions:

- For the low frequency environment, most of the overpredictions are resolved by P120C ignition case correlation (red plots).
- For the mid-frequency range, the overprediction for the Zefiro 9 ignition in Y direction is reduced but the Z direction is underpredicted (purple plots). This is acceptable because in typical CLA an uncertainty factor is applied to the dynamic part of the responses, while correlation CLA is performed with uncertainty factor set to 1. The underprediction is therefore resolved by the application of this factor.
- For higher frequency, the Zefiro 40 ignition in Y direction shows an overprediction with respect to flight, but the amplitude is overall low, so this is acceptable (green plots).

Besides the EQS correlation that was achieved, the first and second bending modes and first longitudinal mode of the launcher have been tuned from an error of 10-15% to an error up to 1%, and the lateral QSL during the wind gust at Mach=1 and MaxQ has been tuned after the FEM correlation to still cover the QSL based on flight measurements.

FUTURE STEPS

The correlation exercise should continue beyond the Lares-2 and Biomass flight to ensure that the ESA CLA tool is up to date and can predict as accurately as possible the QSL and low frequency environment for different spacecraft and launch configurations. For this reason, two future steps are identified for the short term:

1. Implementation of Modal Gain tool: the change from MSC Nastran 2005 + DMAPs to newer versions of Nastran is still on-going. The implementation of the Modal Gain tool will allow

the identification of the coupled launcher/spacecraft modes driving the target responses amplitude, per degree of freedom.

2. Expand CLA vs flight database: To ensure all flights are covered, the same exercise should be done for other flights, for example, Sentinel-1C single launch and FLEX + Sentinel-3C dual launch. This will allow to identify if specific spacecraft properties or launch configurations affect specific CLA results

CONCLUSION

The ESA CLA tool relies on FEM models provided by AVIO, while the forcing functions were developed internally and independently, based on the experience from past CLA tools for Ariane-5 and Vega. Because there are uncertainties in both the FEM models used and in the forcing functions, both were targeted as parameters for this correlation exercise, unlike for the Lares-2 correlation where the FEM remained mostly untouched. For the FEM correlation, PRIMODAL software was used to support the identification of the launcher FEM properties driving the target frequencies to correlate. For the forcing functions correlation, target frequencies are selected based on which frequencies of the EQS at the spacecraft interface are under or overpredicted. To be noted that only the dynamic part of the forcing functions is targeted, as the static part is related to launcher's thrust. An additional note is that the CLA performed for correlation purposes uses an uncertainty factor equal to 1 for the dynamic part of the responses, while CLA for ESA projects (not intended for correlation) includes a dynamic uncertainty factor. Therefore, any underprediction can still be covered in a typical CLA by using this uncertainty factor.

The three objectives for this correlation exercise were achieved:

1) EQS prediction at payload interface improved in most cases.
2) Launcher first and second bending modes and first longitudinal mode frequencies correlated to flight measurements.
3) Wind gust cases lateral QSL predicted by CLA cover the measured maximum lateral QS during flight.

This correlation activity emphasizes the improvement of the launcher FEM, unlike the past correlation exercise for Lares-2 which only targeted forcing functions as correlation parameters. This means that a representative behavior of Vega-C launcher is considered as important as capturing the correct responses at the payload interface.

The ESA internal CLA complements but does not substitute the Launcher CLA. It offers ESA projects an agile assessment of quasi-static and low frequency range loads. CLA is of outmost importance for the design process of spacecraft and can be used in early stages of projects for load derivation, or after design changes for de-risking purposes.

To ensure the CLA tool is able to predict flights loads as accurately as possible, it is of high priority to continue to compare CLA predictions to new flight measurements, to ensure that any variability is taken into account in the tool. This means that the correlation activities should be continued in the future for a proper maintenance of the tool. However, it is expected that after the extensive flight correlation campaign performed for Biomass, future flight correlations would not lead to significant changes in the currently derived forcing functions.

In-orbit demonstration, SpaceMast, telemetry, deployable mast, imaging

ABSTRACT

The DLR Camera SpaceMast integrates a rollable composite mast, deployment module and instrument payload for in-orbit demonstration. This paper reports its first in-orbit deployment test over 8.6 h on 19 August 2026. Across six actuation phases, the mast reached a maximum extension of 1.72 m before final retraction to the fully stowed configuration. A premature deployed-limit signal, attributed to local narrowing of the trimmed mast flange, prevented the planned 2.5 m position but does not preclude further extension tests. Supply voltages remained within limits, and deployment currents of 213 to 290 mA were consistent with ground tests. Forty-eight images documented the deployed configurations. High-rate acceleration and angular-rate data from an IMU at the boom tip revealed responses near 1.0 and 1.85 Hz with preliminary equivalent damping ratios of 0.8% and 1.6% and initial displacement amplitudes of 0.57 and 0.072 mm. Acceleration–rate phase relationships support bending in different directions, while the single sensor location and short record limit modal assignment.

1. INTRODUCTION

The DLR Camera SpaceMast was developed to demonstrate a potential application of DLR's SpaceMast platform and to provide flight evidence in support of qualification of the underlying deployment system. Here, the deployment system comprises a rollable carbon-fibre-reinforced polymer (CFRP) mast of the coilable tubular mast (CTM) subtype and its deployment module.

A compact, low-mass instrument and camera box (ICB) was designed for the mast tip to limit the volume and complexity of the complete system and thereby reduce the cost of the in-orbit demonstration. The cameras serve as a representative instrument application and provide visual evidence of the deployed configuration.

The Camera SpaceMast was integrated into D-Orbit's ION orbital transfer vehicle (OTV) in autumn 2025 (see Fig. 1). It was launched in March 2026 aboard the SpaceX Transporter-16 rideshare mission from Vandenberg Space Force Base, California, USA.

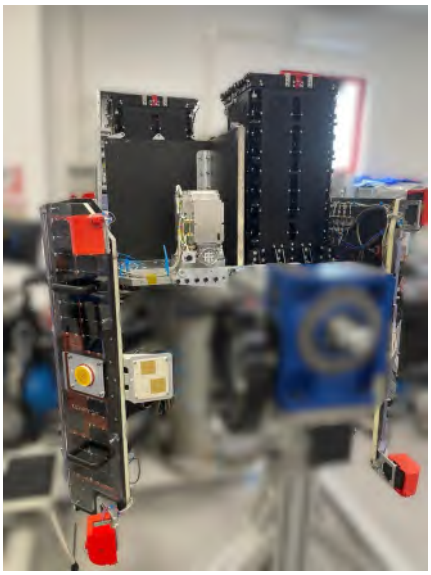

Figure 1: Camera SpaceMast integrated into D-Orbit's ION orbital transfer vehicle. (Source: D-Orbit)

The primary mission objective is to demonstrate mast deployment and retraction while recording supply voltages, motor currents, temperatures, encoder position, limit-switch states and high-rate inertial data to characterise system operation. Further planned tests include repeated deployment and retraction cycles and, towards the end of ION's operational lifetime, continuous cycling until motion is blocked. Camera imaging was a secondary objective, intended to illustrate a potential application of the mast rather than serve as a primary measure of mission success.

This paper describes the flight system, the six-orbit

test design and the results of the first in-orbit mast deployment test. The evaluation covers deployment and retraction performance, thermal and electrical behaviour, camera observations and the dynamic response recorded by the ICB IMU after the final deployment movement.

2. MECHANICAL CONFIGURATION

Fig. 2 provides an overview of the flight hardware and its camera locations. The system consists of a stationary main module mounted on the upper test platform of the host satellite and a deployable module, the ICB. A custom hold-down and release mechanism (HDRM) holds the ICB firmly against the main module. It is released by a release-nut actuator based on a shape memory alloy (SMA). A second HDRM uses a different mechanical design but the same type of actuator to secure the internal drive components of the main module. These two launch-lock mechanisms retain the system in its stowed configuration until initial operation in orbit. Once released, they require manual intervention to be reset.

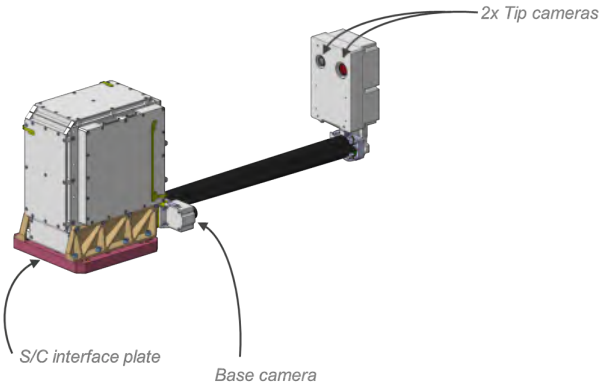

Figure 2: CAD overview of the Camera SpaceMast system.

The rollable mast provides a compact stowed configuration and separates the instrument payload from the stationary deployment module when extended. The deployment module winds and unwinds the mast through its electric drive and associated mechanisms. One encoder and four end switches provide information on mast travel, the fully deployed and stowed positions, and the states of the two launch-lock mechanisms. The architecture is intended to support instrument payloads; the cameras were selected for this demonstration because they provide a useful observation function with a comparatively low payload mass.

The smallest and lightest CTM variant currently available at DLR was selected because the expected mast loads were comparatively low. The deployed mast cross-section measures approximately 55 mm × 35 mm, while its flattened width is 67 mm. The shell consists of a single-layer plain-weave laminate with a thickness of approximately 0.15 mm. In the mast flanges, the laminate is doubled, resulting in a thickness of approximately 0.30 mm. The mass per unit length of this mast configuration is about 21 g/m.

The main module, excluding the ICB, has overall dimensions (length × height × width) of approximately 210 mm × 200 mm × 110 mm (without base camera). In the same axis order, the ICB dimensions are approximately 55 mm × 180 mm × 85 mm. The total mass of the integrated system is approximately 3.2 kg, of which about 400 g is attributable to the ICB.

The installed mast has a total length of 3.8 m. Because the fixed end attached to the coiling mandrel and the portion routed through the internal guide paths remain within the mechanism, the maximum usable deployment length is about 3.2 m.

The main module is a slightly modified version of a deployment module originally designed for a solar sail [1]. The original design had to accommodate a deployment unit for four 6 m booms within a 4U CubeSat envelope. Consequently, the module used here is larger than required for a single, comparatively short mast, and only a small fraction of the coiling mandrel's storage capacity is used. The existing design was nevertheless retained because reducing the module dimensions by a few centimetres did not justify the redesign effort.

3. AVIONICS, INSTRUMENTATION AND SPACECRAFT INTERFACE

3.1. Avionics and sensor instrumentation

The Camera SpaceMast has two avionics units, one located in the stationary main module and the other in the deployable ICB. Each unit incorporates a programmable microcontroller running a real-time operating system. The main avionics unit provides the interface to the on-board computer of the ION host vehicle.

The ICB avionics unit is connected to the main avionics unit through a custom-designed slip ring and a cable routed inside the mast. The cable is unwound and rewound together with the mast during deployment and retraction, respectively. All communication between the ICB avionics unit and the ION on-board computer is relayed through the main avionics unit, as the ICB has no direct connection to the host computer.

The main module has 20 digital temperature sensors. Some sensor integrated circuits (ICs) are soldered directly to the main avionics printed circuit board (PCB) near critical components, such as the

motor driver IC or voltage converters. Others are attached directly to the motor or to structural and mechanical components, such as outer panels or launch-lock actuators.

The main module also incorporates a rotary encoder that monitors the angular position of the mast deployment drive unit, end switches that confirm the fully stowed and fully deployed positions, and switches that indicate the states of the launch-lock mechanisms.

The ICB avionics unit is connected to a distributed sensor harness with five temperature sensors and a 4 W heater unit. In addition, two temperature sensors and a microelectromechanical systems (MEMS) inertial measurement unit (IMU) are mounted directly on the ICB avionics PCB; the IMU measures angular rates about and linear accelerations along all three axes.

The ICB microcontroller samples the six IMU channels at 20 Hz and writes the measurements continuously to a circular buffer. Each new sample is compared with configurable individual trigger thresholds for both acceleration and angular rate. When one threshold is exceeded in two consecutive samples, acquisition in the current buffer continues for 90% of its capacity before the buffer is closed. For a fully primed buffer, the resulting record contains approximately 1 s before and 9 s after the triggering event. Logging then continues in the next of eight buffers. Each buffer holds 200 measurement sets, corresponding to 10 s at the nominal sampling rate; the eight buffers therefore provide a total recording capacity of 80 s. The buffers are stored in the volatile memory of the ICB microcontroller and can be requested by the test script running on the ION onboard computer. This event-triggered approach provides high-rate monitoring throughout deployment, retraction and spacecraft attitude manoeuvres without requiring the complete data stream to be transferred continuously. It was intended to retain transient loads and oscillatory responses that could, if sufficiently excited and measured, support subsequent estimation of the deployed mast's dynamic properties.

Fig. 3 illustrates the rigid-flex PCB design used for the sensor harnesses. PCB traces route signals from sensors distributed across the structure to the avionics units, replacing individual cable connections. Flexible sections allow the harnesses to be folded around corners or wrapped around the cylindrical motor, while rigid sections support the sensors at their required locations and provide attachment points for bolting the harnesses to the structure.

In the main module, the harness also incorporates the end switches that terminate mast deployment and a dedicated connector to a separate rotary encoder PCB. In the ICB, the harness includes sensors

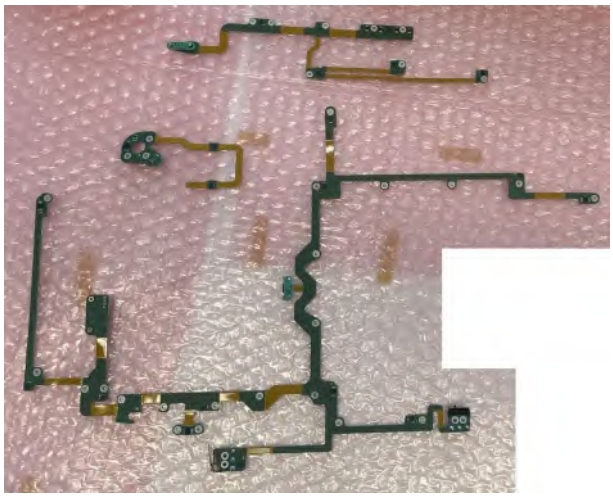

Figure 3: Rigid-flex PCB sensor harnesses: ICB temperature sensor and heater harness (top), motor and gearbox sensor harness (upper centre-left), and main module sensor harness (bottom).

for camera temperature monitoring and a custom-designed heater PCB section for heating one of the two cameras.

Fig. 4 shows the integrated flight model with its dark-green external rigid-flex PCB sensor harness visible.

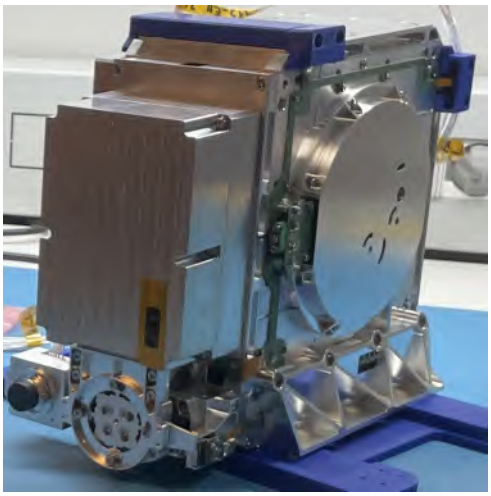

Figure 4: Integrated flight model with the external rigid-flex PCB sensor harness visible.

3.2. Camera system

The system carries three colour cameras based on two different models, designated Type A and Type B. Camera 1 (C1) is a Type A camera, whereas cameras 2 and 3 (C2 and C3) are Type B cameras. C1 and C2 are mounted in the ICB at the mast tip, while C3 is mounted on the deployment

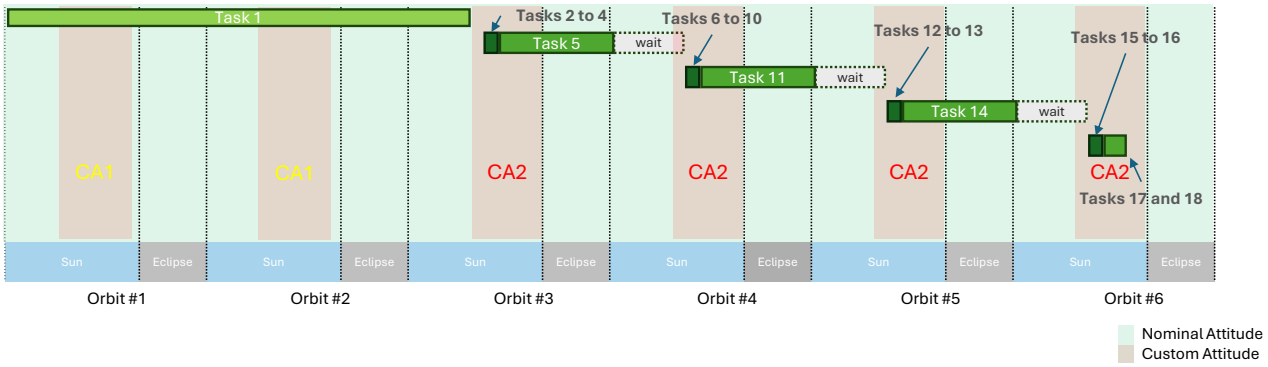

Figure 5: Planned in-orbit test sequence across six orbits, showing task and waiting periods, sunlit and eclipse phases, and nominal and custom spacecraft attitude windows.

module at the mast base and views along the mast towards the ICB. Both types support image resolutions of up to 5 megapixels and can output images in RAW and JPEG formats. Type A can acquire image sequences and store them in local memory for subsequent transfer one image at a time. Type B acquires single images, each of which must be transferred before the next image can be captured. Both camera types provide manual control of image-acquisition settings, including white balance, exposure and gain. Type B additionally supports automatic adjustment of these parameters. Manual control allows the acquisition settings to be tailored to specific structural details under the varying illumination conditions encountered in orbit. Automatic exposure and gain control may not make the features of interest sufficiently visible, in which case manual adjustment is needed.

3.3. Spacecraft interface and test control

The main avionics unit communicates with the ION host spacecraft through an RS-485 link, and the spacecraft supplies electrical power to the payload during payload operation. Test sequences are executed running scripting procedures on an ION onboard computer (OBC). The DLR operations team develops the control scripts on the ground and provides them to the spacecraft provider for upload to the OBC. The scripts can be replaced during the mission, so testing is not limited to the sequences defined before launch.

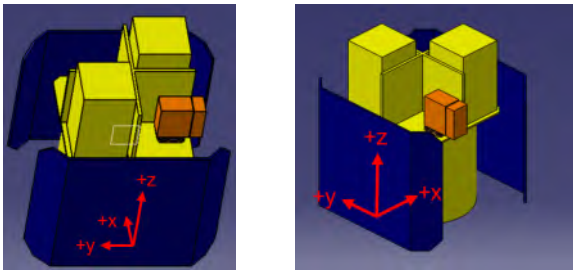
The scripts issue commands to the payload and collect the returned telemetry and images. A storage area on the OBC is available to retain these data for subsequent downlink to the ground. Image transfer from the payload to the host computer and downlink to the ground are thus separate operations.

The DLR Camera SpaceMast firmware provides an extensive set of low-level commands for individual operations, including actuation and requests for sensor readings. Each commanded motor movement can be terminated by four independently configured criteria: the relevant end switch, an adjustable motor-current threshold, an adjustable maximum actuation time, and a commanded encoder target. The host-side scripts combine these commands into complete test sequences, allowing the test logic to run on the OBC while keeping the payload firmware comparatively simple. The scripts can execute a predefined test plan and respond to detected conditions, for example by aborting a test if a critical condition is detected. Within the capabilities of the existing command set, new test sequences and diagnostic or mitigation procedures can therefore be implemented by replacing the scripts without modifying the payload firmware. This separation allows the test programme to be adapted to new objectives and to anomalies observed during the mission.

4. IN-ORBIT TEST DESIGN

4.1. Test objectives

The reported sequence was the first in-orbit deployment test, with further tests planned for October 2026. The primary objective of the in-orbit test was to demonstrate the deployment and retraction of the rollable mast while recording telemetry data to characterise the system's operational behaviour. The secondary objective was to acquire images of the deployed configuration to illustrate a potential application of the mast. The test was deliberately planned for conservative thermal and operational conditions rather than to explore the system's operating limits.



4.2. Test plan

Fig. 5 shows the planned task sequence in relation to the orbital illumination and spacecraft attitude windows; Tab. 1 defines the 18 numbered tasks and their nominal durations. The two custom spacecraft attitudes referenced in the plan are illustrated in Fig. 6a (CA1) and Fig. 6b (CA2). The plan

combined thermal conditioning, incremental deployment, a short retraction check, image acquisition and transfer to the ION OBC, followed by full retraction and payload power-down. Successful retraction from approximately 0.35 m to 0.30 m in Task 6 was a condition for continuing the test; failure to confirm retraction was an abort criterion. The lengths and durations in the table are planning values; the measured movement endpoints and durations are reported in Tab. 2.

4.3. Thermal conditioning and execution windows

The plan allocated approximately 3 h, or two heat-soak orbits, to initial warming with passive telemetry logging; the flight script included an additional 35 min before the first actuation. As shown in Fig. 5, approximately 25 min of each orbit were reserved for ION's nominal attitude to maintain the spacecraft power balance over the six-orbit sequence. In this attitude, the spacecraft $+X$ direction defined in Fig. 6 is pointed towards the Sun, allowing the primary solar array to generate electrical power and recharge the spacecraft batteries. The nominal-attitude intervals are intended to prevent the battery state of charge from falling to a critical level during the extended test. However, with $+X$ pointed towards the Sun, the solar array, CubeSat dispensers and an intervening transverse panel completely shield the Camera SpaceMast on the upper deck from direct sunlight. The deployment system therefore remained at temperatures between -30 °C and -25 °C during the many days of nominal-attitude operation preceding this test.

(a) Custom Attitude 1 (CA1) *(b) Custom Attitude 2 (CA2)*

Figure 6: Visualisations of the two custom spacecraft attitudes referenced in the test plan. The red triads indicate the positive axes of the spacecraft body-fixed coordinate system.

During the custom-attitude portions of the two initial heat-soak orbits, CA1 oriented the spacecraft to expose the deployment system to sunlight. Earlier tests had identified CA1 as the most effective heating attitude, with one to two orbits sufficient to raise the temperatures of the critical components above 0 °C. CA2 provided a compromise between maintaining system temperatures and obtaining suitable illumination for the ICB cameras while avoiding glare in C3.

Ground testing in a thermal-vacuum chamber had already demonstrated system operation from $-40\,^{\circ}$C to $+80\,^{\circ}$C. The initial warming was therefore an additional precaution for the first deployment test, not a prerequisite established by the ground tests. Deployment and retraction were likewise restricted to sunlit orbital intervals, although neither the mast nor the deployment mechanism requires sunlight to operate. The script scheduled six movements and seven image-acquisition sessions, with a time reserve before the end of each sunlit operating window; image transfers could continue beyond these windows.

4.4. Image-transfer time budget

The overall test duration was governed mainly by the two initial heat-soak orbits and the time required to transfer images to the ION OBC. Packet exchanges and acknowledgements on the payload-to-host link add overhead to these transfers. Rates between 0.5 kB/s and 0.8 kB/s are typical. At these rates, a 500 kB JPEG requires approximately 11 min to 17 min, respectively, which explains the extended image-transfer blocks in the plan. These rates describe image transfer to the host computer, not the subsequent downlink to the ground.

5. TEST RESULTS

5.1. Data sources and time alignment

The analysis uses two telemetry sources: payload housekeeping recorded by the test script running on the OBC, and S/C telemetry from the OBC, including orbit and attitude data. Additional sources comprise the flight-script debug log, 27 IMU-buffer files, and two OBC synchronisation records. Decoding produces 1,479 housekeeping records and 1,064 S/C records. The separate IMU files provide 5,172 measurement sets, including their calibration records.

The flight-script log provides explicit movement-completion times, durations and camera attempts. SpaceMast housekeeping is placed on the same elapsed test-time axis using the synchronisation records.

5.2. Boom extension measurement

During ground testing of the flight model, the fully deployed end switch was reached at 4,057 encoder ticks and a measured boom extension of 3,273 mm. This reference corresponds to 0.807 mm per encoder tick and defines the boom extension values

Table 1: Planned tasks corresponding to Fig. 5. Durations are nominal estimates; no duration was specified for payload power-down.

Task	Planned operation	Duration
1	Thermal soak over two orbits with passive telemetry logging.	3 h
2	Acquire initial low-quality reference images in the retracted configuration.	2 min
3	Deploy 0.35 m of mast.	30 s
4	Acquire images at this extension.	10 min
5	Transfer images to the ION OBC.	About 1 h
6	Retract to 0.30 m and verify successful retraction; abort if the check fails.	30 s
7	Deploy to 0.5 m.	1 min
8	Acquire images at this extension.	2 min
9	Deploy to 1.5 m.	3 min
10	Acquire images at this extension.	10 min
11	Transfer images to the ION OBC.	About 1 h
12	Continue deployment to 2.5 m.	3 min
13	Acquire images at this extension.	5 min
14	Transfer images to the ION OBC.	About 1 h
15	Fully retract the mast.	5 min
16	Acquire reference images of the stowed configuration.	2 min
17	Transfer images to the ION OBC.	About 10 min
18	Power down the payload.	—

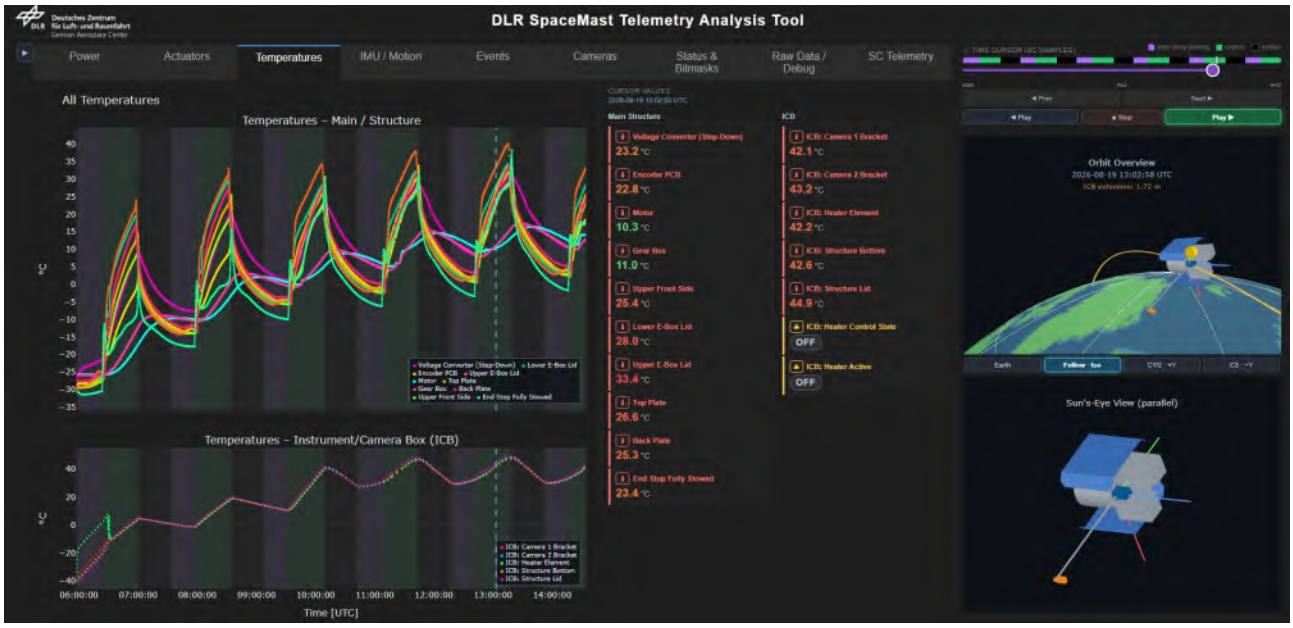


Figure 7: Custom Python-based analysis tool: temperature histories of the main module and ICB (left), numerical values at the selected time (centre), and synchronised orbit and Sun's-eye views (right). Green, purple and black bands indicate custom attitude, nominal attitude and eclipse, respectively.

reported here. The launch-lock mechanisms had already been released in a preceding in-orbit test, during which elastic preload caused a small outward movement of the ICB. The encoder was subsequently zeroed before the reported deployment test while the ICB was no longer fully stowed. Final retraction continued to the fully stowed end switch; the resulting value of -2 ticks therefore reflects the offset between the test-specific encoder zero and the fully stowed position rather than a physical negative extension.

5.3. Custom analysis software tool

A custom Python-based software tool was developed to combine and analyse the different datasets. Despite AI assistance, its development required approximately two weeks of active engineering work. Fig. 7 shows the temperature tab of the analysis tool. Temperature histories for the main module, labelled

“Main / Structure”, and the ICB occupy the left-hand side. The plots cover the complete test of approximately 8.6 h across six orbits.

The time cursor at the upper right allows the user to navigate the dataset and inspect the recorded temperatures together with the reconstructed spacecraft position and attitude at a selected time. A vertical dashed line marks this time in the temperature plots, while the central panel displays the corresponding numerical values. Both the plot backgrounds and the band above the time cursor distinguish custom-attitude intervals in green, nominal-attitude intervals in purple and eclipse intervals in black. This common colour scheme relates the temperature evolution to eclipse entry and exit, nominal-attitude periods for spacecraft battery charging, and custom-attitude periods used for payload heating and operations such as mast deployment.

Two synchronised 3D views on the right provide the spatial context for the selected time. The upper view shows the spacecraft’s position above the Earth, while the lower view presents the spacecraft and deployment system from the Sun’s perspective. The displayed boom extension is derived from the encoder value at the selected time. The latter is particularly useful for thermal interpretation because it allows the user to assess which parts of the deployment system face the Sun and which are geometrically shaded by surrounding spacecraft structures.

The other tabs allow the user to inspect the boom extension, power-related parameters, end-switch states, and IMU measurements in a similar manner.

5.4. Deployment and Retraction Performance

The script executed all six actuation phases and seven image-acquisition sessions and switched off the payload at an elapsed time of 08:36:51.

Tab. 2 separates completion of a movement command from achievement of its intended endpoint. DEPL1, DEPL2 and DEPL3 reached their encoder targets. RETR1 stopped one tick below its nominal value. DEPL4 ended at 2,126 ticks rather than 3,099 ticks, limiting the measured boom extension to 1.72 m. The subsequent RETR2 movement returned from this configuration to the stowed switch in approximately 168 s.

The four extension phases had mean speeds between 6.55 and 7.48 mm/s. DEPL4 lay within this range up to its stop. The final retraction was faster on average, at approximately 10.21 mm/s.

Fig. 8 relates boom extension and motor operation over the complete test. The upper image covers all six orbits, while the lower image resolves the fourth orbit with one retraction and several deployments up to 1.50 m. The displayed channels comprise boom extension, motor current, the temperatures of the motor-driver IC and motor housing, and the commanded motor states.

Most of the elapsed test time was spent in thermal conditioning, acquisition, transfer and waiting intervals, rather than moving the mast.

The premature termination of DEPL4 was not part of the planned sequence. Telemetry shows that the fully deployed end switch became active at a measured boom extension of 1.72 m, although the mechanism provides about 3.2 m of usable mast travel. The state of this switch is shown in the bottom subplot of the upper subfigure in Fig. 8. The payload avionics therefore terminated the deployment as designed and reported the end-switch condition to the test script running on the OBC.

The fully deployed end switch is implemented differently from the fully stowed switch because the mechanism provides no comparably accessible rigid component at the deployed endpoint. During deployment, a roller attached to the switch bears laterally against the narrow edge of the flattened mast flange. A notch in this edge at the intended fully deployed position allows the roller to enter the recess and actuate the switch.

Tests with an equivalent copy of the flight hardware showed that a sufficiently narrow local section of the mast can reproduce premature switch actuation. The current working hypothesis is that local width variation introduced when the laminated mast edges were trimmed caused the flight mast flange near the observed switch point to be narrow enough to mimic the intended notch. This hypothesis is further sup-

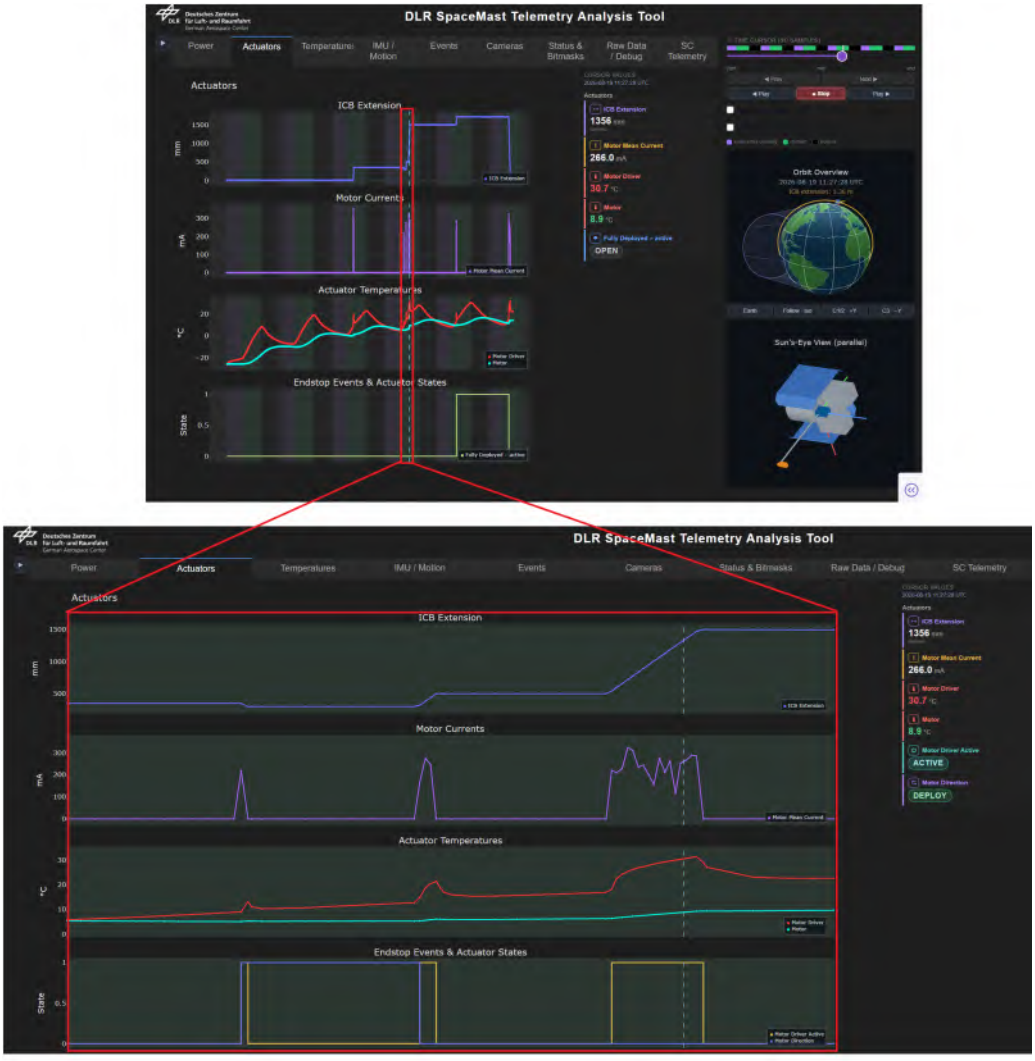

Figure 8: Actuator data across all six orbits (upper image) and a detailed view of the fourth orbit, including one retraction and several deployments up to 1.50 m (lower image).

ported by the fully deployed switch returning to its inactive state during retraction as the suspected locally narrowed section moved away from the roller. The signal therefore did not remain latched, and no persistent failure of the switch was observed after the mast had returned to its fully stowed configuration. The available evidence supports this mechanism as a plausible explanation, but the local width deviation has not been quantified or directly verified on the flight mast.

The event limited the achieved extension but did not prevent the autonomous sequence from continuing. After the payload firmware stopped the motor, the host-side script treated the deployment command as completed, proceeded with the planned camera sessions, and commanded full retraction during the following orbit. The mechanism subsequently returned to its fully stowed configuration.

5.5. Thermal Behaviour

At the beginning of the available housekeeping sequence, the C1 and C2 brackets were at -40.5 and $-40.8\,^{\circ}$C, respectively. The flight procedure permitted this initial cold condition and provided active heating with a configured minimum-temperature set point of $-10\,^{\circ}$C. With the 4 W heater operating, C1 exceeded its lower operating-temperature limit of $-30\,^{\circ}$C after approximately eight minutes and C2 after approximately fifteen minutes. Apart from the heater element, the ICB structure and camera brackets are made of aluminium; the resulting heat distribution kept the remaining ICB temperature measurements within a $7\,^{\circ}$C band.

Fig. 7 shows the active heating of the ICB as well as the passive warm-up and subsequent temperature evolution. The gearbox temperature was above the configured $-10\,^{\circ}$C movement threshold at every ac-

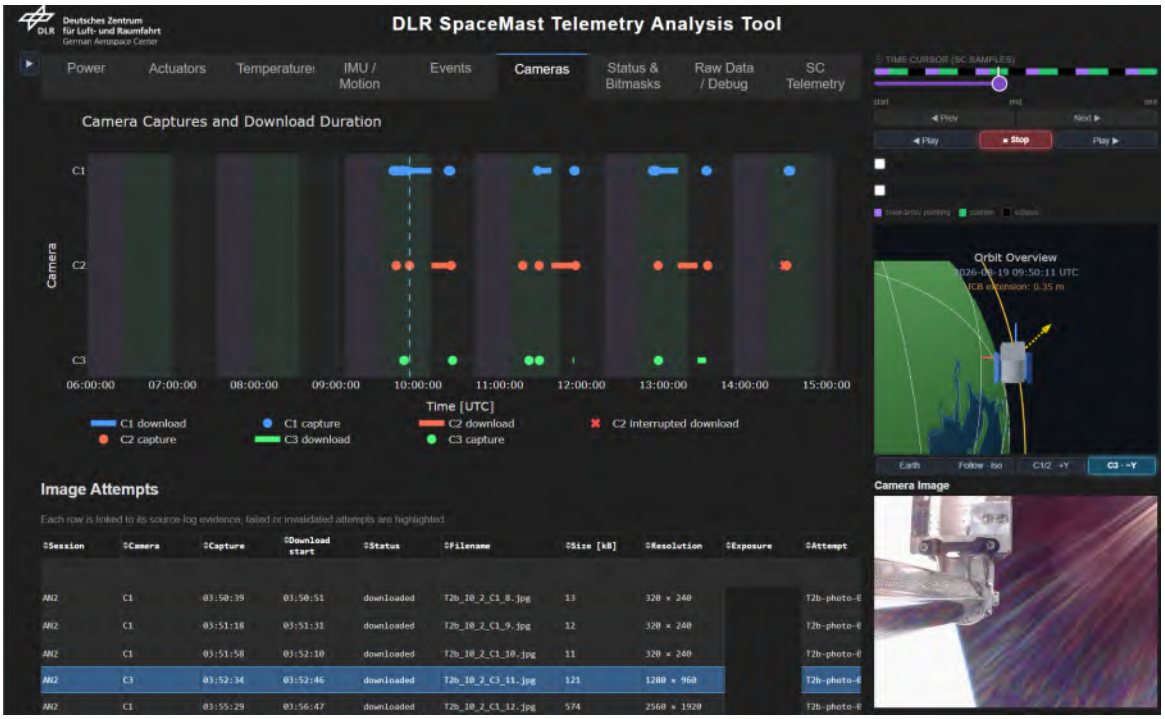

Figure 9: Camera tab of the custom analysis tool, combining capture and transfer events for all three cameras with the associated log records, spacecraft geometry and selected on-board image.

tuation. The long initial soak therefore separated the cold start from the first commanded movement. No post-initialisation overtemperature shutdown was reported in the flight log.

The C1 bracket reached 47.8 °C over the full test, while the PCB channel below the voltage converter reached 55.6 °C. These maxima occurred at different locations and should not be combined into a temperature cycle for a single component. The highest C1-bracket value was approximately 32 °C below the configured 80 °C emergency threshold. This comparison describes margin to that script threshold only.

The test script also included a staged response for an ICB overtemperature condition. At the first protection stage, it would have switched off the cameras to reduce heat dissipation from electrical loads within the ICB. If the temperature had continued to increase, the main avionics would have disconnected power from the ICB avionics and re-enabled it only periodically, at intervals of several minutes, to obtain updated temperature records. This contingency was not invoked during the reported test.

5.6. Electrical Behaviour

All monitored supply voltages remained within their defined operating thresholds throughout the sampled housekeeping data. The external input voltage of the main avionics ranged from approximately 15.63 to 15.97 V, while the 15-V input measured in the ICB ranged from approximately 15.31 to 15.82 V. The locally generated 3.3-V rails remained between approximately 3.323 and 3.332 V in the main avionics and between 3.288 and 3.304 V in the ICB. No relevant voltage excursion or unexpectedly high current was observed in the recorded data. No persistent sensor failure occurred, and all 27 temperature channels provided valid measurements during the test.

Fig. 8 relates the actuator currents and temperatures to the changes in boom extension. In the lower panel, every commanded change in extension coincides with motor-current activity. The phase-averaged filtered motor currents for the four deployment movements ranged from 213 to 290 mA and therefore indicate comparatively low motor loading. For comparison, the motor can sustain currents of approximately 0.8 to 1.0 A for extended operation under substantially greater mechanical load. Ground tests of the integrated deployment system produced maximum motor currents of approximately 400 mA. The phase-averaged flight values are therefore consistent with the ground-test current range and provide no indication of increased mechanical loading or degraded drive performance in orbit.

The temperature response in the same panel follows the actuator activity. Both the motor and the motor-driver IC on the main avionics PCB warm slightly

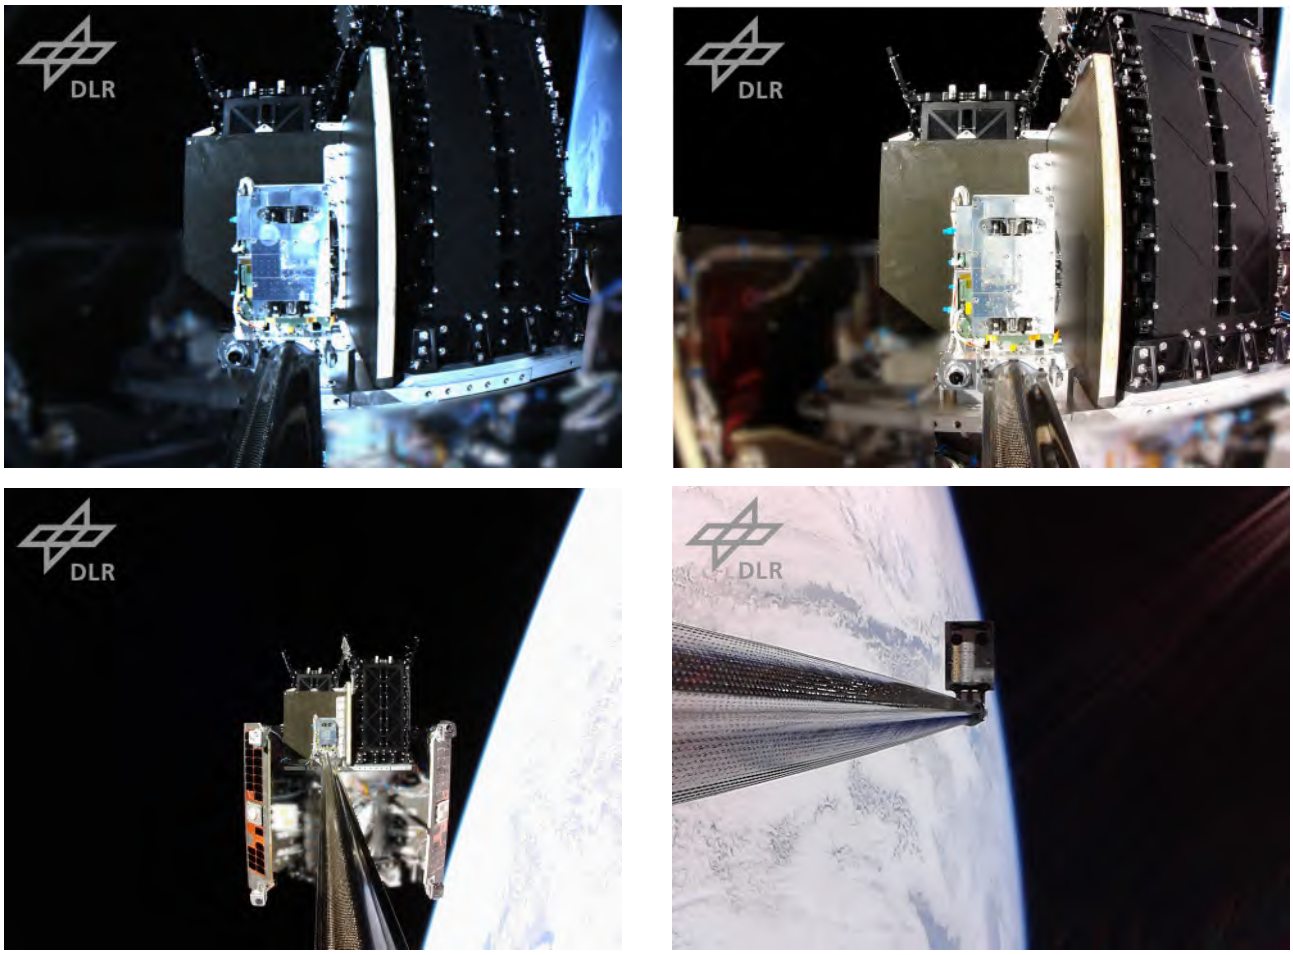

Figure 10: On-board views during sunlit acquisition phases. Top left: C1 at a boom extension of 0.35 m. Top right: C2 at 0.35 m. Bottom left: C2 at 1.72 m. Bottom right: C3 looking along the mast towards the ICB at 1.72 m. The C1 frame and both C2 frames were recorded at the full 5-megapixel resolution; the C3 frame is a 640×480 *pixel test image.*

during operation, with the clearest increase occurring during the longer deployment to a boom extension of 1.50 m. The motor-driver temperature during this interval shows an approximately first-order rise towards an apparent asymptote rather than an uncontrolled increase. Although the finite actuation interval does not establish a steady-state temperature or thermal time constant, the recorded response provides no indication of thermal overload under the executed duty cycle.

6. CAMERA OBSERVATIONS

6.1. Image acquisition

The parsed log records the transfer of 48 unique image files: 34 from C1, nine from C2 and five from C3. Fig. 9 shows the corresponding camera tab of the analysis tool, which combines capture and transfer events with the associated log records, spacecraft attitude, and a selected on-board image.

Fig. 10 compares the C1 and C2 views at a boom extension of 0.35 m with the C2 and opposing C3 views at 1.72 m. In the C1 and C2 images at 0.35 m, the deployment module occupies a substantial part of the image. At 1.72 m, a larger portion of the host is visible in the C2 image and its apparent size is reduced. This is consistent with the increased camera separation. The C3 image shows the mast extending towards the ICB, including the two camera apertures.

6.2. Image quality and camera settings

Of the four frames in Fig. 10, the C1 frame and both C2 frames were acquired at the full 5-megapixel resolution. The C3 frame was acquired at 640×480 pixels as a low-resolution test image. Despite its lower resolution, it provides a clear view along the mast towards the ICB and is therefore included in the figure.

Selected regions in the four presentation images

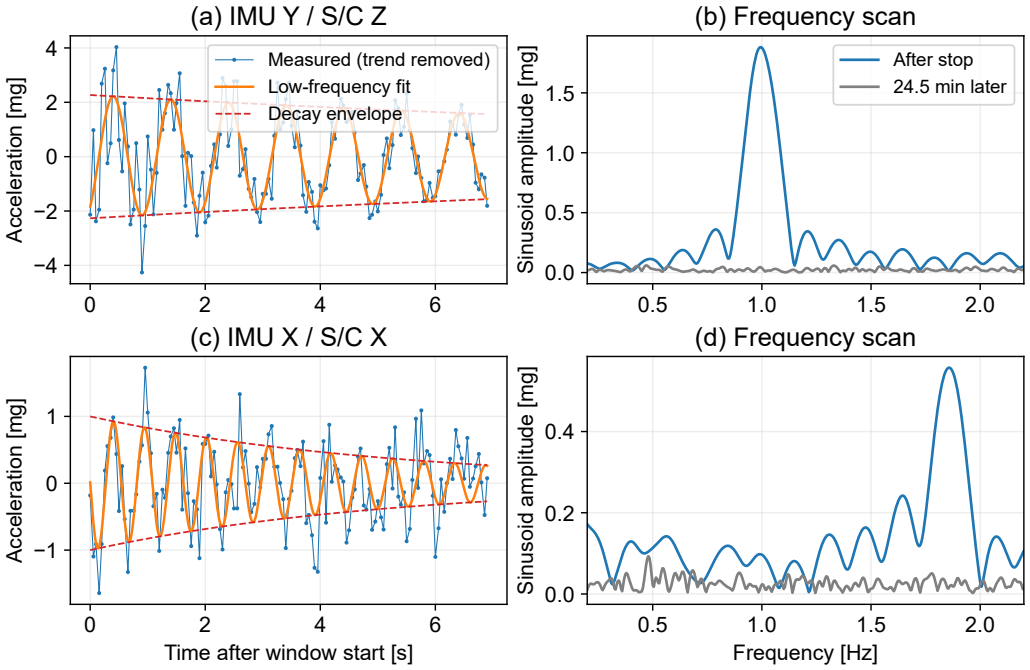

Figure 11: ICB acceleration after deployment to 1.72 m. Left: trend-corrected measurements, fitted low-frequency components and decay envelopes. Right: constant-amplitude sinusoid scans immediately after stopping and 24.5 min later. Time zero is 06:54:48.011 elapsed test time.

were lightly blurred at the request of the host-satellite operator to limit the visibility of spacecraft details. The images should therefore be treated as presentation copies rather than unmodified downlinked files. The processing does not obscure the SpaceMast features discussed here.

The Type B images from C2 and C3 provide a useful exposure balance under the strong scene contrast. Illuminated spacecraft and mast features remain visible, while space and deeply shaded regions are rendered nearly black. The settings used for Type B were therefore suitable for documenting the deployed configuration.

A test series with manually selected exposure settings was acquired with the Type A camera C1. The reviewed images indicate that the selected exposure times were still slightly too short to provide the desired detail in darker regions. Longer exposure times are planned for subsequent tests and are expected to improve the usable image detail to a level comparable with the Type B results.

7. DYNAMIC RESPONSE OF THE DEPLOYED MAST

7.1. Recorded response and frequency content

When the final deployment movement stopped at a boom extension of 1.72 m, the motion of the ICB did not cease immediately. The ICB IMU recorded a decaying oscillatory response even though no dedicated excitation device was available. The movement of the mast–ICB assembly and its subsequent stop are therefore the likely excitation sources.

The analysed interval starts at elapsed test time 06:54:48.011, about one second after the logged movement completion, and contains 139 samples over 6.9 s at a nominal sampling rate of 20 Hz.

Fig. 11 shows distinct oscillatory components near 1.0 and 1.85 Hz. The lower-frequency response appears most clearly in acceleration along IMU Y and angular rate about IMU X; the higher-frequency response appears in acceleration along IMU X and angular rate about IMU Z. The spacecraft body-frame convention is shown in Fig. 6. For the installed sensor, IMU X, Y and Z correspond to spacecraft X, Z and negative Y, respectively. A least-squares frequency scan fitted a sinusoid, offset and linear trend directly to the native samples without band-pass filtering. Both peaks remained when the start of the analysis window was varied, and an additional Fourier-transform check confirmed their locations. A second acquisition 24.5 min later at the same extension contained substantially smaller amplitudes at both frequencies, linking the initial response to the preceding deployment movement.

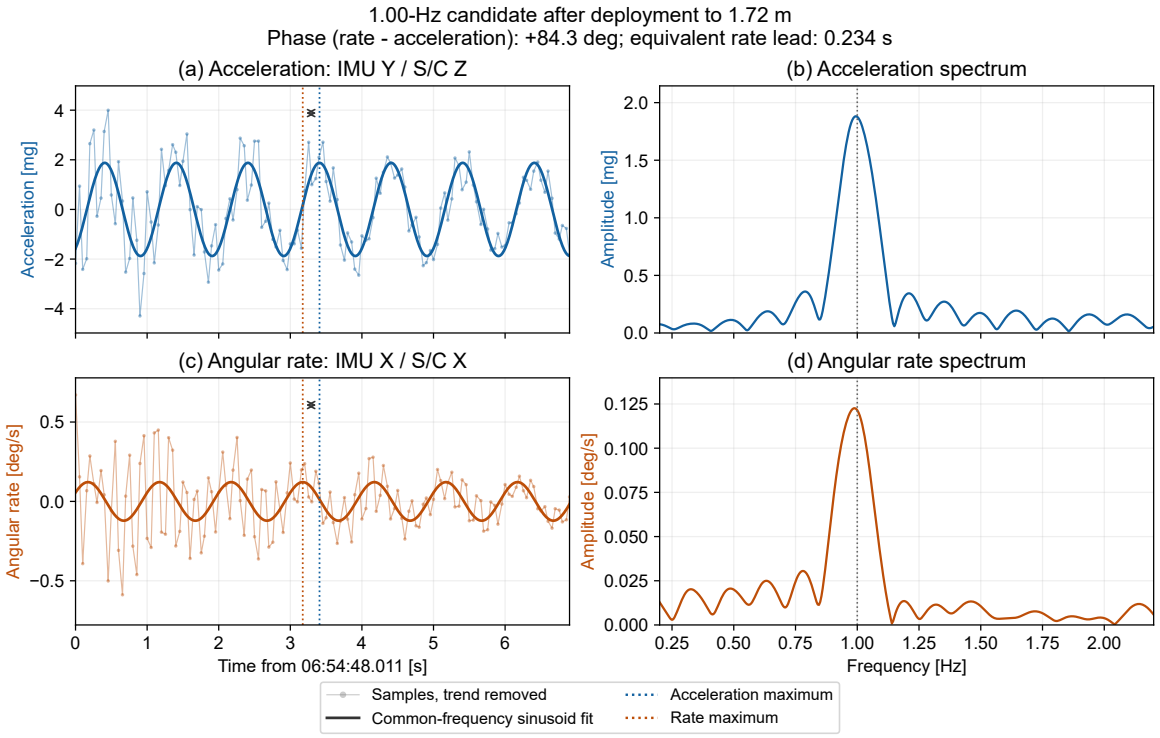

Figure 12: Acceleration and angular rate associated with the 1.0-Hz response. Upper row: IMU Y acceleration; lower row: IMU X angular rate. Left: trend-corrected samples and constant-amplitude sinusoid fits with freely determined phases. Dotted lines mark corresponding fitted maxima. Right: amplitude spectra from sinusoidal least-squares scans.

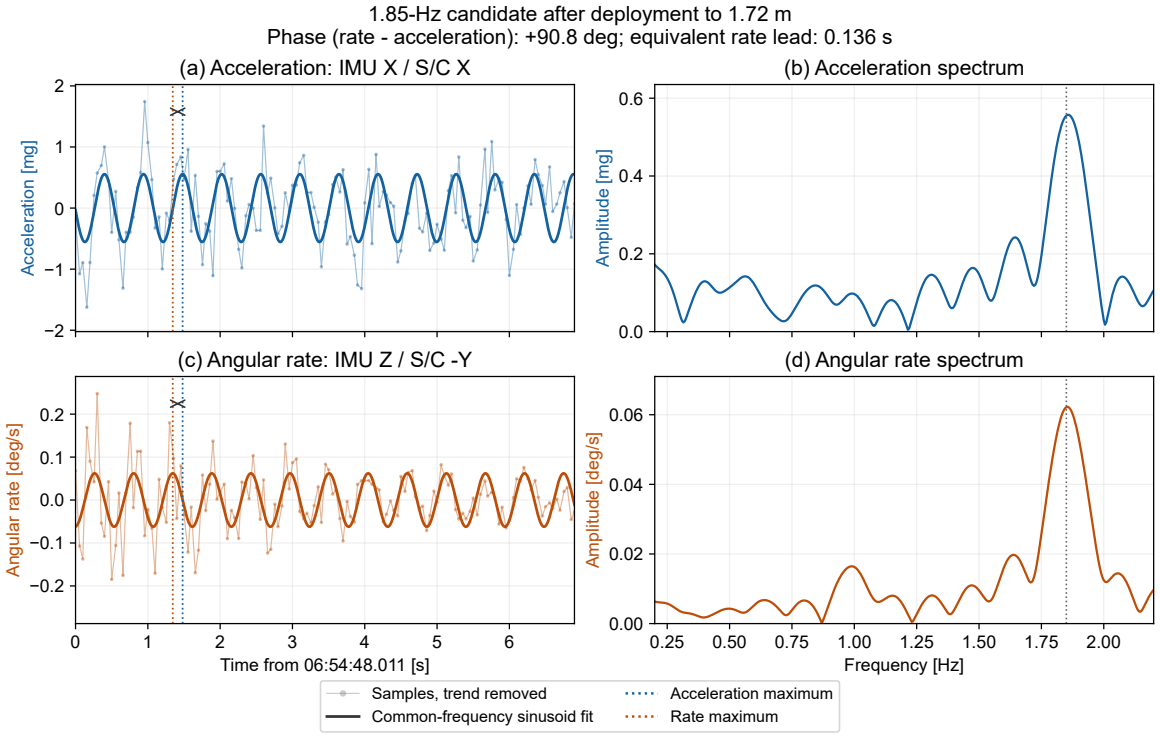

Figure 13: Acceleration and angular rate associated with the 1.85-Hz response, using the same window and display conventions as Fig. 12. Upper row: IMU X acceleration; lower row: IMU Z angular rate, corresponding to rotation about the negative spacecraft Y-axis.

7.2. Phase relationship and mode interpretation

Figs. 12 and 13 compare the associated acceleration and angular-rate channels separately for each frequency component. The time histories use identical time axes, and the spectra show matching dominant peaks within each pair. For each comparison, both channels were fitted at the same frequency, while their phases were determined independently without shifting either signal. In the native IMU coordinates, angular rate leads acceleration by 84.3 degrees at 1.0 Hz and by 90.8 degrees at 1.85 Hz. Including the previously fitted decay and higher-frequency terms gives similar phase differences of 83.3 and 92.1 degrees, respectively.

These near-quarter-period phase differences are consistent with bending motion involving both translation and rotation of the ICB. For a single bending mode, local displacement and slope depend on the same modal coordinate; acceleration contains its second time derivative, whereas angular rate contains its first. An approximately harmonic response therefore gives a phase difference near 90 degrees, with the sign depending on the coordinate directions and local mode shape. This relationship supports the bending interpretation but does not identify the mode order.

The non-circular CTM cross-section gives the mast different bending stiffnesses in its two transverse directions. The two measured frequencies and their different dominant acceleration components are therefore compatible with bending responses in these directions. This difference in bending stiffness provides a physical basis for interpreting the 1.0- and 1.85-Hz components as the lowest bending modes of the mast–ICB assembly in the two respective directions, including the compliance of the root interface.

The present measurement cannot confirm this mode assignment because all six IMU channels originate from a single sensor location and do not describe the spatial mode shapes. A higher bending mode could produce the same local phase relationship, while a lower mode could have remained weakly excited or unresolved in the short record. Ground modal tests with spatially distributed measurements and a model including ICB mass, inertia and root compliance are required to establish the mode order. Longer in-orbit recordings at several boom extensions would then show whether the measured frequencies vary as expected for the proposed modes.

7.3. Damping estimates

The decay visible in Fig. 11 was quantified by fitting an exponentially damped sinusoid together with an offset and linear trend:

$$a(t) = c_0 + c_1 t + A_0 e^{-\sigma t} \cos(2\pi f_d t + \phi). \quad (1)$$

Here, f_d is the damped frequency and σ is the amplitude decay rate. Acceleration amplitudes in mg denote thousandths of standard gravity. Additional fits included a second oscillatory term near 5.3 or 6.9 Hz to account for higher-frequency content visible in the raw signals. Allowing either positive or negative decay rates avoided imposing decay on the data. For an equivalent viscously damped mode, the damping ratio is $\zeta = \sigma / \sqrt{(2\pi f_d)^2 + \sigma^2}$.

The reference-window fits yielded approximate damping ratios of 0.8% and 1.6% for the 1.0- and 1.85-Hz components, respectively (Tab. 3). Separate acceleration and angular-rate fits gave similar values within this window. The corresponding amplitude time constants were about 20 and 5.3 s, showing that the 1.0-Hz response persisted longer.

Table 3: Estimated dynamic-response parameters at 1.72 m. Amplitudes refer to the beginning and end of the 6.9-s reference window.

Parameter	1.0 Hz	1.85 Hz
Equivalent damping ratio	0.8%	1.6%
Amplitude time constant [s]	20	5.3
Initial acceleration amplitude [mg]	2.27	1.00
Initial displacement amplitude [mm]	0.57	0.072
Final displacement amplitude [mm]	0.39	0.020

The damping values are preliminary because the record contains only about seven cycles of the lower-frequency response and less than one of its estimated decay time constants. Across five window starts, three fit models and the associated acceleration and rate channels, the estimates varied from 0.3 to 1.9% at 1.0 Hz and from 1.0 to 2.4% at 1.85 Hz. These ranges describe sensitivity to the selected window and model rather than statistical confidence intervals. The 1.85-Hz angular-rate result was more stable and remained between 1.4 and 1.7%.

7.4. Oscillation amplitudes and interpretation

Analytical double integration of the fitted acceleration components gives the displacement histories in Fig. 14. For the damped sinusoid, the displacement envelope is

$$X(t) = \frac{A_0 e^{-\sigma t}}{(2\pi f_d)^2 + \sigma^2}. \quad (2)$$

Acceleration was converted to SI units before integration; offset, trend and unknown integration constants were excluded. This yields the oscillatory displacement without accumulating drift from direct integration of the full measured signal.

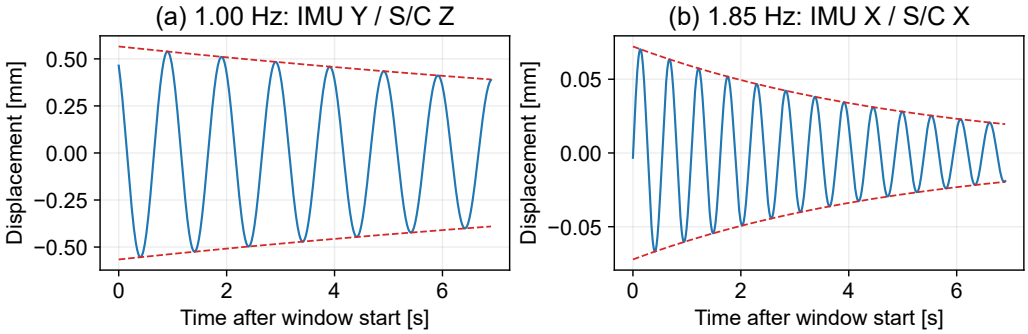

Figure 14: Estimated displacement components at the ICB IMU from analytical double integration of the acceleration fits. Dashed curves show the amplitude envelopes. Time zero is the same as in Fig. 11.

At the beginning of the reference window, the estimated one-sided amplitudes were 0.57 mm along spacecraft Z and 0.072 mm along spacecraft X. They decreased to 0.39 and 0.020 mm, respectively, over the following 6.9 s. These values describe the selected components at the IMU location, rather than the total motion or the maximum excursion during motor stopping. Their interpretation as mast-tip displacement relative to the deployment module assumes negligible base motion; rotation of the ICB also contributes to translation at an offset sensor location.

Although small, these amplitudes provide quantitative evidence of a sub-millimetre dynamic response following deployment and allow first estimates of its damping. The spacecraft telemetry, sampled at roughly 30-s intervals, cannot independently resolve these oscillations. Longer post-stop recordings are needed to improve the damping estimates, check the influence of sensor filtering and aliasing, and support the mode assignment described above.

8. FURTHER IN-ORBIT TESTS

8.1. Dynamic testing

The post-deployment response in Sec. 7 shows that stopping an ordinary mast movement can provide sufficient excitation for an initial in-orbit structural characterisation. A separate release impulse is therefore not essential for the next measurement. Instead, the flight script should reserve IMU-buffer capacity for the stopping event and retain a longer continuous record afterwards. The longer record is particularly important for the slowly decaying 1.0-Hz component and for comparing the response at different boom extensions.

8.2. Further mast deployment

The premature deployed-limit signal does not establish a physical travel limit at 1.72 m and does not preclude subsequent tests at greater extensions. For a subsequent deployment, a low-level command can instruct the payload avionics to ignore the deployed-limit input over a predefined encoder interval around the suspected false-trigger region. The commanded encoder target, motor-current threshold and maximum actuation time remain available as independent termination criteria while the switch input is masked. The masking interval should include suitable margin because the repeatability and exact encoder position of a future false trigger have not yet been established. The consistent deployment velocity and the motor currents within the ground-test range provide reference values for monitoring this movement. Additional deployments across a wider motor-temperature range could further establish a temperature-dependent current envelope for plausibility monitoring.

8.3. Camera operation

The image results show that the cameras can serve as engineering instrumentation when illumination, viewing geometry and acquisition settings are selected for the structural feature of interest. The differences between the two camera types also show that successful image transfer alone is not a sufficient criterion for a useful observation. Future scripts should therefore treat image acquisition, exposure settings and illumination as one operational task. Thermal conditioning must be considered at the same time because extended acquisition and transfer sessions influence the ICB temperature.

9. CONCLUSIONS

The primary objective of the reported in-orbit test was met: the integrated Camera SpaceMast completed controlled intermediate deployments, a short reverse movement and final retraction to the stowed end switch. The maximum boom extension was 1.72 m. The final planned extension to 2.5 m was not achieved because a premature deployed-limit signal terminated further deployment. The premature signal is attributed to a locally narrowed section of

the trimmed mast flange. This explanation is supported by tests on equivalent hardware and by the switch returning to its inactive state during retraction. This event does not impose an operational extension limit at 1.72 m because future commands can mask the switch input over the affected range while retaining the encoder target, motor-current threshold and maximum actuation time as independent termination criteria.

All monitored supply voltages remained within their defined operating thresholds, all 27 temperature channels returned valid measurements, and no persistent sensor failure occurred. The phase-averaged deployment currents of 213 to 290 mA remained within the ground-test range and provided no indication of increased mechanical loading in orbit. Thermal conditioning separated the initially cold ICB from the first actuation, and the configured overtemperature contingency was not invoked.

The autonomous sequence returned 48 unique image files, and the sunlit views provide independent visual evidence of the deployed configurations. The Type B cameras produced a useful exposure balance under the high scene contrast. For the Type A camera, the test series showed that longer manually selected exposure times are required to improve detail in darker regions.

High-rate IMU measurements revealed oscillatory responses near 1.0 and 1.85 Hz following the final deployment movement. The paired acceleration and angular-rate signals exhibit phase differences close to a quarter period, consistent with bending motion. The direction-dependent bending stiffness of the mast makes it plausible that these responses are the lowest bending modes in the two transverse directions, although the single sensor location cannot establish their mode order. Preliminary equivalent damping ratios are 0.8% and 1.6%, with estimated initial displacement amplitudes at the ICB sensor of 0.57 and 0.072 mm in the analysed post-stop window. Despite the short record, the event-triggered instrumentation captured sufficient information for an initial dynamic characterisation in orbit.

The test thus provides the operational reference data needed for further deployments beyond 1.72 m and shows that ordinary mast actuation can also excite a measurable structural response. The next tests should combine greater boom extensions with longer post-stop IMU records and camera settings selected for the expected illumination and structural detail. These measurements are required to improve the damping estimates and establish the modal assignments; full-travel performance and formal system qualification also remain to be demonstrated.

ACKNOWLEDGMENTS

The Camera SpaceMast and the reported in-orbit demonstration build on many years of development and contributions from numerous colleagues at DLR. The project benefited in particular from the longstanding technical and administrative support of Prof. Christian Hühne, Head of the Lightweight Design Department; Olaf Mierheim, Manager of the Space Business Area at the DLR Institute of Lightweight Systems; Prof. Martin Wiedemann, long-serving former Director of the Institute; and Prof. Michael Sinapius, former Deputy Director of the Institute. Their sustained support helped establish the technical and organisational basis for this work. The authors also thank Dr. Andree Altmikus, who succeeded Prof. Wiedemann as Director of the Institute in May 2026, for his support of the continuing in-orbit activities.

The in-orbit demonstration was funded by the German Aerospace Center (DLR) through the Executive Board department “Innovation, Transfer and Research Infrastructure”, under the responsibility of Executive Board Member Prof. Karsten Lemmer. The technical development was carried out within a spin-off project supported by the German Federal Ministry for Economic Affairs and Energy (BMWE) through the EXIST Transfer of Research programme.

DECLARATION OF AI USE

Generative AI tools were used to assist with text drafting and revision, and the development of scripts for telemetry analysis and data visualisation. The authors reviewed and revised the resulting text, checked the analysis procedures and results against the underlying test data, and take responsibility for the final content.

KEYWORDS
Boom dynamics, passive deployment, deployable boom

ABSTRACT
The Tape Spring Unwrapping Nanosatellite Arm (TUNA) is a passive mechanism for deploying small payloads on CubeSats. Housed within a launch pod's "Tuna-Can" kick-off spring volume, TUNA unwraps from a stationary drum—unlike most linearly-extending booms—driven by the tape spring's strain energy. Knowledge of the deployment dynamics is critical for spacecraft control and structural integrity. This paper extends a literature model of a passively unwrapping tape spring with a tip mass, using a single-DoF Lagrangian formulation. Experiments agree well with predicted speed and geometry. Adding $0.87\,\mathrm{g}$ of tip mass reduces predicted maximum speed from 13.9 to $10.5\,\mathrm{m/s}$, matching the measured $\approx 10.2\,\mathrm{m/s}$, and correctly predicts failure to fully deploy in laboratory conditions. With added mass representing a camera payload, the model performs well; removing gravity and drag shows on-orbit deployment differs markedly from laboratory conditions: $\approx 9\,\mathrm{m/s}$ on orbit and $\approx 2\,\mathrm{m/s}$ in the laboratory.

1. INTRODUCTION

Tape springs, deployable booms, and STEMs have become effective solutions for space applications, particularly for small satellite platforms, where they enable the compact stowage and reliable deployment of payloads, such as solar sails, antennas, solar arrays, and sensing instruments [1, 2]. Their main advantage is their ability to undergo large elastic deformations during packaging while recovering a stiff, naturally curved configuration upon deployment. This behaviour enables them to provide structural support and tension to the deployed payload while minimising system mass, stowed volume, and overall mission cost. Typically, the deployment process of STEM and tape springs consists of a "tip-out" release mechanism where a single or a system of booms [3, 4] uncoil from a central hub or spool around which they have been coiled or co-coiled for stowage. In this configuration, the boom root's edge is constrained flat or partially flat [5] to the drum while the tip is maintained at its natural curvature and extends outwards during deployment, as illustrated in Fig. 1 (a).

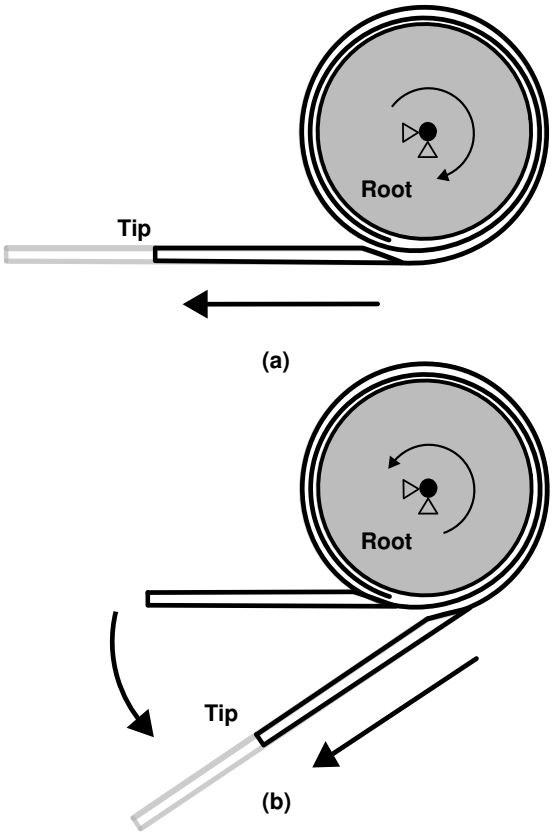

Figure 1: (a) Linear tip-out deployment configuration. (b) Rotating tip-out deployment configuration.

The boom tip-out deployment has been used to support membrane structures [6] and deorbiting mechanisms, such as the deployable gossamer sail [5] developed under the ESA ARTES 5.1 programme, and the dragsail payload designed to fit the "Tuna-Can" volume of a CubeSat and launched as part of the TPA-1 mis-

sion [7]. These systems consist of four tape springs deploying from a central spool and pulling from the tip four quadrants of sails (or membranes) into their deployed configuration. Other examples of linear deployment were used to support deploying antennas [4, 8], solar arrays [9, 10] and imaging systems, such as the inspection boom system developed for the same mission in [7].

Based on the deployer configuration and deployment actuation method, another adopted approach is the "rotating tip-out" mechanism. Unlike linear deployment, this configuration couples the outward boom extension with a rotating motion, as illustrated in Fig. 1(b). These systems are typically passive (i.e. no motorisation or rotating parts), therefore deemed simpler, and have a higher stowage efficiency when compared to active systems. Because the deployment only relies on the elastic stored energy for actuation, the free deployment dynamics are effected by stowage time and temperature, which are critical aspects to successful deployment [11]. Other key design parameters for this type of system are the maximum angular deployment velocity and momentum generated during deployment [12]. Excessively high deployment velocities can induce undesired dynamic disturbances that affect the spacecraft Attitude Determination and Control System (ADCS) [13], while also generating shock loads that may damage both the boom and satellite. An example of rotating tip-out deployment is presented in [12], where a system of two antenna tape springs are mounted and wrapped around a central disk and deploy freely. To evaluate the velocity requirements, angular rates and deployment time for their subsystem's design, they adopted the analytical model on deployment dynamics of tape springs developed by Seffen and Pellegrino [14]. In [14], the authors demonstrate how stored elastic energy drives self-deployment in a purely conservative two-dimensional problem resolved with a Lagrange approach. In their study, they provide a closed-form solution for the case of a tape spring deploying from a fixed spool in a gravity-free vacuum environment. Moreover, the coiling radius is assumed to be equal to the natural radius to favour the tape's natural bending without requiring external forces to maintain the equilibrium state [15]. Starting from [14], a similar approach is developed in [16] to describe the dynamics of multiple tape springs that are uncoiled from a fixed central hub. In this case, the coil thickness is accounted for and the longitudinal section of the coiled part is approximated with an Archimedean spiral.

This paper presents a novel deployable boom that is stowed for launch inside the volume of the deployer's kick-out spring, which is informally known as the "Tuna-Can" volume. The boom extends using the passively driven rotating tip-out deployment method to keep the mechanism design as simple as possible. The development model is illustrated through deployment frames in Fig. 2. Presented first are the details of the mechanism, which is aptly named TUNA – Tape spring Unwrapping Nanosatellite Arm. TUNA is reasonably agnostic to the type of payload that it can support, within the mass and volume limits, but the baseline payload in this paper is a Commercial Off The Shelf (COTS) camera. The payload at the tip will affect the deployment during ground testing and in a micro-gravity environment. To consider the tip mass the Lagrangian model presented in [14] is extended and the new governing equation of motion is presented. The analytical model is used to predict the deployment path and speed of the boom, which are then compared to experimental measurements made on boom samples using a motion capture facility.

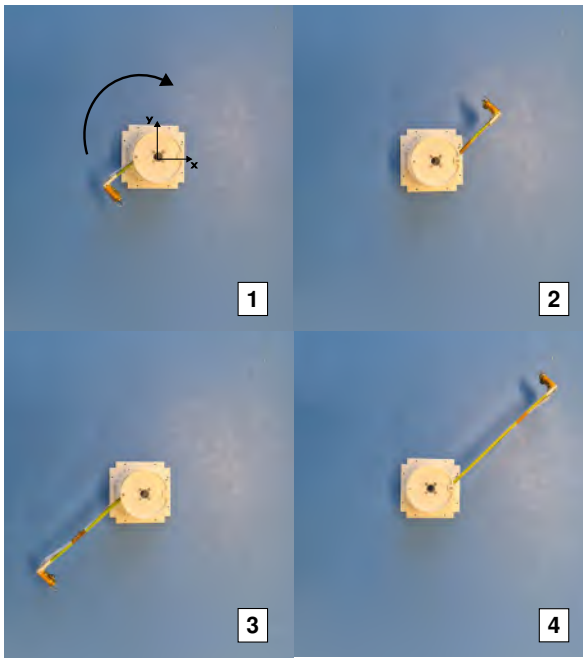

Figure 2: Rotating boom deploying by unwrapping around the central hub.

2. TUNA DESIGN

TUNA is a deployable boom that can extend small payloads from the body of a CubeSat. TUNA has been designed to be accommodated inside the deployment spring of most commercial CubeSat launch pods on the market (ISIS, EXOpod, Maxwell, UARX and NANOrasks). The payload baselined in this paper is a single Raspberry Pi camera, which is mounted to the end of the boom via an interface bracket. The camera would serve to monitor the visible external facets of the spacecraft, as well as providing promotional photographs. With some minor modifications to the bracket and boom material TUNA could also deploy scientific equipment such as magnetometers. A dimensioned CAD model of TUNA is shown in Fig. 3 in both the stowed and

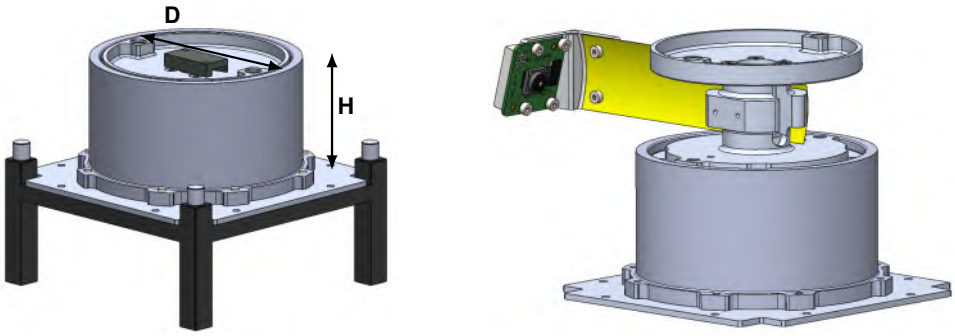

Figure 3: Left, stowed TUNA, which measures 39 mm from the interface of a CubeSat's deployer plate (H), and has an outer diameter (D) of 79 mm. Right, TUNA deployed with a RaspberryPi camera at the tip.

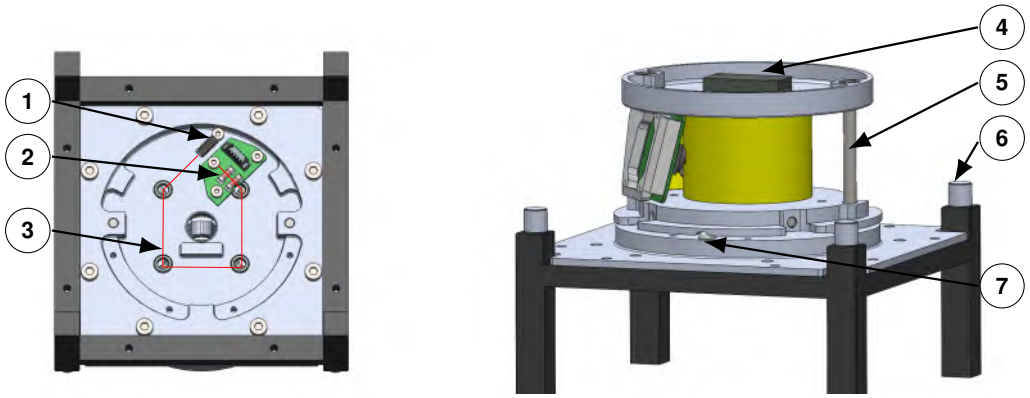

Figure 4: Left, inside face of TUNA showing the burnwire path (3), which is routed from a tensioning spring (1) and terminated shortly after running over two resistors (2). Right, TUNA with the housing hidden to reveal the inside. One of the alignment ball-vee couple is highlighted (7). Sun sensor (4), Linear guide deployment (5) and spacecraft kill switch (6).

deployed configurations. Taking inspiration from the NANOSail unit, a dragsail on TPA-1, TUNA deploys in two stages. First, the sprung assembly is deployed in a jack-in-the-box style by a single compression spring. This step is required to push the rotating boom away from the CubeSat structure's feet and, critically, the kill-switches that open to turn the satellite on. In the second stage of the deployment the boom with the tip-mounted camera unwraps itself from a stationary central hub using the strain energy stored in the boom. At this stage of development, the boom is spring steel, cut from the traditional carpenter's tape measure, but future iterations will explore low-friction coatings and Beryllium Copper for magnetically sensitive tip payloads.

Starting from the fixed baseplate, this structure acts as the entire Z facet with a hole pattern to match whichever CubeSat structure is being baselined: in this case it is a 3U structure from NanoAvionics. The fixed baseplate supports the boom housing, linear deployment spring, deployment guide pins and the Hold-Down Release Mechanism (HDRM) board. The concept for the HDRM is the same of the NANOSail from TPA-1, Dyneema string is run between the sprung assembly and the fixed baseplate through a series of grooved pins and rings, as shown in Fig. 4. Owing to the string's path there is a mechanical advantage of eight. The Dyneema is run over a set of resistors mounted to the board that, when powered, heats up and melts the Dyneema. The HDRM board is internally facing and can therefore be reset by flipping the unit over. The burnwire board is interfaced to the spacecraft via a 5-pin vertical Picoblade connector. The sprung assembly is seated and aligned on the baseplate using a Maxwell clamp configuration (three balls and three vees), one of which is visible in Fig. 4. The sprung assembly consists of just two parts, the body and the lid. The boom is mounted to the body and is wrapped around the central hub. The ribbon cable harness that provides power and data connectivity to the payload is cocoiled with the boom and is constrained to it at intervals along the length of the boom. At the root, there is a cutout in the structure to allow the ribbon cable to pass through and out to the internal spacecraft. To enable the initial vertical deployment of the sprung assembly, the harness is coiled inside the central hub with overlapping layers so that when the assembly is deployed the harness will elongate. Included in both the

body and lid of the sprung assembly there are a total of four bushings. These bushings slide over two fixed stainless-steel pins that are bonded into the baseplate, shown in Fig. 4. The bushing and pin combination prevent the sprung assembly from tilting or laterally moving during deployment. A secondary function of the pins is to keep the payload on the tip of the boom from moving and pressing against the inside of the housing before it is pushed clear. A polycarbonate baffle-like structure is proposed to be bonded to the camera to prevent the lens directly impacting the coiled boom. The lid of the sprung assembly is recessed to accommodate a sunsensor on this facet of the Spacecraft, as shown in Fig. 3. The wiring for the sensor is passed down the same through hole as the ribbon cable harness used by the camera payload. A development model, utilising a combination of 3D printed and metallic parts, is shown in Fig. 5 along with still frames taken of TUNA during its deployment (Fig. 2).

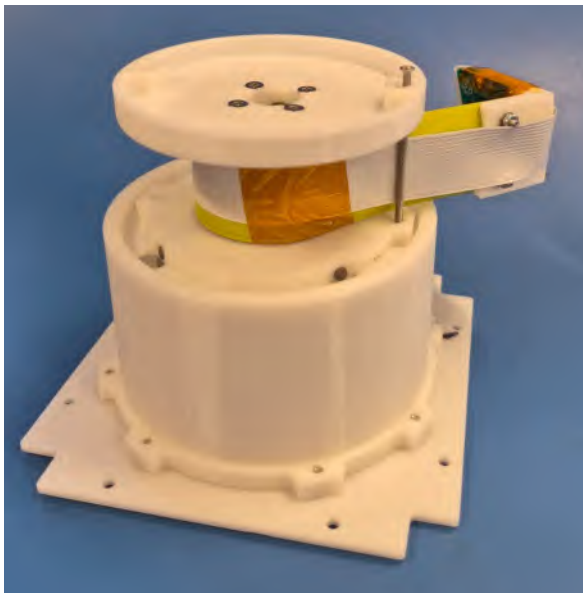

Figure 5: Development model with Raspberry Pi camera and harness.

The total mass of the system, including the wall of the Z facet, is $260\,\mathrm{g}$, with structural analysis and mass optimisation to follow. The mass of the proposed payload is $13\,\mathrm{g}$ and the current allowable tip payload volume is 25 x 13 x 31 mm. While not presented in detail here, this design does allow for a second co-coiled boom and payload to be deployed using the second stainless steel pin to restrain the bracket, as shown in Fig. 6.

3. DEPLOYMENT TESTING SETUP

Deployment testing was conducted to track the motion of the boom tip throughout the deployment process and to characterise the overall deployment dynamics. The experiments provided measurements of the

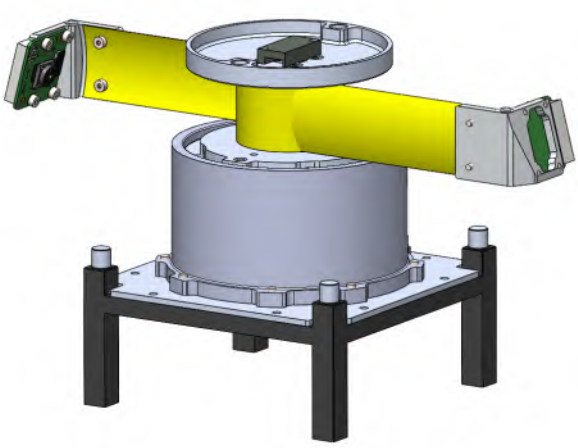

Figure 6: Dual boom TUNA configuration to deploy a second inspection camera.

boom's speed and path in a gravity environment, enabling the evaluation of its repeatability and the comparison with analytical predictions. The boom used for testing was an isotropic COTS steel tape measure with length $L = 0.65\,\mathrm{m}$, width $b = 25\,\mathrm{mm}$ and natural radius $R = 17.8\,\mathrm{mm}$. The material properties are $E = 210\,\mathrm{GPa}$, $\nu = 0.3$, $G_{12} = 80.8\,\mathrm{GPa}$, thickness $h = 0.1\,\mathrm{mm}$ and density $\rho = 7800\,\mathrm{kg\,m^{-3}}$. Fig. 7 shows the testing setup for the stowed and deployed configurations. For stowage, one boom's edge was flattened and screwed to a deployment drum (Fig. 7 (6)) of radius $r = 17.5\,\mathrm{mm}$, while the other edge was left in its stress-free state and coiled around the drum to leave a deployed distance of $42\,\mathrm{mm}$ from the drum's tangent point. Due to the shallow geometry, the ploy region between the flat and curved sections was considered negligible and was therefore omitted from the analytical model. Two retro-reflective markers were used to create a local dynamic object and track the relative displacement during deployment, as illustrated in Fig. 8. One marker was placed at the tip (Marker 1), the other at the centre of the drum (Marker 2) to provide a fixed reference point for calculating the relative displacement, as shown in Fig. 7. The retro-reflective part of the Marker 1 offset from the boom edge by $5\,\mathrm{mm}$ in the y-direction, and the weight of the marker was $0.87\,\mathrm{g}$. Once the boom was released, the tip displacement was recorded and tracked by 12 infrared cameras that were positioned around the testing room. The software used for object tracking was Vicon Nexus Tracker. Displacement and velocity data were collected with a sampling frequency of $320\,\mathrm{Hz}$. The cameras were calibrated to a maximum error of $\pm 0.6\,\mathrm{mm}$, which yields an error of $\pm 0.91 \times 10^{-3}\,\mathrm{ms^{-1}}$ when considering error propagation in the calculation of the speed within the software. Deployment tests were performed on the boom in two configurations: with only the retro-reflective marker attached at the tip, and with an addi-

tional tip mass representing the sensor, resulting in a total tip mass of $13\,\mathrm{g}$. From the experimental observations, the tip marker changed its position relative to the centre of the drum as a result of the boom's radial extension and angular rotation during deployment. This kinematic behaviour was consistent and repeatable across the test series, providing the basis for the formulation of the analytical model.

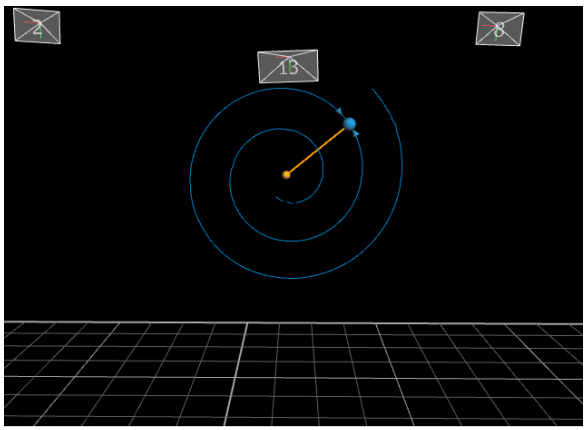

Figure 8: Local dynamic object defined by the two markers by the Vicon Nexus tracking tool. The central marker is orange and the tip is blue. The blue spiral line is the tip's displacement path.

4. ANALYTICAL MODEL

The analytical model presented in this paper is based on the tape spring deployment model developed by Seffen and Pellegrino [14], which provides the foundation for describing the deployment dynamics of TUNA. In [14], the deployment configuration consists of a coiled tape spring that uncoils and tangentially extends driven by a rotating spool. Such motion is fully described by two degrees of freedom: the angle subtended by the coiled tape spring and the spool rotation. In this study, the spool is fixed from the start, and the motion is initiated by the release of the coil's stored energy. This reduces the system to 1 Degree of Freedom (DoF) where the only time-dependent variable is $\theta(t)$, which is the angle subtended by the coil. In fact, during the deployment, as the boom extends, the coil rotates to allow for the extension, varying the arc length and, therefore, θ. As in [14], the coiling radius is constant $r = R$, therefore the coil expansion is not investigated in this model. A schematic illustration of the 1 DoF boom dynamics is shown in Fig. 9.

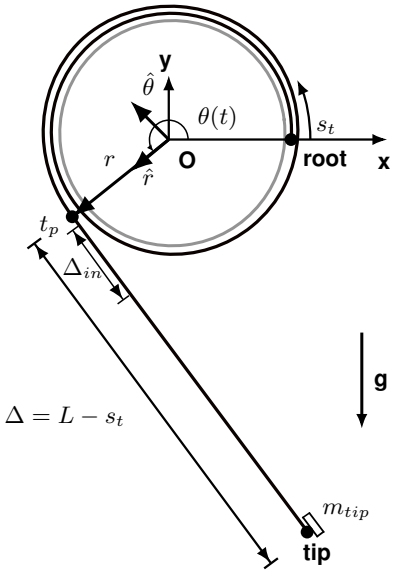

Figure 9: Rotating deploying boom model.

To account for the sensor mass placed at the tip, the total kinetic and gravitational potential energy of the system as calculated in [14] are modified to construct the lagrangian of the system, $\mathcal{L} = T - V$, to resolve the equation of motion:

$$T = \frac{1}{2}\int_0^{\Delta} \rho_m \mathbf{v}^2 \, d\Delta + \frac{1}{2} m_{tip} \mathbf{v}^2 = \frac{1}{2}\rho_m \left(\dot{\theta}^2 \frac{(L - r\theta)^3}{3} \right) + \frac{1}{2} m_{tip} \dot{\theta}^2 (L - r\theta)^2 \tag{1}$$

$$
\begin{aligned}
&V = \frac{1}{2} bD \int_0^{s_t} \left(\frac{1}{r^2} - \frac{2\nu}{rR} + \frac{1}{R^2} \right) ds + \\
&\int_0^{s_t} \rho_m g \left(r \sin(\theta) \right) ds + \\
&\int_0^{\Delta} \rho_m g \left(r \sin(\theta) + \Delta \cos(\theta) \right) d\Delta + \\
&m_{tip} g \big(r \sin(\theta) + (L - r\theta) \cos(\theta) \big) = \\
&br\theta \left(\frac{D(1-\nu)}{R^2} \right) + \rho_m g r^2 \left(1 - \cos(\theta) \right) + \\
&\rho_m g \left(r(L - r\theta) \sin(\theta) + \frac{(L - r\theta)^2}{2} \cos(\theta) \right) + \\
&m_{tip} g \big(r \sin(\theta) + (L - r\theta) \cos(\theta) \big)
\end{aligned}
\tag{2}
$$

Where $\Delta = s - r\theta$ is the deployed length, and s is the curvilinear coordinate of a generic material point along the boom length $s \in [0, L]$. As in [14], the interface between the coil and the extended region is defined by a transition point, t_p, which corresponds to the instantaneous position of θ. This point represents a moving boundary condition that evolves over time to ensure that the geometric constraint in Eq. (3) is continuously satisfied.

$$
s_t = r\theta \tag{3}
$$

Where s_t is the instantaneous arc of a circle for a given position of the moving boundary. The other parameters in Eqs. (1) and (2) are ρ_m, the linear density of the boom, g, gravity and m_{tip} the mass of the sensor; L, b and D are the boom's length, arc width and flexural rigidity, respectively. The zero potential gravity plane is co-linear with the x axis. From the kinematics in [14], the velocity $\mathbf{v}$ is:

$$
\mathbf{v} = \left(-(s - s_t)\dot{\theta} \right) \hat{\mathbf{r}} \tag{4}
$$

The motion starts from an initial configuration where the boom is partially coiled at an initial $\theta_{in}(t) > 2\pi$ around the fixed drum and partially deployed at an initial length Δ_{in}. In this configuration, the centre of the drum is the origin of the system of reference O, and the increment of the radius given by overlapping layers is neglected, as assumed in [17] for coiled thin shells. For the initial state of non-conservative generalised forces Q_i = 0, (i.e. no external forces), the equation of motion in Eq. (5) is resolved by numerical integration using the MATLAB ode15s algorithm.

$$
\begin{aligned}
&\ddot{\theta} \left(\rho_m \frac{(L - r\theta)^3}{3} + m_{tip}(L - r\theta)^2 \right) \\
&- \frac{1}{2} r\dot{\theta}^2 (L - r\theta) \left(\rho_m (L - r\theta) + 2m_{tip} \right) \\
&+ brD \left(\frac{1 - \nu}{R^2} \right) \\
&- \frac{1}{2} (L - r\theta) g \sin(\theta) \left(\rho_m (L - r\theta) + 2m_{tip} \right) = 0
\end{aligned}
\tag{5}
$$
